DEDICATIONS

To the memory of Myriam Puig, MD, PhD, a contributor to the second and third editions of this textbook. Dr. Puig succumbed to cancer in September 2002. Her professional life was dedicated to the nutritional health of underprivileged Venezuelan children and her publications to the benefit of nutrition for children everywhere.

— W. Allan Walker

To my colleagues, students, residents, and fellows, who continue to provide me with the stimulation and inspiration to learn and ask new questions, and to my daughters, Sarah Watkins and Leah Watkins Beane, and my wife, Mary Watkins, for their continued love and support.

— John B. Watkins

To Catherine and John Duggan, who nourished me from the beginning and inspired a career in medicine; to Michael, Brendan, and Emily Duggan, and the rest of the world's children, for their optimal nutrition; and to Deborah Molrine, for constant love and support.

— Christopher Duggan

CONTENTS

PREFACE

Because the field of nutrition is actively evolving and creating major new principles in the care of the pediatric patient, we have embarked on the third edition of this textbook. The editors continue to support the premise that a comprehensive text as a reference source in pediatric nutrition is essential for the proper care of infants and children. As medical care in the twenty-first century is predicated on prevention of disease, the discipline of pediatric nutrition becomes that much more important. For example, we now know from the Barker hypothesis that intrauterine nutrition and weight gain during the first year of life are important predictors of chronic diseases of adulthood (cardiovascular disease, diabetes, and hypertension). In addition, as we attempt to cope with the worldwide epidemic of obesity and its concomitant "syndrome X," we recognize that a healthful diet and attention to weight gain must begin in early childhood before "bad" eating habits are established. Furthermore, as parents seek a more healthful lifestyle for themselves and their children, they are assessing conventional approaches to treatment of disease and are seeking alternative forms of treatment and prevention. An example of this alternative approach is the use of probiotics to treat diarrhea, prevent daycare infections, and cope with the "hygiene hypothesis" for the development of atopic disease. Therefore, an updated access to clinical research-based information on the appropriate use of nutrition as an alternative form of therapy is essential for the practicing physician.

As with the first edition, we commissioned a comprehensive review of the second edition of this textbook to ensure the most updated and extensive coverage of nutrition. This review led to the addition of several chapters to each major section of the book. In the "General Concepts" section, the macronutrient requirement for growth chapter has been expanded to three chapters separately dealing with fat, carbohydrate, and protein. We have added new chapters on nutritional epidemiology, food safety, and international nutrition. In a newly added section entitled "Physiology and Pathophysiology," we have considered the role of nutrition in major body functions and dysfunctions including gene expression, immunophysiology, brain development, obesity, and behavior. The "Perinatal Nutrition" section, added to the second edition, has been expanded further to include chapters on maternal nutrition and pregnancy outcome and fetal nutrition and imprinting. The section on specific disease states has been expanded to include "The Adolescent Athlete and Dietary Supplements," "Nutrition and the Prevention of Cancer in Childhood," and "Evaluation and Management of Obesity." In keeping with the changing approach of care to pediatric patients, chapters have been added in dietary supplements (nutraceuticals) and special diets in the "Nutrition Support" section. Finally, the Appendix has been expanded to provide a more comprehensive resource for nutritional assessment and requirements and updated information on enteral products. As in previous editions, authors have been newly selected or retained based on their expertise in the topic of their chapter and their willingness to provide the most updated views on the subject.

In general, we believe that the third edition will provide a comprehensive resource for the health care provider for children entering the twenty-first century.

For this edition, Dr. Christopher Duggan has been added as an editor. His comprehensive knowledge of clinical care for the hospitalized patient, experience in nutritional issues in developing countries, and extensive experience in clinical nutrition research have been welcomed by the editors.

The editors wish to again thank Ms. Suzzette McCarron for her organizational talents and her ability to liaison between authors, editors, and the publisher. Without her extensive efforts this textbook would never have been possible. We also thank Ms. Carlotta Hayes for her many contributions

The editors are also grateful to Mr. Brian Decker, Ms. Jamie White, and the able staff of BC Decker Inc for their help and support in further developing this edition and in the publication of this textbook.

Christopher Duggan

PREFACE TO FIRST EDITION

The importance of nutrition in pediatrics has become more apparent in recent years as a result of significant observations that have helped both to define the specific needs of young infants to attain optimal growth and development and to prevent the expression of nutritionally related diseases at a later age. Of particular importance to industrialized societies is the awareness of subtle malnutrition present in pediatric patients in general as well as in underprivileged children of large cities and the hospitalized pediatric patient population. We now know that specific nutrient deficiency (e.g., zinc essential fatty acids) can occur in virtually any pediatric patient as well as in unique patient populations such as premature infants, food faddists, or families obsessed with weight reduction. Thus, the increased awareness of nutrition as an important component of the practice of pediatrics has prompted the creation of this book.

The purpose of this text is to offer a comprehensive review of general concepts of nutrition as they pertain to pediatrics as well as relevant information on the nutritional management of specific disease states. Accordingly, the text is divided into four major sections. In the first, general concepts of nutrition, such as nutrient requirements, nutritional assessment, and prevention of disease, are presented. In the second section, a systemic approach to the pathophysiology of nutrition as it pertains to other disciplines—immunology, endocrinology, pharmacology, and gastroenterology—is developed. The third and largest section comprehensively covers specific disease states and is directed at the nutritional management of these conditions, which include diabetes, cystic fibrosis, and anemias. A special effort has been made to provide updated information on the unique nutritional needs of patients with these diseases. These chapters are augmented by appropriate appendix material describing special diets and requirements of patients. In the final section, which presents an approach to nutritional support of pediatric patients, a major effort is directed at updating the reader on the more recent information about breast-feeding. Following a practical discussion concerning problems of nursing mothers, this section addresses enteric and parenteral support of pediatric patients with special needs for nutritional support. In short, this book serves as a comprehensive reference text for the practicing pediatrician, pediatric trainee, and subspecialist requiring nutritional information.

We want to thank our many authors selected to write chapters on subjects for which they have special expertise. By developing a specific format for the textbook and then selecting the most appropriate authors in their fields to develop the topics, we have provided the most comprehensive and updated text on pediatric nutrition presently available.

CHAPTER 1

PEDIATRIC NUTRITION: A DISTINCT SUBSPECIALTY

William C. MacLean Jr, MD, Alan Lucas, MD, FRCP, FMed. Sci

Scientific interest in nutrition has a long history.[1,2] Balance studies were conceived by Sanctorius in the 1620s. Lavoisier researched the oxidation of foods and Magendie discovered that protein was necessary for survival two centuries ago. In 1838, Franz Simon produced his classic dissertation, in Latin, on human milk biochemistry, which for the first time underpinned a rational basis for infant nutrition. It was over 100 years ago, in the late nineteenth century, that Rubner defined the energy content of foods and constructed the first calorimeter for measuring energy expenditure. By the early twentieth century, we already had a broad understanding of nutrient needs and an increasing understanding of micronutrients and of the effects of specific deficiencies (Funk coined the term "vitamines" in 1912). Sophisticated metabolic research on animals fed by continuous intravenous infusion flourished in the first three decades of the last century, and as early as 1944, we saw the first case of a child, age 5 months, fed successfully via the intravenous route.

In parallel with this long-term development of nutritional science has been an equally long-term appreciation of the clinical and public health importance of infant and child nutrition. In the earliest part of the last century, and well before, nutrition was a prominent and vital part of caring for infants. Unquestionably, in the eyes of early clinicians, how and what the infant was fed during health and illness were primary determinants of survival. The infant mortality rate in the United States in 1900 was 165 per 1,000.[1] The unacceptably high rate and the variability from one area of the country to the other related primarily to mode of feeding in infancy.

At that time, pediatrics, both as an academic specialty and in everyday practice, was in its own infancy. At the turn of the nineteenth century, there were probably fewer than a dozen practitioners in the United States who were exclusively devoted to pediatrics.[2] In the first presidential address to the American Pediatric Society in 1889, Abraham Jacobi discussed the rationale for having the specialty of pediatrics distinct from internal medicine: "Pediatrics deals with the entire organism at the very period during which it presents the most interesting features to the student of biology and medicine...there is scarcely a tissue or an organ which behaves exactly alike at different periods of life."[2]

A review of the topics covered in the annual presidential addresses to the American Pediatric Society during its first 35 years shows a frequent return to nutrition and nutrition-related subjects. In 1924, David M. Cowie suggested that feeding in infancy was then sufficiently based on sound physiologic principles and that pediatrics needed to focus more on nutrition and metabolism, among other things, of the older child.[2] By 1940, when the eleventh edition of *Holt's Diseases of Infancy and Childhood* was published, the editors unhesitatingly stated, "Nutrition in its broadest sense is the most important branch of pediatrics. A knowledge of its fundamental principles is essential to the physician if he is to apply preventive and corrective measures intelligently."[3]

WHY HAS PEDIATRIC NUTRITION NOT EMERGED AS A DISTINCT SUBSPECIALTY?

Given that nutrition is the oldest branch of pediatrics based on centuries of major research, it seems paradoxical that it has never emerged as a formal, distinct academic discipline. Indeed, considering its roots in and fundamental relationships to that which makes pediatrics unique—growth and maturation—why has nutrition taken a back seat to other subspecialties? The decline in the importance of nutrition in pediatrics can be explained in two ways.

First, the urgency that fostered nutrition research and the illnesses that made nutrition a prominent part of pediatric practice decreased progressively during the last century. The causes of infantile scurvy and rickets and other deficiency diseases were delineated during the early decades of the twentieth century. In fact, with the exception of iron deficiency, primary nutritional deficiencies are now virtually unknown in the United States and other developed countries, and infant mortality rates relate more to the general level of socioeconomic development than to nutritional practices. With the advent of refrigeration and appropriate milk processing technology, survival of artificially fed infants in clean environments is now routine.

Second, pediatrics has followed the path taken by internal medicine and surgery; the past 40 years have seen the growth of "organ-based" subspecialties: pediatric cardiology, neurology, nephrology, and so on, and, more recently, gastroenterology. The result of this evolutionary course was to imbed clinical nutrition in a variety of "focused" subspecialty areas. This arguably fostered a disease-specific orientation to nutrition and fragmentation of nutrition practice and research. Thus, enteral feeding has come under the wing of gastroenterologists, parenteral nutrition has interested gastroenterologists and pediatric surgeons as well, aspects of growth have fallen into the domain of endocrinology, neonatal nutrition has been taken on by neonatologists, eating disorders by psychologists and psychiatrists, food allergy by allergists and physicians in respiratory medicine, and so forth. This fragmentation and multiple ownership of pediatric nutrition have hindered development of the field as a distinct entity.

WHY IS PEDIATRIC NUTRITION RE-EMERGING IN IMPORTANCE?

In the past, the major focus in the field of nutrition has been one of meeting nutrient needs and the prevention of nutrient deficiencies. There has now been a fundamental sea change in orientation in this field. The major current interest in nutrition is its impact on health.[4] Our new understanding of the potential biologic impacts of nutrition on health has led us to frame two key new questions: Does nutrition matter in terms of patients' responses to their disease? Does it matter for long-term health and development?

With regard to the first, increasing evidence now indicates that good nutritional care may improve the clinical course of disease, reduce hospital stay, reduce the need for more expensive treatments, and, indeed, result in major reduction in health care costs. Such benefits of nutritional care are emerging over a broad range of pediatric domains such as gastroenterology (eg, Crohn's disease, short-bowel syndrome), surgery, renal medicine, care of disabled children (eg, cerebral palsy), infectious disease (eg, human immunodeficiency virus [HIV]), and oncology. Neonatology provides good examples of the effects of good nutrition on clinical course: nutritional practices may have a major influence on the incidence of life-threatening diseases (necrotizing enterocolitis and systemic sepsis),[5] may influence the need for expensive and potentially hazardous parenteral nutrition, and may significantly impact length of hospital stay.

However, the factor that has most influenced the reemergence of interest in pediatric nutrition is the increasing evidence for its effects on long-term health and development. The idea that early nutrition could have long-term consequences is part of a broader concept concerning the impact of early life events in general. To focus attention in this area, Lucas proposed using the term "programming,"[6] the idea that a stimulus or insult applied during a critical or sensitive period of development could have a long-lasting or lifetime impact on the structure or function of the organism. The first description of programming during a sensitive or critical period of development was by Spalding, who in 1873 defined the critical period for imprinting in newborn chicks.[7] Since then, developmentalists have described numerous examples of short-lived stimuli—both endogenous and exogenous—that have had lifetime effects.

What is the evidence that nutrition may behave in this programming way? Since the first studies by McCance in the 1960s, the evidence for such programming in animals is overwhelming. Brief periods of experimental nutritional manipulation in early life influence in adult life many outcomes of potential relevance to humans,[8] including blood pressure, insulin resistance, blood lipids, vascular disease, body fatness, bone health, gut function, endocrine status, learning, behavior, and longevity.[8–11] Nutritional programming effects have been seen in all species studied, including nonhuman primates.[9,10]

In the past 20 years, increasing evidence has shown that humans, like other species, may be highly sensitive to early nutrition in terms of later health outcomes. Deficiencies of single nutrients at critical periods can have long-lasting effects. Animal studies have documented the role of zinc deficiency in the development of neural tube defects in the fetus. Decreased folic acid intake in the periconceptional period also has been linked to neural tube defects in the human.[12]

Iron is another trace element that appears to play a critical role in development. Iron deficiency in rats, for example, produces reversed sleep cycles, altered pain threshold, and difficulty in learning. Dopamine D_2 receptors also are decreased. When the iron-deficient diet is begun at 10 days of age, later iron repletion is unable to reverse these defects completely.[13] In the human, the mechanisms of the detrimental effects of severe iron deficiency in early childhood on subsequent mental development are yet to be elucidated, but several studies suggest that such effects may be permanent.[14,15] On a molecular level, it is possible that iron is required at a critical time for the expression of one or several genes, and if this opportunity is lost, iron sufficiency is unable to reverse the path of development.

Many observational studies have linked growth, size, or nutrition in early life to the types of health outcome influenced by early nutrition in animals. Such observational data might be confounded, but, in more recent years, there has been long-term investment in randomized intervention studies. These trials have now shown that early diet during

the first weeks or months may influence, thus far up to 20 years later, such outcomes as blood pressure, blood lipids, insulin resistance, tendency to obesity, bone health, and cognitive performance.[8,16–18]

The effects of brief early nutritional interventions are often surprisingly large. Studies in the preterm infant show that feeding a standard versus preterm formula for just 1 month may result in a 12-point deficit in verbal IQ (in males) and a more than doubling of motor or cognitive impairment (both sexes) 7 to 8 years later.[15] In the same population, random assignment to banked donated breast milk rather than infant formula resulted in a reduction in diastolic blood pressure 13 to 16 years later of a magnitude greater than that induced by nonpharmacologic interventions used to manage hypertension in adult life (weight loss, exercise, salt restriction).[17]

These new data have major biologic and public health implications. They show that nutrition cannot simply be seen in terms of meeting nutritional needs. Rather, nutrition emerges as a major environmental influence on the genome, influencing lifetime health. It is also apparent that there is now a new onus on health professionals to ensure proper nutrition to optimize the short- and long-term health of sick individuals and healthy populations.

RATIONALE FOR A SEPARATE DISCIPLINE

Viewed in the historical context of a changing subspecialty paradigm and a new appreciation of nutrition's role at the molecular level with profound implications for health, the time would seem right for nutrition to be recognized as a distinct area of pediatric practice. But what other criteria should be fulfilled for nutrition to be formally developed as a pediatric subspecialty? Two questions must be addressed: Is there a defined area of pediatric care that requires specific nutritional expertise and are there readily identifiable deficiencies in current pediatric nutritional patient teaching and research that would benefit from such a development?

Defined Area of Expertise

There is a defined area of pediatric care that requires nutritional expertise. Nutritional advice is probably the most common category of advice sought by parents. Nutritional management problems are possibly the most common problems in pediatric hospital practice; virtually every sick premature infant and a high proportion of sick older children could benefit from specific and expert nutritional attention. Walk on any general ward and the number of patients needing advice from a pediatric cardiologist, nephrologist, or gastroenterologist will be far exceeded by those who would benefit from sound nutritional care.

However, beyond the routine practice of what we know, there are potentially important areas of new expertise that need to be sewn into nutrition practice. Just as a field such as cardiology owes its specialty status in part to the development of specialized techniques—catheterization, diagnostic imaging, etc—so could pediatric nutrition be underpinned by new tools awaiting exploitation in a clinical setting.[6] Isotope probes are available for exploring metabolic process and energy expenditure. Body composition devices (dual x-ray absorptiometry, impedance, isotope dilution, air displacement plethysmography, three-dimensional photonic scanning, ultrasonography, magnetic resonance imaging, etc) are ready to be pioneered in the complex management of sick infants and children. They also are likely to prove useful in the assessment of the impact of public health policy on the nutritional status of the childhood population (for instance, the value of interventions to reduce obesity, which are currently monitored by inappropriately nonspecific and crude methods). New tools are also available to measure and plot growth that will make the diagnosis and management of growth disorders, failure to thrive, and overweight less arbitrary and more precise. Such techniques require trained specialists.

Deficiencies in Patient Care

Subspecialists trained in pediatric nutrition would improve patient care. Specialty advice in nutrition is often sought from physicians whose primary interest is in another area.[19] This results in fragmentation of care and creates a lack of uniformity in how conditions are managed. A "standard of practice" does not exist. Nutrition knowledge has exploded to the point where clinicians in individual specialties no longer can be expected to have a comprehensive grasp even of all aspects relevant to their own practice. The fact that a high percentage of inpatients in any general or pediatric hospital continues to be found to be malnourished by "world-class" criteria suggests that care could be improved. With efforts to contain costs and the move to home care, patients are leaving hospital with more profound nutritional deficits than before, and the situation can be expected to become worse.

For many years in the United States, parenteral nutrition support in many hospitals was overseen by the surgical service, whereas enteral nutrition was handled by virtually any pediatrician. Even with the advent of nutrition support teams, most of the physicians involved have acquired their nutritional skills in an ad hoc fashion. If consultation about enteral nutrition is needed, the gastroenterologist, by default, has assumed responsibility and is likely to be called. To be sure, gastroenterology and nutrition are closely linked, and most pediatric gastroenterologists have considerable expertise in nutrition, especially as it affects their "organ system." But the pediatric gastroenterologist should not be expected to be well versed in all areas of nutrition because only a small part of nutrition science and practice is related directly to gastroenterology.

Deficiencies in Teaching

Teaching of nutrition in medical schools also is fragmented at best: "To almost everyone expressing an opinion about the teaching of nutrition in medical schools, it appears to be entirely unsatisfactory. Rare successes prove to be ephemeral and crucially dependent on individual commitment and outside funding."[20] In most medical schools, the basic science pertaining to nutrition is imbedded in biochemistry and, perhaps, physiology. Formal teaching of clinical nutrition is nearly nonexistent. What teaching there

is generally is done as part of primary care rotations or by subspecialists in other areas in pediatrics. Many medical students never observe breast-feeding and are never trained to make up a formula feed. Most house staff leave training with less than adequate understanding of the physiology and management of breast-feeding, the composition and appropriate use of standard or special infant formulas, or the appraisal of simple feeding problems and the rationale for nutrition advice or care during the second 6 months of life and beyond. Public health and preventive nutrition are equally neglected. McLaren has argued that were nutrition "given its rightful place" in the basic sciences, there would be no need for courses in nutrition or nutrition textbooks.[19] Clinical teaching would revolve around clinical dietetics. This would still leave nutrition primarily relating to and being practiced by organ-based specialties. Although this may be acceptable from the point of view of clinical practice, from the point of view of research, it will ultimately impede inquiry into the important areas.

Deficiencies in Research

The area that perhaps stands to gain most from the development of nutrition as a distinct discipline is research. Although basic laboratory and animal research in nutrition has been active, the key clinical research questions in pediatric nutrition are unlikely to be addressed as long as nutrition is divided among the traditional specialties. This is so because the orientation toward disease of most subspecialties will favor research to answer questions related to therapeutic dietetics (ie, treatment of disease). With infant survival from a nutritional point of view assured in most Western countries, the issue of how early nutrition should be optimized in terms of its effects on later health becomes of paramount importance.

The objective for clinical research in any field of health policy or clinical practice should be to prove outcome benefits for recommended approaches to management, generally by use of formal clinical trials that test the safety and efficacy of the intervention. This would be standard in established clinical areas. Thus, whether or not a clinician should treat high blood pressure, remove a malignancy rather than give chemotherapy, or repair a heart defect at birth rather than later in childhood and other decisions depend on proven clinical benefit for each management option. For example, physicians routinely treat high blood pressure precisely because lowering blood pressure has been shown to reduce morbidity and mortality from cardiovascular disease.

Research in childhood nutrition has been largely unsatisfactory in this respect. Research over the past 50 years has failed to address adequately whether adhering to the nutritional recommendations made by ad hoc groups and governmental bodies confers outcome benefits.[6] The critical issue of whether early nutrition, either in health or disease, influences long-term health or development has, until recently, barely been approached in formal studies. Thus, most recommendations of expert bodies on fundamental areas of practice are based largely on theoretic considerations derived from short-term physiologic experiments and epidemiologic studies rather than on outcome findings from intervention trials. Both physiology and epidemiology can be useful in identifying questions and framing hypotheses for such outcome trials, but neither can replace them.

The paucity of clinical outcome studies in pediatric nutrition contrasts sharply with the major research investment that has been made in pediatric nutritional physiology. Possibly more research effort has been applied here than in any other area of pediatrics. For instance, as far back as 1953, Macy and colleagues summarized the contents of 1,500 publications on the composition of breast milk—just one small area of infant nutrition.[21] The profusion of pediatric nutritional studies in the face of the paucity of outcome data justifying clinical practice suggests that clinical pediatric nutritional research has lacked direction. This lack of research direction, not seen to nearly the same extent in the recognized pediatric specialties, can be traced in part to the absence of guidance on research priorities from specialists trained in nutrition and from centers of excellence in pediatric nutrition.

CONCLUSION

Like the blind men approaching the elephant, each subspecialty comes up with a different view of nutrition. Each subspecialty creates a paradigm that determines how questions are framed and results are interpreted. Depending on one's primary interest, taurine may be thought of as a critical nutrient for neural development and function, a primary determinant of bile acid conjugation, or an osmoregulator of the brain during dehydration. Someone needs to see the elephant for what it is—to collate our knowledge in the field of nutrition, understand its significance for development, and apply it to clinical practice.

Functional specialties in medicine increasingly are interacting in a matrix fashion with organ-based specialties. Clinical nutrition fits comfortably into this new paradigm. The time appears to be right to foster clinical nutrition within pediatrics as a unique discipline. Such a development would address currently identifiable deficiencies in patient care, training, and, especially, research in clinical nutrition.

CHAPTER 2

CLINICAL ASSESSMENT OF NUTRITIONAL STATUS

Irene E. Olsen, PhD, RD, Maria R. Mascarenhas, MD,
Virginia A. Stallings, MD

Nutritional assessment is an integral part of patient care because nutritional status affects a patient's response to illness. Attention to nutritional status is especially important in pediatric patients because they are also undergoing the complex processes of growth and development, which are influenced by the genetic makeup of the individual and coexisting medical illness in addition to nutritional status. Thus, the assessment of nutritional and growth status is an essential part of clinical evaluation and care in the pediatric setting.

The assessment should allow for the early detection of both nutrient deficiencies and excesses. There is no single nutrition measurement that is best; therefore, a combination of different measures is required. Growth is an important indicator of health and nutritional status of a child, and a variety of growth charts are currently available to help with the assessment of growth. These include the 2000 Centers for Disease Control and Prevention (CDC) growth charts that represent the US population. Each growth measurement performed needs to be accurate and obtained at regular intervals. These longitudinal data will help identify at-risk patients (eg, those who are malnourished, obese, stunted; small-for-gestational-age infants; and those with refeeding syndrome) and will allow the monitoring of a patient's clinical response to nutritional therapy.

During infancy, childhood, and adolescence, many changes in growth and body composition occur. Therefore, clinicians must understand normal growth to recognize abnormal patterns. Clinicians also need to recognize the nutritional changes that occur with acute and chronic disease. With the epidemic of pediatric obesity, the proper identification of the overweight or obese patient is also important. A brief nutritional screening assessment may be used to identify patients in need of an in-depth assessment. A typical nutritional screening includes a brief medical and dietary history (including feeding ability), anthropometric measurements (eg, weight, stature), and possibly laboratory data. A full nutritional assessment includes more detailed medical and dietary histories (including a measure of dietary intake), a complete physical examination, further anthropometric and body composition measurements, sexual and skeletal maturation, laboratory data, and the estimation of nutritional requirements. A clinician's global assessment of the child based on these objective data and his/her clinical judgment is also important to consider in determining nutritional status.[1] Most often, health care professionals work as a team in gathering the information for the assessment of nutritional status of children.

MEDICAL HISTORY

Obtaining the medical history is central to the nutritional assessment. Past and present medical information, including the duration of the current illness, relevant symptoms, diagnostic tests and therapies (eg, chemotherapy, radiation), and medications, is documented. Because nutritional abnormalities are often associated with certain disease states, it is essential to identify underlying medical conditions and the concomitant medication history. Medications can cause nutritional deficiencies (eg, 6-mercaptopurine) and drug–nutrient interactions (eg, phenytoin and tube feedings; Table 2-1). Drug–nutrient interactions may occur between drugs (prescription and nonprescription) and foods, beverages, and dietary and vitamin/mineral supplements. Alterations in drug metabolism and absorption by food or pharmacologic interactions may be clinically significant.[2] Past medical history includes previous acute and chronic illness, hospitalizations, and operations. The history of past growth patterns (with previous growth charts, as possible), onset of puberty (for the child and other family members), and a developmental history (including feeding abilities) may also be included. Family history should include a medical history as well as the family's social and cultural background, especially as related to diet therapy and the use of alternative and complementary medicine. The review of systems includes oral motor function, dental development, and gastrointestinal symptoms such as vomiting, gastroesophageal reflux, diarrhea, and constipation.

TABLE 2-1 Examples of Some Common Drug–Nutrient Interactions

Drug	*Nutrient*
Amphotericin B	Hypokalemia, hypomagnesemia
Antacids	Vitamin D and iron deficiency, hypophosphatemia
Phenobarbital	Vitamin D deficiency
Cholestyramine	Vitamin A, D, E, and K malabsorption
Cyclosporin	Elevated triglycerides, hypokalemia, hypomagnesemia
H_2 blockers	Iron deficiency
Methotrexate	Folate deficiency
Phenytoin	Folate deficiency
Corticosteroids	Hyperglycemia, hypophosphatemia
Sucralfate	Hypophosphatemia
Sulfasalazine	Folate deficiency
Trimethoprim	Folate deficiency
Furosemide	Hypokalemia, hypomagnesemia, hypocalcemia

PHYSICAL EXAMINATION

Physical examination includes anthropometrics (see below), including weight, stature, head circumference, and arm measures. The frequency of measurements of well children (Table 2-2) follows the recommendations of the American Academy of Pediatrics.[3] The pattern of measurement for hospitalized patients depends on the age of the patient, illness, and degree of nutritional intervention (see Table 2-2). Nutritional assessments for patients with complex chronic disease states should be conducted every 1 to 2 months and less often in those with milder disease (every 6 to 12 months). The general physical examination includes an assessment of the patient's general condition and close examination of skin, hair, and teeth (see Table 2-3 and Appendix, Table A-12). This includes an assessment for pallor, clinical assessment of body fat stores, wasting of muscle mass, edema, skin rash, thinning of hair, and evidence of specific nutritional deficiencies. Examples of specific signs include the flag sign or the loss of hair color associated with a period of malnutrition followed by recovery with a return of normal hair color and texture to normal. Vitamin A deficiency causes follicular hyperkeratosis and night blindness. It is unusual to see classic signs of marasmus and kwashiorkor in developed countries. Examination of specific organ systems and obtaining medical record information is helpful in assessing the severity of the underlying disease process. It is also important to consider the clinician's clinical judgment in the assessment of nutritional status.[1] Documenting sexual development by Tanner staging is a routine part of the nutritional assessment of adolescents (see below). For a summary of signs and symptoms of specific nutritional abnormalities, see Table 2-3 (see also the Appendix, Table A-12).

DIETARY HISTORY

The dietary history is an essential component of the nutritional assessment. The dietary history provides information not only on the amount and quality of food consumed but also on the eating patterns and behaviors of the family. This part of the nutritional assessment also provides information on the number of meals, snacks, and beverages consumed; special foods eaten by the child and family; vitamin and mineral supplements ingested regularly; food allergies; intolerances; and unusual feeding behaviors. The child and family are asked about psychosocial factors that impact on food selection and intake, including family history, socioeconomic status, and use of the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) and supplemental food programs, parent/caretaker's perception of the child's nutritional status, and religious and cultural considerations. Food-related factors may affect dietary intake and include food allergies, intolerances, self-imposed and prescribed diets, and feeding skills. These factors are also noted in the assessment.

Assessing the dietary intake of breast-fed infants is more difficult because the volume of milk consumed cannot be directly measured. An estimate is obtained by weighing the infant before and after feeds and using a conversion factor of 1 mL volume of breast milk consumed for each gram of weight gained. In formula-fed infants, the clinician should inquire about both the amount and type of formula consumed and the details of the method of preparation (concentrates, powders, modular additives).

The quantity and quality of dietary intake are assessed by prospective food records (with weighed or estimated food portions), retrospective 24-hour recalls (previous 24 hours or of a "typical" 24-hour period), or food frequency questionnaires.[4] The prospective food records are usually carried out for 3 to 7 days (including a combination of weekend and weekdays) and provide the most accurate assessment of actual intake. However, food records are used most often in the research setting because they are labor intensive and time consuming. As available, these records are analyzed and compared to the Dietary Reference Intakes (DRIs) (see below) using a computerized nutrient analysis program. A limitation of food records is that parents tend to overestimate intake and/or forget to record all foods eaten.[5] The retrospective 24-hour diet

TABLE 2-2 Suggested Schedule for Growth Assessments in Hospitalized and Healthy Children

Age	*Weight*	*Length or Height*	*Head Circumference*
Hospitalized child			
Preterm	Daily	Weekly	Weekly
Full term to 12 mo	3×/wk	Monthly	Monthly
1–2 yr	3×/wk	Monthly	Monthly
2–20 yr	2×/wk	Monthly	As indicated
Outpatient well-child visit			
0–2 mo	Monthly	Monthly	Monthly
2–6 mo	Every 2 mo	Every 2 mo	Every 2 mo
6–24 mo	Every 3 mo	Every 3 mo	Every 3 mo
2–6 yr	Annually	Annually	—
6–10 yr	Every 2 yr	Every 2 yr	—

TABLE 2-3 Selected Clinical Findings Associated with Nutritional Inadequacies

Area of Examination	*Finding*	*Considered Nutritional Inadequacy*
General	Underweight; short stature	↓Calories
	Edematous; decreased activity level	↓Protein
	Overweight	↑Calories
Hair	Ease of pluckability; sparse, depigmented; lack of curl; dull, altered texture; flag sign	↓Protein
Skin (general)	Xerosis, follicular keratosis	↓Vitamin A
	Symmetric dermatitis of skin exposed to sunlight, pressure, trauma	↓Niacin
	Edema	↓Protein
	Petechiae, purpura	↓Ascorbic acid
	Scrotal, vulval dermatitis	↓Riboflavin
	Generalized dermatitis	↓Zinc, essential fatty acids
	Erythematous rash around mouth and perianal area	↓Zinc
Skin (face)	Seborrheic dermatitis in nasolabial folds	↓Riboflavin
	Moon face; diffuse depigmentation	↓Protein
Subcutaneous tissue	Decreased	↓Calories
	Increased	↑Calories
Nails	Spoon-shaped; koilonychia	↓Iron
Eyes	Dry conjunctiva; keratomalacia; Bitot's spots	↓Vitamin A
	Circumcorneal injection	↓Riboflavin
Lips	Angular stomatitis	↓Riboflavin, Iron
	Cheilosis	↓B-complex vitamins
Gums	Swollen, bleeding	↓Vitamin C
	Reddened gingiva	↑Vitamin A
Teeth	Caries	↓Fluoride
	Stained teeth	Iron supplements
	Mottled, pitted enamel	↑Fluoride
	Hypoplastic enamel	↓Vitamins A, D
Tongue	Glossitis	↓Niacin, folate, riboflavin, vitamin B_{12}
Skeletal	Costochondral beading	↓Vitamins C, D
	Craniotabes; frontal bossing; epiphyseal enlargement	↓Vitamin D
	Bone tenderness	↓Vitamin C
Muscles	Decreased muscle mass	↓Protein, calories
	Tender calves	↓Thiamin
Neurologic	Ophthalmoplegia	↓Thiamin, vitamin E
	Hyporeflexia	↓Vitamin E
	Ataxia, sensory loss	↓Vitamins B_{12}, E
Endocrine and other	Hypothyroidism	↓Iodine
	Glucose intolerance	↓Chromium
	Altered taste	↓Zinc
	Delayed wound healing	↓Vitamin C, zinc

Adapted from Hubbard VA, Hubbard LR. Clinical assessment of nutritional status. In: Walker WA, Watkins JB, editors. Nutrition in pediatrics, basic science and clinical applications. 2nd ed. Hamilton (ON): BC Decker; 1997. p. 7–28.

recall provides a quicker assessment of dietary intake. For a 24-hour recall, the child/parent is asked to recall what and how much the child ate and drank over the past 24 hours. Recall accuracy depends on the child/parent's memory and ability to estimate portion sizes. Also, because this is only one day of intake, it may not be representative of the usual intake. When the child's intake is affected by acute illness, a 24-hour recall of a "typical day" is more useful to estimate usual intake. The 24-hour recall tends to underestimate food intake when compared with longer intervals of food records.[5]

Another way of assessing dietary intake is the food frequency questionnaire method. These questionnaires collect information on both the frequency and amount consumed of specific foods and are useful in the clinical setting to identify usual eating patterns. A limitation of the food frequency questionnaires is that the amounts of food are often over-reported.[5] All of these methods of dietary assessment are somewhat limited owing to gaps in the nutrient databases, which lack information about bioavailability, presence of inhibitors and enhancers of absorption, and nutrient availability of specific nutrients of interest.[6]

The most commonly used method of dietary assessment in hospitalized patients is the calorie count. This is a variation of the prospective food records as the amount of food consumed from a known quantity of food (as specified by a menu or list) is recorded. The accuracy of the calorie count assessments is limited by the number of individuals required for the completion of these forms throughout a 24-hour period (eg, the dietitian, the nurse for each shift, the child's family, the child). However, calorie counts are a useful part of nutritional assessment follow-up because these provide a rough assessment of the patient's appetite, intake, and compliance with nutrition recommendations.

ANTHROPOMETRICS AND BODY COMPOSITION

At a minimum, nutritional assessment of a child includes a measured weight, length or height, and head circumference (birth to age 3 years), and these measurements are followed over time to assess short- and long-term growth and nutritional status. For children with chronic disease, a midarm circumference (MAC) and triceps skinfold (TSF) thickness are also part of the assessment to determine body fat and protein stores. In addition, a dual-energy x-ray absorptiometry (DXA) scan may be added to more thoroughly assess body composition (percent fat, lean body, and fat mass) and bone mineral density (BMD) (see Chapter 4).

Accurate and reliable anthropometric and body composition measurements require the proper equipment and techniques. Training and practice in anthropometric technique cannot be overemphasized. All growth measures should be taken in triplicate and used as an average. The clinician's assessment for a child depends on the quality of these data. Equipment requirements for each measure are discussed below.

Weight

Weight is a measure of overall nutritional status with age, sex, and height/length required for optimal interpretation. Weight is determined using a digital or beam balance scale. Until the child is approximately 24 months or can cooperate and stand independently, a pan version of the scale is used. Weight should be measured in light or no clothing and without a diaper for infants. It is important that the scale is zeroed prior to each measurement and is calibrated using known weights at least monthly or on movement of the scale.[7] Weights are recorded to the nearest 0.01 kg in infants and 0.1 kg in older children.

Stature: Length or Height

A measure of stature is important for monitoring long-term nutritional status. Recumbent length is measured using a length board for children from birth to 2 or 3 years. The measurement of length requires two individuals. The first person positions the infant straight on the board so that the infant's head is against the headboard and in the Frankfort horizontal plane.[7] The Frankfort plane is the anatomic position when the lower margin of the orbit and the upper margin of the auditory meatus are in line. The second person holds the infant's knees flat to the table and heels flat against the movable footboard.[7] For children able to stand independently and cooperate, height is measured using a stadiometer, with a moveable headboard at a fixed 90-degree angle to the back of the stadiometer. The child is measured barefoot or in thin socks and in minimal clothing to allow the observer to check for correct positioning. For the measurement, the child stands erect, feet together, heels, buttocks, and back of head touching the stadiometer, and looking ahead in the Frankfort horizontal plane.[7] Because length overestimates height by approximately 0.5 to 1.5 cm,[8] it is essential to record the method of measurement during the transition from recumbent length to standing height. The change to standing height is also accompanied by the transition to pediatric (2 to 18 years) growth charts (see below). Both length and height measurements are recorded to the nearest 0.1 cm.

For children in whom stature measurements are not possible owing to physical constraints (eg, contractures, nonambulatory), alternative measures are available. Upper arm and lower leg lengths provide reliable and valid indexes of stature in children.[9,10] These measurements are conducted using sliding calipers in infants and an anthropometer for children. All measurements are recorded to the nearest 0.1 cm.

The shoulder to elbow length is used for the upper arm measurement.[11,12] In infants (birth to 24 months), the arm is bent to a 90-degree angle and the measurement is taken from the superior lateral surface of the acronium to the inferior surface of the elbow.[12] For older ages (2 to 18 years), the arm should hang in a relaxed position at the side, and the distance between the superior lateral surface of the acronium to the tip of the radius is measured.[12] Lower leg length is measured as the knee to heel length[12] for infants (0 to 24 months) and as a calf length[11,12] in older children (2 to 18 years). For infants, the superior surface of the knee to the heel is measured while the leg is bent at a right angle at the hip, knee, and ankle.[12] In older children, the medial tip of the tibia to the distal tip of the medial malleolus is measured while that leg is crossed over the opposite knee.[11,12] The right-side extremity should be measured for these alternative stature estimates.[12] If there are asymmetric extremity abnormalities, the measurement should be taken on the least affected side.

Head Circumference

Head growth, primarily owing to brain development, is most rapid within the first 3 years of life. Routine measurement of head circumference (the frontal occipital circumference) is a component of the nutritional assessment in children up to age 3 and longer in children who are at high nutritional risk. Head circumference is a less sensitive indicator of short-term nutritional status than weight and height because brain growth is generally preserved in cases of nutritional stress. Head circumference is not a helpful nutritional status measure in children with hydrocephalus, microcephaly, and macrocephaly.

Head circumference is measured using a flexible, nonstretch tape measure. The circumference should be taken at the maximum distance around the head, which is found by placing the measuring tape above the supraorbital ridge and extending around the occiput.[12,13] Care should be taken to keep the tape measure flat against the head and parallel on both sides. The measurements should be recorded to the nearest 0.1 cm.[13]

GROWTH CHARTS AND TABLES

Serial measurements are essential for optimal assessment of short- and long-term growth and nutritional status. A number of growth charts and tables are available for the comparison of weight, stature, and head circumference with reference populations by age and sex. Weight is also assessed relative to a child's height (weight for height, weight for height^2 or body mass index [BMI]) for an additional assessment. The types of charts and tables available for clinical assessment in infants and children are reviewed.

Premature Infant Growth Charts

For infants born prematurely, a variety of charts are available for the assessment of growth. Intrauterine growth–based charts are preferred over postnatal growth–based charts as the pattern and rate of normal intrauterine growth are the standard for growth of premature infants. Growth measurements are plotted based on corrected gestational age for the first 12 months of life. In clinical practice, the use of corrected gestational age may continue to 24 to 36 months, depending on the child's size and growth. The Lubchenco growth charts (see Appendix, Figure A-14) are the most widely used owing to ease of clinical use (weekly age intervals, commonly used percentiles) and include charts for weight, length, and head circumference.[14,15] The Babson charts (see Appendix, Figure A-13) are presented in biweekly age intervals up to 40 weeks gestation and as standard deviations, rather than

percentiles, so they are used less in clinical care.[16] More recently, weight charts based on larger national datasets of fetal growth have been published.[8,17] There is still a need for more up-to-date reference standards for length and head circumference.

Once a preterm infant reaches 40 weeks corrected gestational age, it is appropriate to monitor growth on the new CDC growth charts.[18] Former premature infants are plotted on these charts based on their corrected gestational age (as above). Although all premature infants may not achieve "good" placement on these growth charts, these charts provide the appropriate goal for growth. Also available are the Infant Health and Development Program (IHDP) charts for low birth weight (LBW, 1,501 to 2,500 g) and very low birth weight (VLBW, ≤ 1,500 g) premature infants for boys[19,20] and girls[21,22] and the National Institute of Child Health and Human Development (NICHD) Neonatal Research Network Growth Observational Study[23] projected growth charts and tables for VLBW infants (available online: <http://neonatal.rti.org>). These charts provide a comparison of how an LBW or VLBW premature infant grows relative to two reference populations of similar infants. The IHDP and NICHD postnatal charts represent actual, not ideal, patterns of growth for former premature infants. Therefore, these charts may be used in conjunction with but not in place of the CDC growth charts.

CDC Growth Charts, 2000

In 2000, the CDC and National Center for Health Statistics (NCHS) released an updated set of growth charts called the CDC growth charts (see Appendix, Figures A-1 to A-10).[18] Changes to the previously used 1979 NCHS growth charts[24] included (1) BMI (kg/m^2) charts for boys and girls (2 to 20 years); (2) 3rd and 97th percentiles for all charts and 85th percentile for the weight-for-stature and BMI-for-age charts; (3) improved transition from recumbent length to standing height measurements in the stature charts; (4) increased age range from 18 to 20 years; and (5) the use of a combination of breast- and formula-fed infants to establish the reference growth patterns.[18] These charts are available for boys and girls ages 0 to 36 months for weight, length, and head circumference by age and weight for length and ages 2 to 20 years for weight, height, and BMI for age and weight for height. The CDC growth charts are available on the Internet (<www.cdc.gov/growthcharts>).

Incremental Growth Velocity

Reference data are also available for incremental growth velocity for boys and girls in weight, stature, and head circumference from 0 to 18 years (see Appendix, Tables A-6 to A-10).[25–29] These data are presented in time intervals (1, 3, or 6 months) and approximate growth over time by percentile (3rd to 97th or 5th to 95th percentiles). In clinical practice, the incremental tables for weight, length, and head circumference[25,27,29] are helpful in the assessment of former premature infants and other children with growth failure from any cause. The growth increments are easily divided into daily, weekly, or monthly weight gain goals. This method of growth assessment is more sensitive in detecting growth faltering or catch-up growth than the growth charts.

Growth charts for the assessment of height and height velocity in relation to the stage of sexual maturity based on US reference data are also available (see Appendix Figures A-11 and A-12).[30] These charts provide height growth for early, middle, and late maturers by sex and age at which peak height velocity was reached and explain some of the variation in growth related to different stages of puberty. Height velocity charts are often used in the care of children with poor growth and chronic illnesses.

Special Growth Charts

Although the CDC growth charts are recommended for the growth and nutritional assessment for all children, a number of disease-specific charts have been published (eg, achondroplasia, Brachmann-de Lange syndrome, cerebral palsy, Down syndrome, Marfan syndrome, myelomeningocele, Noonan's syndrome, Prader-Willi syndrome, sickle cell disease, Silver-Russell syndrome, Turner's syndrome, Williams syndrome; see Appendix, Table A-13). Weight- and height-for-age growth charts are available for boys and girls ages 0 to 36 months and 2 to 18 years based on a large sample of children with Down syndrome.[31,32] However, many other special charts are based on small samples of children and include children with suboptimal nutritional status. Disease-specific charts may be helpful to use in conjunction with the CDC growth charts.

A set of growth charts is also available for the assessment of alternate stature measures,[9,10] including upper arm length (infants 0 to 24 months, girls 3 to 16 years, boys 3 to 18 years) and lower leg length (infants 0 to 24 months, girls 3 to 16 years, boys 3 to 18 years). Similar to other measures of stature, these linear growth measures are used along with weights to help determine a child's nutritional status.[12]

ASSESSMENT OF ANTHROPOMETRICS

Nutritional status indices are essential for the clinical interpretation of the growth measurements. Every nutritional assessment requires one or more of the following indices for interpretation.

Percentiles for Age and Sex

When each of the growth measures is plotted on a growth curve, a percentile or rank of the individual compared to the reference population is determined. For example, the 25th percentile weight for age means that the individual patient weighs the same or more than 25% of the reference population of the same age and sex, and the 75th percentile weight for age means that the individual patient weighs the same or more than 75% of the reference population of the same age and sex.[8] Percentiles are easily interpreted and used clinically. Available growth charts provide reference growth of children ranging from the 5th to 95th percentiles and now the 3rd to 97th percentiles. In clinical practice, the 5th to 95th percentile growth charts continue to be used in the screening and follow-up of healthy children, whereas the 3rd to 97th percentile growth charts may be used for

children with chronic illness or at nutritional risk. Weight-for-age and height-for-age percentiles are also used to screen for malnutrition using published classifications (see Appendix, Table A-11). Percent ideal body weight (IBW), based on appropriate height and weight for age (see below), is often used as an indicator of wasting or obesity. Height-for-age percentiles are an adequate measure of long-term nutritional status and are used for screening in healthy children with low height for age reflecting stunting. Height for age is generally interpreted as short (< 5th percentile), normal (5 to 95th percentile), and tall (> 95th percentile).

Genetic Growth Potential: Midparental Height

In the assessment of a child's stature, it is helpful to estimate the genetic potential for stature as determined by the biologic parents' adult height.[33] This is of particular interest in the child with short stature because it is important to determine if the child is healthy but short owing to family genetic background, disease, and/or poor nutrition. An adjustment for parental height is used for a child's length (0 to 36 months) or height (3 to 18 years) and is based on the mean of the height of both biologic parents. This allows adjustments to the child's stature for tall or short parents. The corrections are based on the Fels Institute and older NCHS data[24] and therefore are used in conjunction with the 1979 NCHS growth charts. Parental height adjustment is appropriate for use with most of the parents and children in the United States; however, it should not be used when the parents do not meet their genetic potential for height (eg, in situations of poor health and/or nutritional status during the parental childhood or adolescence).[33]

Weight for Height

Weight relative to height provides different information on the growth and nutritional status in an individual than either weight for age or height for age alone. Weight for height helps to determine and classify the nutritional status in the individual patient.[34] For children under the age of 6 years, weight for height is most frequently assessed by determining a percentile on the CDC growth charts.[18] Weight for height is generally interpreted as underweight (< 5th percentile), within normal variation (5th to 95th percentile), and overweight (> 95th percentile) and is used in screening healthy children. Weight-for-height measures are also used for screening classification of protein-calorie malnutrition (see Appendix, Table A-11).

BMI is another measure of weight relative to height. The new CDC growth charts provide BMI for age and sex from age 2 to 20 years.[18,35] With the availability of these new charts, BMI will be used more frequently as an assessment tool for children. However, because both weight and height in children change over time, unlike in adults, there is no fixed BMI value for the diagnosis of obesity in children (eg, BMI ≥ 30). The BMI percentile must be used for interpretation. In the United States, the 85th and 95th BMI percentiles for age and sex are used to define "at risk of overweight" and "overweight" in children.[36] From the International Obesity Task Force, cutoff points for BMI to define overweight and obesity in children based on cross-sectional growth studies from six countries (Brazil, Great Britain, Hong Kong, the Netherlands, Singapore, United States) are also available.[37] A recent study found similar predictions of underweight and overweight in children and adolescents (2 to 19 years) using the BMI-for-age and weight-for-height classifications.[38]

Percent Ideal Body Weight

Percent IBW is an additional indicator of nutritional status. Unlike weight for height, this measure can be used past the age of 6 years (the age limit for the weight-for-height curve). IBW for a child is determined from the CDC growth charts by using the following steps: (1) plotting the child's height for age; (2) extending a line horizontally to the 50th percentile height-for-age line; (3) extending a vertical line from the 50th percentile height for age to the corresponding 50th percentile weight; and (4) noting this IBW. Percent IBW is calculated as [(actual weight divided by IBW) × 100]. In clinical practice, percent IBW may be used to classify the degree of over- or undernutrition. An example of a set of clinical classifications is > 120% IBW as obese; 110 to 120% IBW as overweight; 90 to 110% IBW as normal range; 80 to 90% IBW as mild wasting; 70 to 80% IBW as moderate wasting; and < 70% IBW as severe wasting. IBW is also used as a clinical weight goal in the nutritional rehabilitation of a child.

Percent Weight Loss

Percent of usual body weight loss is an important clinical indicator of nutritional status and nutritional risk. Percent weight loss is calculated as [(previous weight – current weight)/previous weight – 100]. A 5% or greater weight loss in 1 month may be considered an indicator of nutritional risk in children.

Growth Velocity

Growth velocity (change in the growth parameter over time) is useful to detect a change in nutritional status and to monitor the effectiveness of nutritional and medical therapy. As discussed above, age- and sex-specific charts and tables are available for the evaluation of weight, stature, and head circumference growth over time.[25–30]

BODY COMPOSITION

In children with many acute and chronic diseases, the nutritional assessment requires measurement of body composition (body fat and protein stores) in addition to weight, stature, and head circumference (see Chapter 4).

Midarm Circumference

MAC can be used as a measurement of growth and an index of energy and protein stores and can provide information on fat patterning.[13] The measurement is taken at the midpoint of the upper arm, located halfway between the lateral tip of the acromion and the olecranon when the arm is flexed at a 90-degree angle (measured and marked). For the MAC measurement, the child should be upright with the arm relaxed by the side. A flexible, nonstretch

measuring tape is placed perpendicular to the long axis of the arm, tightened around the arm, and recorded to the nearest 0.1 cm.[13]

Triceps Skinfold Thickness

The TSF thickness is an indicator of subcutaneous fat (energy) stores and total body fat and provides information on fat patterning.[39] For the measurement, the child should be upright with the arm relaxed at the side. The TSF thickness is measured at the midpoint of the upper arm (defined above) over the center of the triceps muscle on the back of the arm (measured and marked beforehand). The anthropometrist lifts the skinfold with the thumb and index finger, approximately 1 cm above the marked midpoint, and places the calipers at the marked point. Four seconds after the handles of the calipers are released, the measurement is taken and the calipers are removed. This measurement should be taken in triplicate, used as an average, and recorded to the nearest 0.1 cm.[12]

Reference data (age and sex specific) are available for the assessment of MAC and TSF thickness as a percentage[40] (see Appendix, Tables A-4 and A-5). The MAC and TSF measurements (in mm) are used to calculate upper arm muscle area and fat area (formulas below).[12,40] These are clinical indicators of total body stores of muscle and fat[12]:

Upper arm muscle area (cm^2) = [MAC (cm) – (TSF (cm) × π)]^2/(4 × π), where π = 3.14.

Upper arm fat area (cm^2) = upper arm area (cm^2) – upper arm muscle area (cm^2), where upper arm area (cm^2) = MAC^2/(4 × π).

Dual-Energy X-Ray Absorptiometry

DXA is a noninvasive measurement of BMD. It is an indirect, low-radiation measurement that has increasing clinical utility. DXA scans are performed on the lumbar spine, hips, and whole body in adults and on the lumbar spine and whole body in infants, children, and adolescents. Although primarily used for the assessment of bones, whole-body scans also provide body composition measures of fat-free mass, fat mass, and percent body fat.[41] In addition, the DXA scans provide information on bone mineral content (BMC) in grams per centimeter or BMD in grams per square centimeter in different regions of the skeleton or the whole body. Values for the lumbar spine are used to assess bone health and are compared with reference data in healthy age- and sex-matched infants, children, and adolescents. Usually, an anteroposterior view of the lumbar vertebrae L1 to 4 or L2 to 4 is used for clinical interpretation. It takes approximately 20 minutes to complete both DXA scans (lumbar spine and whole body), including time for positioning. Younger children are measured while asleep, or sedation may be considered. Results for BMC and BMD are assessed using a z-score (standard deviation score), which compares the individual with the reference database. A z-score of 0 is the mean (similar to the 50th percentile on a growth chart) for the reference data, with +1, +2, –1, and –2 representing plus and minus 1 and 2 standard deviations of the reference mean. These results are expressed as z-scores and percent predicted. The World Health Organization (WHO) has defined osteoporosis in young, white, adult women as a BMD z-score of –2.5 or less (ie, 2.5 or more standard deviations below the reference mean).[42] A diagnostic criterion for men, children, and other races is not yet available.[42] In clinical practice, children with z-scores of –2 to + 2 are considered to have normal BMD, whereas a z-score of –1 to –2 is in the low normal group. A z-score of –2 to – is considered in the reduced range, whereas a value of –3 or less is considered to be in the significantly reduced range. Z-scores less than –2 are considered in the fracture range (Table 2-4).

The quality of the DXA-BMD reference ranges available for children is a limitation of this method. The sample sizes are low, and there is minimal detail for children across various pubertal groups. Additionally, the reference dataset is not heterogeneous nor representative of the ethnic diversity of the US population.[43] The advantages of the DXA are the low radiation exposure, fast scan time, and noninvasive nature. The precision of the instrument is excellent. The radiation dose is small (< 1 mrem, Hologic Delphi Clinical Bone Densitometer product specifications) or less than that received during a standard airline flight across the United States.[44] The frequency of measurements depends on the clinical needs (see Table 2-4). Patients with poor BMD measurements may need the scans every 6 to 12 months after the baseline assessment. Those individuals with values in the low normal range but with risk factors may need testing every 1 to 2 years. At-risk patients include those with chronic illness (eg, inflammatory bowel disease, cystic fibrosis, celiac disease), poor growth, and reduced physical activity and those receiving chronic medications (eg, corticosteroids, anticonvulsants).

A newer technique providing data on both cortical and trabecular bone is quantitative computed tomography (QCT). This test describes volumetric BMD and also differentiates between cortical and trabecular bone. Special high-resolution scanners have been developed to decrease radiation exposure for the peripheral skeleton, and this is currently a research tool. Bone health in children and adults is altered by intakes of calcium and vitamin D and weight-bearing physical activity. It is important to be aware of the risk factors for bone disease in children, including conditions such as chronic diarrhea, lactose intolerance, poor dietary intake, fat malabsorption, decreased physical activity, and the use of steroid medications.

TABLE 2-4 Suggested Bone Health Assessment by Dual-Energy X-Ray Absorptiometry

Z-Score	*Interpretation*	*Repeat Measurements*
2.0 or greater	Increased	Annually
+2 to –2	Normal	If clinical status changes
–1 to –2	Low normal	Every 1 to 2 yr
–2 to –3	Reduced	Annually
–3.0 or less	Significantly reduced	Every 6 to 12 mo

SEXUAL AND SKELETAL MATURATION

Because body composition and the rate of growth vary throughout childhood and adolescence, it is important to consider sexual/pubertal and skeletal maturation when assessing an individual patient's anthropometric measurements. For example, a small child who is physically immature (based on sexual and skeletal development) is less of a nutritional concern than a child who is small and appropriately mature for age. The physically immature child with likely growth delay has the potential to catch up to the size of her peers once she advances in maturity.

Sexual maturity is assessed using the Tanner staging system by the clinician physical examination[45] or as a pubertal self-assessment form completed by the child/parent.[46–49] Staging (1 to 5) is based on breast and pubic hair development for girls and genital and pubic hair development for boys (see Appendix, Tables A-1 and A-2).

Skeletal maturation (or bone age) is the second method for assessment of physical maturity. Bone age is assessed by a left hand-wrist radiograph and scored using the standards developed by Greulich and Pyle[50] or the newly revised TW3 method developed by Tanner and colleagues.[51] Bone age provides a measure of "how far a given individual has progressed along his or her road to full maturity"[52] regardless of chronologic age. Sexual and skeletal maturity provide a measure of physical maturity and are valuable in formulating the nutritional assessment of children and adolescents.

LABORATORY TESTS

Laboratory testing is a helpful but less essential part of a nutritional assessment in most children and is presented in detail in Chapter 3. Nutritional information can be obtained from plasma, serum, urine, stool, hair, and nail samples. The latter two are rarely used clinically. Depending on the underlying medical condition and related nutritional problems from the history and physical examination, a focused laboratory assessment may be obtained. Serum albumin and prealbumin reflect the adequacy of protein and calorie intake. Because the half-life of albumin is 14 to 20 days, it also reflects longer-term protein stores. The shorter half-life of prealbumin (2 to 3 days) is a better short-term indicator of calorie and protein intake. However, the usefulness of prealbumin in the hospitalized patient may be limited by the fact that it is decreased in the setting of stress, sepsis, and acute illness. Checking a C-reactive-protein level may help identify when the low prealbumin level is related to stress. Anemia can be attributable to multiple nutritional deficiencies (eg, iron, vitamin B_{12}, folate, vitamin C, protein, and vitamin E), and a careful analysis of the red blood cell indices and peripheral blood smear will help to determine what further nutritional laboratory tests should be obtained (eg, iron studies, vitamin levels). In premature infants, nutritional anemias can be attributable to iron, vitamin E, and copper deficiencies. Nutritional tests to check for bone health may include serum calcium, phosphorus, alkaline phosphatase, magnesium, and 25-hydroxyvitamin D. Additional information on bone health may be obtained from a parathormone level, radiography, and DXA scan. Specific vitamin and mineral levels can be checked when deficiency or excess states are suspected. A urine analysis, along with serum electrolytes, is useful in assessing the hydration status of the patient. See Table 2-3 for a list of selected clinical findings related to nutritional inadequacies and Chapter 3 for a more in-depth look at laboratory assessment of nutritional status.

NUTRITIONAL REQUIREMENTS

The estimation of nutritional requirements is the last step in a nutritional assessment. Recommendations for calorie and protein intake, as well as specific vitamins and minerals, are needed for patient care (see Chapters 5, 6, and 7). The history (medical and dietary), physical examination, and anthropometric and laboratory data obtained are used to help estimate these nutritional requirements. These provide a starting point for nutritional therapy and are modified over time based on the patient's ongoing health status and response to nutritional therapy. The adequacy of the nutritional therapy provided should be vigilantly monitored in children with failure to thrive (FTT) and obesity and in those patients with conditions requiring enteral or parenteral nutrition.

There are a number of methods to estimate caloric needs of children in the clinical setting, including the Dietary Reference Intakes (DRIs) for estimates of total energy needs, the WHO and Schofield prediction equations for estimates of resting energy expenditure (REE), and a direct measurement of REE. In 1989, the National Research Council published the Recommended Dietary Allowances (RDAs) to provide information about the nutrient needs of infants, children, and adolescents, in addition to adults. Longitudinal average dietary intake consistent with good health and appropriate growth in healthy children were used for these estimates.[53] The 1989 RDAs now have been replaced by a more comprehensive set of guidelines called the DRIs. In addition to the RDAs, the DRIs include Estimated Average Requirements, Adequate Intakes (AIs), and Tolerable Upper Intake Levels for most nutrients.[54] The DRIs are used in Canada and the United States, and nutrient intakes at the suggested levels promote nutrient function, biological and physical well-being, and disease prevention.[55] DRIs are available for vitamins, minerals (see Chapters 6 and 7), energy, and macronutrient recommendations (see Chapters 5 and 17). Generally, the DRIs address the nutritional needs of the healthy individual and population. Therefore, DRIs may require adjustments in the clinical setting because they do not address energy or nutrient requirements for individuals who are malnourished or have acute/chronic disease.

The DRI for energy in children 0 to 2 years is estimated from prediction equations derived from total energy expenditure (TEE, by the double-labeled water methods) and energy needs for tissue deposition for growth "at rates consistent with good health."[56] For chil-

dren at this young age, estimated energy requirements (EERs) vary based on weight. The EERs for children 3 to 8 years and 9 to 18 years are also from TEE and energy deposition costs (20 and 25 kcal/day, respectively) and are based on age, weight, height, and level of physical activity (see Appendix). The important role of moderate physical activity in achieving and maintaining the appropriate energy balance for optimal health is emphasized in these new recommendations. Levels of physical activity are categorized into four levels: sedentary, low active, active, and very active.[56,57] EER equations also are available for use in children ages 3 and above who are at "risk of overweight" defined as a BMI > 85th percentile and "overweight" as a BMI > 95th percentile.[36] DRIs provide an estimate of total energy needs in kcal/day and may be adjusted based on nutritional, medical, and growth needs of the individual patient.

The WHO and Schofield REE equations offer another method to estimate energy requirements. The WHO recommendations are based on the evaluation of several thousands of children and are clinically useful. The WHO equations (see Appendix, Table A-24) calculate REE by sex, age, and weight groups and approximate the basal metabolic rate.[58] Total daily energy needs are then estimated by multiplying the REE by a factor to adjust for physical activity, medical status, and/or the need for catch-up growth (Table 2-5). The Schofield equations (see Appendix) use sex, age, weight, and height of the child and may more accurately predict REE in children with altered growth and body composition (ie, FTT and obesity).[59] Schofield REE estimates are also adjusted for the patient's activity, stress, and growth needs (see Table 2-5) to approximate total daily energy needs. The new DRIs for total energy recommendations may replace these equations in clinical research settings.

The best way to determine an individual's REE and daily energy needs is by indirect calorimetry; however, this method is not readily available in all clinical settings. This technique measures oxygen consumption and carbon dioxide production when the child is resting in the early morning, typically after an age-appropriate fast (usually 12 hours). Sedation may be required for younger children. Results are expressed in kcal/day or kcal/kg/day and are compared to standard prediction equations (ie, WHO and Schofield).[60]

In summary, for the estimation of energy needs in the clinical setting, an REE based on indirect calorimetry is preferred for children with complex medical and nutritional needs. If an REE measurement cannot be obtained, then the WHO or Schofield equations are recommended. These estimates of REE are then adjusted based on activity, stress, and growth for an estimate of total daily energy needs for the individualized patient. As above, the new DRIs for total energy recommendations may replace these estimates in the clinical setting. However, these estimates of total energy expenditure are not as reliable as those values obtained by more accurate research methods (eg, doubly labeled water).[61] Finally, it should be remembered that all estimates are guidelines for the initiation of nutritional therapy. Adjustments in the nutritional regimen are made based on objective measures, such as weight gain, laboratory data, and medical condition.

TABLE 2-5 Disease and Physical Activity Factors for Adjustment of Resting Energy Expenditure (REE)

REE × 1.0–1.1	Well-nourished children, sedated on ventilator, extracorporeal membrane oxygenation; minimal stress
REE × 1.3	Well-nourished children with decreased activity, minor surgery, mild-to-moderate sedation; minimal stress
REE × 1.5	Ambulatory child with mild-to-moderate stress Inactive child with sepsis, cancer, trauma, extensive surgery Minimally active child with malnutrition and catch-up growth requirements
REE × 1.7	Active child with catch-up growth requirements Active child with severe stress

Adapted from Mascarenhas MR, Tershakovec AM, Stallings VA. Parenteral and enteral nutrition. In: Wyllie R, Hyams JS, editors. Pediatric gastrointestinal disease. Philadelphia: WB Saunders; 1999. p. 741–57.

DRIs also provide updated protein recommendations (see Appendix; also see Chapter 5). An AI for protein in infants 0 to 6 months is based on the mean protein intake of healthy breast-fed infants.[62] Nitrogen intake, nitrogen balance (the minimum protein intake necessary to maintain nitrogen balance), rates of protein deposition, and efficiency of protein use all influence protein requirements. For individuals 7 months through 18 years of age, the protein recommendations are based on a combination of these factors, plus a safety factor to account for individual variation.[62] The DRIs provide protein recommendations (g/kg/day) by age from birth to 8 years and by age and sex starting from 9 years. Individualized needs can be estimated by multiplying the age/sex appropriate g protein/kg/day by the body weight. As previously noted, DRIs may be further individualized based on the child's nutritional, medical, and growth needs and should be adjusted over time based on clinical status and response to nutritional intervention.

CONCLUSION

In pediatric care, infancy, childhood, and adolescence are recognized as unique phases because adequate nutrition must support both usual nutrient requirements and nutrients needed for optimal growth and development. However, nutritional status depends in part on current and past illnesses, and a child's response to illness is affected by his/her nutritional status. Thus, understanding and addressing the nutritional status of a hospitalized child are important components of clinical care. No one measure provides an adequate assessment of nutrition status. A nutritional assessment often includes the input of many members of the health care team. This chapter provides the factors to consider in the nutritional assessment and monitoring of a hospitalized child. Initial nutritional goals are adjusted over time as the child's medical and nutrition status change to provide optimal care.

CHAPTER 3

LABORATORY ASSESSMENT OF NUTRITIONAL STATUS

Clifford W. Lo, MD, MPH, ScD, Amie O'Bryan, RD, LD, CNSD

Adequately and appropriately assessing the nutritional status of an individual requires the integration of various information gathered by the clinician. Anthropometrics, dietary and medical history, clinical and physical assessment, and laboratory values provide medical personnel with the information to determine the adequacy of an individual's diet, detect nutritional deficiencies, and monitor the effect of treatment.[1] Of these parameters, laboratory values can provide objective confirmation of nutritional deficiencies that might be suspected from the dietary history or clinical physical findings and can allow detection of subclinical abnormalities before functional or anatomic lesions occur. Laboratory tests can also be used to monitor therapy of malnutrition in individuals with greater precision than is usually possible with dietary, anthropometric, or clinical assessment techniques.

Laboratory tests allow detection of underlying causes of malnutrition, such as inadequate dietary intake, malabsorption, increased nutrient requirements, or excretion or destruction of nutrients. These tests can provide a measure of depletion of tissue stores before deficiencies in functional nutrient pools occur. They can be used to determine quantitative alterations in biochemical levels of nutrients, their metabolites, or dependent enzyme activities that are often not detected by anthropometric or clinical methods (Figure 3-1).

Despite the availability of a plethora of proposed biochemical and immunologic assays, the laboratory assessment of nutritional status has so far failed to fulfill its promise for a number of reasons. There have been no widely accepted methods of integrating information about the various nutrients that need to be screened into a battery of a few standard, readily available, inexpensive tests. Part of the reason for this could be that most laboratory tests of nutritional status are too specific. Although they nicely quantitate levels of a certain nutrient in a specific body fluid at a particular time, these measurements might not correlate with values at other times or in other body pools, or with deficiencies of other nutrients. Furthermore, laboratory values can be misleading to a clinician because of the effects of disease, medication, body stress, and environmental conditions not related to the patient's nutritional status. Ideal specimens might not be obtained or could be contaminated, causing inaccurate values. Clinicians must take many factors into consideration when evaluating laboratory values.[2]

ANALYSIS IN BLOOD

One of the major underlying difficulties is that most nutrients are not distributed evenly in the body and are not confined to one body pool. Thus, a single determination of blood, urine, or even tissue concentrations of these nutrients does not always provide a reliable indication of distribution or functional metabolic significance. Amounts of a nutrient in plasma might form only a very small percentage of whole-body stores and could be unrelated to tissue levels. Plasma levels can be regulated so that normal levels are maintained in spite of a severe tissue deficiency. For example, plasma calcium comprises less than 2% of whole-body calcium, and there is an even smaller percentage in the functional form of ionized calcium. Regulated by hormones, plasma calcium levels can be in the normal range even in the presence of severe bone calcium depletion (rickets).

Thus, plasma or serum levels of nutrients might not always be reliable indicators of nutritional status. Although relevant tissues can sometimes be difficult to obtain for biopsy (eg, liver, bone, brain, or muscle), some nutrients (such as vitamin C) can be better assessed by measuring their levels in whole blood, red cells, or leukocytes because these are also centers of metabolic activity. Even more relevant are functional assays of the activity in red cells of certain enzymes that are dependent on a particular nutrient. Good examples of these include transketolase activity for thiamin, glutathione reductase for riboflavin, transaminase for pyridoxine, and glutathione peroxidase for selenium.

ANALYSIS IN HAIR AND NAILS

Because the measurement of vitamin and trace minerals in hair and nail clippings reflects deposition of stores over the long term rather than recent dietary intake, they it has little use in the clinical setting. Despite the apparent easy avail-

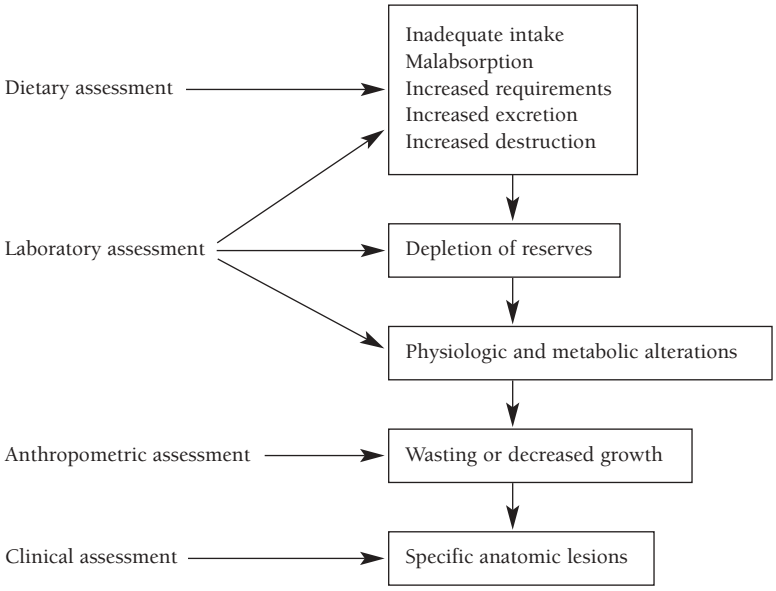

FIGURE 3-1 The levels of assessment of nutritional status as malnutrition progresses from inadequate intake to subclinical alterations to gross clinical signs and symptoms. Malnutrition can potentially be detected by laboratory assessment before it becomes clinically apparent.

ability of tissue samples, collection procedures remain problematic because of contamination by external agents (eg, cosmetics, shampoos, forceps, collection vials) and selection of appropriate specimens (telogen hairs). Many studies continue to address the effect of contamination on the accuracy of measurement and the appropriateness of the use of these samples for nutritional assessment.[3,4]

ANALYSIS IN URINE

Nutrients can be metabolized into inactive (or active) forms that cannot be directly assayed. Most nutrients are eventually excreted in the urine, and many methods involve measuring levels of nutrients or their metabolites in the urine, which can be decreased in deficiency states. Some examples of these metabolites are 2-methyl nicotinamide from niacin and 4-pyridoxic acid from pyridoxine (vitamin B_6). On the other hand, there might be increased urine excretion of metabolic products that accumulate because of a specific nutrient deficiency, for example, methylmalonic acid in vitamin B_{12} deficiency and formiminoglutamic acid in folate deficiency. Urine excretion of metabolites can also be measured after specific "loading" of a nutrient to determine relative depletion, as in the tryptophan load test for pyridoxine deficiency and tyrosine load test for vitamin C deficiency.

The problem with urine collections is that excretion from the bladder varies during the day, and concentrations are less reliable than cumulative daily total amounts. Ideally, a 24-hour urine collection should be used for assessment. Shorter samples continue to be studied for their accuracy when compared with 24-hour collections.[5,6]

METHODS OF ANALYSIS

Many nutrients are present in plasma in extremely low trace concentrations—in the nanogram to picogram per milliliter range. This has necessitated the development of extremely sophisticated assays, some of which are quite expensive. In many cases, these new techniques have replaced even more expensive bioassays, such as those still in use for biotin and pantothenic acid. The advent of multichannel sequential autoanalyzers has been a positive development in providing rapid, inexpensive analysis of a battery of enzymes and electrolytes in a small amount of serum, but they have not been specifically applied to nutritional assessment.

Emission flame photometry is a readily available method for analysis of major minerals, such as sodium, potassium, chloride, and calcium. Somewhat more involved, atomic absorption spectroscopy has now become the preferred method of analysis of many trace elements, such as zinc and copper. The fat-soluble vitamins (A, D, E, and K) and their metabolites can be measured by high-performance liquid chromatography.[7] Other techniques include radioimmunoassay, gas chromatography, thin-layer chromatography, and mass spectrometry.[8] The use of stable isotopes has led researchers to a better understanding of nutrition and metabolism. For example, much of the knowledge of neonatal nutrition has come from studies using stable isotopes.[9,10] Large-scale group or community studies most often use isotope studies for their populations. Using stable isotopes in a clinical setting might not be feasible.[11–13] Most of these methods are too expensive to allow consideration as routine nutritional screening tests.

VITAMIN AND MINERAL ASSESSMENT

With more than 40 essential nutrients to measure, including 13 vitamins and at least 14 trace elements, plus an inexhaustible list of related metabolites, enzymes, hormones, and functional parameters, no battery of laboratory tests can hope to provide a complete comprehensive assessment of all nutrients. Even if this were possible, com-

plete biochemical "normality" would not guarantee adequate health or nutrition, nor would immediate corrections necessarily be desirable in patients who have adapted to their nutritional state. For many nutrients, it is not clear that published normal biochemical values represent ideal levels. There are many genetic, racial, and regional differences in nutrient levels, some of which could represent chronic deficiency in the majority of the population. Iron status can be suboptimal in a large proportion of menstruating women, for example. Age and sex differences in normal levels must also be considered.[14–17] Indeed, the definition of *ideal* could be different to different evaluators. To a surgeon, ideal nutrition could mean lack of postoperative morbidity. To an epidemiologist, it might mean absence of chronic disease. To a pediatrician, it might mean adequate growth and development.

Determining the most useful laboratory values is an ongoing process. The ideal nutritional assessment test has yet to be developed. As proposed by Goldsmith, the ideal test would have a short half-life, have rapid response to improved nutritional intake, reflect moderate decreases in intake early, indicate current nutritional status, reflect the degree of deficit, and be unaffected by non-nutritional factors.[18] Laboratory assessment of nutritional status should not be an indiscriminate application of all possible tests. Rather, it should involve intelligent selection of appropriate tests in conjunction with dietary, anthropometric, and clinical information and consider availability, cost, predictive value, sensitivity, specificity, reliability, and validity.

Although assays for specific vitamins and minerals are covered in other chapters, Table 3-1 lists most of the readily available tests of nutritional status and their relative level of applicability. Generally accepted normal levels are listed in Table 3-2. In addition to the now-classic reference works of Sauberlich and colleagues[19] and Jelliffe and Jelliffe,[20] several reviews and symposia should be consulted for further details and values.[21–28]

ANALYSIS OF SPECIFIC NUTRIENTS

Energy

Although energy in the body is stored mainly as fat (approximately 100,000 kcal in the average adult), most usual diets supply most of this energy as carbohydrate.[29] Analysis of foods in the bomb calorimeter to measure energy intake exactly was pioneered by Atwater and Benedict in the early 1900s. Direct calorimetry precisely determines energy expenditures as metabolic heat production (M) by measuring work performed (W); heat loss by evaporation (E), radiation (R), conduction (K), and convection (C); and body temperature changes (S)[30]:

$$M = S + R + C + K + E + W$$

This requires complete thermal isolation in a chamber or suit and is available only in a few research centers.

Indirect calorimetry bases energy expenditure on oxygen consumption (21.14 kJ/L of oxygen consumed), which can be somewhat more easily obtained by collection and analysis of inspired and expired air. Although many assumptions and calculations must be made, relatively accurate estimates of energy expenditure can be made with portable collection bags and gas analyzers within a few minutes using the Haldane transformation equation[31,32]:

$$O_2 \text{ consumed} = \frac{V_{air\ exp} \times FN_2\ exp \times FO_2\ insp - V_{air\ exp} \times FO_2\ exp}{FN_2\ insp} \\ V_{air\ exp}\left(FN_2\ exp \times \frac{0.2093}{0.7094} - FO_2\ exp\right)$$

and adjusting for protein catabolism by the Weir equation[33,34]:

$$\text{MEE (kcal)} = 3.94 \times VO_2 + 1.06 \times VCO_2 - 2.17 \times \text{UUN}$$

or as modified by Cunningham[35]:

$$\text{MEE (kcal)} = 3.76 \times VO_2 + 1.25 \times VCO_2 - 1.09 \times \text{UUN}$$

Measurement of carbon dioxide consumption divided by oxygen consumption yields the respiratory quotient (RQ), which can give an indication of the relative source of metabolic fuel, carbohydrates giving an RQ of 1.0 and fats decreasing it toward 0.7[36]:

$$RQ = VCO_2/VO_2$$

Collection and analysis of expired carbon dioxide and oxygen intake require expensive instruments and are still subject to wide variation, depending on clinical and environmental conditions. Studies of indirect calorimetry continue to prove its usefulness in measuring resting energy expenditure (REE).[37,38] Unfortunately, indirect calorimetry is not always available to the clinician, and predicting energy needs falls to the use of equations.

If indirect calorimetry is not available, an estimate of basal metabolic rate (BMR) can be obtained by a number of equations, all widely researched in comparison to indirect calorimetry. The most widely known and, until the past few decades, the most widely used of these equations is the Harris-Benedict equation.[36] It should be noted that mistakes in transcribing the constant coefficient (ie, 655 for females and 66 for males) frequently lead to inaccurate estimates.[39,40] The Harris-Benedict equation was developed using information gathered on healthy individuals. The majority of research was done on the adult population. It is therefore difficult to justify its use on critically ill or hospitalized patients, especially in pediatrics.[41] A number of newer equations have been developed that can be used to determine energy needs in pediatrics and in a critical care setting.

In the mid-1980s, a Food and Agricultural Organization/World Health Organization (FAO/WHO) committee established new predictive equations for estimating energy requirements.[42] Subsequent review and evaluation by Schofield led to equations that more closely relate to values obtained by indirect calorimetry, when factors are used for activity, stress, and disease state (Table 3-3).[43,44] Other predictive equations that have been proposed have been unable to relate as closely to measured energy requirements. Efforts

TABLE 3-1 Laboratory Tests for Nutritional Assessment

Nutrient	*Initial Screening*	*Secondary Monitoring*	*Special Investigations*
General status	Hemoglobin, hematocrit	Respiratory quotient	Total body K, total body N, indirect calorimetry
Protein	S albumin, S total protein, U protein (dipstick)	S transferrin, prealbumin, S retinol-binding protein, creatinine height index	U hydroxyproline index; S amino acid profiles, indices; nitrogen balance; stable isotope infusion
Fat		S triglycerides, S cholesterol	S lipoprotein electrophoresis, triene/tetraene ratio
Carbohydrate	S glucose, U sugar (dipstick)	GTT, lactose, sucrose tolerance tests	Breath hydrogen test
Vitamins			
A		S retinol, S carotene	S retinol-binding protein, dark adaptation test
C		S ascorbate	WBC ascorbate, blood ascorbate, tyrosine load test
D		S 25-(OH)-D; S calcium, phosphorus; S alkaline phosphatase; bone radiograph	S 1,25-$(OH)_2$-D (HPLC), S vitamin D^2 (HPLC), S PTH (RIA)
E		S tocopherol	RBC hemolysis test, tocopherol transport capacity
K		Prothrombin time	Clotting time, S vitamin K (HPLC)
Thiamin		RBC transketolase activity	24-hr U thiamin, TPP stimulation test
Riboflavin		RBC glutathione reductase activity	24-hr U riboflavin, blood pyruvate
Niacin		Whole blood NAD	24-hr U 2-Me nicotinamide, U 2-pyridone
B_6		S vitamin B_6, S pyridoxal phosphate	EGOT or EGPT index, U vitamin B_6, U 4-pyridoxic acid, tryptophan load test
B_{12}	Hemoglobin, RBC indices, RBC morphology	S vitamin B_{12}	U methylmalonic acid, RBC vitamin B_{12}, Schilling test
Folate	Hemoglobin, hematocrit, RBC indices, RBC morphology	S folate	U FIGLU, RBC folate
Pantothenate			S pantothenate, 24-hr U pantothenate
Biotin			Whole blood biotin, 24-hr U biotin
Minerals			
Calcium		S calcium, bone radiographs	Bone densitometry, calcium balance, S PTH
Phosphorus		S phosphorus	
Magnesium		S magnesium	
Iron	Hemoglobin, hematocrit, RBC indices, RBC morphology	S iron, S ferritin, S iron-binding capacity, S transferrin saturation	Marrow iron, free RBC protoporphyrin
Zinc		S zinc	RBC zinc, WBC zinc, salivary zinc, hair zinc, zinc isotope turnover
Copper		S copper, S ceruloplasmin	RBC copper, 24-hr U copper, hair copper, RBC superoxide dismutase, radiocopper turnover
Iodine		S thyroxine, S TSH	
Selenium		RBC selenium, RBC glutathione peroxidase	
Immune status	Total lymphocyte count, skin tests	S complement (C_3, CH_{50}), S immunoglobulins	Lymphocyte stimulation, T and B cell quantitation, WBC chemotaxis, NBT phagocytosis

EGOT = erythrocyte glutamic-oxaloacetic transaminase; EGPT = erythrocyte glutamic-pyruvic transaminase; FIGLU = formiminoglutamic acid; GTT = glucose tolerance test; HPLC = high-performance liquid chromatography; NAD = nicotinamide adenine dinucleotide; NBT = nitroblue tetrazolium; P = plasma; PTH = parathyroid hormone; RBC = red blood cell (leukocyte); RIA = radioimmunoassay; S = serum; TPP = thiamin pyrophosphate; TSH = thyroid-stimulating hormone; WBC = white blood cell (leukocyte).

to study predictive equations that will adequately assess energy requirements have only reinforced the fact that indirect calorimetry is the most accurate tool.[45–51]

In normal states, REE is about 10% above BMR, but this does not take into account additional requirements such as postoperative stress, burns, infection, or disease states, which can vary as much as 50% above or below BMR. Originally, calculations of BMR and REE were common for evaluation of thyroid function; their use today has shifted to research in obesity and in critically ill patients requiring nutritional support. Generally, critically ill patients require up to one and a half times their REE to prevent protein breakdown for gluconeogenesis. Precise measurements of individual energy requirements allow tailoring of nutritional support to prevent lean body mass breakdown without needlessly increasing oxygen consumption (which can compromise respiratory status) or fat deposition.

Finally, studies of energy metabolism over longer periods in subjects performing a variety of activities have used

TABLE 3-2 Guidelines for Criteria of Nutritional Status for Laboratory Evaluation

Nutrient and Units	*Age of Subject (yr)*	*Criteria of Status*		
		Deficient	*Marginal*	*Acceptable*
Hemoglobin (g/100 mL)*	6–23 mo	Up to 9.0	9.0– 9.9	10.0+
	2–5 mo	Up to 10.0	10.0–10.9	11.0+

the doubly labeled water method.[52–55] Water enriched with the stable isotopes deuterium and ^{18}O ($^{2}H_2$ ^{18}O) is administered in a single oral or intravenous dose and several blood or urine samples are obtained over the next 5 to 14 days. Because ^{18}O is excreted as both urinary water and respiratory carbon dioxide, but deuterium is excreted only as water, the different rates of excretion can be measured by mass spectrometry and can be used to calculate metabolic rate. Although they are useful in validating long-term energy needs compared to reports of dietary intake,[56–58] their clinical use in the acute care setting is difficult because of the time and expense involved in stable isotope enrichment and mass spectrometry.

TABLE 3-3 Equations for Estimating Resting Energy Expenditure in Children

Harris-Benedict
Men: 66.437 + (13.7516 × W) + (500.33 × H) – (6.755 × A)
Women: 655.0955 + (9.5634 × W) + (184.96 × H) – (4.6756 × A)
Infants: 22.10 + (31.05 × W) + (11.6 × H)

PROTEIN

The assessment of protein nutrition has presented one of the most important yet most problematic questions in the history of nutrition. Widespread protein-energy malnutrition worldwide has fueled interest in determining protein status and requirements, especially in children.[59] Many methods have been devised for measuring protein use, but the central problem of protein turnover remains. Approximately 15% of the body mass consists of protein stored in the liver, muscles, intestines, and other tissues. This, however, is in dynamic equilibrium with the much smaller percentage of body protein carried as plasma amino acids. Concentrations of plasma proteins or amino acids do not necessarily represent their relative concentrations in tissue storage pools.[60–62]

Attempts to measure the flux between these metabolic and storage pools using labeled amino acids generally assume a steady state in which protein synthesis equals protein breakdown. Although radioisotopes were previously used to trace amino acid flux between protein pools, objections to their use in human subjects have led to studies using stable isotopes such as ^{13}C leucine and ^{15}N glycine. Because they require complicated mathematical calculations and mass spectrometer analysis, stable isotope infusions have generally been limited so far to research applications.[63,64] Thus, analysis of plasma proteins or amino acid levels cannot always be depended on to give a direct reflection of whole-body protein status. Of the thousands of plasma proteins, relatively few have been shown to have direct clinical significance as tests of health or nutritional status.[65] The future of protein analysis could lie in microassay chip technology now being developed for genetic analysis. Although the focus of this technology is currently on genetics and disease, it could be of use by clinicians for protein assessment.

Serum Albumin

Total serum proteins can be separated into albumins and globulins (α, β, and γ) by electrophoresis. Because γ-globulins can be increased in infection or malignancy, serum albumin levels are generally a better test of protein status than is total serum protein. Serum albumin levels have been one of the most popular measures of protein-calorie malnutrition, and levels below 3.5 g/dL are a hallmark of kwashiorkor. Although albumin remains widely used as a marker of nutritional status, the clinician must take into account multiple other factors affecting the result. Albumin levels can be normal in mild or even severe marasmus, despite markedly reduced muscle mass. Conversely, serum albumin levels can also be affected by other disease states (eg, rapid blood loss, protein-losing enteropathy), stress, surgery, fluid shifts, and even postural changes. Albumin turnover is fairly slow, with a half-life of about 20 days. Therefore, serum levels do not reflect recent dietary intake; albumin levels might not be reduced even after 3 weeks on a protein-free diet.[66–70]

Other Serum Proteins and Enzymes

Other transport proteins, such as thyroxine-binding prealbumin (transthyretin),[71] retinol-binding protein,[72] transferrin,[73] and ferritin,[74] have been proposed as better markers of protein malnutrition because of their shorter half-lives, but they can also be affected by caloric restriction, iron deficiency, or infection, as well as protein deficiency.[75] Prealbumin is secreted by the liver in a complex containing retinol, retinol-binding protein, and thyroxine (T_4) and thus is also known as transthyretin. Although vitamin A deficiency can affect secretion of retinol-binding protein, it does not affect plasma levels of prealbumin.[76–80] Ferritin is an acute-phase reactant and can be elevated in liver disease or various inflammatory states.

Other plasma proteins that have been proposed as markers of nutritional status include fibronectin[81] and insulin-like growth factor-1 (IGF-1).[82,83] IGF-1 and IGF-1–binding proteins have both been widely studied for their connection with nutritional status.[84,85] Studies have shown that levels of both IGF-I and IGF-1–binding proteins are affected when calories or protein are restricted.[86,87] IGF-I and IGF-binding proteins might not have the same disadvantages as other proteins when used for assessment. Both values appear to be sensitive indicators in an acute setting to changes in nutritional status.[88,89]

Concentrations of various enzymes in plasma have been widely used in diagnosis of many disease states but, for that very reason, are less specific for protein deficiency. Plasma concentrations of pseudocholinesterase, alkaline phosphatase, amylase, and lipase are reported to be reduced in kwashiorkor, whereas lactic dehydrogenase, isocitrate dehydrogenase, and transaminase are increased. In children, elevated plasma ribonuclease activity can be increased in even mild to moderate malnutrition; comparison of plasma and urine activities can distinguish between moderate and severe malnutrition.[90,91]

Attempts have been made to use plasma amino acid profiles to assess nutritional status. Because concentrations of amino acids are not regulated and do not directly reflect tissue uptake and flux, use in clinical settings has not been widely received. Amino acid values are also affected by infection, injury, and other stressors.[92]

Urinary Protein Excretion

Another approach to the assessment of protein status uses urinary excretion of protein breakdown substances. Creatinine is a degradation product of muscle creatine, and urinary excretion of creatinine has been used since 1905 as a measure of lean body mass. The creatinine height index compares urinary creatinine excretion over 24 hours to a control value and has been widely used as a measure of protein depletion in kwashiorkor and marasmus.[93]

Other urinary excretion ratios using creatinine as a standard, such as the urea-creatinine ratio, the sulfur-creatinine ratio, and the urinary hydroxyproline index, have been investigated but tend to reflect recent dietary protein intake rather than long-term nutritional status. Furthermore, these methods all require a 24-hour urine sample to minimize daily fluctuations in urine excretion, and this might not always be easy to obtain. Efforts to short-cut this difficulty have been frustrated by the variability of spot urine creatinine excretion.[94]

Nitrogen Balance Studies

Nitrogen balance studies can be useful in assessing individual protein status, although traditionally they have been used more in controlled metabolic research studies to determine protein requirements in populations or food protein quality. Nitrogen balance measurements can give a direct short-term comparison of dietary nitrogen intake versus fecal and urine excretion.[95] Nitrogen retention is calculated by subtracting fecal and urine nitrogen from oral intake:

$$\text{N retention} = \text{N intake} - \text{fecal N} - \text{urine N}$$

Ideally, this should be performed for several days on a constant protein intake in steady-state conditions. Nitrogen intake can be estimated by dividing dietary protein intake (in grams) by 6.25. Nitrogen output is best analyzed by the rather time-consuming Kjeldahl method of sulfuric acid distillation but can also be estimated in adults by urine urea nitrogen,[96] using an estimate of 4 g/day for stool and skin losses, although this could be much less in children:

$$\text{N retention} = (\text{protein intake}/6.25) - \text{urine urea N} - 4$$

Although nitrogen balance studies are used often in a clinical setting, they should not be used as the only means of assessing protein balance.[97–100]

Lipids

Plasma Lipids and Lipoproteins

Assessment of the fat status of individuals is complicated by similar considerations of storage and metabolic pools. Although fat stores in the body represent a considerable reserve of energy, only a small percentage of this fat is present in the plasma as free fatty acids. Additionally, much of

the free fatty acids and triglycerides in the plasma are derived from endogenous synthesis rather than from recent dietary intake. Triglycerides are transported in the blood along with cholesterol and proteins as lipoproteins. These can be separated by ultracentrifugation or electrophoresis as very-low-density lipoprotein or prebeta, low-density lipoprotein (LDL) or beta, and high-density lipoprotein (HDL) or alpha.[101,102]

Whereas elevated total plasma cholesterol and LDL cholesterol levels are associated with atherosclerosis,[103] higher HDL levels could be protective.[104] Studies of plasma lipids in adults have demonstrated links between multiple risk factors and cardiovascular disease. Risk factors include age, sex, history of hypertension, smoking, diabetes, high LDL levels, and low HDL levels. Various criteria have been developed, such as the Adult Treatment Panel III, to provide clinicians with guidelines for assessment of cardiovascular risk. Family history and various diseases also affect cholesterol levels and do not necessarily reflect nutritional deficiency or excess.[105] Studies in children are few, and recommendations for appropriate levels in the very young have not been assessed.

Essential Fatty Acid Deficiency

Although nutritional fat deficiencies are rare, a greater appreciation of essential fatty acid deficiency has occurred in association with a syndrome of dermatitis, poor growth, and degenerative changes in several tissues.[106,107]

Certain fatty acids cannot be synthesized in the body but must be supplied in the diet. They are important as precursors for cholesterol, prostaglandins, and cell membranes.[108]

This requirement comprises 1 to 2% of total caloric intake, but even this might not be provided if a patient is receiving total parenteral nutrition without periodic intravenous fat supplements.[109] Essential fatty acid deficiency can be assessed by elevation of the triene-tetraene ratio because nonessential eicosatrienoic acid (20:3, a triene) levels rise, whereas arachidonic acid (20:4, a tetraene) levels fall.[110,111] Linolenic acid could be another essential fatty acid; there has been a recent report of typical essential fatty acid deficiency symptoms occurring when linoleic acid but not linolenic acid was supplied for several months.[112]

Body Composition and Obesity

Obesity is less often assessed by biochemical parameters than by anthropometric measurements because most techniques for determining total body fat are practical only for research purposes. Potassium is distributed fairly evenly in fat-free tissue and contains a small percentage of the natural radioisotope ^{40}K. Very sensitive gamma counters can thus detect the amount of radioactive potassium in lean body mass, which can be subtracted from the total body mass to determine total body fat.[111,112] Because adipose tissue is very low in water content, total body fat can also be estimated by dilution of injected tritium, deuterium, or stable ^{18}O in the total body water compartment and subtracting that measurement from total body mass. Alternatively, determination of body density by plethysmography or immersion in water can differentiate between a relative amount of fat (with a lower specific gravity of 0.9) versus other tissues.[113]

Recent availability of dual photon absorptiometers, usually used to measure bone density, has led to their being adapted for body composition measurements because lean body tissue and fat can be differentiated and quantitated with a high degree of precision.[114,115]

Bioelectric impedance has been developed as a quick, inexpensive, and noninvasive measurement of lean body mass, which conducts electrical charge better than fat. However, measurements can be affected by changes in tissue fluid content, such as edema or dehydration.[116–120] Body composition is reviewed in more detail in Chapter 4, "Body Composition and Growth."

Carbohydrates

Obviously, serum glucose levels are regulated by insulin and other factors so that they do not directly reflect nutritional stores or requirements.[121,122] Alterations in serum glucose levels are thus more likely to be the result of impaired regulatory mechanisms (eg, in diabetes mellitus) than of nutritional deficiencies. Rarely, hypoglycemia can be the result of lack of carbohydrate substrate, as in neonatal hypoglycemia, childhood ketotic hypoglycemia, or glycogen synthetase deficiency.[123,124] However, hypoglycemia is too often diagnosed in otherwise healthy persons on the basis of a borderline serum glucose level, either fasting or after a glucose tolerance test, and this should not be considered a nutritional disease.

Glucose tolerance tests and other oral carbohydrate tolerance tests (lactose, sucrose, xylose) have also been used to assess carbohydrate malabsorption, although breath hydrogen testing is superior for this purpose.[125,126] If an oral dose of carbohydrate is malabsorbed, it will pass into the colon, where bacteria will metabolize it to hydrogen. The hydrogen, which is not produced elsewhere in the body, is excreted in the breath, where it can be collected and measured by gas chromatography. Stable isotopes are used to study glucose metabolism but are better suited for research purposes and large populations than for clinical assessment.[127]

IMMUNE STATUS

Although not always sufficiently appreciated, interactions between nutritional status and infections have been amply demonstrated for some time. Not only do infections adversely affect nutritional status, but malnutrition also predisposes the patient to a host of infections: parasitic, viral, bacterial, and fungal.[128] Investigations by Chandra and Kumari[129,130] and others have elucidated some of the immune dysfunctions that accompany protein-calorie malnutrition and specific nutrient deficiencies[131] and mediate impaired resistance to infection (Table 3-4). Conversely, immunologic assays have been proposed as functional tests of nutritional status, tests that reflect the functional ability of the individual to resist infection, instead of mere static measurements of a single nutrient.[132,133]

Immune responses can be divided into three categories: (1) cellular, principally involving T lymphocytes; (2) humoral, including serum and secretory antibodies; and (3) nonspecific, including phagocytosis, complement, and mucosal immunity. Protein-energy malnutrition affects immune responses in all three of these areas but has been most often associated with profound defects in cell-mediated immunity.[134] Skin tests for a number of antigens, such as *Monilia* (*Candida*), streptokinase-streptodornase, *Trichophyton*, and mumps are normally positive (> 5 mm induration after 72 hours) if there has been prior exposure to these antigens in the environment. However, there is a consistent loss of this cutaneous delayed-type hypersensitivity in moderate to severe protein-calorie malnutrition, and skin tests have been used as a sensitive indicator of functional malnutrition in field surveys as well as in hospital settings.[135] Although they do not require blood samples, skin tests do have the disadvantage that they cannot be read until 48 to 72 hours after taking the sample. If common recall antigens do not provoke any response, deliberate contact sensitization with dinitrochlorobenzene and subsequent rechallenge can be performed.[136]

Decreased cell-mediated immunity in malnutrition is also manifest as a decrease in lymphoid tissue, including thymus, tonsils, lymph nodes, and peripheral lymphocytes.[137] A quick estimate of the total lymphocyte count (TLC) can be easily obtained by multiplying the white cell count (WBC) by the percentage of lymphocytes seen on the peripheral smear:

$$TLC = WBC \times \% \text{ lymphocytes}$$

A decrease in the total lymphocyte count to less than 1,500/mm^3 is seen in some, but not all, malnourished patients, although many other conditions can cause lymphopenia as well. Nonspecific transformation of lymphocytes into blast forms by phytohemagglutinin and pokeweed mitogen in the lymphocyte stimulation test is occasionally impaired in severe malnutrition,[138] but this is not a consistent observation.

B lymphocyte response in malnutrition is less affected, and quantitative serum immunoglobulins can be elevated, although this finding could be attributable to constant low-grade infection.[139,140] The complement cascade is important in cytolytic responses, and levels of all complement proteins, except C4, are markedly decreased in protein-energy malnutrition. The most commonly available assays for complement function are C3 and CH50 (50% hemolysis).[141,142] Finally, phagocyte function can be impaired in malnutrition, with decreased leukocyte chemotaxis and decreased intracellular bacterial killing, although these phenomena might be more attributable to infection than to malnutrition per se.[143,144] Leukocyte mobility and chemotaxis can be measured in vivo with a Rebuck skin window or in vitro in a Boyden chamber after separation of leukocytes. The nitroblue tetrazolium dye test measures reduced nicotinamide-adenine dinucleotide phosphate (NADPH) oxidase activity, which accompanies bacterial killing. Specific nutrient deficiencies also cause immune system dysfunction, notably iron, zinc, vitamin A, vitamin B_{12}, pyridoxine, and folate deficiency.

TABLE 3-4 Immunologic Changes in Malnutrition

A. Cell-mediated immunity
1. Delayed hypersensitivity (skin tests to PPD, *Candida*, SKSD, *Trichophyton*, DNCB)
2. Lymphocytes (normal absolute lymphocyte count)
a. ↓ T lymphocytes (E rosettes)
b. ↓ T helper cells, normal T suppressors
3. Lymphocyte proliferation
a. Normal to ↓ PHA stimulation
b. Normal to ↑pokeweed mitogen stimulation
4. ↓ Lymphoid tissue (tonsils, thymus, lymph node, pancreatic tissue)
5. ↓ Thymic hormone
6. Normal lymphokine activity (MIF)
B. Humoral immunity
1. Serum immunoglobulins (normal to ↑ IgG, IgM, IgA; ↑ IgE)
2. ↓ Secretory immunoglobulins (↓ SIgA)
3. Antibody response (normal to ↑ typhoid, pneumococcal polysaccharide; ↓ to normal diphtheria toxoid, yellow fever)
C. Nonspecific immunity
1. ↓ Phagocyte function
a. ↓ Chemotaxis (with infection)
b. ↓ Intracellular bacterial and candidal killing
c. Normal phagocytosis
2. ↓ Lysozyme activity
3. Complement levels
a. ↓ C_3, CH_{50}
b. ↑ Immune complexes
4. ↓ Interferon production
5. ↓ Mucosal immunity

DNCB = dinitrochlorobenzene; ↓ = decreased; ↑ = increased; MIF = migration inhibiting factor; PHA = phytohemagglutinin; PPD = purified protein derivative; SKSD = streptokinase-streptodornase.

APPLICATIONS

Nutritional Field Surveys

In nutritional field surveys, large numbers of relatively healthy people are sampled to determine the prevalence of malnutrition in the population. Because samples are usually collected by mobile field units removed from central laboratories, problems such as refrigeration, centrifugation, and timing put severe restraints on the types of assays possible. Twenty-four-hour urine collections are usually not practical, and reliance must be placed on spot urine samples. Blood samples are generally limited to what can be obtained from one venipuncture, and invasive tests are usually out of the question. In surveys of young children in developing countries, even venipuncture is difficult, and laboratory tests are often limited to a fingerstick hematocrit and blood smear.

Careful selection of tests is of utmost importance to minimize needless duplication of information and to emphasize nutrients that are most likely to be deficient in the populations sampled. Standardization of collection, analysis, and reporting procedures must be maintained, and samples are generally transported to a central laboratory for processing. Some of the most elaborate nutritional surveys undertaken were the Ten-State Nutrition Survey (1968–1970) and its successors, the National Health and

Nutrition Examination Surveys (NHANES). Results from the Third NHANES (1988–1994) continue to be studied and reported. Some of the biochemical tests used in these surveys are listed in Table 3-5.[145–147]

Hospital Malnutrition

Although most of the classic epidemic vitamin deficiency diseases are now rarely seen in the United States, malnutrition in hospitalized patients is still a major problem. Until recently, nutritional assessment of hospitalized patients was rarely systematically or even routinely performed. Increasing attention has been paid to the widespread malnutrition detected by anthropometric and laboratory tests in acute care hospitals.[148] Hendricks and colleagues, using anthropometrics, laboratory assessment, and clinical nutrition assessment, repeated a study on the prevalence of malnutrition in a children's hospital.[149] Although a decrease in malnutrition was found, malnutrition was still prevalent in patients with chronic medical conditions, in children less than 2 years of age, and in patients older than 18 years. Although the need for nutritional assessment has been realized, both adult and pediatric patients still appear at risk for malnutrition, especially in a hospital setting.

Because of the proliferation of possible laboratory tests for the assessment of nutritional status, attempts have been made to identify those values that are clinically significant. Although detection of malnutrition is of interest, the relationship of nutritional values to morbidity and mortality is even more important clinically. A recent study by Naber and colleagues determined that malnutrition was predictive of complications in nonsurgical patients.[150]

Interest in identifying specific patients at risk for excess morbidity and postoperative complications has been the focus of trials of perioperative nutritional rehabilitation, either enterally or parenterally.[151–153] A large, multicenter trial reported that preoperative parenteral nutrition was cost-effective only in a select group of patients who were considered severely malnourished[154] using a Nutrition Risk Index based on serum albumin levels and weight loss.[155]

Using stepwise regression analysis, Buzby and colleagues[156] and Mullen[157] devised a Prognostic Nutritional Index (PNI) for patients about to undergo surgery, based on only four readily measured values (serum albumin [Alb], transferrin [Tfn], triceps skinfold [TSF], and delayed-type hypersensitivity skin tests [DTH]):

$$PNI = 158 - 16.6\,(Alb) - 7.8\,(TSF) - 0.20\,(Tfn) - 5.8\,(DTH)$$

Patients with a high-risk PNI of greater than 50 had increased postoperative complications, infections, and mortality. Harvey and colleagues used a similar index,[158] which includes information about specific diagnosis (cancer) and presence of infection:

$$PNI = 0.91\,(Alb) - 1.0\,(DTH) - 1.44\,(sepsis) + 0.98\,(Dx) - 1.09$$

Seltzer and colleagues reduced the number of values further, using serum albumin and total lymphocyte counts as a means of providing an instant nutritional assessment to determine the need for nutritional therapy.[159,160] Rainey-MacDonald and colleagues also found that the triceps skinfold and cutaneous-delayed hypersensitivity tests, which take 2 days to read, were redundant and added little to the predictive value of serum albumin and transferrin levels.[161] Other investigators,[162,163] despite using techniques such as Boolean analysis and receiver-operating characteristic curve analysis, have not found a substantially good predictive value between any of these biochemical and anthropometric standards and morbidity or changes in body composition.

Indeed, Baker and colleagues suggest that most of the common laboratory tests for nutritional assessment (serum albumin, triceps skinfold, total lymphocyte count, weight, creatinine height index, and delayed cutaneous hypersensitivity) had less sensitivity and specificity than a comprehensive bedside clinical assessment, including simple diet history, physical examination, and knowledge of disease state (Figure 3-2).[164] Furthermore, they showed that any combination of laboratory tests had no better prognostic value than a subjective global clinical assessment.[165–167]

Despite a wide range of available laboratory tests, no simple test or battery of tests has yet proved completely satisfactory for a definitive assessment of nutritional status, and one should include anthropometric and clinical as well as laboratory information for best results (Table 3-6).[168–170] Clinicians continue to create valuable tools that address all aspects of nutritional assessment. For example, WAVE (weight, activity, variety, and excess) is a recent development that provides a quick assessment for clinicians and recommendations for their patients.[171] Assessment tools such as this, in combination with laboratory values, can be useful in determining nutritional status.

TABLE 3–5 Laboratory Tests of Nutritional Status Employed in the Health and Nutrition Examination Surveys

Hemoglobin
Hematocrit
Serum iron
Serum iron-binding capacity
Blood folacin
Total serum protein
Serum albumin
Serum vitamin C
Plasma carotene
Plasma vitamin A
Urinary creatinine
Urinary thiamin
Urinary riboflavin
Urinary iodine

CONCLUSIONS AND RECOMMENDATIONS

Myriad laboratory tests are available for the assessment of nutritional status. Many methods have been devised for quantitation of different proteins, lipids, vitamins, and minerals in the serum, urine, and other body fluids. Unfortunately, no one test or battery of tests gives a completely satisfactory picture of the global nutritional state of the individual. Most common, inexpensive, easily available tests are not sensitive enough to detect early malnutrition before it becomes clinically significant. Conversely, most assays tend to be too specific to reflect abnormalities in a broad

(Select appropriate category with a checkmark or enter numeric value where indicated by "#")

A. History
1. Weight change
Overall loss in past 6 months: amount = # _____ kg; % loss = # _____
Change in past 2 weeks: _____ increase,
_____ no change,
_____ decrease.

2. Dietary intake change (relative to normal)
_____ No change,
_____ Change _____ duration = # _____ weeks.
_____ type: _____ suboptimal solid diet, _____ full liquid diet
_____ hypocaloric liquids, _____ starvation.

3. Gastrointestinal symptoms (that persisted for > 2 weeks)
_____ none, _____ nausea, _____ vomiting, _____ diarrhea, _____ anorexia.

4. Functional capacity
_____ No dysfunction (eg, full capacity),
_____ Dysfunction _____ duration = # _____ weeks.
_____ type: _____ working suboptimally,
_____ ambulatory,
_____ bedridden.

5. Disease and its relation to nutritional requirements
Primary diagnosis (specify) _____
Metabolic demand (stress): _____ no stress, _____ low stress,
_____ moderate stress, _____ high stress.

B. Physical (for each trait specify: 0 = normal, 1+ = mild, 2+ = moderate, 3+ = severe).
_____ loss of subcutaneous fat (triceps, chest)
_____ muscle wasting (quadriceps, deltoids)
_____ ankle edema
_____ sacral edema
_____ ascites

C. SGA rating (select one)
_____ A = Well nourished
_____ B = Moderately (or suspected of being) malnourished
_____ C = Severely malnourished

FIGURE 3-2 Form for subjective global assessment (SGA). Adapted from Baker JP et al.[164]

TABLE 3-6 Initial Screening Tests for Nutritional Assessment

Dietary assessment
24-hour recall or
Typical day recall or
72-hour diary or
Food frequency questionnaire
Anthropometric assessment
Height and height-for-age percentiles
Weight and weight-for-age percentiles, weight-for-height percentiles
Triceps skinfolds and arm circumference
Laboratory assessment
Complete blood count, including hemoglobin, hematocrit, WBC and differential, RBC smear
Serum albumin (or prealbumin or retinol-binding-protein), total protein
Serum electrolyte: sodium, potassium, chloride, bicarbonate
Renal function tests: blood urea nitrogen, creatinine
Serum glucose, triglycerides (fasting)
Serum cholesterol, HDL cholesterol, LDL cholesterol
Serum calcium, phosphorus, magnesium
Liver function tests: alanine aminotransferase, bilirubin
Urinalysis (dipstick)
Clinical assessment
Clinical history
Subjective global assessment
Physical examination

HDL = high-density lipoprotein; LDL = low-density lipoprotein; RBC = red blood cell; WBC = white blood cell.

range of nutrients. Although laboratory assessment has the advantage of providing reproducible, quantitative data, it is not always possible to determine tissue stores or functional reserve from a single serum or urine sample. Many tests require timed collections, complicated analytic methods, and expensive instruments and are more suited for specific research investigations than for clinical screening.

Recent efforts to develop a simple, streamlined battery of tests to detect hospital malnutrition have focused on the prognostic value of tests that predict clinical complications. Although no standard formula has achieved wide use, most include measurements of protein nutrition (serum albumin) and immune status (skin tests or lymphocyte count). However, these quick estimations might not have better predictive value than a global clinical assessment. Thus, laboratory assessment of nutritional status requires an intelligent selection of tests to fit the clinical situation. It should augment the dietary, clinical, and anthropometric data that should also be gathered and evaluated and should not be overemphasized to their exclusion. Used in this way, laboratory data will allow better quantification, reproducibility, and objectivity in the assessment of nutritional status.

CHAPTER 4

BODY COMPOSITION AND GROWTH

Lori Bechard, MEd, RD, LD, Myriam Puig, MD, PhD

Growth is the maturation process characterized by change, compensation, and adaptation; it is genetically predetermined and significantly affected by hormonal, nutritional, and environmental factors. The size and shape of an individual are a result of the dynamic events preceding the time of assessment. The measurement of body composition allows the observer a closer look at the physiologic changes seen during growth and disease.

The recognition of the importance of body composition changes in different areas of acute, chronic, and preventive medicine has prompted an increased interest in studying and refining techniques of measuring these changes.[1] The accurate definition of nutritional status cannot be based only on height and weight. Some measure of body composition is also needed to distinguish, for example, the obese from the overweight, muscular individual.[2] In certain diseases, such as protein-energy malnutrition, cystic fibrosis, inflammatory bowel disease, chronic renal disease, and acquired immune deficiency syndrome (AIDS), which produce malnutrition or fluid and electrolyte derangement, weight measurements can overestimate the nutritional well-being of the patient. In addition, it might be possible, with nutritional rehabilitation, to achieve normal weight in the presence of inadequately repleted body composition or with an excess of fat or water.[3]

The study of body composition allows better comprehension of the effects of the genetic, nutritional, and physical activity factors on fat, muscle, and bone development.[4] It permits the study of the prevalence of obesity in children and youth and allows for better documentation of genetics and tracking of body fatness and bone accretion during the first two or three decades of life, along with their effect on the development of chronic diseases such as diabetes, cardiovascular disease, hypertension, and osteoporosis later in life. In this sense, it is important to define not only the amount of the different components but also the time in which they increase and their regional variations to delineate their possible relations to health risks[5–8] and the best strategies for risk prevention. Changes in the different compartments of the body that occur during fetal life and through infancy, childhood, adolescence, adulthood, and aging are presented in the first part of the chapter. An emphasis is placed on the distribution of fluid, fat, muscle, and bone mass in the different stages of the life cycle during health and disease.

The capacity to measure the body compartments in living human beings has permitted a better understanding of human energy metabolism. With the availability of certain techniques that can be used in the clinical setting, the measurement of body composition has become an indispensable tool in the monitoring of changes of fat and fat-free mass during growth, in circumstances of athletic conditioning, or in the nutritional management of patients with acute or chronic illness. In the past few years, increasing numbers of researchers have used body composition determinations in clinical studies. An understanding of the various methods and measurements of body composition is crucial in the interpretation of this pediatric and nutrition literature. Each method explores body composition from a different perspective, studying the chemical components or taking advantage of certain physical principles. On the whole, the use of different methods in the same set of subjects has allowed the cross-validation of the various techniques and has permitted a more detailed understanding of body composition. A glossary of the most commonly used body composition terms is given in Table 4-1.

CHANGES IN BODY COMPOSITION WITH GROWTH

A schematic representation of the changes in body composition throughout life is shown in Figure 4-1. More specific details of the compositional variation during growth are presented in Table 4-2. Figure 4-2 depicts changes in body compartments during fetal development; this graph can be helpful when assessing the growth of a preterm infant.[13]

Changes in Body Fat Mass

Fat is the most variable of body components, ranging from about 5% to more than 50% of body weight; the normal range is narrower, between about 10 and 30%.[14] During intrauterine life, the differentiation of fat starts in the sec-

Table 4-1 Glossary of Body Composition Terms

Term	*Definition*
Fat mass	All ether-extractable lipids in the body, including nonessential lipid (~90%), mainly triglyceride and essential lipid
Essential lipid	Lipid in bone marrow and cell membranes, and phospholipids in neurons
Adipose tissue	Fat (80–85%) plus its supporting cellular and extracellular structures (2% protein and 13–18% water)
Lean body mass	Part of the body free of adipose tissue
Fat-free mass	Nonfat mass, with four major constituents: water, protein, glycogen, and mineral; lean body mass plus the nonfat components of adipose tissue
Total body water (TBW)	Total water in the body
Intracellular water (ICW)	Water content of the cellular compartment
Extracellular water (ECW)	Nonmetabolizing fluid surrounding cells; distributed in two main compartments: plasma and interstitial fluid
Body cell mass	Cellular components of the body
Extracellular solids	Extracellular chemical compounds distributed in organic (collagen, reticular, and elastic fibers) and nonorganic (total body bone mineral + Na, bicarbonate, and citrate)
Bone mineral content (BMC)	Bone mineral content (g/cm) measured by absorptiometric techniques
Bone mineral density (BMD)	Ratio of BMC/bone width (g/cm^2) measured by absorptiometric techniques

ond trimester of gestation, approximately between the 14th and 24th weeks of pregnancy. It becomes evident in the head (buccal pad area) and neck, progressing rapidly to the trunk, arms, and, finally, the lower limbs. At the beginning of the third trimester, at about the 28th week, adipose tissue is already present in the principal body fat deposit areas. Therefore, it appears that the second trimester of pregnancy is a sensitive period for the development of fat tissue.[15]

The possibility that nutritional alterations at critical periods of development are the source of nutritional states such as adult obesity has been suggested by certain authors.[16] Follow-up studies[17] of infants exposed to famine prenatally or early in life and of infants of diabetic mothers[18–23] strongly suggest that prenatal and perinatal under- or overnutrition influences the development of fatness and its related diseases in later life. Intrauterine conditions could be exclusively or partially responsible for associations between birth weight and adult body composition. A Belgian study examining the relationship between birth weight and adult body composition suggested that genetic factors and the fetal-placental environment are responsible for observed differences in body composition among male twins.[24] Even before birth, there appear to be regional differences in fat accumulation that could have important significance for the future. Cell characteristics and normal growth patterns differ from one fat depot to another. After birth, hormonal responsiveness of fat tissue varies according to its location.[25]

The infant in utero increases its fat content from 2.5% at 1 kg of weight to a fat mass of 13.7% for boys and 14.9% for girls in the full-term newborn.[9,26] From birth, the accumulation of fat progresses rapidly to peak at 29.1% in boys and 32.0% in girls at age 6 months,[12] probably owing to a high intake of energy and little activity.[14] An interesting finding in this area is that breast-fed infants have a different accumulation of fat than formula-fed infants do.[27,28] Breast-fed infants have less fat, with the greatest differences evident between 9 and 15 months of age.[29] Differences in body fat also depend on the proportion of protein and the type of fat contained in certain formulas.[30] With increasing age, fat content drops, and the values fall to a minimum of 12.8% at 7 years in boys and 16.4% at 6 years in girls, with a discrete increase afterward, the "adiposity rebound,"[31] to 13.7% in boys and 19.4% in girls at the age of 10.[9]

Although there are sexual differences in body composition at birth or even sooner, the predominance of fatness in girls becomes remarkable during the adolescent years. In both sexes, puberty is characterized by substantial increases in both adipocyte size and total number and by a

ECW = extracellular water; ICW = intracellular water; TBW = total body water.

centripetal change in fat distribution, which is especially marked in males.[32,33] In terms of fat percentage, males reach peak values during early adolescence and then show a decrease throughout adolescent growth, whereas females, after an initial decline, show a continuous increase in fat percentage throughout their eighteenth year. There are also significant gender differences in subcutaneous fat distribution, with a preponderance of adipose tissue in the upper part of the body (above the umbilicus) in males and in the lower part in females. This tendency for concentration of fat in the abdomen of males and the hips of females is seen at least as early as 4 years, with this sex difference in fat distribution becoming marked during adolescence.[34] Some of this variation can be attributed to the effects of adrenal and ovarian hormones. In females, a significant secretion of estrogen and progesterone induces a slight increase in trochanteric adipocyte volume and number, whereas in males, the latter are significantly reduced by androgens.[25]

With aging, body fat in men slowly increases from about 18% in those 18 to 25 years of age to 36% in those

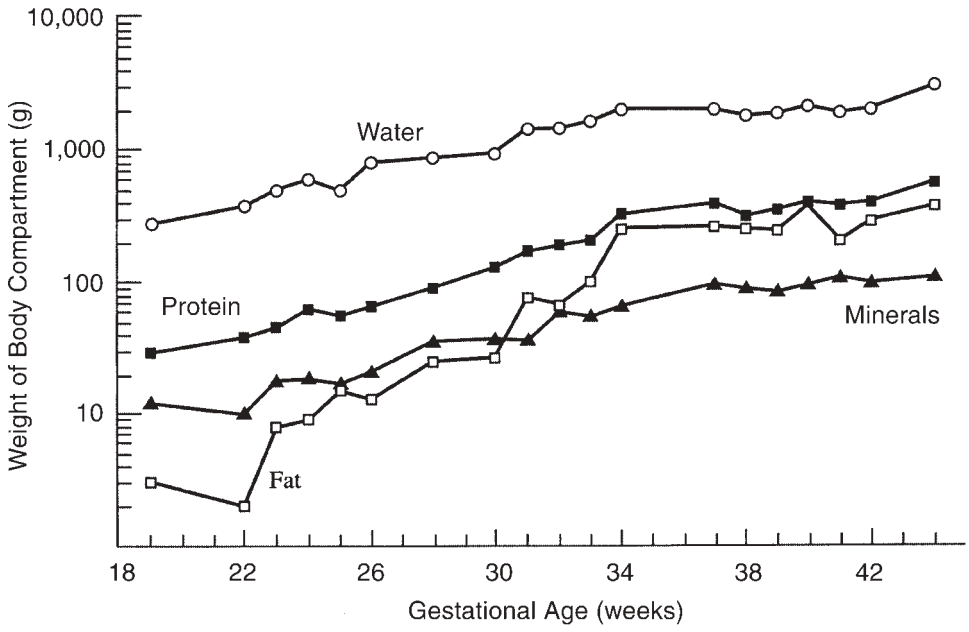

FIGURE 4-2 Changes in body composition during fetal development and early life. Reproduced from Ellis KJ.[13]

65 to 85 years old; in women, a gradual increase from 33 to 45% is found in similar age groups.[35] The preponderance of fat in females at all ages, especially in the lower part of the body, could be related to their capacity for childbearing as an adaptation mechanism for the preservation of the species. There is a need for important reserves for the fetus and newborn.[8] Nevertheless, in a minority of normal males and females, the adipose tissue distribution presents the sexual differentiation of the opposite sex.[8] In women with the android fat distribution, the risk factors for developing diabetes, hypertension, or hyperlipidemia are similar to those of men. In these women, there is no clear explanation for this different pattern of fat distribution, although it has been suggested that they might have an inherited increased sensitivity of their adipocytes to androgens and possibly to cortisol.[8]

Ethnic differences in fat accumulation during growth have been described. A study of white, black, and Hispanic girls reported a higher percentage of body fat in the Hispanic and black groups than in the white group when adjusted for body size. Bone mineral content and lean tissue mass were also greater in black girls than in white or Hispanic girls.[36] A similar study of multiethnic boys showed greater bone mineral content in the black children, but the highest percentage of body fat was found in the Hispanic group and the lowest body fat values were found in the black boys.[37] White children have a more peripheral distribution of body fat than Latin American, Japanese, or black children. Black children tend to have a more centralized pattern. These ethnic differences are evident as early as the preschool period and continue throughout adolescence.[38] The pattern of less peripheral fat has also been found in studies of children from several Latin American countries.[39] It could reflect genetic differences as well as different lifestyles and nutritional and health habits. Ethnic differences have also been found among Asian adolescents[40] and adults.[41] These studies suggest the need for ethnicity-specific references for body composition values.

The tracking of total body fat and fat distribution measurements has not been clearly demonstrated in children. Serial and repetitive measurements of body fat distribution might decrease intraindividual variation and improve reliability of tracking over time.[42] It appears that the majority of overweight 1 year olds display normal levels of fatness as adolescents and adults and that whereas overweight in early childhood is not well correlated with adult obesity, overweight in later childhood and adolescence is.[34]

Long-term follow-up studies have found that truncal fat predominance and increased body mass index (BMI) in childhood were associated with an increased risk of central obesity in adulthood.[43] Correlations have been shown between body fatness and risk factors for coronary heart disease and diabetes as early as 7 years of age,[44] and correlations between body fatness and serum lipid and lipoprotein concentrations have also been found at younger ages.[45] Moreover, overweight in adolescent males has been associated with increased risk of mortality from all causes and from coronary heart disease after 55 years of follow-up.[46]

In addition to total body fat, the location of fat plays an important role in the risks of developing cardiovascular disease, diabetes, hypertension, gallbladder disease, stroke, and overall mortality. It appears that at least three principal components of body fat are associated with health outcome: total amount of fat expressed as a percentage of body weight,[47] amount of subcutaneous truncal or abdominal fat,[48] and quantity of visceral fat located within the intra-abdominal cavity.[7,49] Adult diabetogenic or atherogenic obesity tends to be more centripetal than peripheral, more the abdominal "apple" shape than the gluteofemoral "pear" shape, more intra-abdominal visceral than extra-abdominal subcutaneous, more in the upper body (nape, cheeks, neck, shoulders, upper half of the trunk, and abdomen) than in the lower body; this holds true for both men and women with android distribution of fat.[8]

Risk factors for the development of obesity can be considered as either genetic[50,51] or environmental from changes in diet, exercise, or lifestyle.[52] Several authors have reported a correlation between body fat and the amount of time spent watching television,[53–55] whereas others have not found this association.[56,57] Along with other benefits, regular exercise results in decreased body fat and increased bone mineralization and muscle mass.[58] In general, athletes have a lower percentage of body fat and greater lean body mass than their nonathletic peers. However, there is considerable variability among individuals and types of activities. Athletes participating in sports in which body weight is supported (eg, swimming, cycling, kayaking) or in which body weight is not translocated (eg, throwing, lifting) tend to have a higher percentage of body fat than athletes who participate in sports that require horizontal or vertical translation of body weight (eg, running, jumping).[2,59] In sports in which weight is a factor, such as gymnastics, ballet, and wrestling, the effort to decrease body fat can affect performance and induce eating disorders. This phenomenon has occurred in both male and female athletes.[2,60] In obese adult patients, intensive and extensive aerobic exercise training not only can induce moderate to high fat losses but can also reduce central subcutaneous fat, which is more noticeable in males.[61]

The increased percentage of body fat seen in the elderly population is probably attributable to decreased physical activity. With aging, there is a decline in muscle strength and muscle mass that could be counteracted by regular physical exercise. The capacity to increase muscle mass and muscle strength is retained into old age. Physical training, especially resistance exercise of significant intensity, frequency, and duration, could retard the loss in muscle mass closely associated with bone mineral decline and increase in body fat. Hence, the associated abnormalities of diabetes, coronary heart disease, osteoporosis, and fractures could also be reduced.[62]

With some method of measuring body composition, the physician should assess the contribution of fat to the variation of body weight in order to make the appropriate recommendations concerning nutrition, exercise, or lifestyle to promote lifelong health.

Changes in Body Water

Water content is greatest during fetal life—about 88.6% of body weight at 24 weeks gestation and approximately 75% at term. After birth, it drops rapidly and is about 60% at age 4 months. From then until adolescence, it ranges between 60 and 65%.[14] During the first years of life, the extracellular water (ECW) volume exceeds the intracellular water (ICW) volume, and with growth this relationship changes: the ratio of extracellular to intracellular fluid volume declines during growth. ICW initially is about 25 to 30% of body weight but by adolescence constitutes 35 to 40%, principally because the child's muscle mass increases. At the same time, ECW slowly drops from about 40% to approximately 20 to 25% of body weight.[14] In the elderly there is a diminution of total body water (TBW).[63]

Small-for-gestational-age full-term and preterm infants have a greater proportion of body water at birth than do their appropriately grown peers, suggesting that fetal growth deficits in this population are not attributable to abnormalities in body water regulation.[64] In disease states such as malnutrition, there is an expansion of ECW; similar patterns have been observed after surgery, in patients with cancer, and in sepsis.[65] The ECW-to-ICW ratio appears to be an accurate predictor of clinical outcome and mortality,[65] and it has been proposed as a marker of the quality or health of the fat-free mass.[66] Moreover, a strong correlation between ECW-to-ICW ratio changes and protein and energy intakes has been found. For this reason, the availability of these measurements could aid the clinician in monitoring nutritional rehabilitation in the acute care of critically ill patients.[65]

Changes in Body Mineral Content

Throughout life, bone is constantly being formed and resorbed. The process of bone modeling, characterized by changes in the shape of bones, takes place from birth until the cessation of longitudinal bone growth. Thereafter, bone tissue within the existing skeletal structure is continuously being formed and resorbed, through the remodeling process, with minimal change in bone volume.[6] The skeleton develops through infancy, childhood, and puberty, reaching maturity by late adolescence. The rate of bone modeling varies greatly during these different biologic stages. The skeletal mass of infants doubles during the first year of life, and approximately 37% of the total skeletal mass of adults is accumulated during adolescence.[67] The annual increment in bone mineral density (BMD) values is high during the first 3 years of life and decreases thereafter until puberty, as occurs with height growth velocity. During puberty, an increase also occurs in BMD values, which peaks in late adolescence, corresponding to Tanner stage IV, and continues at a slow rate to adulthood.[68] The adult reference man has a calcium content of 1.2 kg.[69]

Until 10 weeks gestation, the human skeleton is composed entirely of cartilage, a tissue quite distinct histologically and chemically from cortical bone. At about 10 weeks, a primary center of ossification begins to develop in the shafts of long bones (eg, femur) and the collagen laid down is calcified by the deposition of mineral into it. The osseous tissue gradually extends along the shaft, replacing the cartilage and also forming the spongy trabecular bone of the metaphyses.[70] At around 22 weeks gestation, cartilage comprises 42% of the total skeleton in the 500 g fetus; it is 33% in the full-term fetus.[71] The skeleton of a full-term infant contains about 30 g of calcium, most of which was deposited during the last trimester of intrauterine life.[6] Fetal intrauterine calcium accretion increases exponentially during the last trimester of pregnancy, from 130 mg/kg/day at 28 weeks gestation to 150 mg/kg/day at 36 to 38 weeks gestation.[72] These values are so high that human milk can supply to a premature infant only a fraction of the amounts needed to emulate the intrauterine accretion rate.[71] Insufficient intake of calcium and phosphate is the primary cause of osteopenia and rickets of prematurity.[73] In studies of premature infants when calcium and phosphate intake is increased by supplementing their mother's milk[74] or their formula, bone mineralization increases significantly, paralleling the intrauterine rate in some studies.[75–78]

Absorptiometric techniques have permitted the study of bone mineralization measured as bone mineral content or BMD during growth. Intrauterine bone mineralization has been determined by measuring the BMD in appropriate-for-gestational-age infants born at between 30 and 41 weeks gestation[79] and between 22 and 42 weeks gestation.[80] BMD and bone width at birth were found to correlate with gestational age and birth weight.[73] These values of BMD between 30 and 41 weeks gestation have been used as reference curves[81] to compare various feeding regimens in the premature infant.

BMD increases over the first year of life, at a slower rate during the first 6 months, and varies with the type of feeding.[73,82,83] Higher BMD values have been found in supplemented breast-fed infants[74] or cow's milk formula–fed full-term and premature infants[84,85] when compared with those in unsupplemented breast-fed infants. In a longitudinal study of hospitalized preterm infants fed either preterm formula or fortified breast milk, those fed preterm formula demonstrated a greater increase in BMD; however, the significance of this increase was nullified when adjusted for differences in weight gain. Whether there is a relationship of these differences to specific nutrient intake and long-term effects on bone calcium accretion has yet to be determined.[86] Lower values have been observed in infants receiving breast milk or soy-based formula when compared with infants receiving cow's milk formula.[85,87,88] In later studies with soy formulas modified to improve the suspensibility of minerals, no differences in BMD were found when compared with results with cow's milk formula.[82,83,89] The long-term consequences of the differences in BMD with various types of feedings in early infancy are as yet unknown. However, in two studies of bone mineralization at 1 to 6 years of age, the BMD of children who had been breast-fed was similar to that of those who were formula-fed.[90,91]

No gender or ethnicity differences in BMD content have been found in full-term newborns[92] or children up to the age of 4 years.[90,91] After that, there is a wide variation in BMD as a function of age, gender, and ethnicity.[91,93–96] Boys appear to have slightly higher BMD values in the radius

(predominantly cortical bone) than girls do, and blacks have higher values than whites.[91,94,97,98] With the onset of puberty, the difference between males and females increases significantly. Ethnic differences in BMD among blacks, whites, and Asians have also been reported in adolescents and adults.[96,99,100]

In the lumbar spine (predominantly trabecular bone), there is a gradual linear increase in BMD with age in both sexes before puberty, at approximately 9 to 10 years of age,[68,95,97,101] followed by accelerated increments during puberty.[95,96,101] Thereafter, BMD values are higher in girls, possibly because of earlier pubertal development, until the age of 15 years,[95,97,101] with marked slowing afterwards. In girls, peak bone mass in the spine and femoral neck is probably achieved by 15 years of age.[97] In boys, the most rapid increase in axial BMD occurs at 13 years of age, with the steepest increase at 15 and 16 years and no slowing until 17 years of age.[101] In males, peak bone mass is not achieved until the age of 17 or 18 years.[97]

These absorptiometric data, showing the relatively greater importance in accumulating bone mass of early adolescence in girls compared with late adolescence, agree with studies done with other methods. Abrams, in a study of calcium kinetics in girls 4.9 to 16.7 years old using intravenous ^{42}Ca, found that calcium deposition and the size of the exchangeable pool in bone reached a maximum during early puberty and decreased in late puberty,[102] suggesting that the greatest period of calcium transfer to the bone is in the prepubertal and early pubertal periods. Also, the measurement of lumbar spine in adolescent and adult females by quantitative computed tomography (CT) has suggested that vertebral trabecular bone could reach its peak near the end of the second decade of life.[96] Because peak bone mass accumulation is achieved during adolescence, current recommendations for calcium nutrition reflect a greater requirement for these age groups (Appendix 2). Prevention of osteoporosis consists primarily of maximizing peak bone mass during the years of growth and skeletal consolidation.[6]

Genetic factors are probably the strongest predictors of peak bone density. It has been suggested that genetics contribute 70 to 80% of the variance in bone mass, with the environment contributing the remaining 20 to 30%.[103,104] Premenopausal daughters of postmenopausal women with osteoporosis have lower bone mass than other women of the same age.[105] Moreover, BMD correlates more closely in monozygotic than in dizygotic twins.[106]

Within the modifiable environmental factors, calcium intake could play a significant role in peak bone mass. For the growing individual, there is a significant positive relationship between calcium intake and retention. This has been observed in the studies of infants presented earlier and in studies of BMD in children and adolescents.[94,103] Variations in calcium nutrition early in life could account for as much as 5 to 10% of the difference in peak bone mass; such a difference probably contributes to more than 50% of the difference in hip-fracture rate later in life.[6,104] Finally, it has also been found that weight-bearing activity and physical exercise during childhood have a positive impact on peak bone mass.[101,104] During adult life and in the elderly, the role of exercise in preserving bone mass has also been reported in several studies.[104,107]

With this in mind, osteoporosis has become the domain of the pediatrician as the interplay of genetics, nutrition, and activity is better understood and preventive measures can be undertaken. There is an increasing prevalence of obesity in children, and children who are overweight could have an increased risk of fractures owing to lower BMD.[108,109] In practical terms, the pediatrician should encourage the attainment of normal body weight for height and the adequate intake of calcium during the first 3 years of life and also during the prepubertal and pubertal stages, when the highest rates of bone mineralization take place.[68]

Changes in Body Skeletal Muscle Mass

There is no definitive in vivo method of measuring total muscle mass. Neither total body potassium (TBK) nor total body nitrogen (TBN) can identify muscle cells specifically.[110] Although two metabolic end products released from myocytes—creatinine and 3-methyl histidine—have been used to estimate whole body muscle mass, their application is limited by the constraints stated in detail below.[111,112] However, in certain well-controlled conditions, they can give accurate results.[110]

Regional body muscle composition can be assessed by means of imaging techniques and also with absorptiometric techniques.[111] Gross estimates of muscle mass can also be obtained with anthropometric measurements of midarm circumferences or areas. This technique is particularly useful in the clinical setting when followed over time and validated against other methodologies.[113,114]

Skeletal muscle represents 22 to 25% (approximately 850 g) of the mass of a newborn infant and approximately 30 to 45% (approximately 28 kg) of the total body weight of an adult, although the range in values reported for the adult is highly variable. The skeletal muscle of a newborn contains 27% of TBN, 33% of TBK, and 28% of TBW.[69] The chemical change in the composition of skeletal muscle during early development is a decrease in the percentage of water and an increase in the protein concentration. As the fibers increase in number and size, the extracellular material, which makes up a large part of fetal skeletal muscle, is replaced by muscle fibers.[70] The muscle mass constitutes the largest part of the soft tissue mass, except in extremely obese individuals, in whom adipose tissue might predominate.[70,115] Depending on gender, age, and health status, between one-third and half of total body protein is within skeletal muscle.[111]

The process of growth of the total muscle mass is not uniform and develops slowly during childhood, with a growth spurt in the adolescent years, which is more intense and prolonged in boys than in girls.[69] The development of muscle mass is influenced by several factors, including age, sex, nutrition, hormonal and metabolic states, and exercise. Estimated muscle mass as a percentage of body weight increases from 42 to 54% in boys between 5 and 17 years of age. In girls, it increases from about 40 to 45% between 5 and 13 years of age, decreas-

ing somewhat thereafter. This decrease is probably attributable to the relatively higher accumulation of fat in the adolescent female. At all ages from birth to adulthood, muscle mass predominates in males.[115] With advancing age, there is a substantial decrease in muscle mass.[62] At 70 years of age, skeletal muscle has lost 40% of its peak weight in early adult life.[35]

This sarcopenia that occurs in the elderly could be delayed by regular exercise.[62] Physical activity should be promoted during the early periods of life to create positive habits that can continue thereafter, favoring the muscle, bone, and cardiovascular systems, to decrease the tendency toward obesity.

Changes in Body Visceral Mass

Growth and development of the viscera are associated with the same changes in chemical composition as those seen in muscle mass, namely, a decrease in the proportion of water and an increase in the proportion of protein. Extracellular elements such as sodium and chloride decrease, whereas intracellular elements such as potassium and magnesium either remain the same or increase.

The brain grows rapidly from midgestation to 18 months after birth, when it reaches about 70% of its adult mass. Growth and development of the brain are characterized by a decrease in the percentage of water and an increase in protein, but the brain differs from most other tissues in that lipids form an integral part of the structure. Myelination begins before birth, but most of it takes place between birth and 3 years of age, when the brain is 80 to 90% of its mass at maturity. Up to the age of 3 years there is a considerable increase in the concentration of lipid, with a consequent decrease in the percentage of water. After 3 years, the changes in composition are relatively small.[70]

During the myelination period there is a rapid accumulation in the brain of the ω-3 and ω-6 long-chain polyunsaturated fatty acids (PUFAs)—docosahexaenoic acid (DHA; 22:6ω-3), arachidonic acid (AA) (20:4ω-6), and adrenic acid (22:4ω-6)—which are important structural components of the cell membrane phospholipids.[116] The type of lipid that accumulates in the brain during these first few years is influenced by early nutrition and might have functional implications, especially related to visual maturation and cognitive development.[117–120] Preterm infants who receive formulas with a high linoleic-to-α-linolenic acid ratio and practically devoid of longer-chain PUFAs show a marked decrease in the DHA-to-AA ratio in brain and retina.[116] On the other hand, human milk contains enough precursors and long-chain PUFAs to fulfill the infant's requirements for brain growth.[121] These factors have led to the study and development of infant formulas containing DHA and AA, with hopes of mimicking the fatty acid accretion pattern of breast-fed infants in babies who are formula-fed.[116,122,123]

The other major organs—liver, kidney, lung, heart, skin, and spleen—also change in chemical composition in the same way, with a decrease in the proportion of water and an increase in protein. The kidney has more sodium and less potassium at each age than muscle or liver does. In the skin, the protein increases, but it also changes in type: in the fetus, less than 20% by mass is collagen; the rest is mainly elastin. By term, the collagen represents 63% and in the adult 90%.[70] Finally, the immune system is also an important component of the body's lean nonmuscle compartment; lymphocytes alone account for approximately 2% of total body weight and 8% of fat-free solid in the adult. The status of the immune system is intimately related to body composition via the known effects of cytokines on muscle protein metabolism.[124]

The proportion of body weight contributed by major organs and tissues is presented in Table 4-3. At any age, muscle, skeleton, skin, liver, and brain account for more than 70% of body mass. With increasing age, some organs, such as liver, spleen, and kidneys, appear to atrophy, whereas hypertrophy is common in others, such as prostate, lungs, and heart.[35]

Chemical and General Changes in Fat-Free Mass

In general, fat-free mass increases rapidly during the late fetal and newborn period, followed by a rapid deceleration between the first and third years of life. Afterward, growth velocity slows until about 10 years of age, when the adolescent growth spurt is initiated. During the first years of life, there is a slight predominance of fat-free mass in males, which becomes significant during the adolescent period. The pattern of growth in fat-free mass is correlated with height.[69] At the other end of the life cycle, aging is marked by a progressive loss of lean body mass, especially skeletal muscle and bone mass.[62]

Concept of Chemical Maturity

Most healthy young adults have achieved chemical stability of their fat-free mass. This concept of chemical maturity was introduced by Moulton in 1923. Realizing the chemical changes that occur during growth, he found that the body composition of most species approached that of the adult when puberty was reached.[58] At this point, fat-free mass becomes relatively constant, with a water content between 72 and 74%, a protein content of approximately 19%, a potassium content of 60 to 70 mmol/kg in men and 50 to 60 mmol/kg in women, and a mineral content of

Table 4-3 Contributions of Organs and Major Tissues to Body Weight

	Percentage of Body Weight			
			Adult	
Organ or Tissue	*Fetus (20–24 wk)*	*Full-Term Newborn*	*Male*	*Female*

6.8%.[58,125] The completion of chemical maturation is also reflected in the stabilization of various constants relating one component of body composition to another, such as potassium to nitrogen and ECW to ICW, and intracellular potassium concentration.[14] Because conditions such as pregnancy, extreme old age, disease, nutritional status, and physical build can affect fat-free mass composition, the usefulness of these constants is debatable.

The changes in fat-free mass body composition as a function of age are shown in Figure 4-3. Variation in chemical maturity during growth is greater than the changes associated with aging. During growth, chemical maturity occurs at different stages for different constituents of fat-free mass. Muscles, visceral tissues, and bone all reach chemical maturity at different rates. For example, bone mineral maturation appears not to occur until the third decade of life. Body potassium, mainly reflecting increases in muscle mass, increases gradually from birth to 20 years of age in males and until 17 to 18 years of age in females. It then starts to descend and at about the age of 85 years is generally equal to that of a 13- or 14-year-old boy[69] (Figure 4-3A). In children, fat-free mass contains relatively more water than in adults. The hydration constant of fat-free mass ranges from 80.2% in the newborn to 75% in early puberty and to 73% in adults (Figure 4-3B). Protein content increases from about 15% at birth to about 19.5% in boys and 18.7% in girls at age 10 years.[9] Approximately 0.5% of body weight (0.6% of fat-free mass) is carbohydrate. Bone mineral content rises during childhood and especially in adolescence. It gradually increases from 3.7% of fat-free mass in infants to 5.2% in the prepubescent male, 6.2% in the postpubescent male at around 15.5 years of age, and then reaches 6.8% in the adult.[58] Bone gain continues during the third decade of life and then plateaus. Bone loss begins in the fourth or fifth decade of life, varying from one skeletal site to another and between sexes[104] (Figure 4-3C).

The relative content of water, protein, and minerals determines the density of the fat-free mass. During growth, as water content decreases and protein and mineral content rise, there is an increase in body density. Water and bone mineral are the principal factors in the change in density of the fat-free mass, water because it is the largest constituent of the fat-free mass and bone mineral because its density is very high, at 3.0 g/cc^2. With aging there is a decline in body density[69,126,127] (Figure 4-3D). Consequently, body composition in children is not correctly estimated if adult constants are used. For example, fat is

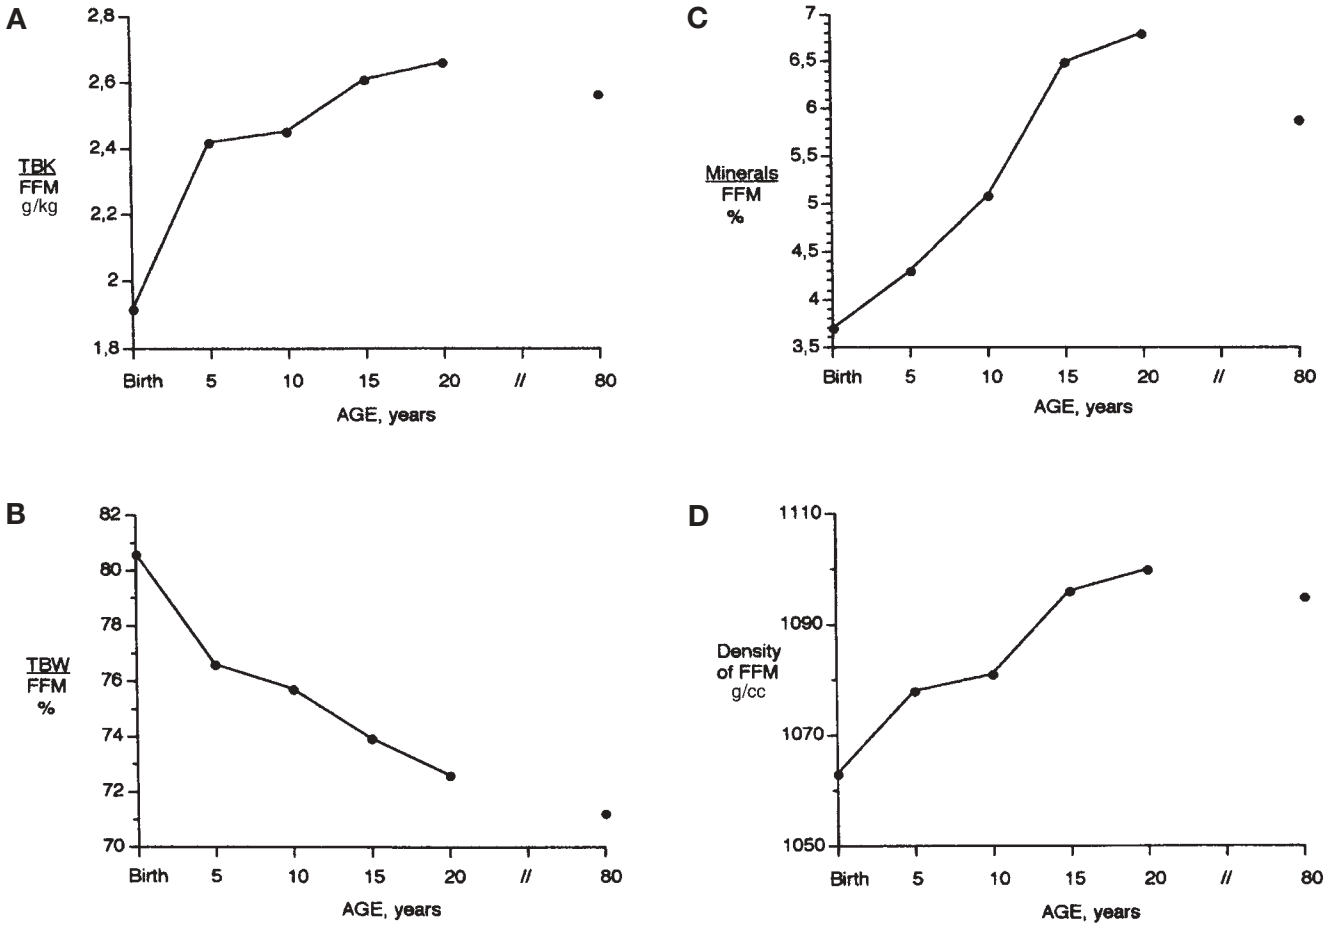

FIGURE 4-3 Changes in fat-free mass (FFM) body composition as a function of age. *A,* Total body potassium (TBK) in relation to FFM. *B,* Total body water (TBW) in relation to FFM. *C,* Bone mineral content in relation to FFM. *D,* Density of the FFM. underestimated when calculated on the basis of TBW and overestimated when calculated on the basis of TBK or body density.[125] Constants adjusted for age and gender during childhood and adolescence have been developed for fat-free mass constituents,[58] making it possible to derive percent fat equations for each age and gender group.[4]

Changes in Linear Growth

Height velocity reaches its peak of 10 to 12 cm/month between 16 and 30 weeks gestation and decreases to 3 cm/month (36 cm/year) at birth. The postnatal curve is signaled by a deceleration in linear growth to 15 cm/year at the end of the first year, 9 cm/year at the end of the second year, and 8 cm/year at the end of the third year. Between the ages of 4 and 5 years, it is 6.5 cm/year, and from then to the time of puberty the growth velocity per year stabilizes to approximately 5 to 6 cm/year.

Girls of Anglo-Saxon descent start the pubertal growth spurt at about 12 years of age, with a peak height velocity of 9 cm/year. Boys start the growth spurt at about 14 years of age, with a peak velocity of 10 cm/year. Total increments in stature after peak height velocity are slightly larger in males than in females. The annual increments decrease significantly after peak height velocity is achieved.[128] In the Fels longitudinal study, adult stature was reached at an average age of 21.2 years for males and 17.3 years for females. In girls, growth in stature continued at a slower rate for almost 5 years after menarche.[128]

Changes in height gain are linked to pubertal status. Some regions of the world show variations in pubertal onset. In Latin American countries, children show an early maturation pattern. The pubertal spurt occurs 1 to 1.5 years before it does in children of Anglo-Saxon descent.[39] The age at which puberty occurs varies among populations and individuals. Therefore, body composition changes are better related to physiologic age than to chronologic age, and some indication of pubertal staging is necessary in studies concerning this age period.

Changes with Weight Loss or Weight Gain

At birth, normal weight velocity is approximately 7 to 9 kg/year; it decreases to 3.5 kg/year at the end of the first year and 2.5 kg/year at the end of the second year and then remains fairly stable at around 2 kg/year until puberty. Changes in weight that result from dietary intervention or that occur spontaneously almost always comprise both fat-free mass and fat. However, the relative contribution of each body component to the total weight change is dependent on several factors.[1,39] In the circumstances of weight reduction, fat mass decreases, but the fat-free mass also diminishes in proportion to the initial body fat content.[1]

The situation is similar for individuals who gain significant amounts of body weight in response to intake. The composition of the weight gain is a function of body fat content: thin individuals put on proportionately more lean, at least initially during weight gain, than do those with larger body fat burdens.[1] In obese subjects, weight gain is between 20 and 30% fat-free mass. In subjects of normal or low weight, such as malnourished children, premature infants, or patients with anorexia nervosa, the proportion of weight gained as fat-free mass is larger, around 60 to 75%, depending on the individual and type of diet. On the other hand, people with sedentary lifestyles and aging individuals tend to accumulate proportionately more fat during weight gain.[39]

Changes in Body Composition in Malnutrition

Malnutrition and disease can cause body composition alterations beyond those expected from underfeeding. Moreover, many of the methods used in measuring body composition changes assume certain conditions that are generally not present in these children. For example, they might have electrolyte derangement and altered body water distributions related to their condition that can invalidate the results of some techniques.[129] However, some of the changes are already well known.

Children with severe protein-energy malnutrition generally have increased TBW in relation to body weight. ECW as a percentage of TBW is also increased. These changes are indicative of severe losses of cell mass and body fat. The cells seem to retract and lose potassium, magnesium, and phosphorus. Total body sodium is increased both extracellularly and intracellularly. The extracellular increase of sodium is generally less than the increase in ECW. This results in hyponatremia with a relative increase in total body sodium. TBK is decreased, although serum potassium levels are usually normal. Deficiencies in magnesium, calcium, phosphorus, and trace elements (zinc, copper, selenium, and chromium) with bone demineralization have also been reported. Total body protein is depleted, especially in kwashiorkor. There is a marked loss of muscle mass, primarily as a result of a decrease in cell size rather than cell number. If the process of energy deficiency continues, the result is slowing or cessation in linear growth and stunting.[39,130] The alterations in ECW, sodium, and potassium should be taken into account in the early management of children with acute malnutrition. The process of recovery should start carefully and slowly by correcting the water and electrolyte derangement to avoid dangers associated with refeeding syndrome, particularly heart failure.[39,129,130] See Chapter 10, "Protein-Energy Malnutrition," for more details.

In marasmus, initially there is a loss in fat mass and ICW. The body cell mass diminishes, at the expense, especially, of muscle protein. In the edematous form of kwashiorkor, there is a loss in muscle and visceral protein, with a relative preservation of subcutaneous fat. The ICW decreases. There is expansion of the extracellular compartment with edema and hypoproteinemia. As the process develops, it becomes manifest with marked losses in muscle mass and an increase in ECW. The effect of this progression can obscure the severity of the malnutrition if body weight alone is used to assess the child. In the combined form of protein-energy malnutrition there are abnormalities in all body compartments.[39,130] Malnourished children can continue to show aberrations in body composition even after regaining weight.[131]

BODY COMPOSITION MODELS

Traditionally, body compartments have been divided into fat mass and fat-free mass. The fat mass includes all ether-extractable lipids in the body. The fat-free mass has four major constituents: water, protein, glycogen, and minerals.[132] Adipose tissue includes the fat and its supporting cellular and extracellular structures.[93,133] Lean body mass refers to the part of the body free of adipose tissue, whereas fat-free mass consists of lean body mass plus the nonfat components of adipose tissue.[133] In very obese individuals, the excess adipose tissue can increase fat-free mass without increasing lean body mass. Therefore, because lean body mass and fat-free mass are not synonyms, it is most accurate to use the terms fat mass and fat-free mass in the two-compartment model of body composition.[133]

Several methods of body composition measurement rely on the two-compartment model of fat mass and fat-free mass, each assumed to be in constant composition. In general, these methods first measure one constituent of the fat-free mass, such as density, water, or potassium. Then they assume that the concentration of that constituent of the fat-free mass is a known constant and that the other components of the fat-free mass also maintain a relatively constant composition to calculate the total fat-free mass. Fat-free mass is then subtracted from body weight to calculate fat mass. The two-compartment model continues to be widely used, mainly because of the simplicity of its interpretation.[93] Both of the assumptions noted above, however, are questionable because the fat-free mass changes with a variety of conditions.[2,4,35,58,124] To address this problem, multicompartment models of body composition assessment have been developed in which more than one constituent of the fat-free mass of each subject is measured.[126,132,134]

MULTICOMPARTMENT MODELS

Recent advances in methodology have allowed the measurement of several body compartments to overcome the limitations of many assumptions. As a result, body composition analysis has evolved from the traditional two-compartment system of fat and fat-free mass to models based on four or more body-weight fractions. Now body composition in humans can be studied using several models at different levels of complexity (Figure 4-4)[13,127,135]: (1) atomic, (2) molecular, (3) cellular, (4) functional, and (5) whole body. The direct or indirect methods used to measure components at the five levels are presented in Table 4-4. Several of these methods are reviewed later.

Atomic Level In the human body, there are approximately 50 different elements, but just six (oxygen, carbon, hydrogen, nitrogen, calcium, and phosphorus) account for more than 98% of body weight. Oxygen constitutes more than 60% of total body mass. The remaining 44 elements make up less than 2% of body weight.[135] Traditionally, elemental analysis of humans was possible only in cadavers, which was confounded by the possible alterations caused by disease and death. The availability of whole-body counting and neutron activation analysis, combined with a measurement of TBW, allows the measure of eight elements directly (hydrogen, carbon, nitrogen, calcium, phosphorus, sodium, potassium, and chlorine). This information is used to calculate the body content of three more elements (oxygen, magnesium, and sulfur). There are consequently 11 body components determined at the atomic level; these comprise at least 99% of body weight in living humans.[127,136] Equations have been developed using atomic components to calculate higher levels of body composition (Table 4-4).

Molecular Level The molecular model of body composition is usually based on three main chemical groups: water, mineral, and organic.[132] The minerals are further separated into bone mineral and soft tissue components, and the organics are mainly defined by protein and fat components. Therefore,

Body weight = lipid mass (fat) + total body protein + bone mineral + soft tissue mineral + TBW.[13,93,132]

At this level, TBW by isotope dilution and bone mineral by whole-body dual-photon absorptiometry can be deter-

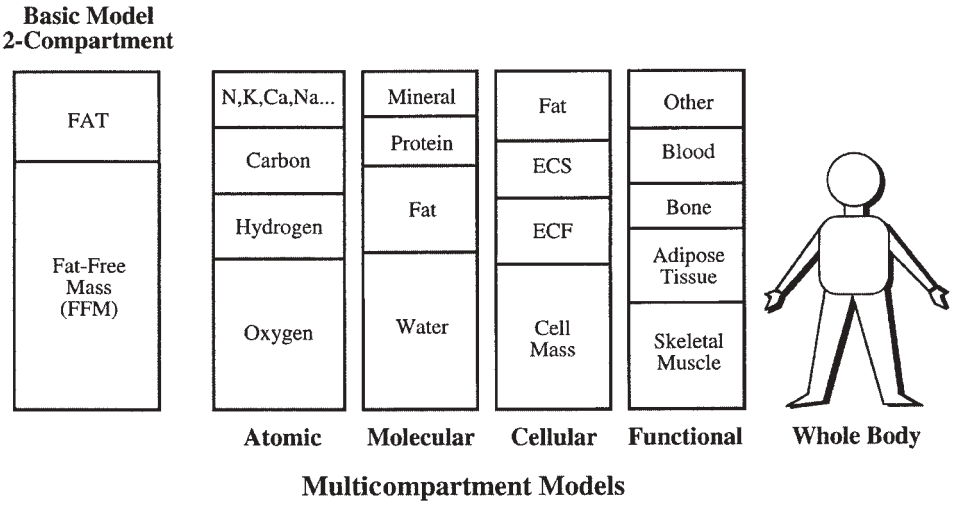

FIGURE 4-4 Body composition models. Reproduced from Ellis KJ.[13]

mined directly.[135] The remaining components must be estimated indirectly. For example, protein can be determined from TBN by making two assumptions: that all body nitrogen is in protein and that 16% of protein is nitrogen.[135,136] Total body fat can be calculated by subtracting the nonlipid carbon from total body carbon and then converting this into fat, assuming that triglyceride is 77.4% carbon.[137] Bone mineral can also be calculated from total body calcium. An important aspect of these estimates drawn from elements is that no known age dependencies are recognized.[126] The main assumption is that the proportions of carbon, nitrogen, and calcium are known and constant within lipid, protein, and bone mineral, respectively.

Cellular Level At the cellular level, the body is divided into four main compartments: cells, extracellular fluid, extracellular solids, and fat. Body cell mass reflects the cellular components of the body. The extracellular fluid is the fluid surrounding the cells. Extracellular solids consist of organic and inorganic chemical compounds. The organic extracellular solids include collagen, reticular, and elastic fibers. The inorganic extracellular solids represent the total body bone mineral (primarily calcium, phosphorus, and oxygen) and other inorganic components such as bicarbonate, citrate, magnesium, and sodium.[135]

At this level, the volume of extracellular fluid and its plasma subcompartment can be quantified directly by dilution methods. Body cell mass can be estimated by the difference between TBW and ECW or by the measurement of TBK. Extracellular solids can be estimated from elements measured by neutron activation analysis (NAA).[135,136]

Functional Level The fourth level of complexity comprises tissues, organs, and systems. Three specific tissues are particularly important in body composition studies: bone, adipose tissue, and muscle, which together comprise approximately 75% of body weight.[135]

The direct methods used to estimate the major compartments at this level are the imaging techniques, such as CT, nuclear magnetic resonance imaging (MRI), and ultrasonography. They can directly determine the regional and total body adipose tissue, skeletal muscle, liver, kidney, and spleen volumes. Brain volume can also be evaluated by CT, and heart mass can be estimated by echocardiography.[132] Dual-photon and dual-energy x-ray absorptiometry (DXA) can be used to estimate fat tissue, bone, and skeletal muscle mass.[138–140] Measurement of total body potassium, nitrogen, and calcium by NAA allows the indirect estimation of skeletal muscle mass and bone mass.

Whole Body Level The whole body level of body composition measurement concerns body size, shape, and exterior and physical characteristics.[135] The techniques used in their estimation are mainly anthropometry and densitometry. Anthropometric evaluations, although less accurate, are simpler and easier to perform than are some of the measurements at the other four levels. Thus, the anthropometric techniques are often well suited for large-scale studies or for field work. Air-displacement plethys-

mography, a densitometric method, is showing promise in children as an acceptable alternative to underwater weighing for determining body volume. It is important to recognize that changes in regional distribution are not measurable at this level.

BODY COMPOSITION MEASUREMENT METHODS

Direct measurement techniques quantify a compartment directly, and indirect methods are based on certain constant, established relationships between compartments that allow the calculation of other components from the direct measurements.[126] All indirect methods for the measurement of body composition have limitations because they make assumptions related to the method or to the interrelations among the different compartments. Because the body composition of children is in constant flux, many of these assumptions of steady-state relationships, based on adult data, are questionable. Therefore, whenever possible, the constants used in the calculations should be based on age, sex, and ethnicity reference data.

These reference data should be obtained with the use of several methods of body composition measurement at different levels in the same subjects to establish the steady-state relationships among compartments at different ages and for both sexes.[126] Unfortunately, there are few laboratories that are able to perform these studies, and they are located principally in large research departments. Nevertheless, the information obtained at these sophisticated facilities will allow the development of more accurate age-, gender-, and ethnicity-related references and constants. These will permit better comprehension of the changes in body composition and a more accurate calibration of the less precise but more practical and portable methods, which can be used in the office or field.

Neutron Activation Analysis

The NAA method of body composition measurement takes advantage of the principle that a given dose of neutrons generates a known amount of radioactivity within a defined mass of substance. If neutrons from a suitable source irradiate the body, some of these neutrons are captured in the atomic nuclei of body elements. The nuclei thus become unstable, and particulate or electromagnetic radiation is emitted to regain stability. These emissions (often gamma rays) can be observed directly (prompt emission) or later owing to the effects of the emissions on other atoms (delayed emission).[141] The total activity therefore reflects the total mass of the substance. A particular element can be identified by the characteristic energy of the electromagnetic radiation it emits, together with the decay rate. This method has been used in adults to determine the amount of a number of elements in the body using three different systems[134]: delayed gamma NAA (total body calcium, sodium, chlorine, and phosphorus), prompt gamma NAA (TBN), and inelastic neutron scattering (total body carbon).[135] Three chemical compartments (protein, mineral, and fat) can be estimated from these elements.[126,132]

This method should permit better understanding of human body composition because of the number of elements it can assay, yet its use in children will be limited because of the radiation exposure.[134] For the in vivo measurement of body nitrogen by NAA, low-dose (30 mrem) radiation techniques have been developed, and some limited data exist regarding TBN in children.[3] In the case of NAA of body calcium, it is the most sensitive and specific method for the detection of changes in total bone mass; however, the associated radiation exposure (> 280 mrem, total body) is substantially higher than that associated with TBN measurement.[142] New techniques for elemental analysis in humans should continue to be developed to improve the practicality of this precise measurement of body composition changes.[143]

Body Potassium Counting

The great advantage of this technique is that it relies on the natural occurrence of radioactive ^{40}K, which emits a characteristic gamma ray at 1.46 MeV.[93,112] It exists in the body at a fixed proportion to total K, assumed to be constant at 0.0118% for all potassium in the biosphere. Thus, no external radiation is necessary for this determination. However, the equipment needed is expensive, and great care must be taken to isolate the detectors from other sources of radioactive decay that might interfere with the measurements.[110]

In the adult, knowledge of TBK permits estimation of the fat-free mass or the body cell mass,[133] assuming constant relationships between TBK and these compartments. In the child, because the potassium content of the fat-free mass increases with growth (Figure 4-3A), age- and gender-adjusted constants should be used when available.[2,58]

Hydrometry

Water-containing body compartments can be measured by tracer dilution techniques. A known dose of a tracer is administered orally or intravenously, and then samples of body fluids are analyzed for tracer content after a sufficient time lapse to allow penetration to the compartment of interest. Corrections for overexpansion, nonequilibrium, and excretion of the tracers are needed to appropriately interpret the data obtained.[13]

Total Body Water The most common method of measuring TBW in children is by isotope dilution using the stable isotopes deuterium (D_2O) or oxygen 18 ($H_2{}^{18}O$). The use of the radioactive tracer tritium (^3H_2O) is contraindicated in children. Deuterium overestimates the total body water space by 0.5 to 5% because of a presumed exchange with hydrogen ions in organic material. However, the advantage of deuterium over $H_2{}^{18}O$ is that it is less expensive.[2] Subjects are asked to drink or are injected with a known amount of labeled water, and after a suitable period of equilibration, the concentration of the isotope in breath, urine, saliva, or plasma is determined.[133]

The measurement of TBW has been used for estimating the nonfat compartment of the body because neutral fat does not bind water and it is assumed that the weight of

water to fat-free body mass ratio is a constant (total body water:fat-free mass = 1:0.732).[132] This assumption is not true in children because the hydration constant changes with age (Figure 4-3B) and can vary among individuals of the same age. As already stated, age- and gender-adjusted hydration constants should be used in calculations.

Extracellular Water. Bromide has been the most widely accepted marker used in estimating ECW volume by dilution.[144] It is nontoxic, produces no discomfort in low concentrations, and can be measured in blood or saliva. Sucrose has also been used in premature babies.[145] ICW can be determined from the subtraction of ECW from TBW; however, this technique typically accumulates a significant measurement error of ± 2 to 3 L in an adult.[13]

Bioelectric Impedance Analysis

Bioelectric impedance analysis (BIA) is based on the principle that lean tissue will conduct a high-frequency electric current better than fat tissue. Body cell fluids are responsible for electric conduction, and the cell membranes determine capacitance. Conductivity is far greater in fat-free mass than in the fat mass of the body because the fat-free mass contains virtually all of the water and conducting electrolytes of the body.

Impedance is the frequency-dependent opposition of a conductor to the flow of an alternating electric current.[146] The impedance of a geometric system is related to conductor length and configuration, as well as to the cross-sectional area and the signal frequency. At low frequencies, the bioelectric current flows primarily through extracellular fluids. As frequency increases, the capacitance aspects of the body (cell membranes, tissue interfaces) start to retard the current, producing an increase in reactance. At high frequencies, the current penetrates all body tissues completely, and again reactance is diminished. With multifrequency bioelectric impedance, the differentiation of total and extracellular body water can be accomplished.[146,147] The bioelectric impedance method for estimating body composition is noninvasive, rapid, inexpensive, portable, easy to do, and applicable to field conditions. Hence, BIA has potential for use with individuals across a broad age spectrum and in a variety of settings.

The precision and accuracy of BIA have been questioned, however, and some authors have stated that its estimates are no more accurate than the ones obtained by anthropometry or DXA, particularly among obese children.[148,149] Diurnal variations have been observed with BIA measurements, although this has also been seen with measures of height.[150] Other concerns include inconsistencies caused by differences in body shape among individuals of the same stature. In regard to children and adolescents, the geometry of the conductor changes during growth as size increases and shape varies, which influences impedance. Also, during growth the composition of the fat-free mass changes markedly as the relative contributions of water decrease and those of protein and minerals increase. Several different prediction equations for calculating TBW, fat-free mass, and ECW have been published for a variety of age groups and types of measurements.[13] Altered states of hydration or a disturbance in the intracellular-to-extracellular fluid ratio can alter BIA findings,[93] and the equipment is highly sensitive to changes in temperature or humidity. Finally, some authors have raised questions about the applicability of the basic equation[151] and have stated that this technique offers no advantage over body weight in predicting body composition changes.[2,93,151] In spite of these reservations, BIA continues to be used in research studies,[55,152–155] and it appears that under well-controlled conditions, using adequate reference data and proper equations, the results can be valuable.

Total Body Electroconductivity

Total body electroconductivity (TOBEC) relies on the properties of hydrated lean tissue and ECW to conduct electric energy when subjected to appropriate radio frequencies.[133] The subject is placed in a measurement chamber consisting of a large cylindrical coil that generates an electric current at a specific radio frequency, which in turn generates an electromagnetic field inside the coil. When a subject is placed in this field, currents are induced that dissipate some of the energy of the electromagnetic field, which is recorded as a change in the coil impedance. The difference between the coil impedance when empty and when the subject is in the field is a function of the subject's conductivity. The electrolytes dissolved in the body water pool are responsible for the conductive properties, and because the dissolved electrolytes are distributed almost exclusively throughout the fat-free mass, a transformed TOBEC signal will vary in proportion to the total volume of fat-free mass.[156]

The TOBEC method is quick and requires minimal cooperation on the part of the subject, who may remain in street clothes.[2] The precision of the measurements appears to be good; however, the accuracy of the measurements could be limited if the population being studied differs from the reference population used to generate the prediction equations.[133] Moreover, changes in electrolyte composition of the body, such as might occur in some diseases, might result in changes in impedance independent of the changes in fat-free mass.[112] Finally, other major limitations are the lack of portability and the cost of the equipment.

Absorptiometry

In absorptiometry, the individual is scanned with photons at two different energy levels and the differential absorption of photons is measured. The photons are generated either by a ^{153}gadolinium source (with dual-photon absorptiometry) or an x-ray source (with DXA). This technique is safe, the average radiation dose is 1 to 3 mrem per scan, it is noninvasive, and its measurements are independent of assumptions of invariant relationships among body components.[112,138] DXA has emerged as a practical standard for validating other techniques of body composition assessment. It is a highly precise and accurate method for evaluating bone status as well as developmental and age-related changes in total fat and fat-free tissues.[139,140,157–159] In addition, this method has the potential for estimating

regional distribution of fat, fat-free mineral-free soft tissue, and bone status; it has also been applied to estimating muscle mass.[111]

DXA has been safely and accurately used in studies of healthy and sick newborns,[92,158,160–163] infants, and children.[44] A portable, low-cost DXA technique for measurement of bone mineral in the forearm of preterm infants has been presented.[164] Pediatric software for use with DXA has been validated and is more precise for use in children than adult software.[165] It should be noted that this technique does not measure absolute bone mass but instead provides a relative measure expressed as bone mineral content in grams per centimeter or BMD in grams per square centimeter.[93] In theory, a triple-energy x-ray absorptiometric technique could measure estimates of body water and protein mass in addition to bone and fat mass; feasibility studies are under way.[13]

Imaging Techniques

Advances in imaging technologies have allowed extensive, direct, in vivo analysis of body composition. These imaging methods are CT and nuclear MRI.[166] CT scanning requires exposure to a significant amount of radiation, whereas MRI does not.[167] Both methods share the problem of deriving an estimate of the composition of the whole body from certain slices. The estimate improves as more images are included in the measurement.[167]

Both CT and MRI provide a visual image of adipose tissue and nonfat tissue within the entire section of the body scanned. The cross-sectional images can be obtained at any level within the body, making possible precise site-specific calculations of subcutaneous and visceral fat content.[166–170] By scanning multiple sections of the body (up to 28 in some techniques[171]) and by summing the volume of adipose tissue in each section serially, it is possible to estimate the total volume of fat within the body.[133,167,168,171] A primary advantage of obtaining multiple images over the entire body is that it permits the analysis of separate anatomic regions, thereby allowing a detailed assessment of regional adipose tissue distribution.[172] These images can also provide an estimation of tissue and organ volumes.[167,173]

CT images provide more accurate information about compartment density and thus are better at differentiating body tissues than is MRI. CT scanning, however, transmits a high level of radiation exposure when determining body composition owing to the need for several scans taken at different levels. This limits the use of CT in children and also in studies requiring repeated measurements on the same subjects.[174] MRI can provide similar information without radiation. This permits serial determinations on the same subjects and also studies in children.[169] Although CT and MRI methods are particularly useful for accurate body composition measurements in the research setting, their risk, availability, and cost generally preclude their routine use in clinical practice.

Anthropometry

Anthropometric measurements of body composition are relatively fast and noninvasive and require a minimum of equipment compared to laboratory techniques. They are used in clinical settings and in public health studies to identify individuals who are vulnerable to under- or overnutrition and to evaluate the effectiveness of nutrition intervention programs.[49] Skinfold and circumference anthropometrics are almost as fundamental among body composition methods as height and weight; every new criterion method will require translation into the universal language of anthropometry.

More than 40 anthropometric dimensions have been proposed,[175] but the principal anthropometric measurements are height, weight, skinfold thickness, circumferences, body segments, and body breadths. Indices include BMI (body weight/stature^2, in kg/m^2), body fat distribution (such as trunk/extremity skinfold thicknesses), or the waist-to-hip and waist-to-thigh circumference ratios. Some of these methods have been validated against more direct measures of body composition. Waist circumference was shown to be a better predictor of truncal fat mass than waist-to-hip ratio when compared with DXA measurements in a large study of children aged 3 to 19.[176] This easy and inexpensive technique could prove to be useful in many pediatric settings as more is learned about central body fat distribution and its associated risks. BMI is part of routine anthropometric monitoring with standardized curves from National Center for Health Statistics data on the latest version of the Centers for Disease Control and Prevention pediatric growth charts (Appendix 1). The validity of BMI as a marker of overweight status has been demonstrated.[177] Upper-arm fat and muscle areas, based on skinfold measurements and circumferences, have been used as predictors of fat mass and lean body mass, respectively.

Skinfold measurements give a more accurate estimate of percentage of fat than weight and height alone. Human skin is 0.5 to 2 mm thick, so most of a skinfold measurement is the subcutaneous fatfold.[2] Skin fatfold thickness measurements are said to provide an estimate of the size of the subcutaneous fat depot, which in turn provides an estimate of total body fat. This extrapolation assumes that the thickness of the subcutaneous mantle reflects the total amount of fat in the body and that the sites chosen represent the average thickness of the entire mantle.[69] These assumptions might be untrue. In fact, the subcutaneous adipose tissue is only about 30 to 40% of total body adipose tissue, and there is a regional variation in fat thickness. There is also an interindividual variation in the subcutaneous fat distribution. Moreover, the relationship between subcutaneous and internal fat is not linear, and it varies with body weight, body build, and age.[134] Nevertheless, in well-controlled studies, some authors have found that in children skinfold measurements are highly correlated (r = .90 for boys and .84 for girls), with estimates of either total body fat or percent body fat from other techniques.[178]

In practice, skinfold thicknesses are measured at standardized regions by an experienced examiner using calipers of known quality.[133] The most commonly used calipers are Harpenden, Holtain, and Lange. The triceps skinfold thickness has been the site most frequently selected for a single, indirect measure of body fat, but no

single body region appears to have skinfold sites that are consistently representative of the whole subcutaneous fat layer. It is recommended that one use at least one limb skinfold (left triceps) and one body skinfold (left scapular) to account for the different distribution of subcutaneous fat, but whenever possible, multiple skinfold measurements should be used to obtain better estimates of body fat mass and its regional distribution.[14]

Many equations to predict body composition using anthropometric measurements such as height, weight, skinfold, and circumference measurements have been developed.[125,175] The prediction equations tend to be specific for the population measured and might not be valid for other populations. Despite careful attention to measurement sites, considerable intraindividual and interindividual variations occur, resulting in different predictions of body fat between examinations and examiners. The best results are obtained by experienced examiners who measure at the exact locations used by the investigators who developed the predictive equations[128] or in situations in which the subjects are similar in body type. There is a large body of literature, however, using anthropometric techniques in which reliability is not so clear.[98,113,114] For example, in very obese patients and in the presence of generalized edema, it is difficult to obtain accurate and reproducible estimates.[2,65]

Densitometry

Densitometry is a technique that requires the direct measurement of body density or separate estimation of total body weight and total body volume. Underwater weighing is the most common method used for determining body density in adults. The principle of underwater weighing is that the weight of a submerged human being is directly related to that person's average body density.[133] By weighing the subject in air and then in water and making appropriate corrections for temperature and air in the respiratory system, it is possible to estimate body density assuming the appropriate densities of fat (0.9 g/cm^3) and fat-free mass (1.1 g/cm^3). The technique is restricted to subjects who can cooperate because total submersion and breath holding at some reproducible lung volume are required. Hence, underwater weighing is not feasible in infants and children nor in most hospitalized patients. The method also might be inappropriate for use in children because, during maturation, the density of the fat-free mass changes (Figure 4-3D), thus invalidating one of the basic assumptions of the method (constant density of the fat-free mass).[134] However, age- and gender-adjusted constants for fat-free mass could be used.[58]

Air-displacement plethysmography (ADP) has recently been demonstrated to be a practical and valid alternative to underwater weighing for measuring body density. Rather than measuring a subject's displacement of water, the displacement of air from an enclosed chamber is measured to indirectly determine body volume and subsequently calculate body density. The BOD POD system (Life Measurement, Concord, CA) is a commercially available ADP system that has been studied with children and adults. The BOD POD is a chamber that allows a quick, noninvasive, simple measure of the two-compartment body composition model. Although it has been correlated closely with underwater weighing results in average adults,[179] its relationship to subjects outside the normal range of body fat has been less favorable.[180] The BOD POD has been successfully used in children aged 5 to 14 years, with acceptable precision for body density measurements.[181] Younger and more heterogeneous populations of children have not been studied. More studies are needed to validate this method with a multicompartment body composition model.[180]

Near-Infrared Interactance

Near-infrared interactance (NIRI) is based on the principles of light absorption and reflection using near-infrared spectroscopy.[112] It involves transmission of electromagnetic radiation through a probe into subcutaneous tissue and analysis of the reflected and scattered energy from that electromagnetic radiation to estimate the chemical composition of the sample. Like skinfold measurements, NIRI relies on the subcutaneous depot to extrapolate compositional data to the whole body and therefore is inherently limited in scope.[112,133] It could, however, be a reasonable alternative when skinfold measurements are refused or not possible.[182] This method has been used in infants, but its results correlated with subcutaneous adipose tissue thickness only when the latter was thin.[183]

There are many methods of measuring body composition; some are more practical than others for office or field determinations. Each method evaluates one or several components of the body using different technical approaches. The multicompartment model serves as the validation tool to cross-reference the reliability and precision of these technical measurements. The physician should become acquainted with several methods of assessing body composition for use in clinical practice and literature review.

CONCLUSIONS

During growth, body composition changes. Chemical maturity occurs at different stages for the various constituents of the fat-free mass. The water content of the fat-free mass decreases, whereas the protein, potassium, and bone mineral content increase, affecting the density of fat-free mass, which also increases. The fat mass varies greatly during the life cycle, depending on heredity, nutrition, and lifestyle.

Body weight alone cannot be used as an acceptable measure of nutritional efficacy or status. An assessment of the composition of weight gain is needed to ascertain the appropriateness of this gain. The elaboration of growth standards in terms of body composition in childhood and adolescence, and in relation to sexual maturation, could allow the recognition of abnormalities in specific body components in disorders affecting growth and puberty; it could also allow recognition of the moment when a differing pattern of distribution or accretion appears in relation to age, gender, ethnicity, or illness.

The evaluation of body fat with some body composition method should allow the pediatrician to define deviations in body weight and to act in the prevention or treatment of

early obesity. In this sense, the beneficial role of exercise and the negative roles of sedentarism and possibly of television have to be taken into account. The possibility of critical periods for fat accretion and an understanding of the long-term consequences of different body fat distributions might have important implications in the nutritional management of children and adolescents.

As new and more accurate methods emerge, and with the combination of different methods in the multicompartment model, the values for the reference fetus, child, or adolescent might be more precisely defined by state-of-the-art techniques. Age, gender, and ethnicity standards will allow the use of less expensive, surrogate field methods suitable for office practice and for population studies. The ideal field method should be inexpensive, easy to use, reliable, noninvasive, portable, validated, and calibrated. No perfect method is yet available. However, the clinician has a variety of methods that can be used. The methods selected can provide valuable estimates if their limitations and assumptions are recognized.

CHAPTER 5.1

MACRONUTRIENT REQUIREMENTS FOR GROWTH: FAT AND FATTY ACIDS

Christine L. Williams, MD, MPH, Richard Deckelbaum, MD

Fat is a major source of fuel energy for children of all ages, providing high relative caloric density compared to protein and carbohydrate. In addition, it aids in the absorption of fat-soluble vitamins A, D, E, and K and carotenoids and is a source of essential fatty acids (EFAs). Although carbohydrate and protein foods can fully substitute as a source of energy, failure to supply EFAs will lead to retardation of growth and development, learning deficiencies, impaired visual and neurologic development, and other abnormalities, including those related to immune-inflammatory responses.[1]

Dietary fat consists primarily (98%) of triacylglycerol, composed of one glycerol molecule esterified with three fatty acid molecules, and smaller amounts of phospholipids and sterols. Other fats or lipids also contain carbohydrate, amino acid, phosphate, and choline moieties, as well as fatty acid esters, such as sphingosine (a major base of sphingolipids), glycolipids, phospholipids, and sterol esters. Cholesteryl esters are composed of a single fatty acid esterified to cholesterol. Fatty acids provide a ready energy source for most organs and tissues in the body, with the exception of red blood cells and brain cells. Carnitine transferase is the carrier system for transporting long-chain fatty acids into mitochondria, where β-oxidation and energy production occurs. The brain can use ketones derived from fatty acids as an energy source. Excess triglycerides are stored in adipose tissue.

Although strong evidence exists for the need of EFAs in the diet, for example, linoleic acid and α-linolenic acid, there is little evidence that dietary cholesterol is necessary for normal growth and development in mammals because in both animals and humans, sufficient cholesterol is produced endogenously to meet all needs for growth and development.[2] The best evidence for the latter lies in that, in utero, all or almost all cholesterol is synthesized endogenously by the fetus during the most rapid phase of growth and development.[3,4] In addition, millions of vegetarian children worldwide who do not consume any animal-derived products grow and develop normally. Similarly, there seems to be no special requirement for phospholipids as long as sufficient choline is present in the diet.

Fatty acids are hydrocarbon chains that contain a methyl (—CH_3) and a carboxyl (—COOH) end. Fatty acids vary by the number of carbon atoms in the chain and by the presence and position of double bonds (unsaturation). In biochemical shorthand, the number of carbon atoms in the chain of fatty acids is written first and then the number of double bonds. The position of the first double bond from the methyl end of the chain is written with the prefix "ω" or "n." Most fatty acids have an even number of carbon atoms because they are synthesized or degraded two carbon units at a time. An example of a short-chain fatty acid is $CH_3CH_2CH_2COOH$, butyric acid, written as $C_{4:0}$.

Fatty acids are derived from both animal and plant foods and are classified into several categories:

- Saturated fatty acids
- Monounsaturated fatty acids
- Polyunsaturated fatty acids (PUFAs; n-6 and n-3 fatty acids)
- *Trans*–fatty acids

Saturated fatty acids contain no double bonds, monounsaturated fatty acids contain a single double bond, and polyunsaturated fatty acids (PUFAs) contain more than one double bond. The major saturated fatty acids in food derived from animals are palmitic ($C_{16:0}$) and stearic acids ($C_{18:0}$). Oleic acid ($C_{18:1}$ ω-9) is the most prevalent monounsaturated fatty acid and is derived from plants or synthesized by animals. Linoleic acid ($C_{18:2}$ ω-6) is the major PUFA derived from plants; α-linolenic acid ($C_{18:3}$ ω-3) is also found in plant oils, and its derivatives, eicosapentaenoic acid (EPA) ($C_{20:5}$ ω-3) and docosahexaenoic acid (DHA) ($C_{22:6}$ ω-3), are produced in animals (fish are an important source) that ingest them. Human milk contains substantial quantities of C_{18} precursors of the ω-3 and ω-6 families as well as their C_{20} and C_{22} derivatives.[5]

Trans–fatty acids are unsaturated fatty acids that contain at least one double bond in the *trans* configuration. When the two hydrogen atoms are on opposite sides of the double bond, the configuration is termed *trans*; when the two hydrogen atoms are on the same side of the double bond, the configuration is termed *cis*. The *trans* double-bond angle is larger than the *cis* configuration, and this results in a more extended fatty acid chain, more similar to that of saturated fatty acids. In addition, fatty acids having a *trans* double bond have different physical properties compared with *cis* fatty acids. Partial hydrogenation of polyunsaturated oils results in an increase of *trans*–fatty acid content and the hardening of fat. Dietary *trans*–fatty acids are derived naturally from meat and dairy products in children's diets and to a greater extent from products made from hydrogenated fat. It has been difficult to accurately quantitate dietary intake of *trans*–fatty acids, however, because of the limited amount of data available on the content of *trans*–fatty acids in commonly consumed foods.

Clinical studies have demonstrated that consumption of *trans*–fatty acids or hydrogenated fat results in higher blood cholesterol levels than consumption of *cis*–fatty acids or naturally occurring oils. Relative to saturated fatty acids, however, *trans*–fatty acids or hydrogenated fat results in lower blood cholesterol levels. Clarification is needed on issues related to the potentially detrimental effects of *trans*–fatty acids or hydrogenated fat compared with saturated fat with respect to decreasing high-density lipoprotein (HDL) cholesterol levels and increasing Lp(a) levels alone and compared with their benefits in decreasing total and low-density lipoprotein (LDL) cholesterol levels.[6,7]

ESSENTIAL FATTY ACIDS

The fatty acids essential for humans are linoleic acid and linolenic acid. Linoleic acid and its derivative, arachidonic acid (AA) ($C_{20:4}$ ω-6), function as precursors for eicosanoids, which include prostaglandins and leukotrienes, components of numerous cellular signaling mechanisms. α-Linolenic acid and its ω-3 derivatives compete for the enzymes involved in the synthesis of AA and oppose many of the activities of its derivatives.[8] Long-chain derivatives of linolenic acids are present in structural lipids and are components of brain, nerve, and other cellular membranes.

The pathways of linoleic and linolenic acid metabolism and related prostaglandin metabolism are shown in Figures 5.1-1 and 5.1-2. Thromboxane derived from AA (an omega-6 fatty acid) is a potent mediator of platelet aggregation, whereas the similarly derived prostacyclin is an anticoagulant and vasodilator. In contrast, thromboxane, derived from omega-3 fatty acids, is a weak mediator of platelet aggregation, whereas the prostacyclins derived from omega-3 fatty acids are mediators of inflammatory and allergic responses and are essential for normal second-messenger action.[9–11] The biologic antioxidant vitamin E appears to help regulate prostaglandin production and prevents oxidation of unsaturated fatty acids. A diet high in polyunsaturated fat should contain an appropriate amount of vitamin E (at least 0.5 mg tocopherol equivalent per gram linoleic acid) to ensure the normal metabolism of these fatty aids. Failure to do so has been associated with a hemolytic state in infants, particularly when extra iron (a free radical generator) is added to the diet.[12]

ABSORPTION OF DIETARY FAT

Digestion of dietary fat starts in the stomach.[13] A lipase termed lingual lipase, because it was first found at the base of the tongue in the rat, initiates triglyceride hydrolysis. The released nonesterified fatty acids emulsify the fat droplets. In the duodenum, bile salts enhance emulsification and pancreatic lipase activity. Colipase fixes lipase to the emulsified fat droplet. Until the age of 6 months, infants can have low concentrations of pancreatic lipase

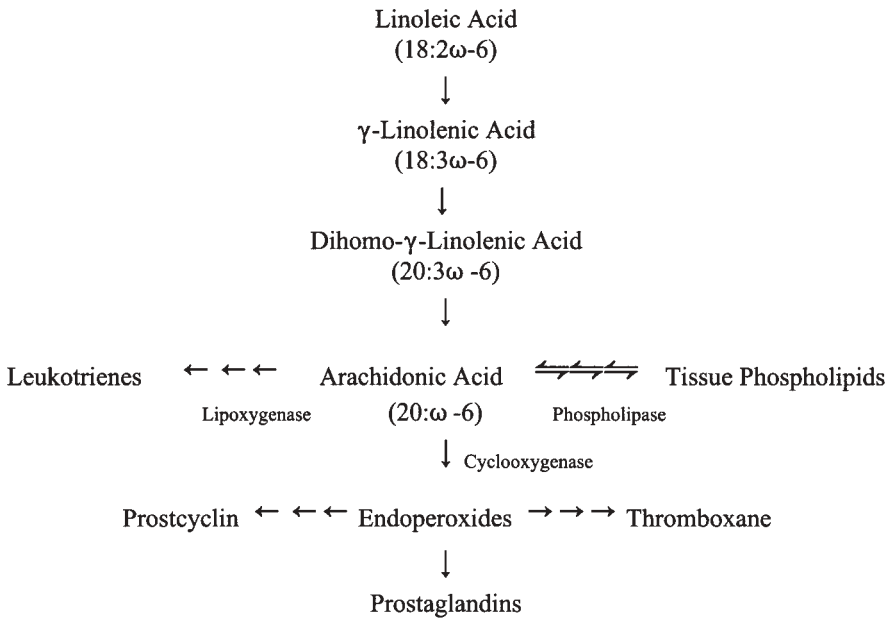

FIGURE 5.1-1 Metabolic pathways of linoleic and arachidonic acid.

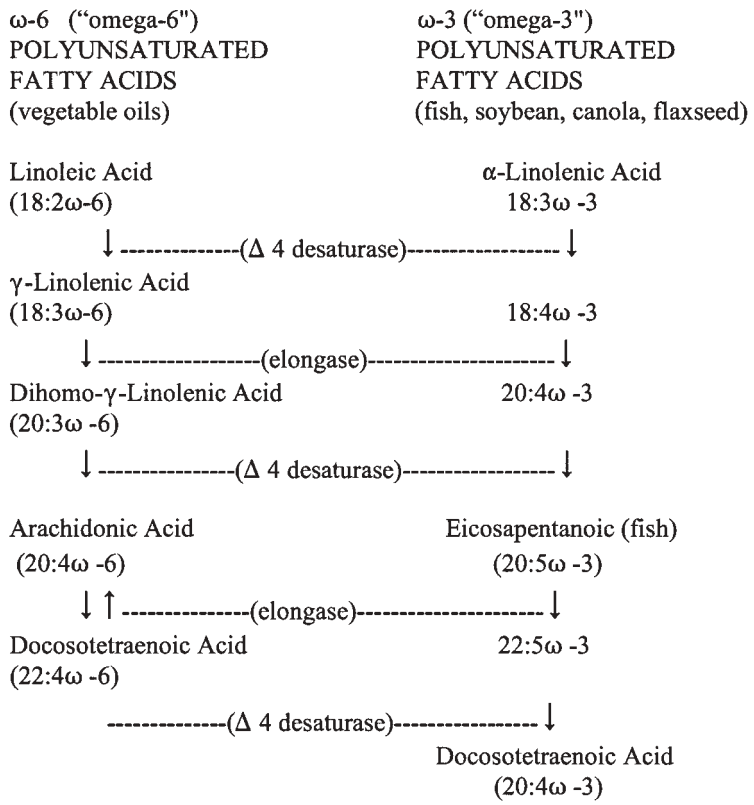

FIGURE 5.1-2 Metabolic pathways of the two essential fatty acids, linoleic (ω-6) and linolenic (ω-3) acids.

and bile acids in the intestinal lumen, which may result in up to 10 to 15% of ingested fat to remain unabsorbed. The ability to absorb fat is facilitated in the breast-fed infant because breast milk contains a bile salt–stimulated lipase.[14]

Bile acid–phospholipid aggregates, termed micelles, provide a large surface area for the action of pancreatic lipase or human milk lipase, which mainly removes the two outer fatty acids from the glycerol and leaves an easily absorbable monoglyceride. The triglyceride is enzymatically reassembled from the monoglyceride and two fatty acids in the upper small bowel mucosa. Long-chain triglycerides are then coated with protein and extruded as chylomicrons into the lymphatics. Medium- and short-chain fatty acids (with 2 to 10 carbon atoms) partially short-circuit this complex system and can be absorbed directly into the portal venous system. The longer the chain length of saturated fatty acids, the slower the rate of absorption. The introduction of double bonds into the longer fatty acids may cause calcium wastage by the information of insoluble soaps.

DEFICIENCY

Hansen and colleagues, in the late 1950s, proved that a fat component present in vegetable oils, linoleic acid, was essential in the human diet.[15] Cow's milk fat contains much less of the EFAs than does human milk fat, which has led manufacturers of some infant formulas to add vegetable oils to a base of skim cow's milk. Symptoms of EFA deficiency in infants may result when linoleic acid is less than 1% of energy intake. Deficiency of linoleic or AA is characterized by symptoms such as scaly skin, hair loss, diarrhea, and impaired wound healing in humans. Such deficiency may result from feeding infants a diet of fat-free milk, prescribing a special fat-free diet for specific pathologic conditions, or a prolonged course of fat-free intravenous alimentation. Absence of trace amounts of linolenic acid causes visual and behavioral symptoms in animals and perhaps in humans.[5,16] In patients with cystic fibrosis and hepatobiliary disease, steatorrhea may also result in malabsorption of EFAs.

Human milk contains 3 to 7% of energy as linoleic acid and a significant amount of omega-3 linolenic acid and its derivatives, depending on the maternal diet. Most commercial infant formulas contain more than 10% of fat as linoleic acid, and all contain some linolenic acid. Unmodified cow's milk contains only about 1% linoleic acid, which is less than the presumed daily requirement of 2.7%. Adequate intakes of linolenic acid and its long-chain derivatives are especially important for premature infants.

RECOMMENDED INTAKES OF EFAS

Both linoleic acid ($C_{18:2}$ ω-6) and α-linolenic acid ($C_{18:3}$ ω-3) are nutritionally essential and must be included in the diets of infants and children to ensure normal growth, cell membrane maintenance, lipid metabolism, and prostaglandin synthesis.

Linoleic and linolenic acids are absolute requirements for the diet of infants. The American Academy of Pediatrics' (AAP) Committee on Nutrition recommends that infants receive at least 3% of total energy from linoleic acid and 0.3% of energy from linolenic acid.[17] For preterm infants, the International Union of Nutritional Sciences recommends higher intakes of linoleic acid and linolenic acid, at 4 to 5% of energy as linoleic acid and 0.5% of

energy from linolenic acid. Because of the need for rapid neurologic growth in preterm infants, the latter group has also made recommendations that preterm infants receive long-chain n-6 fatty acids (C_{20} and C_{22}) as 0.5% of total energy and long-chain n-3 fatty acids (C_{20} and C_{22}) at 0.25% of energy.[18]

The Food and Nutrition Board of the Institute of Medicine, National Academy of Science, after an extensive review of the literature, recently published Dietary Reference Intakes for macronutrients, including those for n-6 and n-3 PUFAs in infants and children. Their recommendations for adequate intakes of these fatty acids are summarized in Table 5.1-1.

A number of studies have suggested that conversion of the precursor EFAs, linoleic acid to AA and linolenic acid to EPA and DHA, is less efficient in formula-fed infants compared with breast-fed infants because the latter have higher plasma concentrations of these long-chain PUFAs. Preterm infants are at greater risk of deficiency, however, because these fatty acids are normally supplied to the fetus from maternal plasma throughout pregnancy.

Human milk contains small amounts of both C_{20} and C_{22} n-6 fatty acids. In the past decade, therefore, a number of randomized clinical trials were conducted to evaluate the benefits of adding these fatty acids to infant formula. Several studies involving preterm babies demonstrated enhanced early visual acuity for infants fed DHA ($C_{22:6}$ n-3) supplemented formula compared with an alternate formula supplemented with its precursor, α-linolenic acid ($C_{18:3}$ n-3).[19–23] These results suggest that, similar to findings in animal studies, the DHA content of the brain may depend more heavily on the dietary supply of DHA rather than on its precursor, α-linolenic acid. A recent study reporting poorer growth (shorter length) in long-chain PUFA–supplemented preterm infants at 18 months of age compared with breast-fed or control-fed (preterm formula without long-chain PUFAs) infants has raised concern, however, and the results of additional clinical trials will be needed to fully assess the risks and benefits of preterm formulas supplemented with long-chain fatty acids.[24]

Among term infants, the results of similar clinical trials have been mixed. Some studies have reported improved visual acuity or better neurodevelopmental outcomes in infants fed formula supplemented with C_{20} and C_{22} n-6 fatty acids, whereas the results have been negative in other studies. These studies, however, vary with respect to design, composition of the formulas used, duration of supplementation, age at testing, and types of outcome measures employed. Table 5.1-2 summarizes the findings for recent clinical trials in term infants.[25–36]

Based on the evidence provided by these studies, formulas supplemented with AA and DHA have been approved for feeding infants in North America and Europe. In the United States, these supplemented formulas contain AA as 0.40 to 0.64% of total fatty acids and DHA as 0.15 to 0.32% of total fatty acids. There is still controversy, however, as to whether the supplementation of infant formula with long-chain PUFAs results in any long-term visual or developmental benefits to the child.

TABLE 5.1-1 Adequate Intake of n-3 and n-6 Polyunsaturated Fatty Acids for Infants and of Linoleic Acid and α-Linolenic Acid for Older Children and Adolescents

Age of Child	*n-6 Polyunsaturated Fatty Acids*	*n-3 Polyunsaturated Fatty Acids*
0–6 mo	4.4 g/d (8% of energy)	0.5 g/d (1% of energy)
7–12 mo	4.6 g/d (6% of energy)	0.5 g/d (1% of energy)
	Linoleic Acid	*α-Linolenic Acid*
1–3 yr	7 g/d	0.7 g/d (1% of energy)
4–8 yr	10 g/d	0.9 g/d (1% of energy)
Boys		
9–13 yr	12 g/d	1.2 g/d
14–18 yr	16 g/d	1.6 g/d
Girls		
9–13 yr	10 g/d	1.0 g/d
14–18 yr	11 g/d	1.1 g/d

Adaped from Dietary Reference Intakes for energy, carbohydrates, fiber, fat, protein and amino acids (macronutrients).[22]

BIOCHEMICAL MARKERS OF EFA DEPLETION

The fatty acid eicosatrienoic acid ($C_{20:3}$ ω-9) can be synthesized by humans but is not normally present in serum. When depletion of omega-6 fatty acids occurs, the level of eicosatrienoic acid increases in serum. The ratio of trienes (C20:3 ω-9, with three double bonds) to tetraenes (C20:4 ω-6, with four double bonds) increases with deficiency of EFAs. An elevated triene-to-tetraene ratio is therefore consistant with EFA deficiency.

Healthy full-term newborns have lower serum levels of EFAs than older children, and the level of eicosatrienoic acid is slightly higher. Normal levels in preterm infants and the requirement for EFAs have not been accurately defined. However, the dietary requirements for EFAs may be higher in preterm infants than older children because of poor fat absorption and minimal stores. Full-term and preterm infants can develop fatty acid deficiency within 1 week when receiving parenteral nutrition without added lipids.[37]

The long-term effects of EFA deficiency in infants are not clear. Platelet dysfunction occurs in neonates with EFA deficiency.[38] Research in experimental animals has shown a greater susceptibility to infection in the presence of EFA deficiency. Thus, infant formulas contain at least 300 mg of linoleic acid per 100 kcal to minimize the risk of EFA deficiency, although this level may be significantly above the minimum need. The recommended intake can be attained readily in infants by the use of human milk or formula containing soy or other vegetable oils. After solid foods are introduced into the diet, the oils found in foods such as margarine, peanut butter, and cereal are good sources of omega-3 long-chain fatty acids (greater than 20 carbons). Hydrogenated coconut oil does not furnish EFAs.

In patients with steatorrhea, the provision of EFAs in the diet or by intravenous alimentation is necessary to maintain normal intake of EFAs. Medium-chain triglycerides (MCTs) are a useful source of calories in malabsorptive states, but MCTs do not provide EFAs. Infants receiving a formula with an MCT as the predominant oil may

demonstrate signs of EFA deficiency and decreased circulating levels of AA.[39] Decreased prostaglandin levels have returned to normal in children with cystic fibrosis after supplementation with linoleic acid or calories.[40]

EFAs should provide at least 3% of energy intake for a healthy child. Ethnic differences exist for the intake of fat by children, but in the United States, mean intake of total fat is currently about 32 to 33% of energy intake. If about half of this intake comes from plant sources, the EFA requirements will be easily met. Corn oils and soybean oils both contain more than 30% linoleic acid.

GUIDELINES FOR TOTAL DIETARY FAT INTAKE IN CHILDREN OVER 2 YEARS OF AGE

Recommendations for dietary fat intake in childhood take into account the child's unique growth and developmental patterns, specific nutrient requirements, vulnerability of sentinel nutrients, factors important to the establishment of healthful eating habits, and nutritional risk factors for childhood and adult-onset diseases. The role of dietary fat as a source of calories and EFAs must be balanced with the desire to avoid excessive fat intake associated with increased risk of future chronic disease.[41]

Many health and nutrition organizations have developed dietary guidelines for children and adolescents based at least in part on the role of dietary fat (especially saturated fat) in the early development of atherosclerosis.[42–47] This rationale is strengthened by studies linking a high intake of dietary fat with some human cancers[48–50] and with obesity.[51–53] The following section summarizes (1) current guidelines for dietary fat intake in children and adolescents, (2) trends in dietary fat intake over the past several decades, and (3) the risks and benefits of these recommendations.

Dietary guidelines for children 2 to 19 years of age are summarized in Table 5.1-3. Similar to adults, it is recommended that children consume no more than 30% energy from total fat, less than 10% energy from saturated fat, no more than 300 mg of cholesterol daily, and dietary fiber.[41,54–56]

LINK BETWEEN DIETARY FAT, BLOOD LIPIDS, AND ATHEROSCLEROSIS

Recommendations to control dietary fat intake beginning in childhood primarily stem from scientific consensus on the role of dietary fat (especially saturated fat) in the early development of atherosclerosis. The National Cholesterol Education Program (NCEP) Pediatric Panel convened by the National Institutes of Health (NIH) stated in their 1992 report that "A variety of studies indicate that the process of atherosclerosis begins in childhood; that this process is

related to elevated levels of blood cholesterol; and that these levels are often predictive of elevated blood cholesterol in adults."[57–62] Autopsy studies have demonstrated that early coronary atherosclerosis or precursors of atherosclerosis often begin in childhood and adolescence. In the aorta, fatty streaks begin to develop soon after birth and are almost universal by 3 years of age. Fatty streaks in the coronary arteries lag behind by about a decade. Studies such as the PDAY (Pathological Determinants of Atherosclerosis in Youth) autopsy study in youth suggest that a critical stage of the disease process is the conversion of childhood fatty streaks into thicker raised lesions.[59] More research also needs to clarify how the conversion occurs and what risk factors influence it. Although atherosclerosis may not be totally preventable, evidence suggests that its progress can be substantially retarded and the associated cardiovascular disease deferred to much later in life.

Dietary fat (especially saturated fat) is associated with high levels of blood cholesterol, a major independent risk factor for atherosclerosis. Elevated cholesterol levels are highly prevalent in children, even in toddlers over 2 years of age.[63–67] In a study we conducted of 700 3- to 5-year-old children in New York, 26% had levels in the borderline high range (170 to 199 mg/dL) and 11% were in the high range (≥ 200 mg/dL).[68] The most recent national data on cholesterol levels in childhood are from NHANES III (National Health and Nutrition Examination Survey, 1988–1994) and indicate that, similar to adults in the United States, mean cholesterol levels in children have decreased slightly since the late 1980s (NHANES II data, 1976–1980). Regional surveys suggest that at least 10% of children are currently in the high-risk category for total cholesterol (≥ 200 mg/dL), and another 25 to 30% have borderline elevated values (170 to 199 mg/dL). These proportions are greater than the 5% and 20% reported previously from the Lipid Research Clinic (LRC) data, which formed the basis for the NCEP guidelines for interpreting pediatric lipids (eg, total cholesterol designated as "high" for children was set at ≥ 200 mg/dL, which was about the 95th percentile value for children evaluated in the LRC study).[69,70]

TABLE 5.1-3 Recommended Dietary Intake for Children ≥ 2 Years of Age

Nutrient	*Recommended Daily Intake*
Total fat	Average of no more than 30% energy and no less than 20% energy
Saturated fatty acids	Less than 10% energy
Polyunsaturated fatty acids	Up to 10% energy
Monounsaturated fatty acids	Remaining total fat calories
Cholesterol	Less than 300 mg/d
Carbohydrates	About 55% energy
Dietary fiber	Minimal: "Age +5" g/d[54]
Protein	About 15–20% energy
Calories	To promote normal growth and development and to maintain desirable body weight

Adapted from American Academy of Pediatrics, Committee on Nutrition and National Cholesterol Education Program.[42,43]

Plasma levels of total and LDL cholesterol show significant tracking from childhood to adulthood.[68–70] The Bogalusa Heart Study, for example, found that about 70% of children in the top quintile for blood cholesterol could be found in the top two quintiles 12 years later[71] and that, similarly, about 70% of children originally in the bottom quintile could later be found in the bottom two quintiles for cholesterol.[72] Obesity strengthens the tracking of both elevated cholesterol and elevated blood pressure, a factor of some importance as the pediatric population becomes more obese.[72]

Blood lipid and lipoprotein levels are correlated with dietary intake of amount and type of dietary fat in children, similar to adults. Cross-sectional studies comparing diets in different countries of children's cholesterol levels indicate a close relationship between total and LDL cholesterol levels in children, with their saturated fat intake in different countries.[73] Moreover, in studies comparing the effects of dietary changes on children's lipid levels, infants, children, and adolescents respond with similar changes in plasma total and LDL cholesterol with changes in the type of fat ingested.[74] Similarly, children decrease HDL cholesterol levels as total fat and saturated fat intake decreases and as the proportion of polyunsaturated fat in the diet increases. Dietary interventions in schools or communities are as effective in children as in adults in improving plasma lipid profiles (decreasing total and LDL cholesterol).[75]

Fasting insulin levels in children also positively correlate with degrees of adiposity, blood pressure, plasma triglyceride, LDL and very LDL cholesterol levels but inversely to HDL cholesterol levels. In addition, these traditional risk factors for coronary heart disease aggregate in children as they do in adults.[76] Of concern, in countries where adult morbidity and mortality from coronary heart disease are very high, children also have substantially higher frequencies of hyperlipidemia, obesity, and hypertension, as well as other risk factors for chronic adult diseases.[77]

Although children and adolescents as a group react to dietary changes in a way similar to adults, there are some differences between male and female adolescents. For example, the decrease in HDL cholesterol in response to increasing dietary polyunsaturated fat occurs less in female adolescents compared with males, so such a diet will have a greater tendency to decrease total cholesterol in boys. In comparing dietary responsiveness of US children from different cultural and ethnic groups, available data indicate that responses to changes in dietary total fat and saturated fat may be similar.[78]

There are interesting data from other countries on the effects of westernization of diets in children, especially the gradual increase in fat/saturated fat consumption. Demonstration of how changes in diet in children and adolescents may have substantial effects on coronary heart disease risk is evident from longitudinal data available from a number of countries. For example, total and LDL cholesterol levels in children in both Spain and Japan have rapidly increased over the last 15 to 20 years. Three decades ago, mean total cholesterol levels of children in Spain and Japan were sub-

stantially below the mean for US children. In the mid-1980s, however, mean total and LDL cholesterol levels for children from both of these countries exceeded the 75th percentile for US children.[79] This increase paralleled changes in diet, particularly dietary fat quantity and quality. In Japan over the past three decades, fat intake has increased threefold, and the saturated fat intake as represented by increased animal fat consumption has increased over eightfold.[79] In Japanese children, the increase in total caloric intake over this period has only been less than 10%, but increases in total fat are closely paralleled by two- to threefold increases in obesity prevalence. Diabetes is also becoming more prevalent in Japanese children and adolescents. In Spain, current data from Madrid schoolchildren show that dietary fat represents up to 42% of total calories, saturated fat contributing 17.5%. Of interest, although children's cholesterol levels are high in both Spain and Japan, Japanese children still ingest less total fat calories and less saturated fat than do American children. This latter observation suggests that there may be genetic differences in response to total and saturated fat in the Japanese population and in other countries that have only recently been exposed to diets high in total and saturated fat. These "country" analyses indicate that childhood populations are sensitive and responsive to dietary fat intake, in terms of plasma lipids, obesity, and diabetes—all major risk factors for premature coronary artery disease.[79,80]

GENOTYPE/PHENOTYPE–ENVIRONMENT INTERACTIONS

A number of major gene polymorphisms are clearly associated with changes in phenotype that relate to risk for disease. A specific example of the latter would include defects in the LDL receptor gene that lead to marked elevations of plasma LDL cholesterol levels and a high risk of coronary heart disease at an early age.[81] More subtle genetic polymorphisms are now being identified that have little or no effect on phenotypic expressions of specific blood parameters unless associated with differences in behavioral or environmental characteristics. Examples include genes controlling coagulation parameters such as the fibrinogen gene or perhaps blood pressure via the angiotensin-converting enzyme gene that has specific alleles associated with increased risk of coronary heart disease.[82] A specific example of environment–gene interaction is evident in subjects expressing an allele for the B-fibrinogen gene, where increases in plasma fibrinogen are much more marked in smokers compared with nonsmokers. Another example is a polymorphism in the gene for lipoprotein lipase, in which especially high increases in plasma triglyceride levels occur only in subjects with a high body mass index (BMI). Little or no knowledge is presently available as to whether specific phenotypes or haplotypes that predict dietary responsiveness in the adult population will also do so in children and adolescents. Nevertheless, it seems prudent to consider the possibility that certain children, because of a specific genetic constitution, might be at higher risk for early coronary heart disease or other chronic diseases and that specific intervention strategies could be designed for these children at particularly high risk (eg, apolipoprotein E-IV versus apolipoprotein E-III versus apolipoprotein E-II).[83] A specific example might be greater reductions in fat intake in children from families in which fibrinogen levels are particularly sensitive to higher levels of fat intake.

LINK BETWEEN DIETARY FAT AND OBESITY

There is some evidence to suggest that a high-fat diet and a sedentary lifestyle may have contributed to the current increase in obesity in the United States and other affluent countries. Fat plays a powerful physiologic role in undermining human body weight regulatory systems. This is in part because the body has the ability to increase the rate at which it oxidizes carbohydrate and protein when ingestion of these macronutrients is increased (necessary because the body has a very limited ability to store these nutrients). When large amounts of dietary fat are consumed, however, the body is unable to increase rates of oxidation to re-establish fat balance. In addition, oxidation of fat is suppressed when an excess of energy or an excess of any of the other macronutrients is consumed. Thus, the human metabolism is not designed to cope with excess fat consumption.[51–53]

Some studies also suggest that dietary fat is not particularly good at satisfying hunger, or, in other words, fat has low satiating power. This seems especially true for obese individuals. Manipulation of the fat content of diets results in reproducible spontaneous fat loss on low-fat diets and fat gain on high-fat diets. Individuals on a high-fat diet develop "passive overconsumption" because it occurs unintentionally and without consuming excess bulk. In addition, some obese individuals have a behavior preference for high-fat foods.[51,53]

Obesity in US children has been increasing over the past several decades.[84–90] Although the percentage of calories consumed as fat has declined, the total amount of calories consumed appears to have increased.[91–93] Therefore, the amount of fat consumed each day in grams may not have changed. In addition, relatively low levels of physical activity are the norm. Physical education in the schools has declined in high school, especially among older girls. In 1996, 23% of children in grades 4 to 12 had no physical education.[94,95] Thus, based on metabolic considerations, physical activity should increase and dietary energy intake decrease to achieve the synergism needed to prevent childhood obesity.

Klesges and colleagues evaluated determinants of accelerated weight gain over 3 years in a cohort of 146 preschool children.[52] Higher baseline levels of percent dietary energy from fat were associated with greater increases in BMI, as were recent increases in percent energy from fat. Total caloric intake did relate to weight gain, however, when percent energy from fat was entered into the regression equation; it explained more of the variance in weight gain than total energy intake. This suggests that for preschool children, the percent calories from total fat may be an important contributor to accelerated weight gain. Baseline aerobic

activity and increased leisure activity were also significant predictors of change in BMI. These modifiable diet/activity variables together accounted for 33% more of the variance in body mass change than the combined set of nonmodifiable variables (such as parental obesity).

It is known that the earlier the age at which adiposity rebound occurs, the more likely it is that a child will become an obese adult.[96,97] Additional studies are needed, however, to determine if the age of adiposity rebound among US children has become earlier over the past several decades and also if a high-fat diet promotes early adiposity rebound.

LINK BETWEEN DIETARY FAT IN CHILDHOOD AND CANCER IN ADULT LIFE

The National Cancer Institute, the American Cancer Society, and others feel that it is important to reduce total and saturated fat in childhood to prevent cancer later in life. Data on migrant studies of Japanese from Japan to Hawaii show an increase in colon cancer among first-generation immigrants as dietary fat increases and an increase in breast cancer in the second generation, perhaps because the effect of high dietary fat on breast cancer incidence is greatest during adolescence, when breast tissue is developing rapidly.[98–101]

Dietary fat stimulates mitotic activity and thereby promotes cancer growth after the initial mutagenic steps. Dietary fat can also lock in spontaneous mutations. For breast cancer, the n-6 fatty acids (PUFAs) have the greatest cancer-promoting effect, and n-3 (also PUFA—fish oil, flaxseed oil) fatty acids are most protective. This is not true for colon cancer. It is also speculated that the oxidation of dietary fatty acids produces free oxygen radicals that can react to and damage DNA. In this way, dietary fat may function as a mutagen.[101]

It is known that menarche occurs earlier for girls on a high-fat diet.[101] Estrogen is produced earlier, and, in turn, breast tissue is stimulated earlier and exposed to increased mitosis before differentiation is complete.[101] Menarche before age 13 is associated with a 30% greater risk of breast cancer than that for a woman with menarche at 16.[101]

LINK BETWEEN EARLY DIET BEHAVIORS AND LATER DIET BEHAVIOR

There is some evidence that dietary patterns established in childhood persist or "track" into later life. Children develop food preferences through their early eating experiences, and these may be sustained over time. The majority of studies examining dietary patterns over time have considered tracking of nutrient intake over time in cohorts of children.

In the Bogalusa Heart Study, significant correlations for 12-year tracking of macronutrient intake were found (in the 0.2 to 0.4 range), indicating a fair consistency of intake for several dietary components over a 5-year period in children from 6 months to 4 years of age. Children with higher intakes of total fat, saturated fat, and cholesterol at baseline continued to have higher intakes of these nutrients after 5 years compared with their peers. Thus, persistence of eating behaviors may begin quite early in life, in part because of parental control over food intake. Other data from the same group reported somewhat higher correlation coefficients, in the range of 0.4 to 0.5.[102] The Framingham Children's Study reported on tracking of nutrient intake in a preschool population. They reported that 40 to 57% of children in the highest quintiles for total and saturated fat intake were still in this quintile 2 to 3 years later.[103] Less is known of actual food consumption over time. That is, do young children who eat large amounts of fruits, vegetables, milk, cereal, or sweets continue to do so later in adolescence and adult life?

NUTRITIONAL ADEQUACY

Numeric guidelines for fat intake in childhood are also based on considerations of nutritional adequacy. When the dietary intake of children is examined with respect to sources of excess calories, 15% are derived from fat and 10% from sugar.[104] These calories replace the consumption of fruits, vegetables, and grains, which would result in meeting the Recommended Dietary Allowances (RDAs) for macro- and micronutrients in the diet. Thus, a moderate reduction in fat intake in childhood, if replaced by healthful fruits, vegetables, and grains, would improve the overall quality of children's diets.[104]

CURRENT GUIDELINES FOR DIETARY FAT INTAKE IN CHILDREN AND ADOLESCENTS

Current US dietary guidelines recommend no more than 30% of dietary energy from total fat, less than 10% from saturated fat, and no more than 300 mg of cholesterol daily.[41,55] These guidelines do not apply to infants and children under 2 years of age because there is consensus that a higher fat intake is needed to support the rapid growth and caloric requirements of this age (Table 5.1-4).

These guidelines were first proposed by the 1985 National Consensus Development Panel, cosponsored by the NIH and the American Heart Association (AHA).[47] They recommended numeric guidelines for dietary fat intake for all Americans > 2 years of age, with total fat intake at no more than 30% of calories and saturated fat at < 10% of calories. In 1991, these guidelines were endorsed by the NCEP report of the Expert Panel on Blood Cholesterol Levels in Children and Adolescents.[43] The AAP, which in 1983 and 1986 declined to recommend numeric fat intake guidelines for children, was represented on the NCEP Expert Panel and in 1992 also recommended "an average daily intake of 30% of total calories from fat, < 10% from saturated fat, and < 300 mg of cholesterol per day."[42] The US national health promotion and disease prevention objectives (Healthy People 2010) also recommend that Americans "reduce total dietary fat intake to an average of 30% of energy or less and saturated fat intake to less than 10% of energy among people 2 years and older."[46] Thus, at present, AAP, the AHA, NIH, US Department of Agriculture (USDA), US Food and Drug Administration, and at least 26 other health-related organizations recommend numeric limits for dietary fat intake for Americans over

age 2 years.[105] Others, however, argue against dietary fat limitations in childhood.[106,107]

The age at which to initiate a fat-controlled or prudent diet varies somewhat according to the source of the recommendation. The AHA recommends that the prudent diet be adopted after 2 years of age.[41] The NCEP considers 2 to 3 years of age as "transitional" between the high-fat diet of infancy and the fat-modified prudent diet. The USDA Dietary Guidelines (fifth edition) recommend that preschool children should gradually reduce dietary fat over a longer period of time, reaching the 30% energy from total fat at about 5 years of age.[55] There may be some rationale for establishing a preschool dietary transition period to avoid an abrupt drop in fat intake after age 2 years and a possible abrupt drop in calories, although dietary fat intake can be safely reduced to 30% of energy intake after 2 years of age without compromising growth and development.[108–113]

TRENDS IN DIETARY FAT INTAKE AMONG US CHILDREN AND ADOLESCENTS

How much dietary fat are US children eating, and how does this compare with current guidelines? There have been a number of national surveys of dietary intake in the past several decades, all of which include data on children. Although there are methodologic differences that should be taken into consideration when analyzing secular trends in dietary intake, these surveys remain the best source of data available at the present time.[92,93,114–119] National surveys of dietary intake include the NHANES I, II, and III; the National Food Consumption Surveys of 1977–78 and 1987–88; and the USDA Continuing Surveys of Food Intake of Individuals (CSFII).

A review of trends in dietary fat intake in children over 2 years of age reveals that (1) children's intake of dietary fat, saturated fat, and cholesterol tends to reflect the trend for the population as a whole; (2) the percentage of daily calories from dietary fat (%kcal) has decreased over the past decade, although the total intake of fat (grams per day) has not decreased because caloric intake has increased as well; (3) a significant proportion of children still consume amounts of total and saturated fat that are above currently recommended levels; and (4) although there are some differences in fat intake by ethnicity and poverty levels, these differences tend to be small.[92,114–118]

TRENDS IN FAT INTAKE IN CHILDHOOD

In the past 20 years since NHANES II (1976–1980), the percentage of energy consumed from total fat has decreased slightly for 3- to 5-year-old preschool children (from 34 to 33% energy) and slightly more for 6- to 11-year-old and 12- to 17-year-old children (from 36 to 34% energy). Saturated fat intake has decreased from 13 to 12% energy for 3 to 5 year olds, from 14 to 13% energy for 6 to 11 year olds, and from 14 to 12% energy for 12 to 17 year olds.[92,115–124]

The percentage of children and adolescents who meet the dietary goals for total fat and saturated fat is still quite low. Data from the CSFII (1995) found that 31 to 37% of 3 to 19 year olds met the total fat goal and 23 to 38% met the goal for saturated fat. A greater proportion of children met the goal for dietary cholesterol, ranging from 59 to 88%.[120] These estimates, however, have improved since phase I of NHANES III (1988–1991), when only 15 to 23% of 2 to 19 year olds met the total fat goal and 7 to 9% met the saturated fat goal.[117]

Total saturated fat intake was highest in both males and females between the ages of 16 and 29 years of age in the recent NHANES III survey. In addition, total and saturated fat intake was higher in non-Hispanic black compared with non-Hispanic white and Mexican American children.[124] Overall, total fat intake in US children 2 to 19 years of age is now estimated at about 33 to 34% of total calories compared with 36 to 38% over two decades ago in the late 1970s.[124] Data from the National Food Consumption Survey (1987–1988) indicate that children below the poverty level consume a greater proportion of their daily calories as fat.[120] This was greatest for children at 100 to 130% of poverty compared with those at 131% and above. Consumption of whole-milk products rather than low-fat products accounted for most of the difference in fat intake by poverty level.[91]

POTENTIAL RISKS AND BENEFITS OF A FAT-MODIFIED DIET IN CHILDHOOD

It is important to consider the potential risks and benefits of a fat-modified diet with respect to child nutrition and health. Dietary fat is a concentrated source of calories, and calories are essential for growth. Studies over the past decade have sought to determine the relative importance of caloric versus fat intake in supporting normal growth and development in childhood. The results of the most recent growth and safety studies indicate that growth is adequately supported on diets in which fat contributes approximately 25 to 30% of calories if there is adequate intake of calories, high-quality protein, and essential nutrients.[108–113]

Studies have employed computer modeling of nutrient adequacy given specific levels of dietary fat.[125] These studies indicate that the fat-modified diet need not be deficient in calories or any essential nutrients. However, care must be taken to ensure adequate intake of some nutrients, such as calcium, iron, and zinc.[91]

The STRIP Baby Project is one of the few studies in which dietary fat reduction was initiated before 2 years of age. This is an ongoing prospective randomized trial in 1,062 Finnish infants randomly assigned at 8 months of age to a usual diet (control) or to a diet with reduced total fat, saturated fat, and cholesterol. The results show that absolute energy intake, along with parental BMI and height, best predict child growth patterns and that children with a consistently low fat intake grew as well as children with a higher fat intake. In addition, intakes of vitamins, minerals, and trace elements did not differ between the intervention and control groups. All of the children in this study are under medical supervision in well-child clinics and have been followed to age 7 years.[108,126]

The SCANs (Studies of Childhood Activity and Nutrition) were observational studies that examined determinants of diet and exercise in young children. In one SCAN study, Shea and colleagues evaluated the effects of reduced fat on blood lipids and growth in a 2-year study of 215 Hispanic children (age 3 to 4 years) and found no difference in crude measurements of growth. Calcium levels were below recommended levels in the low-fat group, however, so that the need to keep up intake of low-fat milk was emphasized.[127,128]

Dietary intervention studies to lower fat intake have generally involved older children. Nicklas and colleagues, in the Bogalusa Heart Study, found that in a cross-sectional sample of 10 year olds, those with fat intake in the lowest quartile were more likely not to consistently meet the RDAs for vitamins B_6 and B_{12}, thiamin, and niacin than 10 year olds on a higher-fat diet. However, children in the lower-fat category tended to make up the missing fat calories with simple sugar rather than the recommended complex carbohydrates (160 g/day sugar in the lowest fat quartile compared with 129 g/day for the highest fat quartile).[129]

In the Child and Adolescent Trial for Cardiovascular Health (CATCH, 1991–1994), 5,000 third grade students (~ age 8 years) participating in a food service modification and education intervention reduced their total fat intake from approximately 33 to 30% of dietary energy. Growth or development was similar in both intervention and control groups after 3 years of follow-up.[112,130–135] Similarly, in the Dietary Intervention Study in Childhood (DISC), 638 8- to 10-year-old children with high LDL cholesterol followed a lower-fat Step II diet (saturated fat ~ 7% energy). After 4 years, the drop in LDL cholesterol was only 3.23 mg/dL, however, on a fat intake averaging about 27% energy from total fat, no adverse effects were observed in any of the growth variables, sexual maturation, iron stores, or psychological well-being.[74]

Recent trends also indicate that concomitant with the gradual reduction in the percentage of energy from fat in children's diets, the rate of growth retardation among vulnerable low-income preschool children has decreased steadily over the past several decades. In 1987, 16% of low-income preschool children were classified as growth retarded (prevalence of children age 5 and under who are below the 5th percentile for height based on NHANES I reference data). By 1992, however, this figure was less than 8%.[136]

Other concerns that have been raised regarding limiting fat and cholesterol intake are that such a diet could result in a lack of cholesterol for myelin formation in the nervous system and for production of steroid hormones that use cholesterol as a substrate.[106,107] However, cholesterol is not an essential nutrient. In healthy children, the body is capable of synthesizing cholesterol for all of its needs.

There is also concern that a fat-restricted diet could lead to mineral deficiencies, especially calcium, iron, and zinc if red meats are avoided.[137] With adequate consumption of low-fat dairy products, both calcium and dietary fat goals can be achieved. Fortified cereal products and inclusion of a variety of lean meats, legumes (eg, peanuts and peanut butter), whole grains, and vegetables help ensure adequate intake of zinc.

Deficiencies in EFAs may occur if dietary fat is severely restricted. EFAs should provide about 3% of energy intake in a child's diet. Generally, if about half of the child's fat intake comes from plant sources, the EFA requirements will be met. Three percent of a 1 to 3 year old's diet would be about 39 calories or 4.3 g of EFA, whereas 3% of a 4 to 6 year old's 1,800 kcal diet would be about 54 calories or 6 g EFA/day (of the total 60 g of total fat in a 30% energy from fat diet). Vegetable oils (eg, corn, soybean, etc) are good sources of EFAs; however, the *trans* isomers of linoleic acid do not have EFA activity.

BENEFITS OF A FAT-MODIFIED DIET IN CHILDHOOD

Most health authorities agree that a diet that is low in saturated fat and cholesterol during childhood reduces the development of cardiovascular disease risk factors (hyperlipidemia and obesity), which, in turn, should reduce the risk of atherosclerosis and coronary heart disease in adult life. In addition, a diet low in total fat may reduce the risk of cancer, in particular cancer of the breast, prostate, colon, and ovary. Because diets high in fat result in greater caloric density of the diet and encourage passive overconsumption of calories, high-fat diets may also foster excessive weight gain and childhood obesity. Finally, diets lower in fat (< 30% energy), along with adequate daily physical activity, may help children achieve and maintain a desirable BMI.

Dietary patterns established during childhood tend to persist over time; thus, it seems reasonable to place greater emphasis on initiation of healthful eating patterns in childhood rather than on trying to change more deeply ingrained unhealthful eating habits later in adult life. In addition, a healthful, lower-fat diet in childhood can be safely and effectively achieved through the application of a wide variety of strategies, following the principles of the USDA Dietary Guidelines and Food Guide Pyramid.[55]

FAMILY AND SCHOOL INFLUENCES ON DIETARY FAT INTAKE IN CHILDREN

Convincing evidence exists showing that chronic disease risk factors aggregate within families. Bush and colleagues found that African American mothers in the highest quartile for cardiovascular disease risk factors (including total cholesterol, blood pressure, BMI, fitness, and activity) had children who were also more likely to be in the highest quartile.[138] Therefore, it seems logical that intervention strategies that may modulate the effect of genetic factors need to be provided in the family as a whole rather than to parents or children as isolated subunits. Children, especially before adolescence, tend to follow dietary patterns set by their parents. It is clear, therefore, that, in planning strategies aimed at lowering fat intake in children, the parents' diet should also meet the Dietary Guidelines. With parents serving as role models, there is greater likelihood of successfully achieving dietary guidelines for all family members.

Schools are also influential in shaping children's nutrition and physical activity behaviors, which, in turn, pro-

mote or protect against diet-related chronic disease risk factors such as blood lipids, blood pressure, and obesity. School-based programs are unique in that they have the ability to provide classroom nutrition and other health education and then are able to extend beyond the classroom to involve food service, health service, and after-school programs. In this way, they offer a tremendous opportunity to positively influence child nutrition and health. In addition, teachers, administrators, and other school staff and peers represent an important network of role models and social supports for children and youth. The CATCH program, as noted previously, is an excellent model for effective school-based nutrition education and food service intervention in elementary schools.[113,130–135]

Preschool nutrition programs are also important in providing appropriate nutrition education as well as meals and snacks that meet state and federal guidelines. The Healthy-Start preschool nutrition and health education program is a model of an effective nutrition program in the preschool setting (<www.Healthy-Start.com>). In this program, classroom nutrition education was combined with food service intervention, teacher training, and family education and demonstrated increased nutrition knowledge, lower blood cholesterol, and decreased intake of saturated fat in children.[139–142] For as many as two-thirds of all younger children (4 to 6 year olds), it is possible to achieve dietary fat guidelines simply by switching from full-fat to 1% or fat-free milk.[143]

Tamir and colleagues performed a randomized trial of 800 first grade children in Jerusalem.[144] Experimental schools received a comprehensive educational and health promotional program (comprising 15 to 20 hours per year) and were reinforced by community activities. After 2 years of intervention, there was a decrease in both serum total cholesterol and BMI in children in the experimental compared with the control school. Similarly, other school-based health programs have shown that significant improvement in parameters relating to blood lipids and fitness can be achieved.[144]

It is important for schools to provide nutrition education for all children and adolescents from preschool through twelfth grade and to ensure that school meals and snacks are consistent with the NCEP and AHA Dietary Guidelines for Americans. The school food service should be viewed as an extension of the comprehensive health education program for the school so that children can learn about healthy nutrition in the classroom and then practice healthful food choices in the cafeteria.[145]

TABLE 5.1-4 Practical Suggestions for Achieving Pediatric Dietary Guidelines (> 2 years of age)

Eat a greater quantity and variety of fruits, vegetables, whole grains, cereals, nuts, and legumes
Eat at least 3 servings of vegetables and 2 servings of fruit daily (1 serving may be fruit juice)
Choose fat-free or low-fat (1%) dairy products and consume 2–4 servings daily
Eat moderate amounts of trimmed, lean red meat, poultry (without skin), or fish in place of choices high in saturated fat
Eat egg yolks only in moderation (less than 3 yolks per week)
Use vegetable-based oils, margarines, and shortenings that contain primarily unsaturated fatty acids instead of saturated fatty acids and that contain little or no *trans*–fatty acids
Read food labels and choose items lowest in saturated fat and cholesterol
When eating out or buying ready-made foods, select items that are low in saturated fat and cholesterol, as well as foods that were baked, boiled, or broiled without fat

SUMMARY

In summary, fat is a critical macronutrient for all children. Recommendations for dietary fat intake in childhood, however, must take into account the child's unique growth and developmental patterns, specific nutrient requirements, vulnerability of sentinel nutrients, factors important to the establishment of healthful food acceptability, preference and intake patterns, and nutritional risk factors for disease during childhood as well as later in life. All of these considerations are crucial in translating scientific findings into public policy. Numeric guidelines for fat intake in children over 2 years of age and adolescents have been recommended by the AAP and more than 25 other health-related organizations. These recommendations are based on the association of dietary fat and chronic conditions and diseases such as cardiovascular disease, cancer, and obesity, as well as on considerations of nutritional adequacy and establishment of healthful eating patterns early in life.

National surveys in the past two decades indicate that children are consuming a lower percentage of their daily energy from total and saturated fat; however, the majority still fail to meet the dietary goals. Concerns have been voiced that diets in which fat is limited to the recommended goals may have adverse effects on growth during childhood; however, a growing number of controlled trials addressing this question have demonstrated that growth is normal for children on diets in which fat contributes approximately 25 to 30% of calories if the diet also includes adequate calories, high-quality protein, and essential nutrients.

CHAPTER 5.2

MACRONUTRIENT REQUIREMENTS FOR GROWTH: CARBOHYDRATES

Jonathan E. Teitelbaum, MD, Susan B. Roberts, PhD

BACKGROUND

Carbohydrates are one of the three macronutrients (the others being protein and fat) that are sources of dietary energy and are present in a wide range of food. The name carbohydrate was originally given to compounds thought to be hydrates of carbon. Formally, carbohydrates are a class of substances with the formula $C_n(H_2O)_n$. This formula, however, fails for larger compounds such as oligosaccharides, polysaccharides, and sugar alcohols. Classification can be based on the number of sugar units found within a given compound.

MONOSACCHARIDES

The simplest form of carbohydrate is the monosaccharide, and as such is often referred to as the "simple sugar." These sugars have variable numbers of carbon atoms and include trioses, tetroses, pentoses, hexoses, and heptoses with 3-, 4-, 5-, 6-, and 7-carbon atoms, respectively (Table 5.2-1).

Glucose (dextrose) is a hexose and represents the most important of those sugars. It is a moderately sweet sugar and is the main form in which carbohydrates circulate throughout the body to provide fuel to various cell types. It is abundant in fruits, sweet corn, corn syrup, honey, and certain roots. Fructose (levulose) is the sugar naturally present in fruits and honey. It is the sweetest of the simple sugars, about 1.5 times the sweetness of sucrose (table sugar). Galactose, typically not found free in foods, is liberated in the hydrolysis of lactose. Other examples of monosaccharides include glycerose (triose), erythrose (tetrose), and ribose (pentose).

DISACCHARIDES

The linking of two monosaccharides forms a disaccharide. These include sucrose (glucose-fructose), lactose (glucose-galactose), and maltose (glucose-glucose). Sucrose, table sugar, is the most prevalent dietary disaccharide. It is found in cane and beet sugar, brown sugar, sorghum cane, molasses, maple syrup, pineapple, and carrots. Lactose, milk sugar, is the least sweet of the disaccharides, being one-sixth as sweet as sucrose. Maltose occurs in malt products of starch hydrolysis and in germinating cereal grains.

POLYSACCHARIDES

Oligosaccharides contain 3 to 10 sugar units and are typically the result of the digestion of polysaccharides (ie, starch and glycogen), which contain greater than 10 sugar units. Starch is the storage carbohydrate of plants, whereas glycogen is that of animals.

TABLE 5.2-1 Source and Use of Various Monosaccharides

Sugar	*Carbon Atoms*	*Natural Sources*	*Use*
Ribose	5	Metabolic processing	Formation of nucleic acids and coenzymes
Glucose	6	Fruit, hydrolysis of starch, sugar cane maltose, and lactose	Cell fuel
Fructose	6	Fruit, honey, hydrolysis of sucrose	Changed to glucose
Galactose	6	Hydrolysis of lactose	Changed to glucose, constituent of glycolipids and glycoproteins
Mannose	6	Hydrolysis of plant mannosans and gums	Component of polysaccharide of albumins, globulins, mucoproteins, and glycoproteins

Starches are composed of glucose polymers with α-(1,4) amylose (straight chain) and α-(1,6) amylopectin (branched chain) linkages. The proportion of amylose to amylopectin depends on the starch type, as do the size and shape of their storage granules. Three crystalline forms of starch are recognized: type A (ie, raw wheat, rice starch) has an open helical structure and is easily digestible; type B (ie, raw potato starch) is densely packed and thus has reduced digestibility owing to decreased access by amylases; and type C (ie, legumes) is a mixture of types A and B.[1]

The cooking of starch helps to improve the flavor as well as soften and rupture the starch cells, thus facilitating their enzymatic digestion. Starch mixtures thicken when cooked because the amylopectin that encases the starch granules has a gel-like quality.

Polyhydroxy Alcohols

The alcohol forms of sucrose, mannose, and xylose (sorbitol, mannitol, and xylitol, respectively) retain some of the sweetness of the original sugar. These sugars are more slowly absorbed from the digestive tract and thus prevent a rapid rise in blood sugar. However, this quality can also contribute to soft stools when consumed in large amounts.

The UK Department of Health originated the term intrinsic sugar to identify those sugars present within the cell walls of plants (ie, naturally occurring), as opposed to extrinsic sugars, which are typically added to foods. The US Department of Agriculture defines added sugars as sugars and syrups added to foods during processing or preparation. Major sources of added sugars include soft drinks, cakes, cookies, pies, fruit drinks, dairy desserts, and candy.

CARBOHYDRATE TYPES

Dietary carbohydrate is a major nutrient for humans and in the Western world represents approximately half of our daily energy intake. Of this ingested carbohydrate, about 60% is derived from polysaccharides, and disaccharides such as sucrose and lactose represent 30% and 10%, respectively. However, there has been an increasing trend for manufacturers to introduce monosaccharides (ie, glucose and fructose) into foods and drinks. Oligosaccharides such as raffinose and stachyose are found in small amounts in legumes.

Resistant starch (RS) is that portion that is indigestible even after prolonged incubation with α-amylase. In cereals, it comprises 0.4 to 2% of the dry matter; in potatoes, 1 to 3.5%; and in legumes, 3.5 to 5.7%. This undigested starch can be divided into three main categories: RS1 physically enclosed starches (ie, mixed grains, seeds), RS2 ungelatinized crystallite granules of the B-type x-ray pattern (ie, banana, potato), and RS3 retrograded amylose. Within the colon, the local resident bacteria ferment RS. The end products of the fermentation process are short-chain fatty acids (ie, acetate, butyrate, proprionate), carbon dioxide, hydrogen, and methane. Luminal starches stimulate the growth of colonic bacteria, and the short-chain fatty acids appear to be essential for normal colonocyte growth and function. In infants, the lower luminal pancreatic α-amylase concentrations give rise to an increased amount of RS. In infants, these RS have been associated with increased calcium, iron, and possibly zinc absorption.[2] However, RS in infancy may also contribute to diarrhea by an increase in osmotic load.

Dietary fiber includes "all plant polysaccarides and ligandin that are resistant to hydrolysis by the digestive enzymes in man."[3]

CARBOHYDRATE DIGESTION

Salivary amylase initiates the digestion of starch while in the mouth. It is detectable from 20 weeks gestation.[4] Its activity increases rapidly after birth and reaches adult levels between 6 months and 1 year. It had previously been thought that the amylase activity is inhibited within the stomach owing to the acidic milieu. However, currently, some suspect that buffering of the gastric acid by the food components allows carbohydrate hydrolysis to continue. Breast milk also contains α-amylase, which is structurally similar to salivary amylase. It is found in highest concentrations within the colostrum. Once the gastric chyle is emptied into the duodenum, pancreatic α-amylase cannot hydrolyze the one to six branching links and has little specificity for the one to four links adjacent to the branching points. Pancreatic amylase concentrations are much lower in the neonate and are not thought to reach adult levels until 5 to 12 years of age.[5] This results in the formation of large oligosaccharides (α-limit dextrans), each with an average of eight glucose units with one or more one to six links (Figure 5.2-1).

The microvilli of the small intestine support the unstirred water-layer phase within the intestinal lumen. Limit dextrans, trisaccharides, and disaccharides within this unstirred water layer are rapidly hydrolyzed by enzymes bound to the border membrane. Specifically, the α-limit dextrans are substrates for glucoamylase, which cleaves single glucose units from the nonreducing end of linear α-(1-4) glucosyl oligosaccharides.

Despite the fact that D-glucose is the major source of energy for most if not all mammalian cells, the lipid-rich cell membrane is relatively impermeable to the hydrophilic polar molecule. To this end, carrier proteins within the cell membrane are required to bind the glucose and transport it intracellularly. Two classes of such proteins have been described: facultative glucose transporters and sodium-glucose transporters (symporters). The former class includes membrane integral proteins on the surface of all cells and transports glucose down a concentration gradient via facilitative diffusion. The energy for this transfer comes from dissipation of the concentration difference of glucose. In contrast, the sodium-glucose transporters allow for uphill movement of D-glucose against the concentration gradient via active transport. The transporters are expressed in the brush border of the enterocyte and of the renal proximal tubule. Small numbers can also be found in the epithelial cells of the lung and liver.[6]

Initial movement of luminal hexoses into the enterocyte is accomplished by the action of sodium-dependent

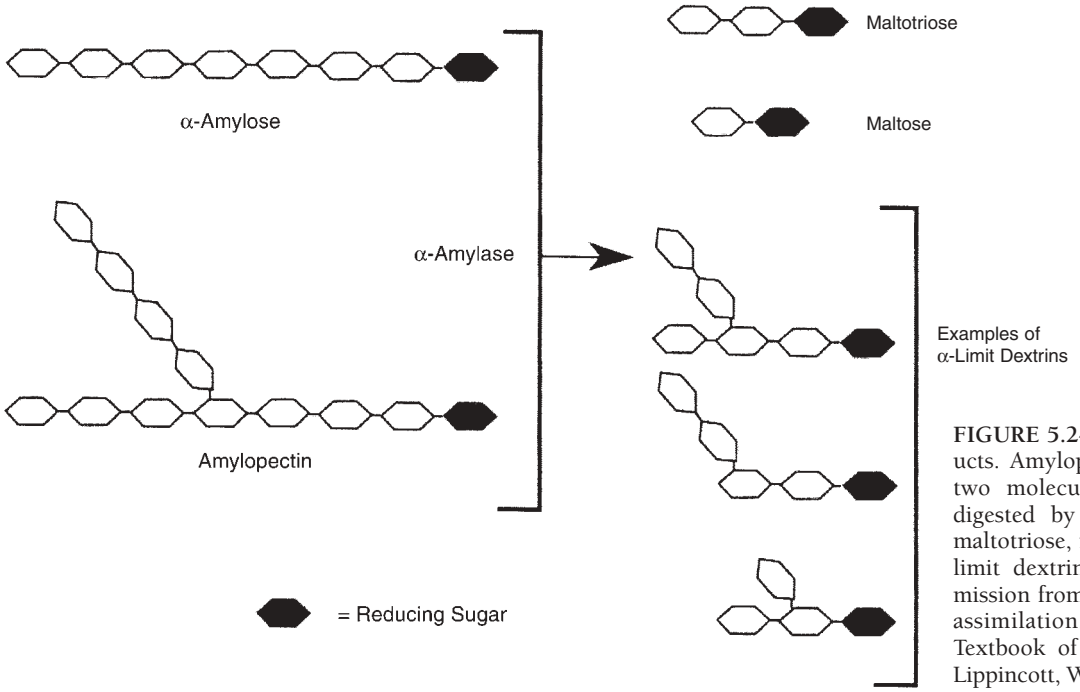

FIGURE 5.2-1 Starch digestion products. Amylopectin and α-amylose, the two molecular forms of starch, are digested by lumenal α-amylase into maltotriose, maltose, and a series of α-limit dextrins. Reproduced with permission from Traber PG. Carbohydrate assimilation. In: Yamada T, editor. Textbook of gastroenterology. 3rd ed. Lippincott, Williams and Wilkins; 1999.

glucose transporters in the brush border (SGLTs). These transporters take advantage of a sodium gradient created by the Na-K adenosine triphosphatase pump or sodium pumps on the basolateral borders of the cell. This allows for the cotransport of one molecule each of sodium and glucose. This is the physiologic basis for the design of oral rehydration solutions for the treatment of diarrhea. Glucose is then transported across the intestinal basolateral membrane by a different glucose transporter. Five major hexose transporters have been identified and cloned and are numbered GLUT 1 to GLUT 5, in order of discovery (Table 5.2-2). There are reports of possible GLUTs 6 and 7. Similar to glucose, galactose uses SGLT cotransporters and basolateral GLUT 2. In contrast, fructose does not use SGLTs but is thought to use GLUT 5, which has been demonstrated to have a high affinity for this hexose.

DIETARY REQUIREMENTS OF CARBOHYDRATES

The primary function of dietary carbohydrates in human nutrition is to provide fuel for energy (Table 5.2-3). Some cells within the body are obligatory carbohydrate users, including the brain, white blood cells, red blood cells, and the medulla of the kidney. When carbohydrates are oxidized in the body as fuel, they render 4 kcal/g.

Various cultures have evolved in which there are minimal amounts of carbohydrate in the diet for extended periods of time beyond infancy. These cultures, including the Masai, Alaska and Greenland natives, Inuit, and the people of the Pampas, exhibit no ill effects on their health or longevity. Children with intractable seizure disorders have also been shown to tolerate a ketogenic diet. Animal models on such diets have been shown to thrive. Indeed, whites who consumed an essentially carbohydrate-free diet for 1 year tolerated the diet well.[7] Azar and Bloom found that adults consuming a carbohydrate-free diet required 100 to 150 g of protein to maintain nitrogen balance.[8] The authors assumed that gluconeogenesis was supported by this protein intake and the conversion of glycerol obtained from triacylglycerol in the diet.

The brain and other parts of the central nervous system maintain an absolute requirement for glucose as an oxidizable fuel but can adapt in part to a fat-derived fuel. In the absence of carbohydrate, de novo synthesis of glucose requires amino acids derived from protein hydrolysis and/or glycerol from fat. Thus, the carbohydrate requirements are based on the composition of the remaining portion of the diet. This requirement approaches zero in infants after weaning as well as in children and adults.

The estimated average dietary requirement for carbohydrates depends on the brain's glucose use rate. The endogenous glucose production rate in a postabsorptive state (approximately 2.8 to 3.6 g/kg/day) correlates very well with the estimated size of the brain from birth to adulthood. In adults, this equates to 110 to 140 g/day.[9] However, as previously stated, there are adaptive measures during times of starvation in which liver glycogen stores are

TABLE 5.2-2 Facilitated Diffusion Glucose Transporter Family

Type	*Chromosome Location*	*Major Expression Site*
GLUT 1	1	Red blood cells, placenta, brain, kidney, colon
GLUT 2	3	Liver, B cell, kidney, small intestine
GLUT 3	12	Brain, testis

AI = Adequate Intake; EAR = Estimated Average Requirement; RDA = Recommended Dietary Allowance.

depleted when "ketosis" provides keto acids as alternate fuels. In subjects fully adapted to starvation, keto acid oxidation can account for approximately 80% of the brain's energy requirements[10]; thus, only 22 to 28 g/day of glucose are required to fuel the brain.

In infants age 0 through 12 months, the brain size relative to the body size increases. The brain uses 60% of the infant's total energy intake.[11] This accounts for up to a fourfold greater turnover in glucose/kg in the infant when compared with adults. Even in the premature infant, the gluconeogenic pathway is developed enough to provide for the majority of glucose turnover. From the limited data available, the lower limit of tolerable carbohydrate intake in infants is approximately 30% of total food energy. However, it is possible that infants may grow and develop normally on a very low-carbohydrate diet. The carbohydrate in human milk is almost exclusively lactose. Lactose is readily hydrolyzed in the infant's intestine, and the resulting glucose and galactose easily pass into the portal venous system. Within the liver, the galactose yields one molecule of glucose so that the net yield from each lactose molecule is two glucose molecules. This may provide a teleologic explanation as to why lactose is the carbohydrate source in mammalian milk as the disaccharide helps to lower the osmolarity of the milk when compared with two monosaccharides. In addition, lactose has been reported to facilitate calcium absorption in the immature infant's intestine.[12] The lactose content of human milk is approximately 74 g/L. Although this does not appear to change over the nursing period, the volume consumed does decrease gradually over the first 12 months of life. For the first 6 months of life, the infant consumes approximately 0.78 L/day or 60 g of carbohydrate, representing 37% of their total food energy. For older infants (7 to 12 months), the adequate intake of carbohydrate is 91 g/day, which is the sum of that supplied from human milk (an average volume of 0.6 L/day or 44 g/day) plus that from complementary foods (estimated by the Third National Health and Nutrition Examination Survey to be 51 g/day).

In children and adolescents, the relative increase in brain size is modest. Thus, the consumption of glucose by the brain after age 1 year is rather constant and similar to that of adults. The Estimated Average Requirement (EAR) is thus determined to be 100 g/day for all children over 1 year of age.[13] The Recommended Dietary Allowance (RDA) equals the EAR plus two times the standard deviation (15% based on variation in brain glucose use). The RDA is thus 130% of the EAR or 130 g/day.

DIETARY CARBOHYDRATE SOURCES AND INTAKE

Sources of dietary carbohydrates abound in the daily diet. Since the introduction of high-fructose corn sweeteners in 1967, the amount of "free" fructose in the American diet has increased considerably.[14] These syrups are derived from cornstarch through the conversion of a portion of the glucose present in starch to fructose. The fructose content in the syrup is 42, 55, or 90%. Beverages such as soft drinks and fruit-flavored drinks are the major dietary sources of added fructose.

According to 1994–1996 US Department of Agriculture food consumption survey data, nondiet soft drinks were the leading source of added sugars in American diets, representing one-third of added sugar intake.[15] Other major sources included candies (16%), sweetened grains (13%), fruit drinks (10%), sweetened dairy (9%), and breakfast cereals (10%). All totaled, these account for 90% of added sugar intake in the American diet.

Data from the 1994–1996 and 1998 Continuing Food Survey of Intakes by Individuals revealed that the median intake of carbohydrates was 220 to 330 g/day for men and 180 to 230 g/day for women, representing approximately 50% of energy intake. Added sugar intake ranged from 40 to 120 g/day and was highest among adolescent males. The mean intake of 82 g/day represents 15.8% of total energy intake, far exceeding that recommended by the Food Guide Pyramid.

A tolerable upper intake level for sugars has not been defined. However, there are ongoing research efforts attempting to determine if increased carbohydrate ingestion can adversely affect behavior, cholesterol levels, or the risk of dental caries, type 2 diabetes, obesity, cancer, or micronutrient displacement. Indeed, a recent article by Ludwig and colleagues demonstrated a relationship between consumption of sugar-sweetened drinks and childhood obesity.[16]

FIBER

Fiber can be divided into two categories: dietary fiber is defined as nondigestible carbohydrates and lignin that are intrinsic and intact in plants; functional fiber is the nondigestible carbohydrate that has beneficial physiologic effects in humans (Table 5.2-4). Total fiber represents the sum of these two forms of fiber. By definition, these dietary fibers are not digested within the mammalian small intestine and pass relatively intact into the large intestine.

Cellulose is a polysaccharide with a high molecular weight. It is a large unbranched glucose polymer similar to starch; however, the linkage bonds are different such that humans lack the enzyme required to break the units apart. Cellulose is the principal structural material in plant cell walls. It is water insoluble but can hold water, adding bulk to the feces and reducing intracolonic pressure.

Noncellulose fiber carbohydrates include hemicellulose, pectins, gums, mucilages, and algal substances. All help to absorb water, slow gastric emptying, and bind bile acids. Lignins are a noncarbohydrate form of fiber. They

TABLE 5.2-4 Dietary Fiber

	Structure		*Sources*		
Fiber Class	*Main Chain*	*Side Branches*	*Grains*	*Fruits*	*Vegetables*
Cellulose	Glucose	None	Bran, whole wheat, whole rye	Apples, pears	Beans, peas, cabbage, roots
Hemicellulose	Glucose, mannose, xylose	Galactose, arabinose	Brans, cereals, whole grains		
Pectins	Galacturonic	Rhamnose, xylose, arabinose, fructose		Apples, citrus, berries	Green beans, carrots
Gums	Galactose, galacturonic acid-mannose, galacturonic acid-rhamnose	Xylose, galactose	Oatmeal	FPTS	Dried beans, legumes
Mucilages	Galactose-mannose, glucose-mannose, arabinose-xylose, galacturonic acid-rhamnose	Galactose		FPTS	
Algal substances	Glucose, mannose, xylose, glucuronic acid	Galactose		FPTS	
Lignin	Phenylpropane alcohols	3-D network	Whole wheat, whole rye	Peaches, pears, plums	Mature vegetables

FPTS = food products thickener, stabilizer.

are large phenylpropane polymers derived from higher alcohols and built into three-dimensional networks comprising the woody parts of plants. They form insoluble compounds with bile acids.

Fiber's effects on digestion include an ability of soluble viscous fiber to delay gastric emptying and contribute to a sense of early satiety.[17] This, in turn, results in a delay in the digestion and absorption of various nutrients. Once in the colon, the fiber is fermented by the indigenous microflora to produce carbon dioxide, methane, hydrogen, and short-chain fatty acids.

In industry, fiber is often added to foods to reduce their caloric content and replace fats or sugars. The energy value of these fibers is the center of controversy. As they are fermented, the resultant short-chain fatty acids can be used locally as an energy source (ie, butyrate for colonocytes) or enter the portal circulation and are used in the liver (ie, acetate and butyrate). A small portion of the energy from fermentation is used to promote bacterial growth and maintenance of the microflora. Some authors have suggested that fermentation of fiber may account for up to 12% of energy needs.[18–20]

Overall, functional fiber has been documented to have the effect of laxation, with an increase in fecal bulk, altering blood lipid concentrations and attenuating blood glucose responses. Ongoing research efforts are looking to determine fiber's role in preventing duodenal ulcers, diverticular disease, hyperlipidemia, hypertension, coronary artery disease, colon cancer, and breast cancer.

Because human milk is thought to be the optimal source of nourishment for infants through the first year of life and because human milk contains no dietary fiber, the adequate intake for infants age 0 to 6 months is considered zero. Between 7 and 12 months, the amount of dietary fiber increases; however, there is no basis on which to determine the adequate intake of fiber in this age group. In children over the age of 1 year, the adequate intake recommendations are based on adult data and are 14 g/1,000 kcal of energy required.[13]

According to data from the Continuing Survey of Intakes of Individuals (1994–1996), median dietary fiber intakes ranged from 16.5 to 17.4 g/day for men and 12.1 to 13.8 g/day for women. These numbers fall below the suggested adequate intake recommendations. Furthermore, there does not appear to be any significant deleterious effect of high intake of fiber if it is part of an overall healthful diet. Therefore, there is no tolerable upper intake level defined.

PREBIOTICS

Prebiotic was defined by Gibson and Roberfroid in 1995 as a "nondigestible food ingredient which beneficially affects the host by selectively stimulating the growth of and/or activating the metabolism of one or a limited number of health promoting bacteria in the intestinal tract, thus improving the host's intestinal balance."[21] Because this concept has only been recently defined, there are not as many data to support their health-promoting effects. Examples of prebiotics include the fructo-oligosaccharides (FOSs) and complex oligosaccharides in human milk.

FOSs are short and medium chains of β-D fructans in which fructosyl units are bound by a β 2-1 osidic linkage. The FOSs are classified based on the number of osyl units, which defines their degree of polymerization (DP). Accordingly, oligofructose has a DP < 9 (average 4.8), and inulin has a DP up to 60 (average 12). Inulin-producing plant species include several monocotyledonous and dicotyledonous families such as Liliaceae, Amaryllidaceae, Gramineae, and Compositae. Commercially, inulin is the

product of hot water extraction from chicory roots (*Cichorium intybus*), and oligofructose is prepared by the partial hydrolysis of inulin under controlled conditions. They are also contained in a number of common foods, including garlic, onion, artichoke, and asparagus.[21]

The β 2-1 osidic bond of FOS, including the first glucose-fructose bond, is not readily hydrolyzed by mammalian digestive systems. However, bifidobacteria possess β-fructosidases that allow them to digest these compounds.[21] The ability of prebiotics such as oligofructose to selectively stimulate the growth of bifidobacteria has been supported by numerous studies.[22] However, the effects of prebiotics appear to be limited to the time during which they are being consumed, so that when supplementation is stopped, their beneficial effect is lost.[22] Despite the effects prebiotics have in manipulating the bacterial flora, they have not been shown to have health-promoting effects to the same degree as probiotics. Some studies suggest that they may enhance mineral absorption and have a role in cancer prevention.[23]

CONCLUSION

Carbohydrates in the form of sugars and starches are common sources of energy for the various organs and cells of the human body. They are present in a wide variety of foods in various forms. Basic science has allowed an impressive understanding of the way in which these macronutrients are digested, absorbed, and transported throughout the body. Age-dependent EARs exist for both carbohydrate and fiber. Ongoing research is attempting to define potential benefits to the ingestion of various dietary forms of carbohydrates (ie, fiber, prebiotics) as well as detrimental consequences to their overconsumption (ie, obesity, cancer, diabetes).

CHAPTER 5.3

MACRONUTRIENT REQUIREMENTS FOR GROWTH: PROTEIN AND AMINO ACIDS

Leticia Castillo, MD

This chapter provides an overview of the current state of knowledge of protein and amino acid requirements in children. The special protein and amino acid needs of premature infants are reviewed in Chapter 28, "Nutritional Support of the Low Birth Weight Infant."

Nitrogen use, and therefore amino acids and protein, is critical in maintaining whole-body homeostasis. Loss of more than 30% of body proteins results in death.[1] Amino acids are needed for tissue formation and multiple physiologic functions.[2] Therefore, maintenance of whole-body nitrogen stores is critical to survival. Proteins are the major functional and structural component of cells, enzymes, membrane transporters, intracellular matrices, and other components, all of which are essential for life. Hence, an adequate provision of dietary protein is essential to maintaining cellular integrity and function.

Proteins are made of carbon, oxygen, and hydrogen; a smaller proportion is also made of sulfur. The chemical characteristic of proteins is their amino nitrogen group. Proteins are macromolecules consisting of a long chain of amino acid subunits. The sequence of amino acids in the chain is known as the primary structure. Proteins fold into a definite three-dimensional structure. Their exact shape depends on their function and interaction with other molecules.

After ingestion of a protein meal, proteins are denatured by the acid in the stomach, where they are also cleaved by pepsin into smaller peptides. In the small intestine the denatured proteins and peptides are hydrolyzed by a variety of pancreatic enzymes, including trypsin, chymotrypsins, elastases, and carboxypeptidases. The mixture of free amino acids and small peptides is transported into the mucosal cells by specific carrier systems. Following intracellular hydrolysis, the free amino acids are secreted into the portal blood by other specific carrier systems, or they are further metabolized within the intestine. Absorbed amino acids pass into the liver, where a fraction is taken up and used. This process is known as first-pass disappearance or splanchnic uptake. Because of this, not all of the amino acids removed from the intestinal lumen reach the systemic circulation. The amino acid fraction that disappears in the splanchnic area differs among the different amino acids. The remainder of the amino acid passes through the systemic circulation to be used in whole-body economy.[3]

The use efficiency of most dietary proteins, or capacity to integrate into body proteins, is about 90%.[4] Protein losses in the intestine account for 25% of obligatory nitrogen losses,[5] such as intestinal cell turnover and secretion of mucin and enzymes. Protein is also lost by skin, urine, and hair. There is controversy regarding the contribution of indispensable amino acids by intestinal bacteria, with conflicting data in favor of and against a significant contribution by intestinal bacteria to the amino acid pool.[6–8]

Protein synthesis and degradation are balanced during the steady state. Both increase during conditions of stress, but degradation offsets synthesis, resulting in a negative balance. Protein degradation occurs by a lysosomal- or ubiquitin-proteasome–dependent mechanism.[9]

AMINO ACIDS

The amino acids that are incorporated into mammalian protein are α-amino acids, with the exception of proline, which is an α-imino acid. This means that they have a carboxyl group, an amino nitrogen group, and a side chain attached to a central α-carbon (Figure 5.3-1). The structure of the side chains determines the functional differences among amino acids. Amino acids are provided in the diet or they can be synthesized from a carbon and nitrogen source. Amino acids are catabolized by removal of the nitrogen group through the process of transamination, which results in formation of other amino acids (alanine, pyruvate, aspartate, and glutamine) or by the process of deamination, which results in the formation of ammonia. Therefore, the nitrogen removed from any amino acid can be directed toward ammonia and aspartate, which are the

NAME	ABBREVIATION	FORMULA
Aliphatic side chains

TABLE 5.3-1 Amino Acid Classification, FAO/WHO/UNU Expert Report, 1985

Essential	*Nonessential*
Histidine	Alanine
Isoleucine	Arginine
Leucine	Aspartic acid
Lysine	Cystine
Methionine	Glutamic acid
Phenylalanine	Glycine
Threonine	Hydroxyproline
Tryptophan	Proline
Valine	Serine
	Tyrosine

precursors of urea. Urea synthesis takes place in the liver. Other organs, such as the intestine and kidney, contain an incomplete set of urea-cycle enzymes. Urea is released into the circulation by the liver and transported to the kidneys, where it is excreted in the urine. Therefore, nitrogen excretion occurs mainly as urea excretion. However, ammonium ions are also excreted, and this contributes to the maintenance of acid–base balance.

The carbon moiety of the amino acids is catabolized by oxidation through the tricarboxylic acid (TCA) pathway of glucose oxidation. Some amino acids enter the TCA cycle as keto acid analogues, and others have specific degradation pathways that produce intermediates that are metabolized in the TCA cycle. The carbon skeleton of amino acids is also available for biosynthesis of glucose and fat. If the carbon skeleton enters as acetyl coenzyme A, then fat or ketone bodies are formed. Other carbon skeletons from amino acids can be used for gluconeogenesis. Hence, amino acids are either ketogenic or glucogenic, although some amino acids can give rise to both ketones and glucose.

Classification

Classification of amino acids was initially based on the classic studies of Rose and colleagues.[10–14] These studies were based on the qualitative significance of each amino acid in human nutrition. Rose defined amino acids as essential or nonessential based on their capacity to maintain nitrogen balance in young men; the classic nutritional classification of amino acids is summarized in Table 5.3-1. Holt, Snyderman, and colleagues,[15–25] as well as Fomon,[26] extended Rose's studies to the pediatric population. In their studies, they demonstrated that only the "essential" amino acids were needed to maintain growth in infants and therefore conformed to the original definition of "essentiality of amino acids."

Through the following decades, it became evident that Rose's classification was limited and that a distinction between essential and nonessential amino acids was complex and could not be made based solely on the nutritional criteria of maintenance of nitrogen balance or growth.[27] For example, histidine, a nonessential amino acid in the rat that was considered nonessential in humans in the original Rose classification, has been proven to be essential in health and disease and was included as an essential amino acid by the Food and Agricultural Organization/World Health Organization/United Nations University (FAO/WHO/UNU) Expert Report in 1985.[28]

Over the past few decades, the concept of amino acid essentiality based on maintenance of growth or of nitrogen equilibrium has been revisited, with contributions by Mitchell,[29] Laidlaw and Kopple,[30] Young and El-Khoury,[31] Chipponi and colleagues,[32] Reeds and Biolo,[33] and Jackson.[34] Mitchell considered a more dynamic concept of "essentiality" based on the ratio of supply to demand rather than on the maintenance of nitrogen balance or growth. The term "conditionally indispensable" has been used to refer to those nonessential or dispensable amino acids that become essential or indispensable under pathophysiologic conditions.[32] Because the carbon skeleton of the amino acid is the moiety that determines its nutritional indispensability, some classifications of amino acids have been based on the ability to synthesize or aminate the carbon skeleton.[33]

In metabolic terms, the amino acids that are generally considered nutritionally essential contain specific chemical structures, the synthesis of which cannot be catalyzed by mammalian enzymes.[33] Examples include the branch aliphatic side chain of leucine, isoleucine, or valine; the primary amine of lysine; the secondary alcohol of threonine; the secondary thiol of methionine; the indol ring of tryptophan; the aromatic ring of phenylalanine; and the imidazol ring of histidine.[35] Table 5.3-2 shows an updated classification of amino acids.

It is important, however, to remember that an amino acid classification should not be based solely on nutritional (growth and maintenance), metabolic (de novo synthesis, tissue use, and catabolism), or chemical aspects of the amino acids but also, and perhaps most importantly, on the maintenance of amino acid function. Some amino acids that would be considered truly dispensable in nutritional, metabolic, and chemical terms are precursors of other amino acids that maintain important physiologic functions, such as glutamate and serine, which serve, respectively, as precursors of glutamine and cystathionine. Other dispensable

TABLE 5.3-2 Nutritional Classification of Amino Acids

Indispensable	(a) Carbon skeleton cannot be synthesized (b) Rate-limiting enzymes of catabolism regulated in relation to adequacy of intake and tissue supply
Conditionally indispensable	(a) Indispensable amino acid is a precursor (ie, phenylalanine-tyrosine) (b) Synthesis and degradation are modulated by dietary supply (ie, arginine, glycine) (c) Stressful states cause tissue depletion where rates of synthesis are insufficient to meet increased rate of metabolic demand (proline, glutamine, arginine, glycine, taurine) or match catabolic rate
Dispensable	(a) Rate of synthesis is not down-regulated by intake of amino acid; metabolism largely a function of metabolic status of major energy-yielding substrates and/or overall nutritional status (alanine, glutamate, aspartate)

amino acids, such as alanine and aspartate, contribute to physiologic and pathophysiologic events.[36,37] The involvement of amino acids in physiologic and metabolic functions is extensive; a partial summary is shown in Table 5.3-3.

PROTEIN AND AMINO ACID HOMEOSTASIS

The distribution of protein among the different organs varies with developmental age. Children have a proportionately larger amount of visceral (liver, kidney, brain, heart, and lung) protein than skeletal muscle protein, whereas in adults, protein constitutes about 15% of body weight.[38] During starvation or low protein intake, visceral protein is mobilized. This is called the "labile protein content." However, these "reserves" account for only 1% of total body protein.[39] During disease states, muscle is the main source of protein loss.[40]

Body proteins are in a continuous dynamic state of synthesis and catabolism (Figure 5.3-2). Under physiologic conditions, the amino acids released by protein breakdown are reused for protein synthesis. Protein turnover under these conditions is increased.

Adequate nitrogen (protein) intake is essential for growth, development, and function. However, estimating "adequate" protein or specific amino acid requirements for the pediatric population is a complex and challenging endeavor.[27,28,38,41] First, the pediatric population constitutes a dynamic group, involving different clusters of individuals from birth to adolescence. The pediatric population shows marked differences among the age groups in weight, rate of growth, hormonal milieu, activity, and other factors that can affect nutritional and metabolic status. Second, dietary recommendations for macro- and micronutrients for the different pediatric groups have been based largely on limited and inadequate data.[28,38,42–52] Because of ethical constraints that prevent the use of healthy children in invasive research studies, data in the pediatric population are based on nitrogen balance studies obtained from children recovering from malnutrition.[47,48,51] Hence, pediatric data are rather limited. Third, with new knowledge emerging on non-nutritional functions of nutrients, and based on the physiologic and pharmacologic properties of amino acids, the concept of amino acid requirement has changed from the traditional nutritional criteria based on growth or weight maintenance to a broader functional outcome, such as induction of gene expression,[52] or nutritional rescue of metabolic conditions, such as prevention of neural tube defects[53–55] or correction of hyperhomocystinemia with folic acid.[56] Therefore, "adequacy" of nutritional support is ill-defined and conditional on the goals to be achieved.

Based on this new knowledge about non-nutritional functions of amino acids,[33,35] a key question regarding nutritional adequacy is what is the objective to be achieved? Is the objective to promote growth and weight maintenance? To maintain non-nutritional functions? To prevent pathophysiologic events? To act as pharmacologic agent(s) to induce gene expression? Or for nutritional rescue? These important questions are just beginning to be explored and will be better answered in the future.

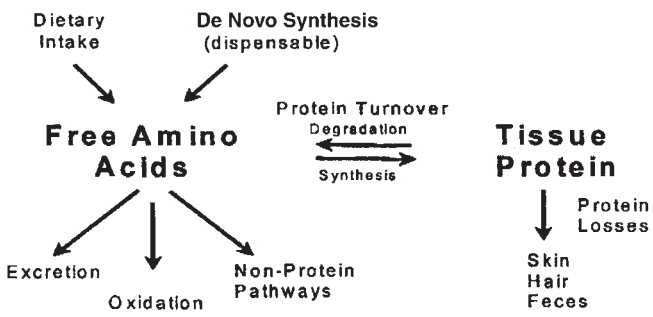

FIGURE 5.3-2 Protein and amino acid turnover. Reproduced from Panel on Macronutrients et al.[38]

ESTIMATES OF PROTEIN REQUIREMENTS

Protein requirement is defined as the "true biologic need for protein or amino acids, the lowest intake that will maintain functional needs of the individual."[38] However, because protein needs vary among individuals, the mean requirement has been taken as the starting point.[28,38] The Food and Nutrition Board of the Institute of Medicine, National Academy of Sciences, recently reviewed values for the intake of nutrients.[38] The Recommended Dietary Allowance (RDA) refers to the level of average daily dietary nutrient intake sufficient to meet the nutrient requirements of nearly all (97 to 98%) healthy individuals in a particular life stage and gender group. When the RDA cannot be estimated, "adequate" intake is recommended; this refers to the average daily intake level based on observed or experimentally determined approximations or estimates of nutrient intake by a group of apparently healthy people, which are assumed to be adequate.[38]

The tolerable upper intake level is the highest average daily nutrient intake level that is likely to pose no risk of adverse health effects to almost all individuals in the general population.[38] Estimated average requirement refers to the average daily nutrient intake level estimated to meet the requirement of half the healthy individuals in a particular life stage and gender group.[38] The "safe level of intake" is defined as the amount that will meet or exceed the requirements of practically all individuals in a population, which is generally calculated as the mean requirement plus 2 standard deviations of the requirement.[28,41]

Dietary protein requirements involve two components: (1) total nitrogen for synthesis of the nutritionally dispensable and conditionally indispensable amino acids and for synthesis of other nitrogen-containing compounds with relevant physiologic functions and (2) to provide for the nutritionally indispensable amino acids, which cannot be synthesized by human tissues to maintain metabolic needs and therefore must be supplied by an exogenous source.[33,35]

The classic nitrogen balance studies by Rose and colleagues[10–14] and others[45,46,51] have been used for estimation of protein and amino acid requirements in older children and adults. Nitrogen balance techniques have been significantly criticized because of the difficulty in obtaining complete collections and measuring all routes of nitrogen loss (sweat, nitrate production, gaseous nitrogen). Furthermore, nitrogen balance techniques do not provide information on the dynamic status of amino acid metabolism.[51] However, although there is a great deal of criticism of using nitrogen balance studies to estimate protein requirements, currently there are no alternative data available to estimate the maintenance nitrogen needs of infants.[27,28,38,41]

Infants Up to 6 Months of Age

In 1985, the FAO/WHO/UNU considered that in early infancy (age 0 to 6 months), the protein intake of breast-fed infants constitutes the gold standard. This is based on the evolutionary assumption that breast milk is best suited to maintaining the nutritional needs of the infant.[28] This approach assumes protein efficiency (weight gain per gram of protein consumed) of 90%, given the high biologic value of the protein consumed. Therefore, the protein needs of an infant would be met if energy needs are met and the food providing the energy contains protein in quantity and quality equivalent to that of breast milk.[28,38,41]

The Food and Nutrition Board recently recommended a protein intake of 9.1 g/d^{-1} or 1.52 $g/kg^{-1}/d^{-1}$ in infants age 0 to 6 months.[38] This recommendation was based on the average volume of milk intake, which was estimated to be 0.78 L/day, and an average protein content in human milk of 11.7 g/L.

In 1996, the International Dietary Energy Consultancy Group (IDECG)[41] re-evaluated the rationale used to determine the 1985 FAO/WHO/UNU recommendations for infants and children[28] and concluded that the FAO/WHO/UNU Expert Report overestimated protein requirements during infancy by about 27 to 35%. These overestimates were felt to be attributable to a number of factors. In infants from birth to 6 months of age, the revision yielded new data estimates on the intake of breast milk, the content of protein nitrogen and nonprotein nitrogen, and the efficiency of retention of nonprotein nitrogen (which the IDECG postulated to be 46 to 61%, in comparison with the 100% assumption used by the FAO/WHO/UNU). The 1996 IDECG estimates also used body weights of breast-fed babies rather than those of formula-fed babies.[41]

Regarding estimates on the intake of breast milk, in the 1985 FAO/WHO/UNU expert report, the average intake of breast-fed infants was assumed to approximate the mean requirement, which was defined as the amount of protein needed for growth in 50% of the children.[28] However, this approach was flawed because it automatically defined half of breast-fed infants as having deficient intakes.[41] Therefore, mean intakes of breast milk do not equal "requirement." The epidemiologic probability approach indicated that at age 3 to 4 months, the nitrogen requirement is less than 170 $mg/kg^{-1}/d^{-1}$, whereas the mean intake is about 231 $mg/kg^{-1}/d^{-1}$. Likewise, milk intake in the FAO/WHO/UNU report was not corrected for insensible water loss.[28] The IDECG revision was based on more extensive data on infants exclusively breast-fed until 6 months of age, correction for insensible water loss was made, and nonprotein nitrogen was taken into account.[41]

The protein content of human milk and use of nonprotein nitrogen was also revisited by the IDECG.[41] The decline in protein content during the course of lactation was taken into account, as was the ratio of whey to casein in human milk throughout lactation. An important consideration in the assessment of the amount of protein available for tissue accretion and function (the biologic value of a protein) is the relative amount of nonprotein nitrogen. The average nonprotein nitrogen in mature human milk has been estimated to be 26% of the total nitrogen content. The major nonprotein nitrogen compounds in human milk are amino acids, creatinine, urea, creatine, and uric acid. It has been estimated that 27% of this nonprotein fraction, or about 7% of total nitrogen, is available for protein synthesis.[38,41]

The proportion of nonprotein nitrogen in human milk was considered by the 1996 IDECG revision of protein requirements.[41] Table 5.3-4 shows the revised IDECG esti-

mates of average protein intake in breast-fed infants up to 6 months of age, compared with the estimates in the 1985 FAO/WHO/UNU expert report.[28] It is important to point out that average intake of protein in breast-fed infants does not necessarily equal the requirement. Table 5.3-4 shows that the estimated protein intake in infancy is lower than that estimated in the FAO/WHO/UNU report when adjusted by the nonprotein nitrogen fraction. It is also important to remember that protein concentration in milk decreases when the infant is between 1 and 2 months old. Decrease in milk protein concentration was not accounted for in the FAO/WHO/UNU report. Therefore, the 1996 IDECG values are 10 to 26% lower than the 1985 FAO/WHO/UNU estimates, assuming that at least 46% of the nonprotein nitrogen in human milk can be used.[28,41]

Infants, Children, and Adolescents

For infants older than 6 months and for children and adolescents, a factorial approach was used in the 1985 FAO/WHO/UNU expert report.[28] This approach takes into account (1) maintenance for obligatory losses, which is estimated by regression analysis of the relationship between nitrogen intake and nitrogen balance; (2) measurement of the rates of protein deposition, which are derived from body composition analysis; and (3) estimates of the efficiency of protein use, which is derived from the slope of the line relating intake and balance. The factorial method is summarized as follows:

> Mean dietary protein requirement = maintenance + protein accretion associated with growth × 100/utilization efficiency

Under this concept, the need for total protein and/or a particular amino acid for growth is equal to the rate of protein deposition and/or the content of that particular amino acid in the protein being deposited.[28,31,41] However, a problem with this approach is that the relationship between protein intake and nitrogen retention is not linear; thus, the efficiency of nitrogen retention is less as the zero balance point is approached.[51]

In the factorial approach used in the 1985 FAO/WHO/UNU expert report, the maintenance requirement at 6 months of age was taken to be 120 mg $N/kg^{-1}/d^{-1}$, declining to 103 mg $N/kg^{-1}/d^{-1}$ by age 18 months. A growth component was estimated and a 50% addition was made to provide a margin of safety because growth rates vary from day to day and because protein is not "stored" when there is a relative excess intake. The fractional efficiency of nitrogen use from high-quality protein sources for both maintenance and growth was taken to be 0.7 and the coefficient of variance (CV) for maintenance and growth was taken to be 12.5 and 35%, respectively, for purposes of calculating the total CV and a recommended safe protein intake level.[28] The total CV was estimated as follows:

$$\text{CV total} = \sqrt{(M \times CV_m)^2 + (G \times CV_g)^2/(M + G)}$$

Where M equals maintenance and G equals growth.

The requirements estimated by the FAO/WHO/UNU used the above data and assumptions. The data and assumptions have since been revisited, and with accrual or newer and updated information, some modifications to recommended protein intakes for children have been proposed. In 1996, the IDECG concluded that the FAO/WHO/UNU's 1985 recommendations overestimated protein requirements in childhood by 17 to 20%.[41]

For infants older than 6 months and for young children, the IDECG revisited the factorial approach used by the FAO/WHO/UNU. The maintenance requirement of nitrogen, estimated at 120 $mg/kg^{-1}/d^{-1}$ by FAO/WHO/UNU, was revised downward to 90 $mg/kg^{-1}/d^{-1}$. The IDECG estimated maintenance nitrogen needs in infants and children based on a series of nitrogen balance studies,[41,44–51] whereas the FAO/WHO/UNU had used only one study of nitrogen balance in children aged 9 to 17 months and other studies in older children, but none in children less than 12 months of age.[28] Based on these revisions, in 1996, the IDECG derived new values of estimated basal and/or maintenance nitrogen needs in infants and children, which were found to be 82 to 93 mg $N/kg^{-1}/d^{-1}$. A value of 90 mg $N/kg^{-1}/d^{-1}$ was used for the factorial model, on which the revisions of protein requirements are based.[41]

Estimated needs for growth were also revised in 1996 by the IDECG.[41] During infancy, the amount of protein required for growth is an important component of total protein needs, decreasing progressively with age. By 2 years of age, the proportion of proteins needed for growth decreases significantly, whereas the proportion needed for maintenance increases. Table 5.3-5 shows the distribution of protein needs for maintenance and growth in children. In young infants, up to 64% of protein needs are for growth, whereas after age 2 years, protein needed for growth accounts for only 11% of total protein needs. Therefore, after 2 years of age, the use of nitrogen for growth and maintenance is very similar to that in the adult population.[28,41,51]

Intraindividual day-to-day variation in the rate of growth, and therefore in the need for protein to maintain that growth, was estimated at about 50% by the FAO/WHO/UNU in 1985, based on the premise that there is no storage capacity for

TABLE 5.3-5 Protein Needs for Growth and Maintenance in Children

Maintenance nitrogen assumed to be 90 mg/kg^{-1}/d^{-1}.

amino acids and therefore it would be necessary to allow for extra demand on days of rapid growth.[28] There is no evidence to support a 50% day-to-day variation in the rate of growth; therefore, the 1996 IDECG recommendations discarded the 50% augmentation.[41]

The retention efficiency value or efficiency in conversion from dietary protein to body protein was left unchanged at 0.7 in the 1996 recommendations. Based on available data, it was presumed that efficiency is the same for maintenance as for growth. Efficiency is calculated as nitrogen retained divided by nitrogen intake; obligatory losses are subtracted.[41]

The CV for the interindividual variability in the average requirement estimates for maintenance and growth in infants were also revised by the IDECG. The average requirement estimates were modified based on the extent of interindividual variability. Therefore, accurate estimation of CV is important. The 12.5% CV used by the FAO/WHO/UNU was obtained from short-term nitrogen balance studies in adults, and it was assumed to be the same in the pediatric population. Interindividual variability in growth was estimated to yield a CV of 35%. However, the CV for growth depends on the interval of measurement. The CV will be lower if the interval is longer. Although an arbitrary interval of 3 months was used by the IDECG, it yielded a more reliable CV.[41]

In summary, the 1996 IDECG revision[41] of the 1985 FAO/WHO/UNU report[28] found that (1) for infants up to 6 months of age, the estimates of protein requirement were based on breast milk intake data; intake is not equivalent to requirement, and adjustment for nonprotein nitrogen yielded a lower estimate of protein requirement; and (2) for infants older than 6 months and for children, a modified factorial approach estimating lower maintenance nitrogen needs of about 90 mg/kg^{-1}/d^{-1}, removing a 50% safety margin for intraindividual variation in growth and estimating interindividual variation in growth at a different interval, yielded lower estimates of protein requirements. It is expected that a new FAO/WHO/UNU committee will convene in the future and that the observations from the 1985 FAO/WHO/UNU report will be revisited.

The current RDAs from the Food and Nutrition Board[38] are based on the factorial approach used in the 1985 WHO/FAO/UNU report[28] and on more recent data collected over the past decade.[57–62] However, the Food and Nutrition Board stated that "the use of nitrogen balance should no longer be regarded as the gold standard for the assessment of the adequacy of protein intake, and alternative means should be sought."[38] Table 5.3-6 shows the estimated protein intake recommended by the Food and Nutrition Board.

Other Approaches to Estimating Protein Requirements in Infants

Protein requirements in infants have also been determined by a direct experimental approach, using plasma amino acid and urea nitrogen concentrations as rough indicators of the balance between intake and use.[28,38,41] Postprandial plasma amino acid concentrations are indicative of protein turnover; this is influx into the amino acid pool from protein breakdown, synthesis, and dietary intake and outflow from the plasma pool via catabolism and excretion (Figure 5.3-2). An "operational" approach involving protein-to-energy ratios has also been used to estimate protein requirements.[41] The protein requirements per unit of energy intake decrease rapidly in the first several months of life.[28,41,60] The protein-to-energy ratios for 3 to 6 months and for 6 to 9 months of age have been described as 1.5 and 1.4 g protein/100 kcal, respectively.[22,35] The use of protein-to-energy ratios requires estimating the ratio of the safe level for protein to the mean requirement for energy at each age.[38,46,63,64]

Other Factors Influencing Protein Requirements

Other factors, such as intakes of other nutrients, protein digestibility, amino acid content of proteins, and protein quality, will influence protein requirements.[28,38,41,51] Vitamin B_6 is intimately linked to protein metabolism, and high protein intakes will require higher intakes of vitamin B_6.[65]

Estimating digestibility requires measurement of dietary and fecal nitrogen loss associated with a given protein source. The derivation of the fecal index used in the estimate of "apparent protein digestibility" involves the calculation of a percentage of intake based on the subtraction of the fecal nitrogen output from the dietary nitrogen ingested. However, the input from the metabolism of endogenous proteins is not taken into account by this approach.[38,41,66,67] Hence,

$$\text{Apparent protein digestibility (\%)} = \frac{\text{N intake} - \text{fecal N output on test diet} \times 100}{\text{N intake}}$$

$$\text{True protein digestibility (\%)} = \frac{\text{N intake} - \text{fecal N output on test diet} - \text{fecal N output on nonprotein diet}}{\text{N intake}}$$

True protein digestibility has been established mainly in rat models for a variety of proteins.[38,41]

The content and metabolic availability of individual indispensable amino acids are important variables affecting the nutritional value of a protein food. If the content of a single dispensable amino acid is less than the individual's requirement, the use of other amino acids will be limited. Therefore, normal rates of protein synthesis will be affected, even if the total intake of nitrogen (protein) is adequate. The "limiting amino acid" determines the nutritional value of the total protein in the diet.[68–70] For example, a larger intake of soy protein is required to maintain balance. This difference is eliminated if sulfur amino acids are supplemented. Therefore, sulfur amino acids are the limiting amino acid in soy protein intake.[38] Lysine is the most limiting indispensable amino acid in diets based on cereal proteins.[31,69]

Protein quality refers to the amino acid pattern of food proteins that will efficiently meet both the nitrogen and indispensable amino acid requirements of the individual. The amino acid requirement, or "scoring," pattern is based on estimated average requirements for the individual indispensable amino acids and on total protein requirement. Therefore, nitrogen × 6.25 estimates the weight ratio of protein to the nitrogen content in food. It is assumed that, on average, nitrogen accounts for 16% by weight of mixed proteins. The protein-to-nitrogen ratio for whole milk is 5.62; for egg, 5.38; and for soy milk, 6.07.[38] Table 5.3-7 shows the proposed amino acid scoring pattern in infants and in children aged 1 year or older. There is no difference between preschool children and adults. Therefore, the scoring pattern remains the same after 1 year of age.[38]

The 1989 FAO/WHO expert consultation on protein quality established standards for many protein sources, such as egg (97%), soy flour (86%), and wheat (96%).[70] Animal sources of protein provide all nine indispensable amino acids and for this reason are referred to as "complete proteins," whereas "incomplete" proteins are found in plants, grains, and vegetables and tend to be deficient in one or more of the indispensable amino acids.

The protein digestibility–corrected amino acid score (PDCAAS) has been proposed for the assessment of protein quality[4,70–72] The PDCAAS is obtained by comparing the concentration of a "limiting" amino acid in the food protein source to that of a standard, such as egg protein, and multiplying by the true digestibility.[72] It is expressed as the percentage of the same limiting amino acid in the referenced amino acid pattern.[71] This assessment of protein quality is limited, however. Some investigators[71] have considered the use of ileal rather than fecal digestibility for inclusion in the scoring procedure and to determine if total dietary nitrogen digestibility represents a valid indicator of the bioavailability of the individual amino acid. It has been suggested by the same authors that the deposition of nitrogen during the prandial phase would constitute a critical factor in the deter-

mination of food protein quality, and this could be used to assess significant differences among dietary protein sources.

AMINO ACID REQUIREMENTS

The complexity of estimating individual amino acid requirement was described earlier. Traditionally, amino acid requirement had been based on nutritional use: growth and maintenance, with protein deposition being the predominant influence. The composition of the indispensable amino acids in body proteins of immature mammals is similar. Therefore, the composition of body protein through different species is very similar. Hence, the relative needs of each indispensable amino acid (milligrams of amino acids to grams of total amino acid) for growth will be the same across species.[28] The amino acid requirements for the support of protein deposition in humans will differ from other mammals only to the extent of the difference in growth rates between species.[41] Furthermore, even in young children, the major demand on amino acid requirement is for maintenance rather than for growth. Young and Borgonha estimated that for a 2-year-old child, maintenance accounts for 80 to 90% of the total protein requirement.[51] This is in agreement with data published by Millward, who suggested a value of 85%.[73] Given that, in humans, the obligatory amino acid needs for protein deposition are a minor fraction of the total amino acid requirement,[38,41] the greater demand for amino acid requirement will depend on amino acid use for maintenance.

Amino acid needs for maintenance have been the subject of much controversy.[8,28,31,68,73–76] It has been proposed by Reeds and Hutchens that nitrogen requirements for maintenance could depend on (1) continuous loss in the intestine, (2) maintenance of key metabolites derived from amino acids, and (3) maintenance of pathways that use amino acids involved in host defense and nucleotide synthesis.[35,76] It has been observed that amino acids are consumed in physiologic functions that are not directly related to protein metabolism,[35] and it is important now to quantify the effect of metabolic pathways on the needs for their precursor amino acids. Lyons and colleagues observed that in septic children receiving limited nutritional support, the rates of synthesis of glutathione were decreased by 60%.[77] Glutathione is an important antioxidant, and its synthesis depends on the availability of cysteine. These findings suggest that under pathophysiologic conditions, requirements for some amino acids might need to be revised based on functional rather than nutritional terms.

Specific nutritional amino acid requirements have been determined by nitrogen or amino acid carbon balance. Nitrogen balance values were obtained from the early studies of several investigators[15–26,45,47–49] and from carbon balance studies in adults and sick children performed more recently with stable isotopic techniques.[78–80]

Infants Up to 6 Months of Age

In infants from birth to 6 months of age, the requirements for indispensable amino acids were reported in 1985 in the FAO/WHO/UNU expert report.[28] These recommendations were obtained using the intakes of cow's milk or breast milk that supported satisfactory growth. These estimates are unchanged from the FAO's 1971 report.[27] In 1996, the IDECG used a factorial approach to estimate amino acid intakes in infants up to 6 months of age.[41] Amino acid needs for growth were calculated using data from Fomon and colleagues,[57] based on the daily increment in body protein of breast-fed infants and the amino acid pattern of whole-body protein.

Maintenance protein was calculated as follows: (1) by using the value of 120 mg $N/kg^{-1}/d^{-1}$ and (2) by using nitrogen requirements from balance studies but normalized to metabolic body size (0.75). The factorial approach gave lower estimates for essential amino acids in the 3 to 6 months age group. However, given the significance of the non-nutritional functions of amino acids, and because the functional implications of amino acids in breast milk have not been fully understood, it appeared safer to continue to support the 1971 estimates, and no revision was proposed by the IDECG in 1996.[41]

The recommended adequate intakes for infants up to age 6 months estimated by the Food and Nutrition Board are based on the methods used in 1985 by the FAO/WHO/UNU,[28] using an average volume of milk intake of 0.78 L/day and the mean indispensable amino acid content of human milk. The recommended values are similar to those recommended by the FAO/WHO/UNU in 1985. Table 5.3-8 shows the estimated average requirement and RDA for amino acids at different ages recommended by the Food and Nutrition Board.

Children and Adolescents

For preschool children, amino acid requirements are based on nitrogen balance studies conducted at the Institute of Nutrition for Central America and Panama, in Guatemala.[28,38,41,51] The data were presented only in summary form at a conference.[51] For older children, the requirements from the 1971 FAO/WHO report were upheld. These data were obtained from studies conducted by Nakagawa and colleagues in the 1960s in Japan[49] but were re-examined by the National Research Council and the National Academy of Sciences in Washington.[50] Because of significant methodologic limitations, the data from the

nitrogen balance studies were not used to determine requirements of indispensable amino acids in children aged 7 months through 18 years. Instead, the factorial approach has been used by the IDECG,[41] Millward,[73] Young and Borgonha,[51] and the Food and Nutrition Board[38] to estimate indispensable amino acid requirements. The values obtained are similar to, but slightly lower than, the estimates of the 1985 FAO/WHO/UNU expert report.[28]

The recommendations from the Food and Nutrition Board for amino acid scoring patterns for use in children older than 1 year of age are shown in Table 5.3-7. These data are based in part on the 1985 FAO/WHO/UNU expert report and on more recent data. There is great need for further studies on the protein and amino acid requirements of children, for both nutritional and functional outcomes.

Other Methods for Estimating Individual Amino Acid Requirements

Isotopic studies for quantitative estimates of amino acid requirements and for determination of the efficiency of dietary protein use in meeting these requirements are based on bolus or continuous infusion of amino acid tracers or ingestion of single amino acid–labeled protein or uniformly labeled protein.[38,80]

Indicator Amino Acid Balance In the indicator amino acid balance method, the amino acid test of interest is given at graded levels, and measurements of the carbon oxidation of single indispensable amino acids are taken as indicators of the adequacy of the test amino acid.[81] This method is based on the idea that the nutritional indispensability of an amino acid is attributable to the inability to synthesize its carbon skeleton. Therefore, if the test amino acid is labeled with ^{13}C, the production of $^{13}CO_2$ in breath is assumed to accurately reflect the irreversible oxidative loss of the test amino acid. When this method is used at progressively lower levels of test amino acid intake, a minimum level, or "break point," in the relationship between carbon catabolism, as estimated from the $^{13}CO_2$ in breath, and test amino acid intake can be established. It is assumed that below intake requirement, the test amino acid will be conserved and the rates of oxidation will be low and constant, but once the requirement is exceeded, the oxidation of the test amino acid will increase. Therefore, nutritional requirement will be established at the break point level.[81]

Indicator Amino Acid Oxidation This method is based on the measurement of the oxidation of an indicator amino acid (^{13}C phenylalanine or ^{13}C lysine), which falls to a break point when the amino acid test requirement is achieved.

24-Hour Amino Acid Balance Amino acid balance studies carried out over 24 hours have been obtained for leucine,[82] phenylalanine and tyrosine,[83] lysine,[84] and threonine.[85] This approach provides a more accurate estimate of amino acid needs. However, the intake of tracer over the 24-hour period has been considered a drawback. Twenty-four-hour balance studies have not been conducted in children.

All of these methods have drawbacks and strengths. To date, these are the most reliable data on quantitative estimates of amino acid requirement in adults.

AMINO ACID SUPPLEMENTATION

It has been proposed that supplementation with some amino acids could improve specific physiologic or pathophysiologic conditions.[86–90] However, there have been no dose-response human studies, and only a few controlled, randomized trials have been conducted. Because of the lack of evidence, the value of dietary supplementation with a particular amino acid for improvement of a functional outcome remains to be established.

CHAPTER 6

TRACE ELEMENTS

Nancy F. Krebs, MD, MS, K. Michael Hambidge, MD, ScD

More than 99.7% of the body weight is accounted for by 11 elements, termed the major elements (Table 6-1). The remainder of the body weight consists of approximately 25 trace elements, each of which contributes less than 0.01% to the body weight. Of these, a mammalian nutritional requirement has been established for iron, iodine, zinc, copper, chromium, selenium, molybdenum, manganese, cobalt, nickel, vanadium, silicon, arsenic, boron, and fluoride. Unconfirmed reports suggest that lead, cadmium, and tin may also be required in trace quantities, and it is quite possible that a nutritional requirement for additional trace elements will be elucidated in the future. Although it is reasonable to assume that the trace elements required by humans are similar to those required by other mammalian species, currently, a human nutritional requirement is accepted only for iron, iodine, zinc, copper, chromium, selenium, molybdenum, manganese, and cobalt (as vitamin B_{12}). Because of its beneficial effects in the prevention of dental caries, fluoride is also included in this list.

BIOLOGIC ROLES

Many enzyme systems depend on one or more specific trace elements, either as key components of metalloenzymes or as catalysts of metal ion–activated enzymes. The roles of metal ions in metalloenzymes may be structural, that is, maintaining the conformation of the protein, catalytic, or both. Iron, copper, zinc, molybdenum, selenium, and manganese have been identified as constituents of specific enzymes. Certain trace elements are of fundamental importance in the structure or metabolic activity of other compounds, including hemoglobin (iron), nucleic acids (multiple trace elements), transcription factor proteins (zinc), and vitamin B_{12} (cobalt). The roles of iodine in thyroxine (T_4) and triiodothyronine (T_3), zinc in steroid hormone receptors, and chromium in facilitating the action of insulin are examples of the importance of trace elements in the activity of certain hormones. The dependence of many vital metabolic processes on trace elements confers a physiologic importance on these micronutrients that is analogous to that of vitamins and is out of proportion to their small contribution to body weight. Although considerable progress has been achieved in determining the functions of several trace elements, little is yet known about the biochemistry of others.

TABLE 6-1 Elements with a Role in Human Physiology

	Trace Elements	
Major Elements	*Recognized*	*Probable*
Carbon (C)	Iron (Fe)	Nickel (Ni)
Hydrogen (H)	Iodine (I)	Vanadium (V)
Nitrogen (N)	Zinc (Zn)	Silicon (Si)
Oxygen (O)	Copper (Cu)	Arsenic (As)
Sodium (Na)	Chromium (Cr)	Boron (B)
Potassium (K)	Selenium (Se)	
Phosphorus (P)	Molybdenum (Mo)	
Sulfur (S)	Manganese (Mn)	
Chloride (Cl^-)	Cobalt (Co)	
Calcium (Ca)	Fluoride (F^-)	
Magnesium (Mg)		

DOSE RESPONSE

An elementary but important concept is that the biologic effect of any trace element depends on the dose or, more specifically, on the level of intake and on tissue concentrations (Figure 6-1). For each element, there is an optimal range of intake, the magnitude of which varies considerably between different elements and depends on a number of factors, including the efficiency of homeostatic mechanisms. Obviously, if intakes are sufficiently high, any element will prove toxic. In the case of nonessential elements (eg, mercury), harmful effects can result only from toxic levels of intake. However, in the case of the "essential" trace elements, problems may result from intakes that are too low as well as too high. In animal husbandry, the economic importance of trace deficiency states has been recognized for many years.[1] However, in human nutrition, only iron and iodine deficiencies were recognized prior to the 1960s, and it is only more recently that a broader concept of trace element nutrition has started to develop with the recognition of zinc, copper, chromium, selenium, molybdenum, and possibly manganese deficiency states in humans.

ETIOLOGY OF HUMAN TRACE DEFICIENCY STATES

The last several decades have been notable not only for the number of new trace elements implicated in deficiency disease but, perhaps more surprisingly, for the wide variety of

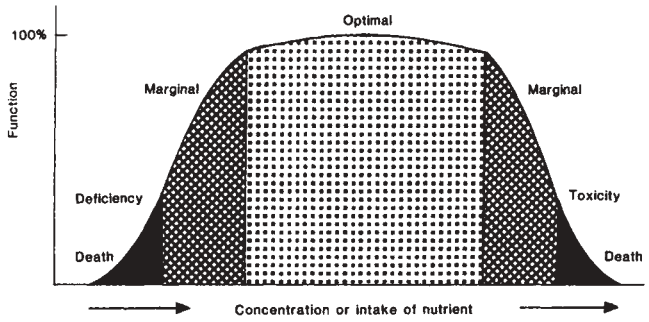

FIGURE 6-1 Dependence of biologic function on tissue concentration or intake of a nutrient. Reproduced from Mertz W. The essential trace elements. Science 1981; 213:1330.

different factors that have been discovered to play a role in the etiology of these deficiency states (Table 6-2). These include inherited or acquired alterations in metabolism and other special circumstances leading to increased nutritional requirements as well as factors that contribute to inadequate intakes of one or more of the trace elements.

Clinically, the most notable examples of the former are provided by inborn errors of trace element metabolism.[2,3] Although these entities are rare and not strictly nutritional deficiency diseases, some of them are important in a nutritional context because of the insight they provide into the clinical and metabolic effects of severe nutritional deficiencies. Moreover, in some instances, manipulation of dietary intake has remarkable therapeutic benefits. Both of these points are well illustrated by acrodermatitis enteropathica, which is discussed below. Although unresponsive to dietary supplements, Menkes' steely-hair syndrome (MSHS) is attributable in part to a de facto deficiency of copper in certain tissues and subcellular sites, resulting from deranged copper transport. An inborn error of molybdenum metabolism has also been described, the clinical features of which suggest a severe molybdenum deficiency state.

TABLE 6-2 Etiology of Trace Deficiencies

Etiology	*Trace Elements**
Inadequate Intake	
No special circumstances required but risk increased during infancy and pregnancy	Fe, Zn
Losses during food processing, including preparation of "humanized" infant milk formulas	Zn, Cr, Cu, Se
Poor bioavailability	Fe, Zn
Local deficiencies in geochemical environment	I,Se
In association with protein-energy malnutrition	Zn, Cu, Cr
Synthetic diets, including intravenous feeding	Zn, Cu, Cr, Se, Mo
Other Circumstances	
Prematurity	Fe, Cu, Zn
Diseases and other unusual circumstances causing impaired intestinal absorption or excessive losses of trace elements	Zn, Cu, Cr
Inborn errors of trace element metabolism	Zn, Cu, Mo

*Elements given are notable examples, but not necessarily a complete list.

Diseases that cause intestinal malabsorption of fat and other nutrients may also lead to trace element deficiencies.[4] Excessive losses of trace elements occur in certain diseases through the kidneys, gastrointestinal tract, sweat, exudates, or hemorrhage. Low blood plasma concentrations of specific trace elements can occur in certain disease states in association with the redistribution of these elements within the body. For example, movement of zinc and iron from the plasma to the liver occurs in stress situations, including infectious diseases. Correction of hypozincemia in these circumstances may be contraindicated, although the host response may depend on the specific cause of the stress.

The premature infant with very low birth weight provides a unique nutritional challenge that includes the provision of adequate trace elements.[5] Some elements, notably copper, iron, and possibly zinc, are stored extensively by the fetus during the last trimester. These stores, which are available to the term infant in early postnatal life, are diminished in the premature infant. Immaturity of intestinal absorption mechanisms and relatively high losses of endogenous zinc have been reported. These problems are aggravated further by the high nutritional requirements that are imposed by the rapid growth of the premature infant after the early postnatal period. Nutritional requirements may also be relatively high during periods of rapid growth in the term infant and in later childhood, as well as during pregnancy and lactation.

Although nutritional requirements for trace elements are small and these nutrients are ubiquitous in the environment, the quantities present in food and water are usually correspondingly low. Hence, contrary to earlier concepts, it is not surprising that humans are at risk from nutritional deficiencies of the trace elements. Iron deficiency, although outside the scope of this chapter, remains one of the most common human nutritional disorders. Other trace deficiencies occur in more restricted geographic locations owing to localized deficiencies in soils, plants, or water. The classic example of a geographic deficiency is that of endemic goiter. The body content of selenium is relatively low in some countries, including New Zealand, and selenium depletion is even more marked in large areas of China. Diets deficient in other nutrients may also contain inadequate quantities of trace elements. Thus, deficiencies of zinc, copper, and chromium have been documented in association with protein-energy malnutrition.

In North America, there is evidence that diets may frequently be marginal or deficient in zinc. Losses during food processing have been implicated as at least a contributory cause. For example, it has been estimated that the milling of grain removes more than three-quarters of the zinc and manganese normally present with substantial losses of other elements, including copper and molybdenum. Refining of sugar also causes losses of trace elements, including chromium. A process that is of special concern for pediatricians is the humanizing of cow's milk in the production of infant formulas. All infant formulas in the United States are now supplemented with variable quantities of iron, zinc, and copper, and, more recently, with sele-

nium. Overall, there remain substantial variations in trace element concentrations in different formulas on a worldwide basis.

Variations in bioavailability are a major factor in determining the adequacy of dietary intake of some of the trace elements. This also applies especially to the infant because of its dependence on one major food staple. Thus, if the milk or milk substitute that provides most or all of the nutrients consumed by the infant is low in available trace elements, there is no chance that this deficit will be compensated for by a more favorable supply in other food items. Although our understanding of this complex subject is far from complete, it is known that human milk confers important advantages with respect to the bioavailability of iron and zinc. Although not proven, it seems probable that this may also be true of other trace elements. As a corollary, the trace element concentrations in breast milk should be considered a minimum guideline for corresponding concentrations in infant milk formulas, and higher concentrations of at least some elements, including iron and zinc, are necessary in the latter. However, indiscriminate supplementation may have adverse consequences, especially through undesirable interactions with other trace elements. Additional research directed at mineral–mineral interactions is needed to determine optimal fortification levels in foods and formulas.

The increasing use of synthetic diets in medical practice, including those used in intravenous feeding, has provided some of the most dramatic examples of acquired trace-deficient states. The development of this area of specialized nutritional support illustrates the extent of our continuing ignorance, not only of the quantities of trace elements required, both orally and intravenously, but also of which micronutrients are desirable additions to synthetic diets. Deficiencies of zinc, copper, chromium, molybdenum, and probably selenium have been documented in association with long-term intravenous feeding.

NUTRITIONAL REQUIREMENTS

The evolving nutritional importance of trace elements has been recognized by the publication of guidelines, including those of the Food and Nutrition Board of the National Academy of Sciences (see Appendix 2).[6] A formal Recommended Dietary Allowance (RDA) has been established for copper, iodine, iron, molybdenum, selenium, and zinc. An Adequate Intake (AI) has been set for chromium and manganese, which reflects the more limited data available on which to base an Estimated Average Requirement (EAR).[6] Information is limited on the quantities of some of these elements in individual food items, which limits the application of these guidelines by nutritionists and other health professionals. There are theoretic advantages to defining recommendations for such elements as zinc according to the bioavailability from different diets, as has been done by the World Health Organization (WHO),[7] but caution is warranted when currently available data are not adequate to support precise tailoring of such recommendations. A specific point that merits emphasis is that intakes below the recommended levels are not necessarily inadequate. In particular, it is wrong to conclude that human milk is deficient in a specific trace element because it provides relatively low quantities of that element.

Guidelines have also been published for intravenous administration of trace elements to children who have to be maintained with total intravenous nutrition (Table 6-3).[8] Intravenous requirements for zinc vary according to the extent of ongoing losses, especially from the gastrointestinal tract. Hence, it is desirable to monitor zinc status at regular intervals.

LABORATORY ANALYSES AND THE DETECTION OF TRACE ELEMENT DEFICIENCY STATES

Fundamental advances in analytic instrumentation, especially the advent and progressive refinement of atomic absorption spectrophotometry, have facilitated the quantitative measurement of trace elements that are present in the parts-per-billion as well as parts-per-million concentration ranges. Yet formidable analytic difficulties remain. For example, accurate measurement of chromium, which now appears to be present in blood plasma, urine, and milk in only parts-per-trillion concentrations, is extraordinarily difficult. Even for relatively simple measurements, such as those of zinc in plasma or serum, substantial interlaboratory differences in analytic results continue to be evident, and it is necessary for each laboratory to establish its own normal range. Even when analytic data are accurate, interpretation is frequently problematic. Plasma concentrations of zinc, for example, may be depressed for reasons other than a deficiency of these elements and frequently fail to provide a sufficiently sensitive or reliable guide to body status. Established physiologic indices, such as the measurement of the activity of an enzyme that depends on a specific trace element, are generally unavailable. The depression of glutathione peroxidase activity in selenium deficiency states is one exception, but the clinical significance of this observation remains uncertain. Overall, laboratory indices for detection of "newer" trace element deficiencies are not as dependable as those available for the detection of iron deficiency. Hence, for research purposes, more cumbersome approaches are necessary to confirm the suspicion of a specific deficiency, including especially the effects of supplementation on specific physiologic parameters under carefully controlled conditions. Meanwhile, the health professional needs to be aware of the circumstances in

TABLE 6-3 Guidelines for Maintenance Intravenous Administration of Trace Elements during Parenteral Nutrition

Trace Element	*Maintenance Requirement (μg/kg/day)*
Zinc	100*
Copper	20
Chromium	0.2
Manganese	1
Selenium	2
Iodine	1

*Requirements for zinc may be much greater in patients who continue to excrete excessive quantities of zinc; also, in premature infants, 300 μg/kg/day should be administered.

which there is a risk of specific trace deficiencies and of the clinical features that may be attributable to such a deficiency.

Hair analyses merit special mention because of their widespread misuse and the unsubstantiated claims for this diagnostic tool. Currently, the value of chemical analyses of hair in clinical practice is extremely limited.[9] Moreover, because of the inherent difficulties in interpretation of analytic data, it is unlikely that future research will lead to more than very limited clinical applications of hair analyses.

ZINC

A nutritional requirement for zinc was first recognized in microorganisms in 1869, in plants in 1914, and in mammals in 1934.[1] In 1954, zinc deficiency was shown to be the cause of porcine parakeratosis. The first of the zinc metalloenzymes to be identified was carbonic anhydrase in 1940.[1] Subsequently, over 100 zinc metalloenzymes have been identified, including at least one in every major enzyme classification. Appreciation of the role of zinc in nucleic acid metabolism, mitosis, and protein synthesis developed in the 1960s and was extended in the 1970s. Understanding of the role of zinc in cell growth and differentiation took a major step forward with recognition of "zinc fingers" as the most frequent deoxyribonucleic acid (DNA) binding motif for transcription factor proteins.[10] Studies of human zinc status were very limited prior to 1960 but included the first documentation of altered zinc metabolism in alcoholic cirrhosis.[11] The first reports of human zinc deficiency attributable to dietary factors emerged in the Middle East in the early 1960s in relation to the syndrome of adolescent nutritional dwarfism.[12] The 1970s were a time of rapid growth in knowledge about the extent, causes, and effects of human zinc deficiency states.[13] In the 1990s, the importance of zinc deficiency on childhood morbidity and mortality in the developing world was documented by a number of carefully conducted, large-scale, randomized, controlled supplementation trials in vulnerable populations.

Clinical Features of Zinc Deficiency

The clinical features of human zinc deficiency range from a life-threatening disease state, characterized by acro-orificial skin rashes, diarrhea, growth arrest, anorexia, depressed mood, and increased susceptibility to infection, to a mild impairment of growth velocity, often accompanied by other problems, including poor appetite and possibly impaired taste perception (Table 6-4). In addition to the severity of the zinc depletion, the clinical sequelae appear to depend on other factors, including the speed of onset and associated clinical and dietary factors such as protein-energy malnutrition.

Decreased growth velocity or growth arrest is a consistent and early result of even mild zinc deficiency in young experimental animals and in infants, children, and adolescents. In severe acute zinc deficiency states (eg, acrodermatitis enteropathica), there is an abrupt cessation of weight gain when the skin rash becomes manifest, and "catch-up" growth occurs when adequate zinc supplements are administered.[14]

Randomized, double-blind, controlled studies in young formula-fed infants, older infants and toddlers, and young children in Colorado have demonstrated increases in weight and/or linear velocity in association with the daily administration of a small dietary zinc supplement for 6 to 12 months duration.[15–18] During the 1990s, the results of more than 20 randomized, controlled zinc supplementation trials were reported from five continents, from developed and developing countries. A meta-analysis of trials in prepubertal children that met strict criteria indicated that supplementation was associated with significant responses in both height and weight increments. Responses were strongest in those initially underweight and in children > 6 months of age with evidence of stunting.[19] These collective results suggest that zinc deficiency is a common cause of retarded growth velocity in the developing world. The first reports of human zinc deficiency concerned severely growth-retarded adolescents in the Middle East,[12] and the need for adequate zinc for optimal weight gain during recovery from protein-energy malnutrition has been reported from Jamaica.[20] Zinc deficiency has also been linked to poor growth in association with certain diseases, including regional enteritis and sickle cell anemia.[21,22]

One large-scale, randomized, controlled study of maternal dietary zinc supplementation during the second and third trimesters of pregnancy showed a beneficial effect on fetal growth and resulted in significantly greater birth weight and head circumference in the offspring of zinc-supplemented mothers, owing in part to a significantly lower incidence of prematurity.[23] Other studies of maternal zinc supplementation have demonstrated mixed results with respect to maternal, fetal, and infant outcomes. Additional well-designed studies in populations in developing countries are warranted before universal fortification or supplementation programs can be recommended.[24]

Anorexia is an early manifestation of zinc deficiency in experimental animals. Although this has long been recognized as a feature of acrodermatitis enteropathica and is also noted in association with milder zinc deficiency syndromes, it has been difficult to acquire objective evidence of a direct cause-and-effect relationship in humans. However, a significant effect of zinc supplementation on food intake has been observed in a double-blind, controlled study.[25]

TABLE 6-4 Clinical Features of Zinc Deficiency*

Decrease in growth velocity
Impaired appetite and decreased food intake
Diarrhea
Increased susceptibility to infection with associated abnormalities of the immune system
Acro-orificial skin lesions; other epithelial lesions, including glossitis, alopecia, nail dystrophy, and hair loss
Behavioral abnormalities, including impairment of hedonic tone
Delayed sexual maturation and impotence
Eye lesions, including photophobia and lack of dark adaptation
Delayed healing of wounds, burns, and decubitus ulcers
Hypogeusia or dysgeusia
Low birth weight
Prematurity

*Features are dependent on severity of deficiency and other factors.

Appetite may not be impaired in zinc-deficient children who are also protein depleted.[20] In addition to decreased food intake, zinc deficiency may be one cause of pica.[26]

Diarrhea is one of the hallmark features of the early descriptions of acrodermatitis enteropathica and occurs in a high percentage of cases. There is growing evidence that zinc deficiency contributes to the incidence, severity, and duration of acute infectious and persistent diarrhea in infants and young children in the developing world. On the basis of pooled analysis of zinc supplementation trials, a 42% reduction in the rate of treatment failure or death in children given zinc supplements has been estimated.[27,28] Diarrhea can itself also contribute to zinc deficiency because of the losses of endogenous zinc in diarrheal fluids.[29] Requirements for zinc are likely to be greater in the presence of diarrhea.

The skin lesions of severe acute zinc deficiency syndromes have a characteristic distribution, primarily at the extremities and adjacent to the body orifices (Figure 6-2). However, lesions do occur elsewhere and may become generalized. Most commonly, the rashes are erythematous, vesiculobullous, and pustular. Secondary infection is common, especially with staphylococci or *Candida*. Hyperkeratotic plaques may develop when severe zinc deficiency persists, and chronic skin lesions have also been reported in moderate zinc deficiency complicating chelation therapy.[1] In acrodermatitis enteropathica, the skin lesions typically occur in early infancy, although they are usually delayed until after weaning if the infant is breast-fed. Similar lesions occur in severe acquired zinc deficiency states, including patients fed intravenously without zinc supplements,[30] and in premature infants, especially those whose mothers have an inability to secrete normal quantities of zinc into their milk.[31] Other epidermal lesions include gingivitis, dermatitis, glossitis, conjunctivitis, blepharitis, alopecia, and, in chronic cases, nail dystrophies. The open skin sores that occur characteristically in kwashiorkor have been reported to respond specifically to topical zinc applications and appear to be caused or at least aggravated by a concurrent zinc deficiency,[32] which is not necessarily as severe as that responsible for the typical acrodermatitis rash. A dry hyperkeratotic skin and acne have been reported in some cases of more moderate zinc deficiency states.

Behavioral abnormalities are a notable feature of severe zinc deficiency states. Irritability, lethargy, and depression occur typically in conjunction with the skin rash of severe zinc deficiency. Hedonic tone and motivation to engage in the environment[33] improve dramatically after the commencement of zinc therapy.[26] Cognitive development is impaired in young zinc-deficient animals, and there is growing evidence that the same applies in the human.[34]

Frequent bacterial and monilial infections, associated with abnormalities of the immune system, contribute to the progressive and often fatal course that characterizes untreated acrodermatitis enteropathica. Abnormalities of the immune system also occur in less severe zinc deficiency states. Compared with studies of zinc and diarrhea, there are fewer trials examining the effects of zinc on the incidence of pneumonia, but the results of a pooled analysis suggest a 41% lower rate of pneumonia in zinc-supplemented children.[27,28] Zinc supplementation may also have a positive impact on clinical attacks of malaria, although the results of controlled trials have been somewhat mixed.[28] Chronic zinc deficiency in adolescents may cause prolonged delay of sexual maturation.[12] Some cases of impotence complicating chronic renal disease have responded to zinc supplementation. Eye lesions that may occur in severe chronic zinc deficiency states include severe photophobia and keratopathies.[1] Visual adaptation to the dark may also be impaired.

FIGURE 6-2 The acute skin lesions of acrodermatitis enteropathica are demonstrated in this 10-month-old infant. Reproduced from Hambidge KM, Nichols PL Jr, editors. Zinc and copper in clinical medicine. Jamaica (NY): Spectrum Publications; 1978.

Another feature of zinc deficiency that has been more definitively studied in animals than in humans is the delayed healing of wounds. However, there is substantial evidence that zinc deficiency can delay the healing of surgical wounds, burns, and decubitus ulcers in humans.[4]

Biochemical Correlates

Although there is now extensive knowledge about the biochemistry of zinc, especially its role in a wide range of enzyme systems, the biochemical correlates of the clinical features of human zinc deficiency remain poorly defined. Many of the features of zinc deficiency, including growth retardation, poor wound healing, and abnormalities of fetal development and the immune system, are thought to be attributable, at least in part, to disturbances in nucleic acid metabolism and protein synthesis. Its role as a stabilizer of the molecular structure of subcellular constituents and membranes is exemplified by the observation of altered membrane signaling and postreceptor events that coordinate the response to insulin-like growth factor 1 when zinc availability is limited.[35] Such observations provide another

plausible link to the growth retardation and impaired immune function during zinc deficiency. The so-called zinc fingers are the most common motif for the repetitive sites on transcription proteins that bind with DNA to initiate transcription.[10] Through this mechanism, which can be compromised by zinc restriction, zinc has an extraordinarily important role in gene expression. Similar zinc finger motifs are involved at the receptor sites of some steroid hormones,[36] including those for testosterone and in nuclear receptors for vitamins A and D. Several of the enzymes involved in nucleic acid synthesis are zinc dependent, including DNA and ribonucleic acid (RNA) polymerases, reverse transcriptase, and thymidine kinase, the activity of which is known to be reduced in human zinc deficiency.[37]

Zinc is critical for normal immune function and interacts with several components of the immune system, ranging from the skin and its barrier function to aspects of both cellular and humeral immunity. In vitro studies emphasize the responsiveness of some components to zinc concentrations, with both deficiency and supraphysiologic levels leading to impaired immune function. As a highly proliferative organ, the immune system strongly depends on an adequate zinc supply. Recent reviews address in vitro and in vivo studies of the role of zinc in normal immune function and the impact of zinc deficiency.[38,39] Controlled supplementation trials in humans that examine specific markers of immune function are limited. Zinc supplementation of malnourished preschool-aged children was associated with a significant reduction in anergic/hypoergic children and a significantly greater rise in lymphocyte subsets.[40] Positive effects have also been observed with zinc therapy in acrodermatitis enteropathica,[41] Down syndrome,[4] and generalized malnutrition.[42] In Jamaica, improvement in delayed cutaneous hypersensitivity and an increase in thymic size in undernourished infants have resulted from topical and oral zinc therapy, respectively.[42,43] In acrodermatitis enteropathica, impairment of monocyte and neutrophil chemotaxis has been corrected by zinc therapy in vivo and by incubation with zinc in vitro.[44]

Abnormalities of essential fatty acid metabolism and of prostaglandin synthesis may result from zinc depletion.[45] It is possible that some of the features of zinc deficiency, including dysfunctional uterine labor patterns and postpartum hemorrhage, are mediated through these abnormalities. Currently, this remains a poorly clarified but potentially interesting area of research in zinc metabolism. Membrane sodium transport is affected by zinc deficiency, and the diarrhea characteristic of zinc deficiency may be attributable to altered membrane permeability. Other proposed mechanisms include induction during zinc deficiency of specific gene products that alter fluid balance in the intestine.[4,46]

Although the activity of so many enzymes is zinc dependent, there have been very few direct links between clinical features of disease and impaired activity of specific zinc-dependent enzymes. Some of the effects of zinc deficiency may be mediated through effects on hormones. For example, testosterone secretion is decreased in experimental zinc deficiency, and increases in circulating insulin with concurrent decreases of blood glucose have been observed in the treatment of human zinc deficiency.[47] In the same study, zinc supplementation was associated with improved nitrogen balance. The importance of zinc to normal function of the central nervous system, including as a prominent neurosecretory product in the cerebrocortex, has recently been reviewed.[48]

Etiologic Factors in Zinc Deficiency

The prototype of the severest forms of human zinc deficiency is provided by acrodermatitis enteropathica, a rare autosomal recessively inherited disorder. The phenotypic expression of this disease is attributable entirely to a severe zinc-deficiency state.[2] The zinc deficiency results from a partial block in the intestinal absorption of this trace metal. A candidate gene has been proposed that codes for a transmembrane histidine-rich protein that functions as a zinc-uptake protein.[49] Although total body zinc is not greatly reduced, plasma zinc concentrations are typically extremely low. Before the beneficial effects of zinc therapy were recognized, this was a severe, progressive, and often fatal disease. Similar clinical syndromes result from severe acquired zinc deficiency and have been observed frequently in pediatric and adult patients who are fed intravenously. The most important etiologic factor is failure to add zinc supplements to the intravenous infusate. Contributory factors may include excessive urine losses of zinc liganded to amino acids and, in some cases, extraordinary gastrointestinal losses attributable to the gastrointestinal pathology for which intravenous nutrition was administered.[47]

There have been numerous reports of similar severe zinc deficiency states in a few breast-fed infants, especially those delivered prematurely. Several of these cases have been attributable to an inability of the mother's mammary gland to secrete normal quantities of zinc into the milk despite an otherwise apparently normal maternal zinc status.[31] A mutation of one of the recently identified zinc transporters, ZnT-4, whose expression has been localized primarily to the mammary gland, has been proposed to be responsible for the lethal milk mutation in mice.[50] This mutation is characterized by markedly low serum zinc concentrations in the dam and in the milk, which lead to severe zinc deficiency in suckling pups within approximately the first week of life. Death follows shortly thereafter if supplemental zinc or alternative feeding is not initiated. Current understanding suggests that the abnormal zinc concentrations in human milk, with resulting severe deficiency in the breast-fed infants, may be analogous to the lethal milk mutation seen in mice and represent another inherited defect in human zinc metabolism.

Zinc deficiency has been well documented in premature and low birth weight infants. Contributory factors may include immaturity of the gastrointestinal homeostatic processes, including both absorption of exogenous zinc and conservation of endogenous zinc, relatively high urine losses, and relatively high zinc requirements when rapid postnatal growth commences. Fortification of human milk and use of fortified formulas designed to meet the needs of premature infants have been associated with positive net absorption and

retention of zinc.[51] The results of zinc supplementation trials in low birth weight infants in developing countries have resulted in a striking reduction in morbidity and mortality, illustrating the apparent vulnerability of these infants without a generous dietary intake to zinc deficiency.[52]

A wide variety of etiologic factors may contribute to more moderate and mild zinc deficiency states. An "absolute" dietary deficiency is rare, although it may occur with the use of synthetic diets lacking zinc or in other exceptional circumstances. Usually, however, the diet is deficient in zinc because of special needs for rapid growth, excessive losses of endogenous zinc (intestinal and urine), and/or dietary factors that have an unfavorable effect on zinc bioavailability. Older breast-fed infants are susceptible to zinc deficiency because of the low zinc concentrations in human milk by 6 months. Deficiency has been documented in infants in impoverished conditions, in whom both a combination of complementary foods with low zinc content and/or bioavailability and a high infectious burden may contribute to the risk of deficiency.[53,54] Poor bioavailability of zinc, attributed to high levels of dietary phytate and fiber, coupled with low animal protein intakes, was considered to be the major etiologic factor in the syndrome of adolescent nutritional dwarfism in Egypt and Iran.[12] As phytate intakes are high in many developing countries owing to dependence on plant staples such as maize, wheat, or legumes, there is special concern about the adequacy of zinc intake in children in the developing world. Zinc deficiency in malnourished Jamaican infants was most pronounced in infants who were rehabilitated with a soy protein formula, probably because of the adverse effect of phytate on zinc absorption. Another important factor in this instance was the high zinc requirement necessary to meet the needs of rapid growth during the recovery phase.

The subject of zinc bioavailability is also of special importance in infant feeding because of the infant's dependence on one food. Bioavailability of zinc from human milk is considerably more favorable than that from cow's milk or infant formulas.[55,56] "Humanized" cow's milk formulas require supplementation with zinc to prevent limitation of infant growth by an inadequate zinc intake.[16] Excessive iron may inhibit zinc absorption, and iron-fortified formulas require additional zinc. The potential for interaction among trace elements at the level of gastrointestinal absorption adds to the complexity of determining optimal quantities of trace elements in infant formulas.

The risk of zinc deficiency is enhanced in certain disease states owing to malabsorption of zinc or excessive losses.[4] Fat malabsorption or intestinal inflammation may impair zinc absorption and enhance losses of intestinal endogenous zinc, as in regional enteritis,[21] celiac disease, and cystic fibrosis.[57,58] Excessive urinary losses of zinc occur in liver disease,[59] diabetes mellitus, sickle cell disease,[22] nephrosis, and catabolic conditions.[4] A number of chelating agents, diuretics, and other drugs can also cause excessive zinc excretion. More extensive data are needed to determine whether such clinical conditions pose a significant risk to zinc status.

Diagnosis of Zinc Deficiency

The characteristic distribution of the skin lesions facilitates the clinical diagnosis of severe zinc deficiency states. Unfortunately, however, the clinical features of more moderate and mild zinc-deficient states are nonspecific. Currently, laboratory parameters are of only limited value in the confirmation of zinc deficiency. Plasma zinc concentrations are markedly depressed (< 40 μg/dL) in the severest deficiency states, and moderate hypozincemia (40 to 60 μg/dL) occurs in more moderate zinc deficiency states. However, plasma zinc levels may be depressed to this extent in other circumstances as well, including the physiologic decline that occurs in pregnancy and that attributable to the effects of various stresses, including infections, in redistributing body zinc. Hypozincemia is not a consistent feature of mild chronic zinc deficiency states. Interlaboratory differences in normal ranges make it necessary to use local normal ranges for reference purposes. Serum zinc levels have been reported to be higher than plasma zinc levels; this is attributable to a delay in separation from red cells.[60] Erythrocyte zinc is little affected by zinc deficiency and is not a sensitive index, although zinc is primarily an intracellular cation. Leukocyte zinc concentrations as an index of status have not withstood the test of time. Hair zinc levels may be markedly depressed in mild zinc deficiency states but are normal in severe zinc deficiency when hair growth is arrested. Difficulties in interpretation severely limit the value of hair analyses, especially in infants and very young children. Urine excretion rates are diminished in marked zinc deficiency, but this is not a sufficiently sensitive assay. Unfortunately, no blood zinc fraction has been identified that will provide a good measure of zinc status or that is comparable to serum ferritin levels in the assessment of iron status. Initial comparisons of lymphocyte metallothioneine messenger RNA levels in conditions of zinc restriction and supplementation appear promising but require more corroboration.[61,62] Serum alkaline phosphatase activity is depressed in severe zinc deficiency states and increases with zinc supplementation in cases of more moderate zinc deficiency. However, this assay is not a sufficiently specific diagnostic tool used alone, and no other assays of zinc-dependent enzymes have yet proved satisfactory. Because of the limitations of currently available laboratory indices in the detection of mild zinc deficiency states, the most reliable approach remains the demonstration of the effects of zinc supplementation under adequately controlled conditions.

Treatment of Zinc Deficiency

Acrodermatitis enteropathica can be treated effectively with 40 to 50 mg/day of elemental zinc administered as the sulfate, gluconate, or other salt. One milligram of elemental zinc is equivalent to 4.4 mg of $ZnSO_4$ $7H_2O$, 7 mg of zinc gluconate, and 2.8 mg of zinc acetate (anhydrous). This dose is not dependent on body weight, but requirements in infants and toddlers with acrodermatitis enteropathica may be considerably less (ie, zinc, 20 to 30 mg/day). In severe zinc deficiency in premature breast-fed infants, temporary zinc supplements are necessary until other sources of zinc are added to the diet. Most other milder cases of zinc defi-

ciency can be treated effectively with zinc, 1 mg/kg body weight/day, up to a maximum of 20 to 30 mg zinc/day. Somewhat larger quantities may be required in the presence of excessive ongoing losses or malabsorption.

Maintenance intravenous requirements in adults are approximately 2 mg and in infants 100 μg/kg body weight/day. In premature infants, 300 μg/kg body weight/day have been recommended.[8] Ongoing losses through the gastrointestinal tract owing, for example, to intractable diarrhea may increase the intravenous requirement 10-fold.[47] For intravenous administration, zinc chloride is frequently used; 1 mg zinc is equivalent to 2.1 mg $ZnCl_2$.

Toxicity

Acute toxicity is rare but can occur, for example, from the ingestion of large quantities of pharmacologic preparations of zinc or from the consumption of acidic drinks from galvanized cans. Symptoms are usually limited to diarrhea and vomiting, but there may be severe lethargy. Toxicity has also resulted from storage of dialysis water in a galvanized tank. Administration of zinc in quantities of 50 mg/day to adults can cause anemia owing to copper deficiency and may depress plasma high-density lipoprotein cholesterol levels. Even lower doses may impair copper balance.

Absorption and Metabolism

Fractional absorption of zinc averages about 60% when ingested in solution in water but is usually only in the range of 20 to 40% from composite meals or infant formulas. Fractional absorption of zinc from human milk and some synthetic formulas approaches that of zinc absorption when taken with water alone.[55,56] On the other hand, fractional absorption is depressed by certain dietary constituents, notably phytate (inositol hexaphosphate; see next section). Total absorption of zinc is considerably greater than net (apparent) absorption owing to the substantial intestinal excretion of endogenous zinc. The postprandial secretion of endogenous zinc into the intestinal lumen, mainly via the pancreas and the small intestinal mucosa, is greater than fecal excretion of endogenous zinc, and reabsorption of some of this secreted zinc is likely to be necessary if balance is to be maintained.[4] Even with reabsorption, the intestine is the major route for excretion of endogenous zinc. Approximately 0.5 mg/day of zinc is excreted by adults in the urine, and in temperate climates, a similar quantity is lost in the sweat. The intestine has a major role in the maintenance of zinc homeostasis. Higher zinc intake will be accompanied by diminished fractional absorption, but when dietary zinc is limited, intestinal conservation of endogenous zinc appears to have the greatest role in maintaining or restoring zinc balance.[4,63] The ability of the intestine to conserve endogenous zinc may be impaired by a high intake of phytate from vegetable foods and by malabsorption, including cystic fibrosis.[58,64]

Absorption of zinc occurs by a saturable mechanism that is consistent with a carrier-mediated or enzyme-dependent process. There is a rapid initial phase followed by a slower phase that probably involves two different mechanisms. Data from studies in humans suggest that absorption occurs primarily in the proximal small bowel.[4] Mechanisms of absorption of exogenous dietary zinc and of secretion and reabsorption of endogenous zinc at a molecular level remain to be elucidated.[65,66] The metabolism of zinc is complex. About 10% of total body zinc, 100 to 200 mg, intermixes with circulating plasma zinc within 2 days.[67] This zinc is thought to be of special physiologic importance to many of the zinc-dependent metabolic processes in the body, and it is also this zinc that is vulnerable to dietary zinc restriction. This is likely to explain why symptoms of zinc deficiency occur with very little change in total body zinc. It has been found that the quantity of readily exchangeable zinc has a strong positive correlation with dietary zinc and an even stronger correlation with quantity of zinc absorbed.[4,63] A substantial part of this rapidly exchanging zinc, which is thought to be important for many zinc-dependent processes, is located in the liver. Humoral factors that may increase liver uptake include cytokines (interleukin-6), corticosteroids, and glucagon. Interleukin-6 and other cytokines are responsible for the decline in plasma zinc associated with infections.

In the systemic circulation, approximately 75% of the plasma zinc is loosely bound to albumin, and most of the remainder is bound to α_2-macroglobulin. A small fraction is bound to amino acids. The normal zinc concentration in plasma averages about 0.85 μg/mL (13 μmol/L), with a range from 0.70 to 1.00 μg/mL. The zinc concentration in erythrocytes, most of which is incorporated in carbonic anhydrase, is approximately 12 μg/g wet weight. Leukocyte zinc concentrations are higher, with mean literature values of about 100 μg/10^{10} cells. The highest known zinc concentrations are in certain regions of the eye, including the retina. Bone, prostate, and hair all have concentrations near 100 μg/g or even greater. Muscle, liver, and kidney contain about 50 μg/g, whereas the value for heart and intestinal mucosa is 20 to 30 μg/g. The total body zinc content of an adult has been calculated to be about 2 g.[1]

Dietary Requirements

The results of recent studies of breast-fed and formula-fed infants using zinc stable isotope techniques allow reasonably accurate factorial estimates of zinc requirements. The major route of endogenous zinc excretion is via the intestine. In fully breast-fed infants receiving mature human milk, conservation of endogenous zinc is critical to maintaining positive net absorption and averages approximately 50 μg zinc/kg body weight/day.[55] Because the amount of endogenous fecal zinc is positively correlated with dietary zinc intake and absorbed zinc, this figure is considerably higher in formula-fed infants receiving zinc-fortified formulas.[56,68] Allowing 10 μg zinc/kg body weight/day for urine, sweat, and integumental losses, total calculated minimal endogenous losses are 60 μg zinc/kg body weight/day. With an average fractional absorption of approximately 0.5, this figure translates into a dietary zinc requirement of approximately 150 μg zinc/kg/day. Actual zinc intake of breast-fed infants varies considerably over the first 3 months of life as milk zinc concentrations decline. Mean intakes at 5 months of age have been found to be close to

this projected dietary requirement.[69] Retention required for normal growth is approximately 20 μg zinc/g new tissue. In the young infant, the growth requirement may therefore reach 600 μg zinc (ie, approximately 150 μg zinc/kg body weight/day) or more per day, but part of this may be met by hepatic stores acquired in utero.[70] In the older infant and toddler, retention required for normal growth will have declined to approximately 300 μg zinc/day or approximately 30 μg zinc/kg/day. Factorial estimations are higher for rapidly growing premature infants, for malnourished infants during the "catch-up" growth phase, and to compensate for unusual endogenous losses that occur, for example, with diarrhea and malabsorption.

The AI of 2 mg zinc/day for 0 to 6 months is based on the zinc intake of exclusively breast-fed infants at approximately 2 months of age (Appendix 2). This does not imply that lower zinc intakes of exclusively breast-fed infants at 4 to 6 months are inadequate. EARs and RDAs for older infants and children have been calculated by extrapolation from factorial data for infants, as described above, or adults. These RDAs are substantially lower than those in the tenth edition of the RDAs and, in contrast, are based on calculations of requirements that are substantially higher than those published by WHO.[7] Although further research is necessary, they are the best available figures that may well be subject to only minor refinements in the future. In contrast, the Tolerable Upper Intake Levels (Uls) have simply failed to take into account the fact that the majority of North American infants and young children who are not exclusively breast-fed consume substantially more zinc than the Uls, with no detectable evidence of any harm. It is assumed that these aberrant levels will be revised at the first opportunity and, meanwhile, should not alone influence food fortification or zinc supplementation decisions.

Zinc in Foods

The highest concentrations of zinc are found generally in animal products, especially meats; whole grains, nuts, and legumes also contain substantial quantities of zinc, but this is less likely to be bioavailable.[71] The zinc content and bioavailability of typical complementary foods for the older breast-fed infant vary widely.[54] The choices available will strongly influence the risk of deficiency to the older infant.[72] Several ready-to-eat breakfast cereals and some infant cereals are now fortified with zinc as well as iron and other micronutrients. The zinc content of human milk declines by several-fold from colostrum to mature milk. Concentrations are not influenced by maternal zinc intake when dietary intake is generous. Whether this is also true in populations with marginal intake or less favorable bioavailability remains uncertain.[73] Infant formulas and a wide range of special formulas are now routinely zinc supplemented/fortified. An overview of the zinc and copper content of major food items is given in Table 6-5.

COPPER

Copper-dependent redox reactions developed very early in the evolutionary process. Because the earth's atmosphere changed from a reducing to an oxidizing environment, copper, together with iron, has been involved at the active sites of respiratory proteins. A mammalian nutritional requirement for copper was first demonstrated in 1928, and subsequent studies revealed numerous copper-dependent mammalian enzymes. During the 1920s, several reports suggested that copper supplements may have a role in the treatment of some cases of hypochromic anemia in infants and adults, but the occurrence of human copper deficiency failed to achieve recognition until 1964.[74] Since then, copper deficiency has been identified in several special circumstances, but its frequency and the extent of its clinical importance in some conditions remain unclear, for example, in the very low birth weight premature infant.

Although beyond the scope of this chapter, an introduction to copper would not be complete without reference to two inborn errors of copper metabolism, which have attracted more clinical interest than has human copper deficiency. The central role of copper in the pathophysiology of Wilson's disease was recognized in 1945 and of MSHS in 1962. The research stimulated by these inborn errors of copper metabolism has led to a clearer understanding of normal human copper metabolism. It is now recognized that these two conditions represent disruption of copper transport across cell membranes. The two homologous cation-transporting P-type adenosine triphosphatases (ATPases), the Menkes P-type ATPase (MNK) and Wilson ATPase (WND), are the gene products primarily responsible for cellular copper homeostasis. The MNK functions in copper, trafficking to the secretory pathway for efflux from cells, including enterocytes. In Menkes' syndrome, there is reduced copper absorption and placental copper transport. Although the pathophysiology of MSHS is complex, at least some of the principal clinical features can be attributed to a de facto severe copper deficiency state, at least in certain tissues, including the brain. The WND P-type ATPase also functions in copper trafficking to secrete excess copper into the biliary canalicular system. In Wilson's disease, mutations of the WND ATPase result in copper accumulation.[75,76] Hence, recognition of the role of disordered copper metabolism in these diseases has helped to improve our understanding of the effects of severe human copper deficiency and of copper toxicity.[77]

Clinical Features of Copper Deficiency

The principal features of copper deficiency are hypocupremia, a hypochromic, normocytic anemia that is unresponsive to iron therapy, neutropenia, and osteoporosis. The bone marrow shows megaloblastic changes and vacuolization of the erythroid series. Iron deposits may be seen by electron microscopy in mitochondria and in some of the cytoplasmic vacuoles in red blood cell precursors. Maturation arrest of the granulocytic series may be evident. Iron stores in the intestinal mucosa, reticuloendothelial system, and liver cells are increased. The anemia is initially hypoferremic but later becomes hyperferremic because of the decreased uptake of transferrin-bound iron by the developing erythrocytes.

TABLE 6-5 Trace Element Content of Common Foods

Item	*Zinc (mg/100 g)*	*Copper (mg/100 g)*
Meat group		
Regular ground beef	4.4	0.06
Round steak	5.8	0.05
Beef liver	5.1	4.6
Chicken—drumstick, fried	2.7	0.01

Early radiologic findings are osteoporosis of the metaphyses and epiphyses and retarded bone age. Typical findings in the established case are increased density of the provisional zone of calcification and cupping with sickle-shaped spurs in the metaphyseal region.[78] Other skeletal abnormalities include periosteal layering and submetaphyseal and rib fractures.

Other clinical findings have been observed in association with copper deficiency, especially in premature infants.[79,80] These are pallor, decreased pigmentation of skin and hair, prominent superficial veins, skin lesions similar to those of seborrheic dermatitis, failure to thrive, diarrhea, and hepatosplenomegaly. Features suggestive of central nervous system involvement are hypotonia, lack of interest in outside surroundings, psychomotor retardation, apparent lack of visual responses, and apneic episodes. In MSHS, there is severe and eventually fatal central nervous system involvement owing to disordered copper metabolism within the brain cells, which probably results in localized intracellular deficiencies at physiologically important subcellular sites. Other features attributable to copper deficiency in this complex entity include the hair changes, which are reminiscent of the wool of copper-deficient sheep and which led to the initial recognition of the role of disordered copper metabolism; hypothermia; and evidence of defective elastin and collagen formation.

Copper-deficient animals exhibit a number of characteristics similar to those seen in human ischemic heart disease, for example, hypercholesterolemia, decreased high-density lipoprotein cholesterol, hypercoagulability, and cardiac arrhythmias.[81] Premature ventricular contractions have been linked to copper intake in humans,[82] but this has not been supported by other trials of copper depletion.[83,84] Thus, an association between copper deficiency and ischemic heart disease remains an unproven hypothesis.

Biochemistry and Biochemical Correlates

Copper is an essential component of several oxidase enzymes, the decreased activity of which can explain many of the features of copper deficiency. Cytochrome oxidase is the terminal enzyme in the electron transport chain and catalyzes the oxidation of reduced cytochrome-*c* by molecular oxygen, which is itself reduced to water. This enzyme, which is necessary for normal cellular respiration, has been shown to be markedly reduced in the brains of copper-deficient lambs suffering from swayback. Reduced activity of this enzyme may be responsible for certain other features of copper deficiency, for example, the hypothermia that occurs in MSHS.

More than 90% of the circulating copper in plasma is tightly and specifically bound to ceruloplasmin, a glycoprotein that contains six copper atoms per molecule. The functions of this protein, which was first identified in 1948, have been and continue to be the focus of considerable interest and controversy. Roles in copper metabolism include copper transport, mobilization of iron for transfer in the plasma, and regulation of the biogenic amines.[84] Ceruloplasmin (ferroxidase I) exhibits enzymatic ferroxidase activity and is necessary for the oxidation of ferrous iron stored in the liver and bone marrow to ferric iron. This is an essential step in the release of iron from body stores and its attachment to transferrin for transport to developing erythrocytes in the bone marrow.[85] Aceruloplasminemia, an autosomal recessive condition in humans, does not produce obvious disordered copper metabolism but results in iron accumulation in tissues.[75] There is a second copper-containing enzyme in the circulation, designated ferroxidase II, which may have a role in preventing anemia in Wilson's disease when ceruloplasmin levels are low. Depressed activity of the ferroxidase role of ceruloplasmin is likely to be related to the hypoferremic, hypochromic anemia of copper deficiency. However, there are, in addition, abnormalities of iron metabolism within the erythroid cell line, and it appears that intracellular transport of iron is defective, so that, despite an abnormal accumulation of iron, there is a lack of iron available for normal heme synthesis in the

mitochondria. The pathologic mechanisms for the neutropenia remain unexplained.

The bone lesions of copper deficiency are attributable, at least in part, to a lack of copper-dependent amino oxidases or, more specifically, lysyl oxidase, which is required in the cross-linking of collagen. Similar oxidases are necessary for this cross-linking of elastin, defects that are responsible for the gross structural defects seen in arteries and veins in copper-deficient animals and in MSHS. Lysyl oxidase catalyzes the oxidative deamination of ε-amino groups of lysine, which are necessary for the synthesis of desmosine, which, in turn, is essential for the cross-linking bonding of elastin.

Among other copper-containing oxidases is tyrosinase, which catalyzes the first two steps in the oxidation of tyrosine to melanin. Lack of pigmentation is a prominent feature of copper deficiency in some species but is only mild in human copper deficiency. Superoxide dismutase contains two copper atoms and two zinc atoms. Copper proteins previously given other names such as cerebrocuprein, hepatocuprein, and erythrocuprein are now known to be superoxide dismutase, which catalyzes the dismutation of superoxide-free radical ions:

$$O_2^- + O_2 + 2\ H^+ \rightarrow O_2 + H_2O_2$$

Detoxification of dangerous free radicals within the cell is of the greatest importance, but little is known about the activity of this enzyme in human copper deficiency states and what role decreased activity may play in the pathophysiology of copper deficiency.

Etiologic Factors in Copper Deficiency

The first cases of human copper deficiency were reported in infants and children in Peru who were recovering from protein-energy malnutrition.[86] Prior to their initial hospitalization, the infants had long histories of inadequate nutrition, which consisted mainly of diluted milk. Cow's milk is a relatively poor dietary source of copper, and copper deficiency has been reported in otherwise healthy infants whose diets have consisted primarily of unmodified cow's milk.[87] Frequent episodes of diarrhea were thought to contribute to the copper loss in the malnourished infants, although the diarrhea may have resulted in part from the copper deficiency state. Symptoms of copper deficiency did not usually appear until late infancy, when the child was recuperating from the protein-energy malnutrition but receiving a milk-based diet relatively low in copper. Neonatal stores of copper would have been dissipated by this age. In a retrospective analysis of these data, it was concluded that about one-third of the malnourished infants were copper deficient, including 25% who were deficient on admission.[86] Copper deficiency in association with malnutrition is not limited to Peru and is probably not uncommon. For example, copper supplementation was associated with improved growth rates in copper-deficient Chilean infants recovering from malnutrition.[88]

The term infant accumulates substantial hepatic stores of copper, which is attached to metallothioneine during the last 3 months of gestation. These stores are released postnatally and are thought to ensure protection of the young infant against copper deficiency. Very low birth weight infants born prematurely do not have the benefit of these stores and have very little copper at birth.[89] Although premature infants are at risk for copper deficiency, positive copper balance is apparently achieved in early postnatal life in premature infants with current fortification of human milk and formulas, although the adequacy of retention is not yet clear.[51,90] Symptomatic copper deficiency was documented in formula-fed premature infants in the early 1970s, a time when cow's milk formulas in the United States were not supplemented with copper, at least to the extent that is customary today.[79,80,90] The copper content of unmodified cow's milk is usually lower than that of human milk, and levels may be further decreased during processing. The incidence of copper deficiency in very low birth weight infants has been substantially reduced by the routine use of copper-fortified premature infant formulas.[91] The extent to which a mild deficiency contributes to osteoporosis, anemia, and to otherwise unexplained neutropenia in this population is unknown.[90]

Copper deficiency has been observed during intravenous feeding in both infants[92] and adults. Other causes of human copper deficiency include intestinal malabsorption syndromes, chronic diarrhea, and chelation therapy. Symptomatic copper deficiency has also been reported in normal infants who were fed primarily unmodified cow's milk and who developed severe anemia, neutropenia, and bone changes at the age of 6 months.[87] High intakes of zinc and possibly iron can precipitate a deficiency of copper.[90,93] Human copper deficiency has been documented in an infant and in adults who have received high doses of zinc therapy.

Diagnosis of Copper Deficiency

Both plasma copper and ceruloplasmin levels are depressed in copper-deficiency states. Unfortunately, these parameters are also influenced by other factors, some of which are likely to be operative when the possibility of copper deficiency is considered. Ceruloplasmin synthesis is limited in the liver of the term neonate, and neither serum copper nor ceruloplasmin concentrations reach adult levels until at least 1 month of age. In the very low birth weight infant, copper concentrations are even lower, averaging about 0.30 to 0.40 μg/mL, and do not start to increase until 41 weeks of gestational age.[94] It has been suggested that concentrations lower than 0.25 μg/mL may be abnormal in the young preterm infant and may be associated with neutropenia.[90,94a] However, the interpretation and value of the data on serum copper levels prior to 40 to 44 weeks of gestational age remain uncertain. By 6 months of postnatal age, serum copper and ceruloplasmin concentrations are similar to, or higher than, adult levels.[95,96]

Ceruloplasmin synthesis in the liver may be reduced in protein-energy malnutrition, and protein-losing enteropathy is associated with losses of ceruloplasmin, both situations leading to low circulating levels of ceruloplasmin and copper in clinical circumstances requiring assessment of copper status. Hypocupremia is also a feature of both Wilson's disease and MSHS.

Copper deficiency can also be difficult to confirm by laboratory assays when there is an increase in synthesis of ceruloplasmin. Ceruloplasmin is regarded as an acute-phase reactant and is elevated in stress situations and in response to inflammatory stimuli. Hence, hypercupremia occurs, for example, in association with infections, in the postoperative period, and in patients with neoplasms. Several hormones cause hypercupremia, most notably estrogens, and levels are increased substantially throughout pregnancy and for several weeks postpartum. Hypercupremia also occurs in obstructive liver disease owing to failure of the normal biliary excretory mechanisms.

Erythrocyte superoxide dismutase (ESOD) has been investigated as an index of copper status and has been reported to be an early indicator of disturbed copper metabolism. Its activity seems to be stable across age and sex categories and with hormonal therapy.[82] In infants recovering from protein-energy malnutrition, copper supplementation was associated with a significant rise in ESOD as well as plasma copper and ceruloplasmin concentrations.[97] Significantly lower ESOD activities were reported in preterm infants supplemented with iron from approximately 4 weeks through 20 weeks postnatal age, but there was no effect on plasma copper or zinc concentrations, hematologic indices, or growth parameters.[93]

Radiologically, separation of the epiphyses, an absence of metaphyseal fraying, and the increased density of the provisional zone of calcification may all help to distinguish copper deficiency from rickets. In contrast to scurvy, copper deficiency does not produce either a lucent line beneath the increased density of the provisional zone of calcification or a "corner sign," nor does it cause hemorrhages.

The diagnosis of copper deficiency should be considered in the presence of suggestive etiologic circumstances, particularly when there is a hypochromic anemia unresponsive to iron therapy. If the anemia is accompanied by neutropenia and osteoporosis, together with low ceruloplasmin or plasma copper levels, the diagnosis becomes likely. Confirmation will be provided by a prompt response to copper therapy with a reticulocytosis and increases in circulating neutrophils and in ceruloplasmin or plasma copper levels.

Treatment of Copper Deficiency

Nutritional copper deficiency in infants has been treated successfully with 2 to 3 mg/day of copper sulfate as a 1% solution, which provides 400 to 600 μg of copper. Maintenance requirements for copper during intravenous nutrition are 0.5 to 1.0 mg/day for adults; as little as 20 μg/kg/day appears to be adequate for infants.[8] Although higher quantities may be required to achieve a positive balance, there is concern that the immature liver of the premature infant may be prone to cholestasis and thus to hepatotoxicity from intravenous copper.

Toxicity

Copper toxicity has resulted from the accidental or deliberate ingestion of excess copper, hemodialysis with copper-contaminated solutions, and absorption of topically administered copper salts. Acute poisoning by the oral route causes a metallic taste, nausea, epigastric pain, green-blue vomitus, and diarrhea. Jaundice and hepatomegaly may occur 2 to 3 days later. Laboratory parameters are indicative of hepatic injury, and there is histologic evidence of centrilobular necrosis and biliary stasis. Jaundice may also result from intravascular hemolysis caused by free copper ions, which also cause hematuria and a direct renal tubular toxic effect, leading to oliguria and anuria. Copper salts may have a cardiotoxic effect, which is responsible for the hypotonia and coma seen in severe cases. Chronic copper poisoning is a rare entity that has been associated with drinking water with a high copper content. Indian childhood cirrhosis, a liver disorder associated with greatly increased hepatic copper concentration, has been attributed, in some instances, to copper contamination of animal milk that was introduced at an early age—milk that had been in contact with brass vessels.[98–100] Acrodynia and cirrhosis have both been attributed to chronic copper poisoning. A concentration of 2 mg/L in potable water has been recommended as safe for infants without causing gastrointestinal symptoms,[101] and this level has been provisionally endorsed by WHO.[102] However, higher levels (8 mg/L) in drinking water have not been associated with apparent toxicity, suggesting that copper intake may be only one of several factors for the expression of these diseases.[103]

Absorption and Metabolism

Approximately 35% of ingested copper is absorbed in the stomach and upper small intestine. The percentage of absorption is inversely related to the quantity ingested and is increased in copper deficiency states. The percentage of absorption also depends on the dietary form and on other dietary constituents. Absorption from human milk is favorable compared with that from cow's milk or from cow's milk–based or soy-based infant formulas. Studies using stable isotopes demonstrated a 40% absorption of copper in formula-fed premature infants, whereas absorption from human milk was approximately 70%. Studies in animal models have reported a range of copper absorption from infant formula, from 25 to 70%.[90] The wide range likely reflects the technical difficulty of accurate determinations with isotope techniques for copper.[90] Zinc, iron, cadmium, calcium, sulfate, and molybdenum will interfere with copper absorption if given in sufficient quantities. In contrast to other trace elements, cellulose and phytate have not been found to have marked effects on copper absorption.[104]

Absorbed copper passes through the portal circulation attached to albumin and is taken up by the hepatocytes. Copper may then be used by the hepatocytes for the synthesis of cuproproteins, especially ceruloplasmin, which is released 3 days later into the systemic circulation. Excess copper is excreted by the bile. Ceruloplasmin copper accounts for 90 to 95% of the circulating copper in plasma. The possible functions of this controversial cuproprotein have been discussed above. The remainder of the copper in plasma is bound to albumin and to amino acids. Copper bound to amino acids is thought to be important for uptake by cells in other organs, but ceruloplasmin copper may also be available for this purpose. The highest copper

concentrations are found in the liver, brain, heart, and kidneys. Because of their large mass, bone and muscle contain 50% of the body copper, whereas the liver contains only 10%. The liver of full-term infants contains 200 to 400 μg of copper/g of dry weight, which is 10 to 20 times the adult concentration (12 to 48 μg/g dry weight). Forty percent of neonatal hepatic copper occurs in the lysosomes attached to metallothioneine. In contrast to liver copper, brain copper increases twofold from birth to adulthood. The highest concentrations are in the locus ceruleus of the brainstem and in the cortical gray matter. In erythrocytes, the copper concentration is similar to that of normal plasma (75 to 120 μg/dL). This copper concentration remains stable; 60% is associated with superoxide dismutase. The total copper content of an adult man is approximately 75 mg.

Dietary Requirements

Earlier, minimal estimates of copper requirements for older children and adults were 2 mg/day, and most diets were thought to contain at least this quantity. The most recent EAR, based on studies in normal adults under experimental depletion conditions, was set at 700 μg/day for adult men and women. The RDA was set at 900 μg/day. Most recent national survey data indicate that median copper intakes for men and women are 1.0 to 1.6 mg/day. Six RDAs were established for children by extrapolation from the adult EAR; these are given in Appendix 2.

The young term infant is protected from copper deficiency by hepatic stores accumulated in utero. Moreover, the term infant usually achieves a positive copper balance by 1 week of age or a little later. The Food and Nutrition Board has recommended a daily copper intake of 200 μg/day (30 μg/kg/day) for infants 0 to 6 months of age and 220 μg/day (24 μg/kg/day) for infants 7 to 12 months.[6] The estimated dietary requirement of the very low birth weight premature infant is approximately 100 μg/kg/day of copper.[90]

Food Sources

The richest sources of copper are oysters, followed by nuts, liver, kidney, corn oil, margarine, and dry legumes. The contribution of drinking water to the total copper intake varies with the type of piping and the hardness of the water. Information on the copper content of food items remains inadequate for optimal calculations of dietary intakes.

Infant formulas in North America now contain a minimum of 60 μg/100 kcal of copper, and those designed specifically for the premature infant contain substantially higher quantities, with a recommended range of 100 to 250 μg/100 kcal.[90] However, on a worldwide basis, there is still considerable variation in the copper content of infant formulas, and some contain higher quantities. Unprocessed cow's milk contains about 150 μg/L of copper, which is lower than that usually found in human milk (200 to 600 μg/L of copper) at any stage of lactation.[95,105]

SELENIUM

Interest in the toxicity of selenium in mammals developed in the 1930s with the discovery of both acute and chronic forms of selenosis among grazing animals in Nebraska and Wyoming. The proved toxicity of selenium in animal husbandry in "natural" circumstances (in seleniferous areas) has resulted in extreme and only partially justified caution in adding selenium supplements to diets that are low in selenium. A beneficial role for selenium was not demonstrated until 1957, when selenium supplements were found to protect against liver necrosis in rats fed certain diets. The following year, selenium deficiency was shown to cause naturally occurring muscular dystrophy in lambs and calves, a problem that occurs in many areas of the world. The early nutritional studies indicated that there was a close association between selenium and vitamin E. In 1973, selenium was shown to be an integral component of glutathione peroxidase, an enzyme that destroys peroxides.[106] Although other selenoproteins have been identified, it is only recently that the metabolic role of a second selenoprotein has been identified. This is type 1 iodothyronine 5′ deiodinase enzyme, which is partially responsible for conversion of T_4 to T_3 in the liver.[107] Experimentally, selenium restriction has been shown to cause hypothyroidism.

Although low selenium states have been recognized in certain populations, notably in New Zealand,[107a] for many years, it was not until the 1970s, when a geochemical deficiency of selenium in a large area of China was recognized as the major etiologic factor in Keshan disease (KD), that the clinical importance of human selenium deficiency was unequivocally demonstrated. Similar individual cases, as well as skeletal myopathies, have since been identified in North America and elsewhere, although less well-characterized milder selenium deficiency syndromes have also been reported. An RDA for selenium was included for the first time in the tenth edition of the RDAs published by the National Academy of Sciences, and this has recently been revised.[6]

Clinical Features and Etiology of Selenium Deficiency

KD is an endemic cardiomyopathy affecting children and women of childbearing age. The disease, named for a county in northeastern China, has a clear-cut geographic distribution in a broad area of China from the northeast to the southwest, an area in which the selenium content of food staples has been shown to be exceptionally low.[108] A series of controlled selenium supplementation studies was associated with an 80% reduction in the incidence of KD, whereas the mortality of identified cases was only 1% of that of untreated children.[109] Some of the etiologic circumstances of KD have not been explained clearly. The seasonal and annual fluctuations in KD have raised the possibility of an interaction between nutritional state and an infectious etiology. The recognition that selenium deficiency increases the cardiovirulence of coxsackievirus in animal models by changing the viral genome sequence is particularly intriguing.[110] Further supportive evidence is the isolation of coxsackievirus from patients with KD in the selenium-deficient area of China, although not all serotypes are equally pathogenic.[111] More studies will be required to determine whether the observations in animal

models are relevant to humans with KD. However, the primary role of selenium deficiency and the public health benefits of selenium supplementation in prevention of KD have been established convincingly.

The main pathologic feature of KD consists of multiple focal areas of myocardial necrosis. Presentation may be acute, with heart failure, arrhythmias, and cardiogenic shock, or chronic, with cardiomegaly with or without congestive failure. Electrocardiographic features include low-voltage ST-T wave changes, right bundle branch block, or complete atrioventricular block. Serum selenium levels in KD are extremely low, typically less than 10 μg/L. Other laboratory indices are correspondingly low.[112]

Long-term total parenteral nutrition devoid of selenium supplements can also cause severe selenium deficiency with cardiomyopathy or skeletal myopathy.[112–114] Some of these and other case reports have involved children.[115]

Kashin-Bek disease (KBD), a degenerative osteoarthropathy named for two investigators who studied patients in Siberia in the nineteenth century, has a geographic distribution similar to that of KD within China. KBD is an endemic osteoarthropathy involving children aged 5 to 13 years. The disease is characterized pathologically by degeneration and necrosis of multiple articular cartilages and growth plates, causing enlargement especially of fingers, toes, and knees and shortened extremities. Disabilities are typically permanent. Millions of people are likely to be affected with KBD. The relationship between selenium deficiency and KBD is unclear, but evidence from epidemiologic studies suggests that selenium and iodine deficiencies may interact to cause the condition. Deficiencies of both of these trace elements often coexist in geographic regions, including China and central Africa. In Tibet, a comparison of those with and without KBD showed selenium deficiency in both groups, but iodine deficiency was more severe in those with KBD.[116]

Although our current understanding of the changes in thyroid hormone metabolism with selenium deficiency has resulted principally from animal studies, observations in human populations are accumulating. For example, in goitrous children, the severity of selenium deficiency predicted the response to iodine supplementation, both with respect to reduction in thyroid size and to improved biochemical measures of thyroid function.[117] Limited data from observational studies suggest a possible sex difference in the interaction of selenium and iodine on thyroid function, but this clearly requires additional testing under controlled conditions. Impaired T_4 conversion to T_3 and low regulation of T_3 production have been reported in children with phenylketonuria (PKU) who were fed a phenylalanine-restricted diet that was also low in selenium,[118] but this has not been found consistently in children with PKU, even those with evidence of selenium deficiency and compromised antioxidant status.[119]

Moderately depressed levels of erythrocyte glutathione peroxidase activity, hair selenium, serum selenium, or blood selenium have been found in association with protein-energy malnutrition in developing countries and in low birth weight infants.[120] One report found significantly lower selenium levels in Malawian children with kwashiorkor who had congestive heart failure compared with those who did not develop this complication.[121] The clinical significance of these low selenium states remains unresolved. Milder degrees of selenium depletion, notably those associated with low dietary levels in New Zealand and certain other geographic areas, do not appear to be associated with any adverse clinical consequences. However, subtle chronic effects cannot be entirely ruled out at this time. For example, there have been case reports of children on long-term parenteral nutrition[122] or synthetic oral diets[123] without selenium supplements who had macrocytosis and loss of hair pigment, both of which normalized following selenium supplementation.

Interest in selenium in adult and pediatric patients with human immunodeficiency virus (HIV) has been prompted by observations suggesting an ameliorating role in the pathophysiologic processes of this infection. The effects seem to be mediated by its antioxidant effects as well as inhibition of viral replication.[124] In HIV-positive pediatric patients, low plasma selenium levels were an independent predictor of mortality and faster disease progression.[125]

Biochemistry and Metabolism

Several selenium proteins have been identified, but only two of these have an established physiologic role: glutathione peroxidase and iodothyronine deiodinase (ID). Selenium is an essential component of cellular glutathione peroxidase (GPx), its plasma homologue, and the membrane-bound phospholipid-hydroperoxide GPx. Glutathione peroxidase uses two molecules of reduced glutathione to reduce hydrogen peroxide and convert it to two molecules of water. This enzyme also catalyzes the reduction of fatty acid hydroperoxides to hydroxy acids in the tissues and thus helps to protect the lipids in cell membranes from peroxidation. GPx is present in a wide variety of tissues and accounts for 90% of the selenium in erythrocytes. Messenger RNA levels of liver GPx decrease with dietary selenium restriction.[126]

ID I has been identified as a selenoenzyme. This enzyme catalyzes the conversion of T_4 to T_3 in the liver and other tissues. Selenium, as selenocysteine, is an integral component of ID, and its expression is influenced by dietary selenium. This enzyme provides the link between iodine and selenium because both are involved in thyroid hormone production.

Absorption of selenium depends to some extent on its chemical form. Selenomethionine is better absorbed than inorganic forms of selenium. Intestinal absorption of food selenium is as high as 80%. Selenium homeostasis in the rat is controlled by the kidney, and the principal route of excretion in humans is the urine. The total body selenium content is estimated to be about 6 mg in the New Zealand adult but is probably higher in areas with higher environmental levels.[127] The highest concentrations are found in liver, tooth enamel, and nails. In the body, selenium is intimately associated with specific proteins, especially as selenocysteine. More than 80% of the selenium in the rat is present as selenocysteine.

Diagnosis and Treatment of Selenium Deficiency

Selenium depletion is associated with low levels of selenium in whole blood, plasma, and hair and low erythrocyte GPx activity.[128] Care must be taken, however, to distinguish between selenium-dependent and -independent activity. A strong positive correlation between erythrocyte GPx activity and whole blood selenium levels has been found in some populations. However, it is not yet clear how well these indicators may correlate with clinical features of selenium deficiency. Remarkably, low blood selenium levels in New Zealand are not associated with any apparent deficiency symptoms.[127]

The optimal treatment for selenium deficiency has not been determined. Currently, there are no clear-cut indications for oral selenium therapy apart from the prevention of KD, for which a weekly supplement of 500 μg in younger children and 1,000 μg in older children appears to suffice. On a daily basis, these quantities are somewhat above the RDA recommended by the Food and Nutrition Board.[6]

Selenium supplements should be added routinely to intravenous infusates, at least for those patients who receive a substantial portion of their nutrient intakes by the intravenous route for more than 2 weeks. The dose recommended is 2 μg/kg body weight/day.[8]

Toxicity

Although excess selenium can cause undesirable consequences in agriculture, chronic selenium toxicity does not appear to be a problem in humans. Blood selenium levels are elevated in children living in seleniferous areas of Venezuela, but the only clinical findings were the somewhat poorly defined ones of nausea and pathologic nails.[129] Loss of hair, brittleness of fingernails, garlic odor, a higher incidence of dental caries, and increased fatigue and irritability were reported to be signs of selenosis in an early survey of residents of South Dakota, where selenium toxicity occurred in farm animals. Urinary selenium excretion was elevated in these people.

Acute selenium poisoning is rare in humans but has been reported as a result of self-administration of selenium supplements. The outcome of acute toxicity appears to depend on both the amount ingested and the type of selenium compound. Acute ingestion of sodium selenite caused garlic odor on the breath and diarrhea in several cases. Evidence of mild, temporary liver damage and cardiac abnormality was seen in one case,[130] but there were no permanent sequelae.

The highest selenium concentration observed in human milk in the United States, 60 μg/L, was used as the basis for the "no observed adverse effect level" in the 2000 DRIs,[6] and the DRI upper limit was set at 45 μg/day (7 μg/kg) for term infants 0 to 6 months. This amount was used parenterally in a supplementation trial of very low birth weight infants until the infants advanced to enteral feeds, at which time they received ~ 5 μg/kg until 36 weeks postmenstrual age, with no apparent adverse effects.[131]

Dietary Requirements

Dietary surveys of selenium intake in endemic and adjacent nonendemic KD areas have led to the conclusion that selenium requirements for adult Chinese men and women are 19 and 13 μg/day, respectively.[132] This is the quantity calculated to be necessary to prevent KD. RDAs in this country have been set at 55 μg selenium/day for adult men and women.[133]

An AI was established for infants in 2000, recommending 15 μg/day (2.1 μg/kg/day) for infants up to 6 months of age, based on a mean selenium concentration of 18 μg/L in human milk and an average intake of 780 mL/day. The AI for older infants and young children (7 to 36 months) is 20 μg/day, for older children (4 to 8 years) 30 μg/day, and for adolescents 40 to 55 μg/day.[6] These recommendations have been extrapolated for adults with a generous addition for growth; actual requirements are substantially less. The intake of formula-fed infants prior to weaning has generally been 4 to 5 μg selenium/day in this country. Although higher intakes are desirable, there is no evidence that any harmful effects have resulted from this relatively low selenium intake.

Food Sources

The selenium content of human milk depends on maternal dietary selenium intake. Extremely low values, that is, less than 3 μg selenium/L, have been reported from areas where KD is endemic.[90] Concentrations between 5 and 10 μg selenium/L have been reported from other countries where maternal selenium intake is relatively low (eg, New Zealand, Finland, and Poland).[134,135] In the United States, the mean value for the selenium content of human milk is approximately 18 μg selenium/L.[90]

The selenium content of cow's milk is generally lower than that of human milk in this country. The selenium content is reduced in the preparation of cow's milk–based infant formulas. The minimum for standard infant formulas was recommended to be 1.5 μg/100 kcal.[136] Whether the low plasma selenium and GPx levels in low birth weight infants are increased by providing generous selenium supplementation of formulas has been controversial,[137] and feeding regimens that have provided amounts adequate to increase biochemical markers of selenium status in low birth weight infants have not demonstrated clear clinical benefit. Nevertheless, premature infants are born with strikingly low serum selenium levels and GSPx, and, without supplementation, these levels decline further.[131] An expert panel recently recommended a minimum concentration in formulas for preterm infants of 1.8 μg/100 kcal and a maximum of 5.0 μg/100 kcal, while acknowledging that it was unknown whether the lower amount would be adequate or optimal for preterm low birth weight infants.[90]

Concentrations of selenium in foods vary with geographic region and soil content.[138] Generally, seafoods (approximately 0.5 μg/g), kidney, liver, and meats (approximately 0.2 μg/g) are the best sources of selenium.[139] Whole grains are also generally good sources of selenium provided that the soils in which they are grown are not low in selenium. Vegetables and fruits, with the exception of garlic, provide little. Daily intake in North America has been reported to range from 60 to 220 μg/day,[138] but in New Zealand, intake is only 6 to 35 μg/day.

CHROMIUM

A role for chromium in mammalian physiology was indicated first in 1959, when it was reported that trace amounts of this element are necessary for normal glucose tolerance in the rat. Subsequent research suggested that chromium acted as a cofactor for insulin.[140] These observations stimulated considerable interest in a possible role for chromium deficiency in the high incidence of impaired glucose tolerance in industrialized societies. Progress has been hampered, however, by a lack of laboratory indices of chromium status that would be of the greatest value in identifying appropriate subjects to include in clinical trials of chromium supplementation.

Clinical Features and Etiology of Chromium Deficiency

Experimental chromium deficiency in several animal species has been reported to result in impaired glucose tolerance in the presence of normal concentrations of circulating insulin. Features of chromium deficiency have been reported to include impaired glucose tolerance with relative insulin resistance and peripheral and/or central neuropathy. Weight loss and poor childhood growth have also been reported.

In the pediatric age range, chromium supplementation studies have been undertaken in infants and young children suffering from protein-energy malnutrition. The results of these studies, which involved the use of a single oral dose of 250 μg trivalent chromium, suggested that chromium deficiency may be one factor responsible for the impaired glucose tolerance that occurs in association with severe generalized malnutrition. Chromium deficiency appears to complicate protein-energy malnutrition in some but not all geographic areas. Turkey is notable among countries in which studies have been performed.[141] Chromium deficiency has also been reported to limit weight gain during recovery from malnutrition in Turkish infants.[142] Lack of controls in some studies and limited subject numbers hamper definitive interpretation of these data.

Several trials of chromium supplementation have been reported in adults, including elderly subjects.[143] Most of these trials have been small. Subjects have included non–insulin-dependent diabetic patients and otherwise normal subjects with evidence of impaired glucose tolerance. Supplements have always been trivalent chromium, on some occasions as an inorganic salt and on others as brewer's yeast or in other forms that are thought to have favorable absorption. In several studies, chromium supplementation has been associated with improved glucose tolerance in more than 50% of the chromium-supplemented subjects. Other apparent effects noted in some studies include a decrease in insulin response to an oral glucose load, a decrease in total blood lipids, and an increase in high-density lipoprotein cholesterol. A meta-analysis of chromium supplementation trials reported for healthy individuals and in those with glucose intolerance or type 2 diabetes found no effect of chromium on glucose or insulin concentrations in nondiabetic subjects, whereas the results from trials in diabetic subjects were inconclusive.[144]

Chromium deficiency has also been reported in patients receiving long-term parenteral nutrition.[145] Clinical features attributed to the chromium deficiency were weight loss, peripheral neuropathy, and encephalopathy. An abnormally low removal rate of intravenous glucose and an abnormally low respiratory quotient indicating difficulty in metabolizing glucose for energy, dependence on exogenous insulin, and abnormalities of nitrogen and lipid metabolism all responded rapidly to intravenous chromium.[145]

Biochemical Correlates

Although chromium may have several physiologic roles, for example, in nucleic acid metabolism, the role that has received most attention is its action as a cofactor for insulin. Experimental evidence is consistent with the hypothesis that chromium acts as a cofactor for insulin at the site of peripheral insulin receptors. Specifically, it has been hypothesized that a low molecular weight chromium-binding substance facilitates the initial attachment of insulin to its receptors both at the cell membrane and intracellularly.[146] Chromium may have to be in the form of a biologically active organic compound, termed glucose tolerance factor (GTF), to exert this physiologic effect or at least to exert an optimal effect. GTF is thought to be a nicotinic acid, amino acid, chromium compound. The biologic role of chromium as a cofactor for insulin requires further clarification and confirmation.

Diagnosis of Chromium Deficiency

The lack of established laboratory assays is especially evident for chromium, and deficiency states can be confirmed currently only by means of careful monitoring of the effects of chromium supplementation under controlled conditions. Normal values in such samples as blood plasma and urine have had a disconcerting tendency to fall as analytic techniques improve so that they remain near the detection limits of the equipment available at any particular time. Currently, normal levels for plasma chromium, for example, are considered to be only about 0.1 parts per billion (100 pg/mL). This means that it continues to be extraordinarily difficult to measure low values accurately. An additional difficulty in interpretation results from uncertainties about the physiologic meaning of low chromium levels. For example, it is thought that solitary plasma chromium levels do not reflect body chromium status but only recent intake. However, low plasma chromium levels have been reported in chromium-deficient subjects,[145] in pregnant women,[147] and in association with experimental infections that cause impaired glucose tolerance.[148] There have been conflicting reports about a measurable increase in plasma chromium in response to a glucose load. At best, this is a tedious and difficult test for assessing chromium status. Absence of a detectable plasma chromium "response" has been reported in some diabetic patients, including gestational diabetic patients, and in some elderly people. An inverse correlation has been reported between the postprandial increase in plasma chromium and fasting blood glucose. Hair analyses provide only a crude index of chromium status. Theoretically, urine

chromium levels, perhaps including measurement of the increase in urine excretion following a glucose load, should provide a useful index of chromium status. To date, however, this approach has not proved to have any conclusive value. Excessive urine chromium losses have been noted in diabetic patients, and it has been suggested that the low chromium content of adult American tissues could result from excessive urine losses triggered by a diet high in sucrose. Confirmation of excessive chromium losses during the consumption of such diets is lacking. In summary, chromium measurements in tissue and body fluids are of no proven value in the diagnosis of chromium deficiency even if adequate laboratory facilities are available.

Treatment of Chromium Deficiency

Suspected chromium deficiency states can be treated with 200 μg of trivalent chromium daily for several weeks or months in adults. In malnourished children, a single dose of Cr^{3+} 250 μg has been effective. Current recommendations for chromium during parenteral nutrition are 10 to 15 μg/day for adults or 0.1 to 0.2 μg/kg body weight/day for infants and young children. Levels considerably lower than this are probably adequate and may be preferable.

Toxicity

Trivalent chromium has a low toxicity, and there are no reports of toxicity from oral administration. The minimum lethal dose of intravenous chromium as chromic chloride in mice is 800 mg/kg. Hexavalent chromium is more toxic, but 100 parts per million in drinking water can be tolerated by animals for many years. Chromate is a local irritant and is a cause of acute and chronic disease of the respiratory system, including bronchogenic carcinoma in workers in the chromate industry.

Plasma chromium concentrations have been reported to be elevated in patients receiving total parenteral nutrition, including standard quantities of intravenous chromium, who develop evidence of renal disease.[149] Chronic interstitial nephritis has been associated with ingestion of chromium picolinate as a dietary supplement.[150,151] It has been suggested that the renal disease is a result of chromium toxicity, although animal studies have not confirmed such toxicity.[152] It is also possible that the elevated plasma chromium levels are secondary to impaired chromium excretion via the kidneys. It appears prudent to reduce or withhold intravenous chromium supplements in the presence of renal disease.

Absorption/Metabolism

Inorganic trivalent chromium is absorbed poorly. Absorption of ^{51}Cr-labeled chromium chloride is limited to approximately 0.5%. A larger percentage of chromium is thought to be absorbed from organic chromium complexes found, for example, in brewer's yeast. Chromium picolinate has been marketed aggressively with claims that it is well absorbed and has some special beneficial metabolic effects, but documentation of these claims is poor. It is thought that the liver may be the site of a specific pool of biologically active chromium and that GTF chromium is released from this pool in response to a glucose load. This response may be mediated by the response of endogenous insulin. GTF has been reported to be the only form in which chromium can cross the placenta to the fetus. The major excretory route for chromium is through the kidney, and the urine contains at least 80% of excreted chromium. The total body chromium content of adults has been estimated to be about 6 mg.

Dietary Requirements and Food Sources

Dietary chromium intakes for adults in the United States range from 25 μg/day for women to 50 μg chromium/day for men. The estimated AI for dietary chromium intake for adults set by the Food and Nutrition Board is 35 μg/day for men and 25 μg/day for women.[6] The AI recommended for infants 0 to 6 months is 0.2 μg/day and 5.5 μg/day for infants 7 to 12 months. The large increase in the second half of the first year of life reflects the contribution of complementary foods. The AIs for children and adolescents range from 11 to 35 μg/day.[6]

The mean chromium concentration of breast milk is approximately 0.25 μg/L.[153] Hence, the intake of the breast-fed infant would be about 0.2 μg/day. The bioavailability of this chromium may be high by comparison with that of other trace elements, but this has not been determined. Concentrations of chromium in cow's milk and infant formulas have been reported to be higher than those in human milk.[154]

Spices, brewer's yeast, liver, and kidney are especially good sources of chromium, but only small quantities are present in fish, vegetables, and fruit. Major losses of chromium have been reported during milling of wheat and refining of sugar, but stainless steel cooking containers may add to the chromium intake. Calculations of chromium in food have undoubtedly varied, depending on methods of sample preparation and analyses. Moreover, absolute quantities may not be as important as the form in which the chromium is present in foods.

MOLYBDENUM

The first evidence of a biologic role for molybdenum was obtained in 1930, when it was shown to be necessary for the growth of a microorganism. In 1938, the drastic scouring disease of cattle known as "teart" was traced to molybdenum poisoning. A physiologic role for molybdenum in mammals was demonstrated in 1953, when xanthine oxidase was discovered to be a molybdenum-containing metalloenzyme.[6] Experimental molybdenum deficiency in animals is difficult to achieve but has been reported in goats and lambs. Because of the difficulties of deliberately inducing molybdenum deficiency experimentally, human deficiency of this trace element was thought to be unlikely.

Clinical Features and Biochemical Correlates of Molybdenum Deficiency

The features of human molybdenum deficiency can be correlated with the known biochemical functions of this trace element. Four molybdoenzymes have been identified in

animals. The role of molybdenum in the activity of these enzymes is linked to the fact that molybdenum readily changes its oxidation states and can thus act as an electron transfer agent in redox reactions. Xanthine oxidase is best known for its role in purine metabolism, oxidizing hypoxanthine to xanthine and xanthine to uric acid. Xanthine dehydrogenase is nearly identical in structure and function except that it uses nicotinamide-adenine dinucleotide as a hydrogen acceptor, whereas xanthine oxidase uses molecular oxygen. Apparently, there is interconversion between these two molecules. Sulfite oxidase oxidizes reduced sulfur to $(SO_4)^{2-}$. Relatively little is yet known about the fourth molybdoenzyme, aldehyde oxidase.

One case of human molybdenum deficiency has been described in a patient receiving prolonged intravenous nutrition.[155] This patient was intolerant of intravenous amino acids, especially L-methionine. Clinical features include tachycardia, tachypnea, central scotomata, night blindness, and irritability leading to coma. The symptoms disappeared when intravenous amino acids were withheld. The same symptoms could be elicited by infusion of sodium bisulfite, a preservative used in the amino acid solution, but amino acid infusates without bisulfite as a preservative produced similar features. The clinical features of the disease were associated with high plasma methionine levels, low urinary inorganic sulfate, and a high level of thiosulfate in the urine. Low serum uric acid and hypouricosuria were also observed. There was rapid clinical and biochemical improvement following the addition of ammonium molybdate (300 μg/day) to the intravenous infusate.

Apart from this one case of acquired human molybdenum deficiency, there have been case reports of individuals, including children, with congenital deficiencies in both sulfite and xanthine oxidase activity.[156] Molybdenum levels in the blood were normal, but there was no detectable molybdenum in the liver. More than 50% of molybdenum in the liver is in the form of a nonprotein cofactor containing "active" molybdenum, which has to be bound to the apoprotein of xanthine or sulfite oxidase before these enzymes are active. These children, who had severe neurologic abnormalities, appeared to have an inability to synthesize active molybdenum cofactor.

Metabolism and Diagnosis of Molybdenum Deficiency

Molybdenum absorption in the rat occurs in both the stomach and the small intestine, although there are conflicting reports about the main site within the small intestine. The mechanisms of absorption have not been clearly defined. At high luminal concentrations, molybdenum may move mainly by diffusion, whereas at low luminal concentrations, active transport may provide a major pathway of absorption. Sulfur, copper, and tungsten may interfere with molybdenum absorption if their luminal concentrations are sufficiently high, and molybdenum absorption with meals appears to be much less than that of the nutrient taken alone. After an oral tracer dose, blood levels rise and fall quickly, and molybdenum moves in and out of tissues rapidly, suggesting passive transport. Liver levels fall only a little and maintain a plateau, whereas kidney levels remain relatively high. The total body content of adults has been calculated to be about 10 mg. Most of the absorbed molybdenum is excreted rapidly in the urine. There is little excretion of endogenous molybdenum through the feces.

Because of the rapid temporary effects of dietary molybdenum on blood and urine levels, these levels must be interpreted with caution in assessing molybdenum status. The combination of reduced activity of both xanthine oxidase and sulfite oxidase is strongly suggestive of molybdenum deficiency.

Toxicity

Because excess molybdenum is excreted rapidly through the kidneys, accumulation is limited, and greatly elevated levels of intake are necessary in nonruminant animals to produce toxicity. However, there is some concern that chronic moderately excessive intake can produce deleterious subclinical effects in humans. For example, villagers in areas of Russian Armenia with high molybdenum content in the soil and a daily intake of molybdenum as high as 10 to 15 mg had elevated xanthine oxidase activity, hyperuricemia, and a high incidence of gout. Similar symptoms have been reported in Russia as a result of industrial exposure. Copper metabolism appears to be mildly affected by industrial exposure to molybdenum in Colorado.[157] Serum uric acid, although normal, was higher than in controls.

Dietary Requirements and Food Sources

Daily average intakes of molybdenum for adults in the United States have been calculated as 180 μg, but there is a wide individual range.[6] Drinking water is usually a minor source, with water supplies containing 0.20 μg/L. However, molybdenum levels in drinking water are raised by mining effluents to as high as 400 μg/g in parts of Colorado. Foods highest in molybdenum are dried legumes, grains, cereal products, and organ meats. Average concentration in human milk is 2 μg/L.[6]

Recent stable isotope studies of molybdenum metabolism at different levels of molybdenum intake indicate that the minimum requirement for young adult men is 25 μg molybdenum/day.[158] The Food and Nutrition Board has established an RDA for molybdenum of 45 μg/day for adults and 2 to 3 μg/day for infants.[6] The risk of subclinical toxicity appears to be greater than that of deficiency. Naturally occurring molybdenum deficiency, uncomplicated by molybdenum antagonists, has not been documented in animals, and it is extremely unlikely that humans are at risk of molybdenum deficiency except in the most unusual circumstances, such as the prolonged use of a synthetic diet.

MANGANESE

A nutritional requirement for manganese has been established in a wide variety of organisms and was first shown to be "essential" for animals in 1931. Interest was stimulated by the discovery in the 1930s that two economically important diseases of poultry, perosis and chondrodystrophy,

were caused by manganese deficiency. There are now extensive data on animal requirements, but knowledge of human manganese requirements and status is much more limited.[6]

One probable case of human manganese deficiency has been reported in a subject who was receiving an experimental synthetic diet that was retrospectively found to be low in manganese, providing only 350 μg/day of manganese for 3 months.[159] Features attributed to manganese deficiency were hypercholesterolemia, depressed levels of clotting proteins in the plasma, weight loss, and slow growth of hair and nails. Low serum manganese levels have been reported in some diabetic and in epileptic children, and a negative manganese balance has been observed in children with pancreatic insufficiency. The clinical significance of any of these observations remains obscure. Opinions differ on the likelihood of manganese deficiency occurring in free-living human populations, although, in general, it is thought to be unlikely.[6] Experimental manganese depletion in animal models affects cartilage and bone structure and neurologic function and is associated with stunted growth and ataxia in newborns. Deficiency was also associated with lipid accumulation in liver and kidney and with hypercholesterolemia, a finding also observed in humans.[160]

The low manganese concentrations found in blood plasma (approximately 1 ng/mL) and, until recently, the difficulty of obtaining accurate analyses have hindered progress in our understanding of manganese status in humans. Erythrocyte, plasma, and serum manganese concentrations demonstrate an age-dependent pattern, with the highest levels observed in young infants. Blood concentrations increase during pregnancy, which apparently result in high manganese concentrations in the fetus. Infants born prematurely have higher blood levels than term infants, and these relatively high levels persist for several weeks postnatally.[90]

Biochemically, manganese is required for the synthesis of mucopolysaccharides through the manganese-dependent enzymes polymerase and galactotransferase. Reduced activity of these enzymes, resulting in impaired mucopolysaccharide synthesis, accounts for the extensive skeletal abnormalities and the ataxia owing to impaired otolith synthesis that are seen in animals with manganese deficiency. Pyruvate carboxylase is a manganese metalloenzyme, and manganese is a potent, although not necessarily specific, promoter of oxidative phosphorylation. Peptidases, manganese superoxide dismutase, succinic dehydrogenase, and arginase appear to be manganese-dependent enzymes.

Adults absorb less than 5% of an ingested dose of ^{54}Mn.[90] Only half of this amount is retained 10 days later, but retention of the ingested dose at 10 days is 8% in the newborn and 16% in the premature infant. Breast-fed infants maintain positive balance on much lower manganese intakes than formula-fed infants. The higher retention of infants, especially those born prematurely, may reflect higher absorption efficiency but may also reflect less efficient excretory mechanisms. Manganese absorption is enhanced by iron deficiency, but the long-term effects on retention are less clear. Neither the effects in infants of feeding iron-fortified formula on achieving optimal manganese status nor of iron deficiency on predisposing to manganese toxicity are well understood.[90] The emerging understanding of shared transport of manganese and iron in the brain and the potential for neurotoxicity highlight the potential importance of the interaction between these elements.[161] Manganese is excreted almost entirely through the bile, and urine losses are small.

Chronic manganese toxicity, owing principally to inhalation from occupational exposure, causes extrapyramidal neurologic disease similar to Parkinson's disease, Alzheimer's disease, and Huntington's disease. Such neurologic symptoms are associated with neuronal death in the globus pallidus.[162] Experimental manganese overload in rodents can cause cholestatic liver disease. Likewise, cholestatic liver disease, including that associated with total parenteral nutrition,[163] has been associated with manganese accumulation in the liver[164] and brain. Manganese, as well as copper, should be reduced or withheld from parenteral nutrition patients with cholestatic liver disease, and iron deficiency should also be avoided if possible.[161]

Adults are in positive manganese balance with an intake of 2.5 mg/day, but intakes of 0.7 mg/day result in negative balance. Human milk contains only 3 to 4 μg/L of manganese.[90,105] Hence, it appears that the requirements of young infants are extremely small. The Daily Recommended Intake (DRI) AI level for healthy 0- to 6-month-old infants was set at 3 μg/day (0.4 μg/kg), based on the mean manganese intake of exclusively breast-fed infants.[6] Formula-fed infants ingest much more manganese than breast-fed infants. Fortunately, the toxicity of manganese administered by the oral route appears to be low, and a wide range of intakes is tolerated without any apparent clinical problems. Nuts and unrefined grain are rich sources of manganese. Vegetables and fruits contain moderate amounts, whereas animal products and seafood are relatively low in this trace element.

FLUORIDE

Fluoride has both beneficial (prevention of dental caries) and toxic (fluorosis) effects on teeth, with a small margin between intakes that are beneficial and those that are toxic.

Fluoride has proved to have beneficial cariostatic properties during tooth development and, for this reason, is generally accepted as a necessary micronutrient. Other beneficial properties, for example, in ameliorating osteoporosis and protecting against arterial calcification, have not been substantiated convincingly.

Prevention of Dental Caries

Fluoride is, without question, effective in preventing dental caries.[165] The principal means by which this protection is conferred is via a local effect at the tooth surface. Fluoride decreases demineralization of the enamel when the pH of the dental plaque is low owing to the action of oral bacteria on fermentable carbohydrates. Fluoride also accelerates remineralization when the pH rises.[166] In addition, fluoride appears to decrease production of organic acids

from fermentable carbohydrates on the teeth. The fluoride concentration in saliva and in dental plaque fluid necessary to achieve effects is only 0.1 part per million.[167] The systemic effect of fluoride on teeth prior to eruption appears to be small,[168] although some protection may be conferred by incorporation of fluoride into enamel crystals during tooth development.[169]

Prior to the widespread use of fluoridated dentifrices, lifelong use of a water supply containing 1 part per million fluoride resulted in a 50 to 60% decrease in the prevalence of dental caries in permanent teeth. The beneficial effect on primary teeth was only slightly less. With the current widespread use of fluoridated dentifrices, the benefits of a fluoridated water supply have dropped to about a 25% decrease in prevalence of dental caries.[170]

Near-maximal protective effect is achieved with a fluoride concentration of 1 part per million in the drinking water. The beneficial effects are likely to be greatest among children from low-income families, whose use of fluoridated dentifrices is more restricted.

Fluorosis

Dental fluorosis is characterized by undermineralization of the surface and subsurface enamel, resulting in increased porosity. This is a developmental abnormality affecting both primary and permanent teeth.[171,172] Although the mechanism is not fully understood, fluoride appears to damage the ameloblasts that produce the enamel. The enamel appears opaque. Visible changes range from barely discernible fine white lines across the teeth to entirely chalky-white teeth. The outer enamel may break apart, and the exposed subsurface then becomes discolored.

The incidence of fluorosis has a linear relationship to calculated fluoride intake per unit body weight.[168] This relationship is evident even at levels of fluoride intake that approach zero. The infant is thought to be especially susceptible to the effects of fluoride, with fluorosis resulting once the fluoride intake has reached a level of 40 to 100 μg/kg/day. The incidence of fluorosis appears to have increased recently in communities with and without fluoridated water.[173] The teeth of greatest cosmetic concern are the permanent incisors and cuspids. Enamel formation in these teeth begins at 3 months and is completed by 7 years.

Intake of Fluoride by Infants

The fluoride content of breast milk is uniformly low whatever the maternal intake of this trace element.[174] Remarkably, the incidence of dental caries is relatively low in children who have been breast-fed as infants. Fluorosis is uncommon in children who have been breast-fed as infants. The intake of fluoride from unmodified cow's milk is also low, although not as low as from human milk. Fluoride concentrations approximate 40 and 60 μg/L, respectively.[168] The fluoride intake from formula tends to be higher and potentially in a range that can cause fluorosis, even though the fluoride content of water used in the manufacture of infant formulas has been restricted since 1978 and even when dried formulas are made up with water of relatively low fluoride content. For example, the calculated intake of fluoride of a young infant receiving 150 mL formula/kg body weight/day, prepared by mixing powdered milk–based formula (fluoride content = 690 μg/L) with water containing only 200 μg fluoride/L, is 41 μg/kg/day.[168] If a concentrated liquid milk–based formula is used, fluoride intake would be a little lower, and if isolated soy protein formula is used, the fluoride intake would be a little more. Ready-to-feed formulas contain ≤ 20 μg fluoride/L.[90] The fluoride content of bottled distilled water is low, but this does not apply to all bottled waters. Weaning foods may also provide significant quantities of fluoride, especially fruit juices, cereals, and poultry products.

Overall, the fluoride intake of young infants is less than it was two decades ago because of a decrease in fluoride content of formulas and because of the increased incidence of breast-feeding. On the other hand, the intake of older infants tends to be higher because of the progressive substitution of infant formulas for whole cow's milk at this age. Older infants may also start to use fluoridated dentifrices. Small children ingest most of this dentifrice, and the fluoride is subsequently absorbed. The AI for 0 to 6 months is 10 μg/day (1.4 μg/kg/day).[175] The American Academy of Pediatric Dentistry and the American Academy of Pediatrics recommend no fluoride supplementation for infants under 6 months of age. For older infants and children from 6 months to 3 years for whom the community water supply is less than 0.3 parts per million, a supplement of 250 μg/day is recommended. These recommendations and a broad discussion of use of fluoride to prevent and control dental caries has recently been published.[176]

It is recommended that fluoride supplements be withheld from infants because of the risk of fluorosis and the limited benefits of ingested fluoride. Fluoridated water can, with advantage, be given several times a day to infants who are feeding on a milk/formula with a fluoride content of less than 0.3 μg/L.[168]

IODINE

The clinical importance of adequate iodine intake has, like that of iron, been recognized for many years. Iodine was used in the treatment of goiter in the early years of the nineteenth century, and the major role of iodine deficiency in the etiology of endemic goiter was confirmed early in this century when the prophylactic value of iodine was demonstrated in Ohio schools. The early recognition of the nutritional role of this trace element can be attributed to the specific nature of the clinical features of iodine deficiency, the relative simplicity of measuring iodine in foods and other biologic samples, and the high concentration of iodine in one specific organ, the thyroid gland. Sixty percent of T_4 by weight is iodine, and the biologic importance of iodine is related entirely to its role in the thyroid hormones.[177]

Iodine deficiency disorders remain a global problem, despite aggressive prophylactic measures, and are the most prevalent cause of brain damage. WHO estimates that there are 740 million people affected by iodine deficiency disorders, and as much as one-third of the world's population is

at risk. Endemic goiter now occurs mainly in developing countries, typically mountainous areas such as the Andes and Himalayas and the mountainous chain extending through Southeast Asia and the South Pacific. Iodine deficiency also remains a problem in certain parts of Africa. Endemic goiter also persists in the Alps and in several Western and mid-European countries.[177]

There are two clinical types of endemic cretinism, the neurologic and the myxedematous, both of which exhibit severe mental retardation. The neurologic type prevails in most regions and is characterized by severe mental retardation, deaf mutism, spastic diplegia, and strabismus. The cretin appears normal at birth but is obviously retarded by 6 months of age. There is a characteristic vacant face with a large protruding tongue. The head appears large, and a lordosis is usually prominent. Clinical evidence of hypothyroidism is usually absent. The neurologic damage does not appear to be attributable to maternal or fetal hypothyroidism; there has been speculation that it may be owing to the direct effects of fetal iodine deficiency or to an imbalance between serum T_4 and T_3. In iodine deficiency, T_4 decreases, but T_3 remains normal or even elevated. The myxedematous type of cretin predominantly has the signs of congenital hypothyroidism but typically has only modest enlargement of the thyroid gland. This type, which may result from a combination of a dietary goitrogen and iodine deficiency, predominates in some Central African countries. Endemic cretinism is not a distinct entity in a region of endemic goiter but rather the severe end of a spectrum of neurologic damage.[177]

In mildly iodine-deficient areas, goiters may not occur until adolescence or during pregnancy. These goiters disappear in adult males, but in women they become large. Degenerative changes then occur, and myxedema or, paradoxically, sometimes thyrotoxicosis, may follow. Milder cognitive and neuromuscular impairment owing to chronic iodine deficiency is much more common.

Earlier this century, prophylaxis with iodized salt proved to be highly effective in North America. Although sporadic goiters still occur, these are apparently attributable primarily to unidentified goitrogens. Bread, water, milk, and chocolate are other vehicles that have been used to provide supplemental iodine. In areas of endemic goiter, intramuscular depot injections of 5 mL of iodized oil, providing 400 μg/mL of iodine, have also been used extensively. With the relatively high iodide concentrations now found in foods, especially milk, and the nationwide food distribution system in the United States, iodized salt is no longer needed.[178] In contrast, WHO and other international agencies have spearheaded national salt iodization programs in developing countries to eliminate the full spectrum of iodine deficiency disorders. In the 1990s, the number of countries with iodization programs doubled from 46 to 93, and there has been an accompanying improvement in the iodine status of these populations.

Measurement of iodide excretion in casual or spot urine samples provides an excellent index of recent iodide intake and is a useful assay for assessing community iodide status. Once iodide deficiency is established, T_4 levels will be decreased (normal range equals 0.8 to 2.4 ng/dL). Thyroid size and thyroid-stimulating hormone and thyroglobulin concentrations reflect chronic iodine deficiency disorders.

With the increasing levels of iodide in the US food supply, the risk of iodide toxicity is currently of greater concern than that of iodide deficiency. More cases of goiter in this country are currently attributable to excess rather than to a lack of iodide. The effects of excessive iodide intake include thyroiditis, goiter, hypothyroidism, and hyperthyroidism.[179] Intake of more than 1,000 μg iodide/day (14 μg/kg) in adults may cause toxicity, especially in those who have previously had chronic iodine deficiency.[177] The corresponding figure in young children is uncertain.

Cow's milk is a major dietary source of iodide in the United States, one that has increased in recent years. This has resulted not only from use of iodized salt in the dairy industry but also from the use of iodates as sanitizers, especially in teat dips. A 1984 report of a survey of farms in New York State indicated that milk iodide concentrations were greater than 500 μg/L from 10% of farms and between 200 and 500 μg iodide/L from another 28% of farms.[180,181] Iodide concentrations in human milk are also relatively high in this country (ie, 140 to 180 μg iodide/L), much higher than the concentration in other countries.[182–184] The recommended range for term infant formulas is 53 to 230 μg iodide/L[136]; the comparable recommendation for preterm formulas is 48 to 280 μg iodide/L.[90] Fish is notable among other foods as naturally rich in iodide. Iodide in water does not usually contribute more than 10% of intake.

The adult EAR of iodide is 95 μg/day or approximately 1 μg iodide/kg body weight/day; the RDA is 150 μg/day.[6] AIs for infants are 110 μg/day before the age of 6 months and 130 μg/day in older infants.[6] These recommendations are generous. Some centers do not add iodide to intravenous nutrition because of that already present as contamination, including that derived from iodates used to clean tube connections. We recommend providing 1 μg iodide/kg body weight/day in case these alternative sources are not always effective. This low dose carries no risk of toxicity.

CONCLUSION

Recognition of the practical importance of the trace elements in human nutrition has progressed substantially within the past few years. Concurrently, there have been exciting advances in understanding of the biology, especially the molecular/subcellular biology of these micronutrients. Recent advances have been most notable for zinc, both in terms of basic biology and global public health. Identification of "new" biologic roles for selenium and increasing respect for its importance for human health serve as a reminder that knowledge of less prominent trace elements is likely far from complete. Although, globally, issues of trace element deficiencies pose major public health challenges, there are also issues of overabundance owing especially to food fortification programs. The latter tend to underscore the importance of both vigilance toward and further research on interactions and other possible adverse effects.

CHAPTER 7

VITAMINS

Eduardo Villamor, MD, DrPH, Roland Kupka, BS, Wafaie Fawzi, MD, DrPH

Since ancient times, diet has been used to prevent and treat ailments such as night blindness, pellagra, scurvy, and rickets. However, it was not until the end of the nineteenth century that specific compounds in foodstuffs, beyond the three major sources of energy and building units (carbohydrates, fats, and proteins), began to be identified as responsible for vital functions in animals. The term "vitamine" was coined by Casimir Funk in 1911 to describe an antineuritic water-soluble compound discovered in rice bran that was initially believed to consist of an "amine" structure.[1] This compound, thiamin, would later be identified as a "vitamin," together with other vital compounds of varied chemical structures that were discovered in the early twentieth century.

Traditionally, vitamins have been classified according to their hydrophilic potential as fat soluble (hydrophobic) (A, D, E, and K) or water soluble (C, thiamin [B_1], riboflavin [B_2], niacin, pyridoxine [B_6], folate, cobalamin [B_{12}], biotin, and pantothenic acid). This chapter presents a succinct discussion on each vitamin, emphasizing the basic chemistry, physiology, and current epidemiologic knowledge, with special focus on issues pertaining to child health. The reader is referred to the Appendix to a list of the Recommended Dietary Allowances (RDAs); Table 7-1 lists the tolerable upper intake levels (ULs) of the vitamins discussed, and Table 7-2 provides a summary of sources and functions of vitamins and their assessment.

VITAMIN A

Structure and Metabolism

The importance of a substance present in certain foods for the treatment of night blindness was already known in ancient Egypt. The Greek physician Hippocrates (460–327 BC) recommended the intake of "raw beef liver, soaked in honey, once or twice by mouth" for the treatment of "nyktalopia," or the total inability to see in darkness.[2] However, it was only in the late nineteenth and early twentieth centuries that the biochemistry of this compound was clarified. In 1881, Nicholai Lunin reported that mice could not survive on a purified diet of fats, carbohydrates, proteins, and salts alone, but survival was more likely when whole milk was added.[3] Similar findings led Sir Frederick Gowland Hopkins to postulate in 1906 the existence of "unsuspected dietetic factors" that were necessary for life and growth.[4] For this he was awarded the Nobel Prize in 1929. A fat-soluble factor was isolated from egg yolk in 1909 by Wilhelm Stepp[5]; the same factor isolated from alfalfa leaves, liver, kidney, or butter fat was independently shown to promote growth in rats by Elmer V. McCollum[6,7] and Thomas Osborne and Lafayette Mendel[8,9] in 1913 and was dubbed "fat-soluble factor A." The factor was finally named vitamin A in 1920.[10] Before the discovery of vitamin A, various carotenoid pigments had been described in the nineteenth century. They were later found to be precursors of vitamin A,[11] and the structure of betacarotene, the major provitamin A carotenoid, was disclosed by Paul Karrer in 1930.[12] He won the Nobel Prize in 1937.

The term vitamin A groups a number of retinoid compounds with the biologic activity of all-*trans* retinol. Retinoids usually consist of four isoprenoid units with five conjugated carbon-carbon double bonds.[13] 11-*Cis* retinal is the oxidation product of retinol primarily involved in visual functions. Retinal can be further oxidized to retinoic acid, which possesses growth but not visual or reproductive functions. Retinyl palmitate, an ester, is the principal storage form of vitamin A. More than 600 carotenoids have been identified in nature, but only about 50 have the unsubstituted β-ionone ring that guarantees vitamin A activity. As opposed to retinol, most carotenoids have antioxidant properties owing to their long chain of conjugated double bonds.

Vitamin A is usually ingested as retinyl palmitate from animal sources and as carotenoids from plants and animal tissue. In the stomach, preformed vitamin A and carotenoids are released from protein by proteolysis; they then aggregate with other lipids and pass into the upper part of the small intestine. Bile salts stimulate pancreatic lipase and other esterases that hydrolyze retinyl esters to retinol in enterocytes. Retinol subsequently binds to the cellular retinol–binding protein (CRBP) II. Carotenoids, on the other hand, pass into the mucosal cells unaltered and are cleaved by a 15-15-oxygenase into retinal, which also binds to CRBP II. Retinal reductase and lecithin-retinol acyltransferase (LRAT) recognize the CRBP II complexes and synthesize retinol, which is then packed into chylomicra before entering the circulation via the lymphatic system.[14] Triacylglycerol is hydrolyzed from circu-

Adapted from Food and Nutrition Board. Dietary reference intakes for thiamin, riboflavin, niacin, vitamin B_6, folate, vitamin B_{12}, pantothenic acid, biotin, and choline. Washington (DC): National Academy Press; 1998, and from references 22, 88, and 99.

DFE = dietary folate equivalent; NE = niacin equivalent; RE = retinol equivalent; TE = tocopherol equivalent.

'—' denotes no evidence of adverse effects.

*Upper intake levels (ULs) represent the highest level of nutrient intake that is likely to pose no risk of adverse health effects.

†For both niacin and folate, ULs apply to intakes of synthetic forms obtained from fortified foods, supplements, or both.

‡Applies to preformed vitamin A only.

§Applies to any form of supplemental α-tocopherol, fortified foods, or both.

‖Not possible to establish. Source of intake should be from formula and food only.

TABLE 7-2 Sources and Functions of Vitamins and Their Assessment

Nutrient	*Sources*	*Major Functions*	*Deficiency Symptoms*	*Status Assessment**
Vitamin A	Preformed vitamin A: liver, fish liver oils, eggs, dairy products Provitamin A: dark green leafy vegetables, deep orange fruits, vegetables	Vision, immunity, maintenance and differentiation of cells, growth	Night blindness, xerophthalmia, hyperkeratosis, anemia, suppressed immunity	Plasma retinol (HPLC), plasma retinol-binding protein
Vitamin D	Skin synthesis, vitamin D–fortified foods (milk, margarine, butter), fish oils	Homeostasis of calcium and phosphate, mineralization of bones	Signs of rickets or osteomalacia	Plasma 25-hydroxycholecalciferol (HPLC), serum alkaline phosphatase, bone densitometry
Vitamin E	Vegetable oils, wheat germ, nuts, green leafy vegetables	Antioxidant defense	Hemolytic anemia in newborns (esp. premature), increased risk of erythrocyte hemolysis, neurologic alterations	Plasma tocopherol (HPLC), adjusted for blood lipids, detection of malonaldehyde
Vitamin K	Colonic bacterial synthesis, vegetables (esp. green leafy), milk, liver	Carboxylation of blood clotting and bone proteins	Hemorrhaging, skeletal weakness	Prolonged prothrombin time, plasma phylloquinone levels, presence of undercarboxylated proteins (PIVKAs)
Vitamin C	Citrus fruits, broccoli, bell peppers, tomatoes, brussels sprouts, many berries	Antioxidant defense, collagen synthesis, fatty acid metabolism, immunity	Scurvy, impaired wound healing, petechiae, anemia	Plasma levels (HPLC/enzyme assay), leukocyte levels, urinary levels
Thiamin	Pork, whole grains, fortified grain products, yeast	Part of TPP (thiamine pyrophosphate in energy metabolism), synthesis of neurotransmitters	Beriberi, cardiac failure, peripheral neuropathy, confusion, anorexia, weakness	Erythrocyte transketolase activity, with and without added TPP
Vitamin B_6	Poultry, fish, liver, eggs, whole-grain products, vegetables	As part of cofactors PLP (pyridoxal phosphate) and PMP (pyridoxamine phosphate) used in amino acid and fatty acid metabolism	Hypochromic and microcytic anemia, convulsions, abnormal encephalograms, weight loss, vomiting	Erythrocyte aminotransferase activity, plasma PLP (HPLC), urinary levels of 4-pyridoxic acid
Folate	Green leafy vegetables, legumes, orange juice, fortified grain products	In the form of tetrahydrofolate (THF), functions in 1-C transfer and DNA synthesis	Megaloblastic anemia, hypersegmented neutrophils, glossitis, stomatitis, neural tube defects during pregnancy, elevated blood homocysteine levels	Serum/erythrocyte folate concentrations (microbial/competitive binding assays)
Vitamin B_{12}	Animal foods (meat, poultry, milk, fish)	As part of methylcobalamin and 5-deoxyadenosylcobalamin, required for formation of erythrocytes, nerve sheaths; folate metabolism; amino acid and fatty acid metabolism	Pernicious anemia, megaloblastic anemia	Saturation of serum transcobalamin II, plasma levels (microbial/radioimmunologic assay), Schilling test for absorption, urinary methylmalonic acid levels (HPLC)
Biotin	Egg yolk, organ meats, fish, certain vegetables, colonic bacterial synthesis	As part of cofactors, used in energy metabolism, fatty acid synthesis, amino acid metabolism, glycogen metabolism	Nausea, vomiting, depresssion, lethargy, hair loss, dry, scaly dermatitis	Plasma levels (microbiologic assay)
Pantothenic acid	Widespread in foods; high levels in organ meats, chicken, beef	As part of coenzyme A, used in energy metabolism; as part of 4-phosphopantetheine (Ppant), used in fatty acid synthesis	Extremely rare; mild neurologic symptoms, vomiting, abdominal cramps	Urinary excretion, whole blood levels (radioimmunologic/microbiologic assay)

HPLC = high-performance liquid chromatography.

lating chylomicra by plasma lipoprotein lipase to form chylomicron remnants. These remnants deliver retinol to the liver, where it is taken up by hepatocytes through high-affinity receptors of apolipoproteins E and B-48. In hepatic lysosomes, an acidic hydrolase releases retinol to bind with apo-CRBP. At least three pathways could follow after this CRBP-retinol complex is formed: (1) synthesis of CRBP-retinal through retinol dehydrogenase and later retinal through retinal dehydrogenase, (2) retinol esterification mediated by LRAT, and (3) rapid mobilization of retinol catalyzed by the bile salt–independent reductase.[14]

From the hepatocyte, vitamin A can be locally transported to fat-storing stellate cells or released to the systemic circulation. For the latter, all-*trans* retinol binds to retinol-binding protein (apo-RBP), which is produced by the hepatic parenchymal cells. RBP is a single-chain polypeptide with a unique binding site for retinol. It protects circulating retinol from oxidation and destruction. Plasma concentration of RBP in children ranges from 1 to 1.5 μmol/L (20 to 30 μg/mL) and reaches adult levels (2 to 2.5 μmol/L) at puberty.[15] Under repletion conditions, RBP is 90% saturated with retinol. Both plasma vitamin A and RBP may be elevated during chronic renal failure and diminished in protein-energy malnutrition. The holo-RBP complex is secreted in plasma together with transthyretin, a tetramer that minimizes the loss of RBP in urine. The complex is then distributed to peripheral tissues or recycled back to the liver in a tightly regulated system that allows retinol molecules to recirculate more than seven times before final excretion. In the retina, holo-RBP binds to membrane receptors for internalization by endocytosis. These receptors have also been found in skin, placenta, and the blood-testes and blood-brain barriers.[16] However, they are not present in lung, kidney, or muscle. It is possible that in these and other organs, retinol is taken up directly by lipid membranes on a receptor-independent fashion.

Bioconversion of carotenoids is inversely regulated by vitamin A status[17]; this offers a potential explanation to the lack of toxic effects even at an extremely elevated intake of carotenoids. The bioavailability of vitamin A and carotenoids is influenced by the integrity of the intestinal mucosa and the intake of other nutrients.[18] Factors that increase bioavailability include the presence of fat, protein, vitamin E, zinc, and possibly iron; cooking; and processing. Dietary fiber from highly methoxylated pectins reduces absorption of carotenoids.[19] During the first 6 months of life, the most important sources of vitamin A for the infant are breast milk and vitamin A available from the infant's own liver stores. The concentration of vitamin A in breast milk is dependent on the mother's vitamin A status, so that the infant's vitamin A status may be compromised if the mother's vitamin A status is inadequate.[20] After 6 months of age, complementary foods increase in importance to meet the infant's vitamin A requirements. Among American children age 2 to 18 years, ready-to-eat cereals and milk supply more than 40% of vitamin A intakes.[21] Excessive amounts of vitamin A lead to symptoms of toxicity in infants and children such as anorexia, bulging fontanels, increased intracranial pressure, occipital edema, and bone and liver damage. Women of childbearing age in particular should be advised against consumption of vitamin A levels in excess of 2,800 to 3,000 μg of preformed vitamin A owing to increased risk of teratogenicity.[22]

Functions

Vitamin A exhibits an overarching function in gene expression that affects various physiologic processes. In the form of its metabolite, all-*trans* retinoic acid, vitamin A is a ligand for a family of nuclear receptors known as retinoic acid receptors (RARs), whereas another metabolite, 9-*cis* retinoic acid, activates two families: RARs and retinoid X receptors (RXRs). These receptors form heterodimers and bind to genes in regulatory regions known as retinoic acid response elements. The regulation of gene induction by retinoic acid can be further modulated by a large number of transcriptional mediators and repressors that include hormonal receptors. Metabolites of the retroretinoid family may also have a role in gene transcription.

Specific physiologic functions exhibited by vitamin A include vision, immunity, cell differentiation, and growth. The visual role of vitamin A occurs in the rod cells of the eye and enables sight in dim-light conditions. In this biochemical process, all-*trans* retinol undergoes isomerization and oxidation to yield the light-sensitive molecule 11-*cis* retinal. The 11-*cis* retinal molecule binds to opsin to form rhodopsin. As rhodopsin absorbs light, 11-*cis* retinal changes to all-*trans* retinal, causing it to dissociate from opsin. As all-*trans* retinal is released, opsin undergoes a confirmational change, which induces an alteration in permeability to cations, increased polarization of the membrane, and generation of a nerve impulse. Rhodopsin can be regenerated, which completes the vitamin A–dependent visual cycle (Figure 7-1).[23]

The role of vitamin A in immunity has been recently reviewed.[24] The immune effects of vitamin A seem to be mediated mainly through the acid metabolites of the vitamin, all-*trans* retinoic acid, and 9-*cis* retinoic acid. The immune response elements that are potentially associated with retinoid regulation have been reviewed.[25] At the level of mucosal immunity, vitamin A deficiency (VAD) is related to alterations in the integrity of ocular, respiratory, gastrointestinal, and genitourinary epithelia. These alterations include replacement of normal ciliated and mucus-producing cells by keratinized epithelium. Keratinization and mucin production may be additionally regulated by vitamin A at the transcriptional level. Local secretion of specific and unspecific humoral immune factors (secretory immunoglobulin [Ig]A, lactoferrin) may also be impaired by VAD.

Retinoids influence the differentiation of white cell lines in the bone marrow, as well as the function of circulating immune cells. Phagocytosis, chemotaxis, and production of free radicals carried out by neutrophils are altered in vitamin A–deficient animals, as well as the number and cytotoxic activity of natural killer cells. Retinoic acid enhances various functions of mononuclear cells in vitro, such as phagocytic activity of macrophages and release of tumor necrosis factor-α, interleukin-1 (IL-1), transforming growth factor-β, and expression of Ig recep-

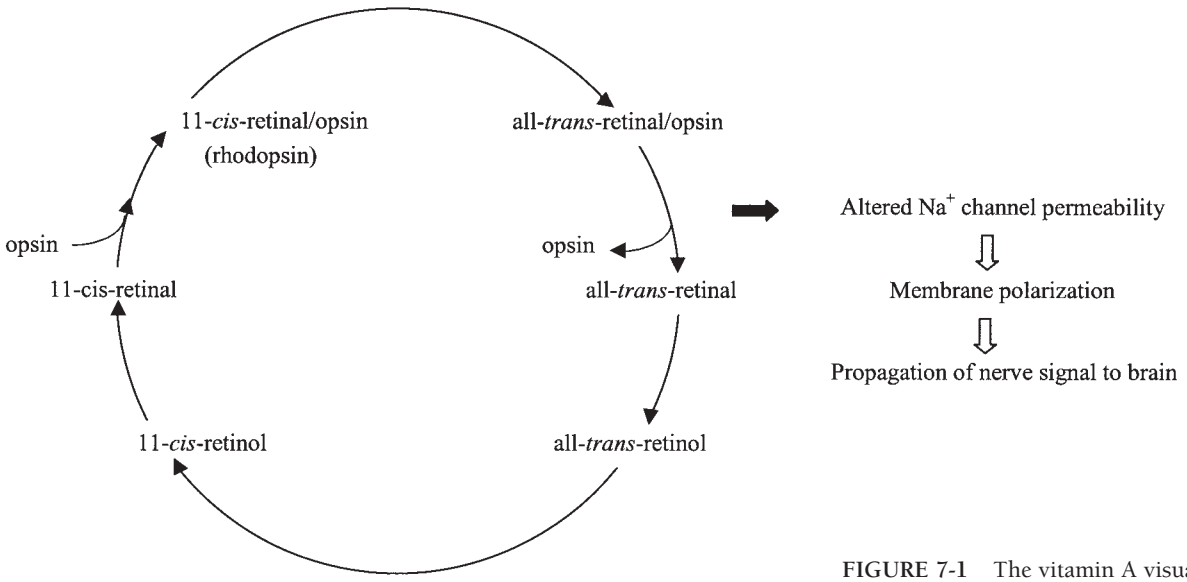

FIGURE 7-1 The vitamin A visual cycle.

tors by monocytes that modulate proliferation of B lymphocytes. It also increases the capacity of Langerhans' cells to present antigens to T lymphocytes in the skin.

Vitamin A appears to influence the antigen-specific proliferation of T lymphocytes. In animals, VAD impairs cytotoxic T-lymphocyte activity. Growth and differentiation of B lymphocytes into Ig-producing cells also requires retinol, possibly through the induction of cytokine secretion by T helper lymphocytes. The antibody response against T cell–dependent antigens is usually impaired by VAD in animals, particularly during infections that would normally induce a T helper type 2–like response. In this case, instead of high production of IgG, IL-4, IL-5, and IL-10, a T helper type 1 response seems to be favored with low antibody production and increased levels of IL-2 and interferon (IFN)-γ. During infections that predominantly stimulate a T helper type 1 immune response, it has also been suggested that VAD further up-regulates such a response. Only a few studies have directly addressed the impact of vitamin A supplementation to humans on indicators of the immune function. The protective effect of vitamin A supplementation against infant morbidity and mortality is attributed to the vitamin's vital role in sustaining and enhancing the immune response at various levels.

A range of trials has examined the effect of vitamin A supplementation on mortality among children older than 6 months who live in developing countries. In two trials, vitamin A supplements had no effect on mortality, whereas a beneficial effect ranging from 19 to 54% was observed in the remaining studies. The pooled effect from eight clinical trials was estimated to be around 30%.[26] The effect varied with the dosage and frequency of administration; small weekly or daily doses were associated with a 42% mortality reduction, whereas large spaced doses (every 4 to 6 months) were associated with a 19% risk decline. The effect also seemed greater among children ≤ 1 year old and was more strongly protective against death from diarrheal disease. More recent studies suggest that vitamin A supplements could be particularly protective against death associated with other infectious diseases such as human immunodeficiency virus (HIV) (in the absence of antiretroviral therapy).[27] The effect of supplementation of infants < 6 months is not clear. Administration of vitamin A to newborns resulted in a 64% mortality reduction in only one of three trials.[28–30] There does not appear to be a positive effect of vitamin A on respiratory infections–specific mortality in this age group.[31] Variation in the effect of vitamin A supplements across populations can be attributed to setting-specific conditions such as the presence of concomitant nutrient deficiencies that affect the absorption and use of vitamin A, the prevalence of infectious diseases, and the underlying severity of vitamin A deficiency in the population.

The effect of vitamin A on the incidence and severity of infections has been assessed in several community- and hospital-based trials. There is a clear benefit of vitamin A supplementation among children hospitalized with measles; the average mortality risk reduction is estimated to be 60%.[26] The effect is larger in children with measles-pneumonia and among infants compared with older children. Also, vitamin A reduces the risk of acquiring pneumonia in children with uncomplicated measles.[32] Children with measles and diarrhea who received vitamin A recovered more rapidly from the diarrheal episode.[33] Vitamin A also appears to have a beneficial effect on the incidence and severity of certain types of diarrhea. Several community-based studies demonstrated reductions in diarrhea-specific mortality[34] and the number of severe diarrheal episodes,[35,36] including acute watery diarrhea.[37] Among hospitalized children in Bangladesh, vitamin A supplementation reduced diarrheal symptoms caused by shigellosis[38] but not symptoms related to rotavirus and enterotoxigenic *Escherichia coli* infections.[39] The varying efficacy of vitamin A supplements between the two studies may reflect differences in the pathogenesis of diarrhea attributable to the etiologic factors involved. A few studies have shown that vitamin A supplements may increase the occurrence of cough and other signs of respiratory infection.[40,41]

It is not clear whether this is the result of an improved inflammatory response associated with vitamin A therapy. Some data suggest that vitamin A supplementation may reduce the occurrence and severity of malaria in children.[42] In observational studies on the role of vitamin A in mother-to-child transmission of HIV, protective associations were noted suggesting that vitamin A supplementation may be beneficial. However, evidence from clinical trials showed either no effect of vitamin A supplements or a detrimental effect.

Vitamin A was discovered as a growth-promoting factor[6,7]; in the 1930s, growth arrest, particularly on weight gain, was demonstrated in vitamin A–depleted rats.[43] However, the role of vitamin A in growth and body composition of humans is less clear. Positive relationships between vitamin A status and growth have been reported from observational studies, particularly in malnourished populations. Children with ocular signs of severe VAD, including night blindness and xerophthalmia, are usually stunted[44]; however, at subclinical stages of vitamin A deficiency, other determinants of poor linear growth might be important.[45] High dietary betacarotene and total vitamin A intake have been positively related to linear growth in children 2 to 19 years[46] and 6 to 72 months,[47] respectively. However, these observational studies are limited by potential confounding by other nutrient deficiencies and infection. In Asia and Africa, various randomized clinical trials of vitamin A supplementation to children showed an overall lack of effect on weight or height gains.[48–53] However, when the effect was examined in subgroups of children, vitamin A supplements were found to selectively improve the growth pattern of children at higher risk of VAD as reflected in their age above 2 years,[54,55] poor breast-feeding status,[52–56] low seasonal availability of vitamin A–rich foods,[57] and low serum vitamin A levels.[56,57] Lately, vitamin A supplementation has been related to large improvements in growth among children suffering from debilitating infectious diseases including HIV, malaria, and persistent diarrhea.[58]

Vitamin A functions in the normal metabolism of iron, and research indicates that vitamin A deficiency is a risk factor for iron deficiency anemia.[59,60] Vitamin A enhances the growth and differentiation of erythrocyte progenitor cells, aids in the mobilization of iron stores from tissues, and improves resistance to infections, all of which prevent the development of anemia.[61] The trace element zinc plays a role in the absorption, transport, and use of vitamin A.[62] Zinc supplements have been shown to restore vision under dim-light conditions, which suggests an interaction between zinc status and vitamin A–related functions.[63] However, more research is needed on the synergy between zinc and vitamin A, particularly with regard to other end points.

VITAMIN D

Structure and Metabolism

Rickets, a disorder caused by vitamin D deficiency, has afflicted humanity since Neanderthal times some 200,000 years ago; however, it was described scientifically only in the seventeenth century and was linked to a nutritional deficit in 1919 by Sir Edward Mellanby. He induced rickets in dogs fed with a synthetic diet and showed that it could be prevented with the administration of cod liver or butter.[64] This led him to propose that the dietary factor responsible for rickets was vitamin A. In 1922, McCollum distinguished the antirachitic from the antixerophthalmic factors in diet because the former did not lose its properties after intense heating and aeration and called it vitamin D.[65] Also in 1919, Huldschinsky had shown that rickets could be cured with exposure to ultraviolet (UV) rays, but the realization that there was a relationship between the UV and dietary actions against rickets only occurred later, when Goldblatt and Soames demonstrated that irradiation of food could also cure rickets[66] and when Hess and Weinstock showed that UV irradiation induced the formation of an antirachitic factor in the skin.[67]

Vitamin D designates a group of compounds derived from the cyclopentanoperhydrophenanthrene molecule, which have antirachitic activity.[68] All of these substances have a conjugated triene system of double bonds. The two most abundant forms of the vitamin are D_3 and D_2. Vitamin D_3 is also called cholecalciferol and is produced in the skin from 7-dehydrocholesterol by solar radiation. Vitamin D_2, or ergocalciferol, is derived industrially from ergosterol, a plant steroid. Given that vitamin D can be produced by the human body, there is no dietary requirement for the vitamin as long as access to sunlight is available. For these reasons, vitamin D does not strictly fulfill the definition of a vitamin, and based on its various metabolic functions, it is currently classified as a steroid hormone.[69]

Absorption of vitamin D from the diet is relatively low, with around 50% of it being absorbed. The major source of the vitamin in humans is from photochemical conversion of 7-dehydrocholesterol to previtamin D in the skin and posterior isomerization to vitamin D (Figure 7-2). Vitamin D then passes to the systemic circulation bound to its transporter, the vitamin D–binding protein (DBP).[70] DBP carries most biologic forms and metabolites of the vitamin. It is taken up rapidly by the liver but is not preferentially stored there.[68] The highest concentrations of vitamin D are found in blood, although adipose and muscle tissue in humans are also major storage sites for vitamin D.[71] During deprivation, turnover from these sites is slow, and the supply of vitamin D to peripheral organs can be sustained for a period of time.

Vitamin D_3 does not have known biologic functions[69]; first, it must be hydroxylated to 25-hydroxycholecalciferol ($25(OH)D_3$) in the liver. $25(OH)D_3$ is the most abundant circulating form of the vitamin and is considered a good proxy of vitamin D_3 status. It is transported to the proximal tubules of the kidney, where a 1-hydroxylase converts it into $1\alpha,25(OH)_2D_3$. This hydroxylase is considered the most important regulatory mechanism of the vitamin D endocrine system,[68] and its activity is regulated by the concentration of $1\alpha,25(OH)_2D_3$, parathyroid hormone (PTH), calcium, and phosphate. The second hydroxylated metabolite of D_3 produced in the kidney is $24R,25(OH)_2D_3$. Although this metabolite may play unique roles in vitamin D functions such as regulation of PTH and bone mineral-

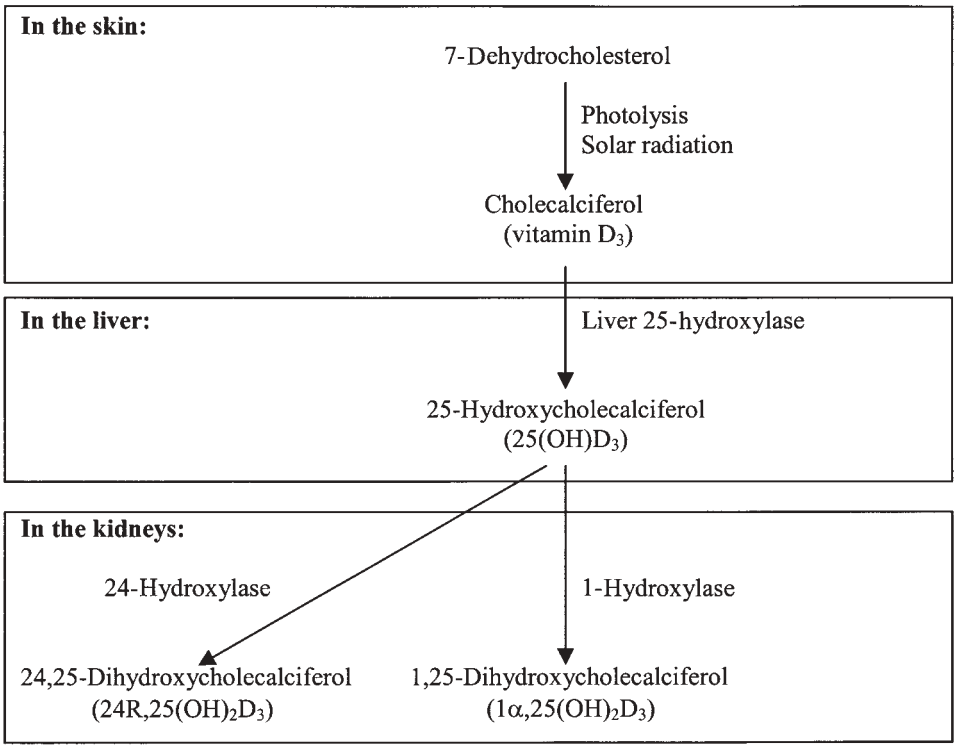

FIGURE 7-2 Vitamin D metabolism.

ization, it is likely that both $25(OH)_2D_3$ and $24R,25(OH)_2D_3$ may be required. Vitamin D metabolites are excreted mostly in the feces via the bile through catabolic pathways that are not yet well understood. Glucuronide forms are also excreted in urine.[72]

Functions

In target organs, $1\alpha,25(OH)_2D_3$ binds to its nuclear receptor, VDR_{nuc}, which has domains also found in other steroid hormone receptors. After binding, VDR forms a heterodimer with RXR, and later, the complex interacts with the vitamin D response element in the transcription control region of target genes. These activated promoter genes may also bind to coactivator proteins such as TATA, TBP, and TFIIB, and the resulting transcriptional complex is then able to modulate deoxyribonucleic acid (DNA) transcription.[73]

In addition to the nuclear receptor–mediated responses to vitamin D, there are also rapid physiologic responses triggered by the interaction of $1\alpha,25(OH)_2D_3$ with the membrane receptor VDR_{mem} in target cells.[74] These functions include the stimulation of Ca^{2+} absorption in the intestine (transcaltachia), opening of Ca^{2+} and Cl^- channels, activation of protein kinase C and mitogen-activated kinase, Ca^{2+} entry in skeletal muscle cells, and uptake of Ca^{2+} by osteoblasts.[69]

Of the more than 50 genes regulated by $1\alpha,25(OH)_2D_3$, the gene linked to the induction of the calcium-binding protein calbindin D is one of the most important ones as it is directly related to many of the known physiologic functions of vitamin D.[68] Regulation of mineral homeostasis is the classic function attributed to vitamin D. This process occurs at various target organs. In the intestine, $1\alpha,25(OH)_2D_3$ induces the transport of calcium and phosphate from lumen to plasma, possibly by activating calbindin and also through changes in the membrane composition of the brush border cells.[75] In the kidney, the major known role of $1\alpha,25(OH)_2D_3$ is the down-regulation of $25(OH)D_3$-1α-hydroxylase, thus controlling its own production.[76] It also stimulates the activity of $25(OH)D_3$-24-hydroxylase. In bone, vitamin D stimulates bone resorption that results in increased blood concentrations of calcium and phosphorus.[77] Increased serum calcium stimulates the secretion of PTH, which induces the production of $1\alpha,25(OH)_2D_3$ in kidney. However, steadily high concentrations of $1\alpha,25(OH)_2D_3$ may shut down PTH production through direct suppression of the prepro-PTH gene or via increased circulating calcium. These mechanisms are crucial in maintaining constant serum calcium concentrations independently of calcium intake. $1\alpha,25(OH)_2D_3$ may promote bone growth and mineralization through its effect on increasing intestinal calcium absorption and perhaps also by promoting differentiation of growth plate cells via chondrocyte membrane receptors[78] and augmenting the proliferation of osteoblasts and calcium uptake. Other actions of $1\alpha,25(OH)_2D_3$ on the osteoblasts include a decrease in type I collagen production and an increase in alkaline phosphatase, osteocalcin, and matrix G_{la} protein syntheses. Osteoclasts do not possess nuclear receptors for vitamin D; therefore, increased osteoclast proliferation in the presence of $1\alpha,25(OH)_2D_3$ may indicate an effect on progenitor cells or a nongenomic effect.

Vitamin D nuclear receptors have been found in other tissues, and some of their functions are being clarified. In skeletal muscle, vitamin D may be an important stimulant of calcium release during hypocalcemia. Myopathy frequently

accompanies bone diseases related to vitamin D deficiency. In the skin, $1\alpha,25(OH)_2D_3$ appears to foster differentiation of keratinocytes and protects them from UV stress.[79] Some types of psoriasis can improve with the topical application of vitamin D analogues.[80] Pancreatic beta cells respond to vitamin D with insulin secretion, and vitamin D deficiency is accompanied by impaired insulin production.[81] Some studies suggest that high doses of vitamin D may decrease the risk of type 1 diabetes in children.[82]

Various actions of vitamin D on the immune system have been reported. It induces differentiation of promyelocytic leukemia cells to macrophages or monocytes and decreases the expression of surface antigens in mononuclear cells that are involved in autoimmunity disorders. Vitamin D also inhibits the activation of B and T lymphocytes, the proliferation of activated lymphocytes, and the production of antibodies by activated B lymphocytes. T-cell suppressor lines may be enhanced by $1\alpha,25(OH)_2D_3$, whereas the activity of natural killer and T cytotoxic cells may be down-regulated. Decreased secretion of both T helper types 1 and 2 cytokines (IL-2, -4, -10, -12, and IL-13; IFN-γ; and granulocyte-macrophage colony-stimulating factor) is also related to vitamin D activity.[83,84] This has been associated with the potential development of allergies in children who are exposed to vitamin D early in life. In spite of these apparent immunosuppressing actions, $1\alpha,25(OH)_2D_3$ does not appear to induce systemic, generalized immunosuppression. Therefore, many of these findings may represent a local, vitamin D–dependent autocrine or paracrine regulation of the immune function.

Newborn vitamin D status is heavily dependent on maternal status. If a woman is deficient in vitamin D during pregnancy, her infant will accumulate insufficient vitamin D stores during intrauterine life and display low plasma concentrations of the vitamin.[85] The infant's vitamin D status is further compromised by low availability of vitamin D in the breast milk of vitamin D–deficient mothers. However, regular small exposure to sunlight can offset low dietary intakes of vitamin D. Dark-skinned individuals are at an increased risk for vitamin D deficiency at least partly owing to decreased skin synthesis of vitamin D.[86,87] Establishing dietary reference intakes for vitamin D has proven difficult owing to the major contribution of endogenously derived vitamin D to vitamin D status. Current guidelines for vitamin D are conservative in proposing levels that are adequate for children with insufficient exposure to sunshine to synthesize vitamin D.[88]

VITAMIN E

Structure and Metabolism

Vitamin E was discovered in 1922 as a fat-soluble compound in wheat and lettuce that was necessary to avoid fetal death in rats.[89] Its essentiality in humans was only recognized in the late 1960s in connection with the occurrence of hemolytic anemia among premature infants who were vitamin E deficient.[90] The potential protective role of vitamin E as an antioxidant against chronic and degenerative illness is currently an active field of research.

The term vitamin E groups all chemical compounds with the biologic activity of α-tocopherol. Tocopherols are molecules consisting of a 6-chromanol ring or head and a phytyl chain or tail. Eight naturally occurring compounds comprise the tocopherol family: α-, β-, γ-, and δ-tocopherols and α-, β-, γ-, and δ-tocotrienols.[91] The antioxidant potency of tocopherols depends on their ability to donate phenolic hydrogens to free radicals such as molecular oxygen, superoxide radicals, and peroxyl radicals and to inhibit auto-oxidation of fats. It is generally accepted that α-tocopherol (prefixed "*RRR*-," as a single steroisomer) has the highest antioxidant activity in vivo.[90] Synthetic forms of vitamin E are mainly esters and consist of a mixture of eight steroisomers (prefixed "*all-rac*-," as all racemic). These forms are less susceptible to oxidation and less biologically potent than α-tocopherol according to the fetal resorption test in rats.[92]

After ingestion, tocopherols are emulsified with bile salts in the intestinal lumen and absorbed by the enterocytes in the upper half of the small intestine through passive diffusion.[93] Absorption is inversely related to intake and reduced by long-chain polyunsaturated fatty acids. It is increased by medium-chain triglycerides.[90] At the enterocyte, tocopherols are incorporated into chylomicrons and absorbed mostly via the lymph ductus. Some chylomicron-bound α-tocopherol is transported to peripheral tissues after catabolism by lipoprotein lipase; the rest is taken up by the liver as chylomicron remnants. In the liver, α-tocopherol is reincorporated into nascent very low-density lipoproteins (VLDLs) by α-tocopherol transfer protein and recirculated through the body.[94] The precise nature and function of tocopherol-associated proteins are unclear.[95] Parenchymal cells of extrahepatic organs including adipose, muscle, and brain take up α-tocopherol from all lipoproteins, particularly low-density lipoprotein (LDL) and high-density lipoprotein (HDL), through a number of mechanisms that can be receptor dependent or receptor independent.[96] At the cell level, tocopherol is mostly localized in the membranes. In human tissues, the predominant form of vitamin E is α-tocopherol.[97] Excess tocopherol is excreted into the bile and then into the feces. The metabolic products of α-tocopherol after oxidation are dimers and trimers, as well as tocopheryl chromanoxy radicals that can be reverted to tocopherol by reducing agents such as vitamin C and glutathione. Subsequent oxidation of the tocopheroxyl radical produces tocopheryl quinone, which, after reduction, can be excreted in the feces or converted into tocopheronic acid by side chain oxidation and excreted in urine as glucuronate conjugates.[90] Other nonoxidation metabolites of tocopherol's phytyl tail are excreted in urine. These include 2,5,7,8-tetramethyl-2-(2′-carboxyethyl)-6-hydroxychroman, or α-CEHC,[98] and γ-CEHC.

Functions

Vitamin E deficiency is associated with a large number of manifestations in animals, the most common of which is necrotizing myopathy. Encephalomalacia and exudative diathesis have also been described, in addition to embryonic degeneration. Vitamin E deficiency syndromes seem

to be specific to the animal species and also appear to depend on the status of other nutrients, such as selenium and some amino acids.[90] Most recent dietary recommendations are based exclusively on α-tocopherol, recognizing that the other naturally occurring forms of vitamin E (β-, γ-, and δ-tocopherol and tocotrienols) do not have vitamin E activity.[99] In humans, vitamin E deficiency is associated with neurologic alterations,[100] as reported in patients suffering from familial isolated vitamin E deficiency and pathologies causing malabsorption such as abetalipoproteinemia, cystic fibrosis, and cholestatic disease. Erythrocyte hemolysis occurs at a plasma concentration below 5 μg/mL (11.6 μmol/L).[101]

The specific mechanisms of vitamin E deficiency syndromes are not clearly understood. However, it is accepted that the most important function of vitamin E is protection against tissue damage caused by lipid peroxidation.[102] Primordial free radicals (eg, superoxide) can be originated in normal metabolism and through the effect of toxins. These free radicals may contribute to the formation of lipid free radicals when conjugated with polyunsaturated fatty acids (PUFAs). The lipid radicals undergo a propagation sequence whose final products are lipid hydroperoxides (LOOHs). LOOHs enter an auto-oxidative chain sequence until two radicals combine in a two-electron bond. Vitamin E prevents auto-oxidation in at least two steps: (1) it traps peroxyl radicals; thus, a stable LOOH molecule is formed with a vitamin E radical subproduct; and (2) this vitamin E radical can still bind to another lipid radical. It is estimated that one tocopherol molecule is enough to protect 100 PUFA molecules from auto-oxidation.[101] Some functions of vitamin E are strongly dependent on interactions with other nutrients. The antioxidant efficacy of tocopherol is enhanced by the presence of other antioxidant systems. The glutathione peroxidase system is selenium dependent and may explain the fact that selenium reduces the severity of vitamin E deficiency and that both may act synergistically against oxidative stress.[103] Ascorbic acid (vitamin C) appears to reduce the vitamin E requirement possibly owing to the role of vitamin C in tocopherol regeneration after it has been oxidized.[104] Betacarotene also may be a coadjuvant of vitamin E in its membrane antioxidant functions; on the other hand, vitamin E increases the lymphatic uptake of betacarotene and its conversion to retinol.[105] Iron and amino acids containing sulfur may also interact with vitamin E activities.[90]

Vitamin E appears to have other functions not necessarily related to its antioxidant role. Tocopherol may be an important structural part of cell membranes that contributes to stability and permeability.[106] It regulates the synthesis of xanthine oxidase, an important enzyme in the conversion of purine bases to uric acid,[107] and modulates the activity of microsomal oxidases, protein kinases, and proliferation of smooth muscle[108] and endothelial[109] cells. α-Tocopherol decreases the genetic expression of important regulatory receptors, the collagenase and scavenger receptor (SR-A and CD36), and up-regulates the expression of connective tissue growth factor.[110] Vitamin E has positive effects on the immune function at various levels. It inhibits the activity of cyclooxygenase in macrophages, thus decreasing the production of proinflammatory prostaglandins like prostaglandin E_2[111]; it also increases the mitogenic activity of T cells and the production of IL-2[112] and IFN-γ.[113] Vitamin E has anti-DNA mutagenic damage properties[114] and down-regulates the generation of hydrogen peroxide in the mitochondria.[115] These mechanisms could help explain the protective effects of vitamin E against degenerative pathologies in humans, such as certain cancers,[116] cardiovascular disease,[117,118] and Alzheimer's disease.[119]

VITAMIN K

Structure and Metabolism

Vitamin K was discovered by Henrik Dam in 1935 as a fat-soluble compound that prevented hemorrhagic disease in chicks.[120] Almost simultaneously, Almquist and Stokstad demonstrated the antihemorrhagic properties of an ether-soluble compound from alfalfa.[121] They also suggested that microbial activity in bran and fish preparations was related to antihemorrhagic activity. Later, Dam and colleagues demonstrated that prothrombin activity was diminished in vitamin K–deficient chicks,[122] and a few years later it would be shown that other coagulation factors were also dependent on vitamin K. Dam and Karrer's groups isolated the vitamin from alfalfa, and it was characterized and synthesized as a quinone by Doisy's group in 1939.[123] The same group discovered a form of the vitamin in putrified fish meal, and, in 1958, Martius and Esser showed that vitamin K could be formed in animals from the parent compound, menadione.[124] In the 1970s, vitamin K was shown to participate in the synthesis of γ-carboxyglutamic acid (Gla).[125]

Vitamin K describes all compounds with a 2-methyl-1,4-naphthoquinone ring (menadione or vitamin K_3) that have antihemorrhagic properties in animals fed a vitamin K–deficient diet. Two natural forms of the vitamin have been described: phylloquinone or vitamin K_1, which possesses a phytyl group in the –3 carbon and is the main dietary source of vitamin K from plants, and menaquinones or vitamin K_2, which is produced by bacteria and has an unsaturated isoprenyl side chain at position –3.[126]

Vitamin K is absorbed from the first half of the small intestine in micelles that form with the presence of pancreatic enzymes and bile salts. Absorption of pharmacologic preparations of phylloquinone in adult humans is about 80%, but it is significantly lower from food sources.[127] Whereas cooking and preparation do not appear to affect the bioavailability of vitamin K, addition of fat may increase its absorption by a factor of three.[128] After lymphatic absorption, phylloquinone circulates with lipoproteins, mostly VLDL, at low concentrations (0.3 to 2.7 μmol/L),[129] and is taken up by the liver from chylomicron remnants through apolipoprotein E receptors. The main storage organ for vitamin K is the liver, although it is also found at relatively high concentrations in trabecular and cortical bone, as well as in heart, pancreas, brain, and kidney.[126] The functional significance of the menaquinones

produced in the gut is not well understood. Dietary restriction of vitamin K has been related to deficiency in healthy humans, suggesting that the bioavailability of bacteria-produced menaquinones may be low[130] and not enough to avoid deficiency. The total pool of vitamin K is smaller compared with other vitamins and is rapidly exhausted under conditions of restricted intake.[131] Phylloquinone is excreted in the feces via the bile and the urine.

Functions

Vitamin K is fundamental for the carboxylation of a large number of proteins in vertebrates and invertebrates. Undercarboxylation of these proteins decreases their affinity for calcium and may render them nonfunctional. The process of carboxylation consists of transferring a carboxyl group from glutamic acid residues in proteins to form γ-Gla, in the presence of vitamin K–dependent carboxylase, hydroquinone, carbon dioxide, and oxygen.[132] This reaction occurs at the luminal surface of the endoplasmic reticulum. After carboxylation, vitamin K is oxidized to vitamin K 2,3-epoxide, which can be successively recycled to quinone and hydroquinone in reactions catalyzed by dithiol-dependent reductases. These reductases can be inhibited by coumarinic drugs such as warfarin, which explains their anticoagulant effects. There is an alternative pathway for reducing quinone into hydroquinone, which is catalyzed by a reduced form of nicotinamide adenine dinucleotide phosphate (NADPH)-dependent enzyme and is therefore unaffected by coumarinics. It is possible to use this enzyme pharmacologically in the treatment of coumarin intoxication. Undercarboxylated proteins, also referred to as proteins induced by vitamin K absence (PIVKAs), can be used to assess vitamin K status (PIVKA-II or prothrombin and PIVKA-osteocalcin).[133]

Vitamin K–dependent proteins have been found mainly in blood and bone, although the newly discovered Gas6 protein has been found in vascular smooth muscle cell and the nervous system.[134] Blood proteins include prothrombin (factor II); factors VII, IX, and X; and proteins C, S, and Z.[135] All are synthesized in the liver and contain 12 Gla residues that facilitate calcium-mediated binding to membrane phospholipids in platelets and endothelial cells in the process of forming a clot. During the coagulation cascade, factors VII and IX activate factor X through the extrinsic and intrinsic pathways, respectively. Factor X activates the synthesis of prothrombin from thrombin. Proteins C and S are anticoagulants. The first one inhibits factors V and VII, and both increase fibrinolysis.

Bone vitamin K–dependent proteins are osteocalcin (bone Gla protein), matrix Gla protein, and protein S. Osteocalcin is produced by osteoblasts and odontoblasts and binds to hydroxyapatite crystals through its three Gla residues. Although the specific functions of osteocalcin remain unclear, it has been suggested that this protein may promote the differentiation of osteoclasts and induce bone resorption as well as closure of the growth plate. Osteoporosis has been associated with low plasmatic concentrations of vitamin K,[136] and vitamin K supplementation results in decreased undercarboxylated osteocalcin and increased bone density.[137] Supplementation is also related to lower incidence of osteoporosis and fractures[138]; however, it is suggested that these effects may be independent of the carboxylation function of vitamin K. Matrix Gla protein (MGP) appears to be an inhibitor of cartilage calcification. In animal studies, MGP depletion leads to calcification of arteries and heart valves, whereas low vitamin K intake among women is associated with calcification of the abdominal aorta.[139] This suggests a potential role for vitamin K in cardiovascular health. The role of protein S in bone is unknown; however, evidence from studies among protein S–deficient children suggests that it may be important in bone mineralization. Other recently discovered vitamin K–dependent proteins include nephrocalcin, atherocalcin (plaque Gla protein), and praline-rich Gla proteins 1 and 2.[126] Their function has not been established yet. Vitamin K appears to play a role also in the synthesis of some sphingolipids, possibly as a cofactor in phosphorylation reactions.

Deficiency of vitamin K is uncommon in adults. It may occur among patients with fat malabsorption from any cause. Some agents have been implicated in precipitating vitamin K deficiency states; these include antibiotics that inhibit the epoxide reductase (cephalosporin, cefamandole, moxalactam) and megadoses of vitamins A and E.[126] Newborns are at risk of hemorrhage during the first weeks after birth (hemorrhagic disease of the newborn), in association with vitamin K deficiency. This occurs because of limited transfer of the vitamin through placenta and breast milk and as a consequence of insufficient production of clotting factors in the liver. Prophylaxis is carried out by administering 0.5 to 1 mg phylloquinone intramuscularly or 2 mg orally within 6 hours of birth.[140] Analyses conducted by researchers in the United Kingdom in the early 1990s associated intramuscular vitamin K with an increased risk of childhood cancer, especially leukemia.[141,142] However, various subsequent studies with rigorous epidemiologic designs did not replicate these findings. Furthermore, no strong biologic evidence can support the purported association. Modification of existing recommendations supporting the use of an intramuscular dose to the infant after birth is therefore not warranted.[140] An additional motivation to administer an intramuscular dose of vitamin K to the newborn is that there is currently no licensed form of oral vitamin K available in the United States, that is, the parenteral form is given orally when needed. Some studies suggest that oral forms of vitamin K are less effective at reducing the risk of hemorrhagic disease of the newborn, yet new oral forms with greater reliability of absorption promise to be equally as efficacious as intramuscular vitamin K.[143,144] In least developed countries, stand-alone prophylactic programs of vitamin K are not recommended owing to the complicated delivery of the prophylaxis in the presence of a high percentage of at-home deliveries and constrained health budgets that should favor more cost-effective public health measures, such as prevention and treatment of infectious diseases. Vitamin K prophylaxis has been recommended for middle-income and industrialized countries given its demonstrated public health benefit.[145]

VITAMIN C

Structure and Metabolism

Medical writings from ancient Egyptians, Greeks, and Romans described a syndrome that was probably scurvy, the disease associated with vitamin C deficiency. The first modern accounts of scurvy appear in the sailing logs of the Portuguese and Spanish marine expeditions of the early sixteenth century.[146] During Vasco da Gama's expedition to the Cape of Good Hope, intake of oranges was associated with relief from the symptoms of scurvy. However, this practice did not become popular knowledge, and it was only in 1747, when James Lind conducted his famous clinical trial on board the British vessel *Salisbury*, that the dietary origin of scurvy was completely proven. It took the British navy another 50 years to routinely provide lemon juice to its sailors.[147] Zilva isolated a compound with antiscorbutic properties in 1915, and the name vitamin C was proposed because factors A and B had already been postulated. In the early 1930s, Szent-Gyorgyi, Haworth, and King isolated vitamin C and showed its antiscorbutic activity.[148] For this, Szent-Gyorgyi and Haworth received the Nobel Prize in 1937.

Vitamin C has been defined as a redox system composed of L-ascorbic acid, monodehydro-L-ascorbic acid (a free radical), and oxidized ascorbate (dehydro-L-ascorbic acid [DHA]).[149] Chemically, ascorbic acid is composed of a 6-carbon γ-lactone. Except in guinea pigs, bats, and primates, including humans, most animals can synthesize ascorbic acid from glucose via the hexuronic acid pathway. Humans lack L-gluconolactone oxidase, an enzyme necessary for the synthesis of ascorbic acid, and depend completely on the diet for the supply of vitamin C.[149] After ingestion, ascorbic acid is absorbed in the small intestine, preferentially in the distal segment, through a sodium-dependent mechanism that can be inhibited by glucose.[150] It then moves to the systemic circulation via facilitated diffusion and is oxidized to DHA, which enters the cells on glucose transporters 1, 2, or 4 by facilitated diffusion.[149] Once in the cell, it is reduced again to ascorbate by glutathione-dependent mechanisms. If this recycling reduction does not occur, DHA is degraded to oxalic acid and excreted in urine. Unmetabolized ascorbic acid is also excreted in direct proportion to intake, reaching 100% excretion after about 500 mg of an injected dose.[151] The recycling mechanism of ascorbic acid may be compromised in diabetics,[152] smokers,[153] and patients with the glucose transporter protein syndrome.[154]

Functions

Ascorbic acid maintains metal ions in a reduced state, which allows the proper function of some mixed-function oxidases in the synthesis of important molecules. Vitamin C deficiency affects collagen synthesis by impeding the hydroxylation of lysine and proline residues in precursor polypeptide chains, which become unable to fold into their final triple helical structure. The accumulation of immature collagen molecules is reflected in weakness of collagen-rich tissues and explains many of the symptoms of scurvy, including gum bleeding, bruising, and inadequate repair of damaged tissue. Vitamin C supplementation is effective in improving collagen synthesis among patients with the Ehlers-Danlos syndrome, who suffer from genetic abnormalities of lysyl hydroxylase. Vitamin C also plays an important role as a cofactor of hydroxylase enzymes involved in the synthesis of carnitine, a molecule that is necessary for the incorporation of long-chain fatty acids into the mitochondria. Carnitine deficiency and decreased oxidation of fatty acids in muscle may also be responsible for the muscular weakness characteristic of scurvy. Vitamin C is a cofactor of dopamine-β hydroxylase in the synthesis of norepinephrine from dopamine. The activation of other neutrotransmitters and hormones through α-amidation is also likely to depend on vitamin C.

Ascorbic acid possesses strong antioxidant properties. It acts as a scavenger of reactive oxygen and nitrogen radicals. In combination with vitamin E, ascorbic acid delays the formation of peroxyl radicals in LDL.[155] Vitamin C supplementation is associated with decreased concentration of oxidated DNA bases in human sperm[156]; however, a direct antioxidant effect of ascorbic acid in the nucleus has not yet been demonstrated. Some proteins may also be protected from oxidation by vitamin C. Ascorbic acid positively interacts with the glutathione system (GSH) as a scavenger of reactive oxygen radicals.

There is evidence to suggest that vitamin C is related to several aspects of the immune function. Ascorbic acid supplementation improves neutrophil chemotaxis. However, it does not appear to enhance bactericidal activity or lymphocyte proliferation. Vitamin C destroys histamine, and it has been suggested that this antihistaminic effect may be responsible for the reduction in the severity of cold symptoms that is observed among supplemented patients. In vitro assays indicate a possible antiviral role of the vitamin. It inhibits intracellular replication of HIV in chronically infected lymphocytes and inhibits the reverse transcriptase enzyme.[157] In humans, local application of ascorbic acid on herpes simplex lesions reduces viral shedding and accelerates the disappearance of the lesions.[158]

The antioxidant properties of ascorbic acid suggest that the vitamin could have protective properties against degenerative diseases such as atherosclerosis and cancer. Large supplemental doses of vitamin C have been related to decreased LDL peroxidation and improved vasomotor function in humans.[159,160] However, a protective effect of vitamin C against mortality from coronary heart disease or the incidence of cancers of the digestive tract has yet to be demonstrated in clinical trials. The potential effect of vitamin C against *Helicobacter pylori* infection is under investigation.

It is very likely that the effects of nutrients in vivo depend on interactions with each other rather than on the properties of a single nutrient. For example, the short-term absorption of nonheme iron is augmented by more than 100% by vitamin C, possibly because ascorbic acid increases the reduction of ferric iron to ferrous iron, which is less likely of chelation by phytates.[149] The benefit from this interaction in increasing the iron reserves among people consuming mainly nonheme iron seems to be lower.

THIAMIN

Structure and Metabolism

Descriptions of beriberi or *kakke*, the disease caused by thiamin deficiency, appeared in Chinese medical manuscripts more than four millennia ago. The prevalence of this polyneuritic paralysis had been traditionally higher in Far East societies with a high consumption of rice than in the rest of the world. However, it increased in Europe during the nineteenth century, with the advent of highly efficient polishing rice mills that remove the aleurone layer of thiamin-rich cells between the germ and the endosperm.[161] The first reference to a potential nutritional cause of beriberi appeared in 1884 when a Japanese surgeon, Takaki, showed that the prevalence of the disease in the navy could be reduced by feeding sailors meat, wheat, and milk instead of their usual diet, which consisted of polished rice and dried fish.[162] In 1890, a Dutch physician working in Java, Christian Eijkman, documented polyneuritis in chicken caused by a diet of polished rice and proposed that an antitoxin should be present in the bran. In 1901, Gerrit Grijns found that the antineuritic factor in rice bran was water soluble, and Casimir Funk coined the term "vitamine" in 1911 to refer to this compound.[1] Frazier and Stanton successfully used extracts of rice polishing to cure beriberi in humans in 1909 to 1915, and Roger Williams elucidated the structure of the vitamin in 1936.

Thiamin, also called vitamin B_1, vitamin F, and aneurine, is composed of a pyrimidine ring with an amino group and a thiazole ring with a sulfur group, linked by a methylene bridge. The natural form of the vitamin is a base, and the commercial form is usually a chloride hydrochloride salt. In addition to rice bran and wheat germ, thiamin is also abundant in yeast extract, pork meat and ham, animal liver and kidney, and vegetables, including peas, asparagus, and okra. The thiamin content of foods can be decreased by sodium bicarbonate, residual chlorine, excess water, sulfites, intense heating, alcohol, and irradiation with x-, gamma, and UV rays. There are also known antithiamin factors in foods, including thiaminase I, found in raw fish and fern, and thiaminase II, found in various microorganisms.[163] Some polyhydroxyphenols such as caffeic acid, chlorogenic acid, and tannins can also exhibit antithiamin properties. In humans, tea and coffee drinking may induce thiamin depletion, whereas ascorbic acid intake enhances thiamin status. After ingestion, thiamin is absorbed preferentially in the jejunum and ileum by an active, saturable, energy-dependent transport or by passive diffusion when the concentration is high. In the gut cells, phosphate esters are formed. Absorption can be inhibited by alcohol and folate deficiency.[164] Thiamin is transported from the general circulation to the liver mainly as thiamin pyrophosphate, which is the most abundant form of the vitamin. Although a specific thiamin-binding protein has been identified, its specific role is still unclear. The uptake mechanism by peripheral tissues varies and may consist of facilitated diffusion (as in erythrocytes) or active transport. High concentrations of the vitamin are found in skeletal muscle, heart, liver, kidney, and brain. Tissue depletion of thiamin occurs relatively rapidly under low dietary intake, and this is the reason why thiamin deficiency is one of the first to appear during nutritional emergencies.

Functions

Thiamin pyrophosphate (TPP) acts in conjunction with Mg^{2+} as a coenzyme in biochemical reactions involving active aldehyde transfers. These reactions can be grouped into (1) oxidative decarboxylation of α-keto acids and (2) transketolase reaction.[163]

Oxidative decarboxylation of α-keto acids includes (1) oxidative decarboxylation of pyruvic acid, the first step in the conversion of pyruvate to acetyl coenzyme A (CoA) in the mitochondria; (2) oxidation decarboxylation of α-ketoglutaric acid, a step within the tricarboxylic acid cycle in which α-ketoglutarate is converted into succinyl CoA; and (3) oxidative decarboxylation of branched-chain α-keto acids: α-ketoisocaproate, α-keto-β-methylvalerate, and α-ketoisovalerate, to produce isovaleryl CoA, α-methylbutyryl CoA, and isobutyryl CoA, respectively, in high energy–generating pathways. The transketolase reaction catalyzed by TPP occurs in the cytosol as part of the pentose phosphate pathway, whose primary purpose is to generate NADPH, an electron and hydrogen donor in the biosynthesis of fatty acids and pentoses.

Studies in animals suggest that thiamin may be necessary in the synthesis of neurotransmitters, including acetylcholine, catecholamines, serotonin, and amino acids with neurotransmitter functions that are produced through the oxidative metabolism of glucose such as γ-aminobutyric acid, glutamate, and aspartate. Thiamin also appears to play a role in nerve conduction, possibly mediated through the control of sodium channel proteins in axons.

Thiamin deficiency may be caused by suboptimal dietary intake, absorption, transport, or metabolism and by increased requirement or losses. In adults, beriberi can occur as a consequence of low intake of thiamin accompanied with high intake of carbohydrate from milled rice. Thiamin depletion is also related to fermented raw fish consumption, chewing betel nuts or fermented tea leaves, and chronic alcoholism. In the 1990s, nationwide shortages of intravenous multivitamins used in US hospitals and home health care agencies led to the development of acute thiamin deficiency among several patients receiving total parenteral nutrition.[165,166] The chief deficiency symptom in these patients was severe lactic acidosis, based on an impairment in the oxidation of α-keto acids. Patients who received treatment with parenteral thiamin showed rapid clinical improvements.

Infantile beriberi may be found in children 2 to 3 months of age whose mothers have low thiamin concentrations in breast milk. It may be manifested in any of at least four syndromes.[163] The cardiac or acute fulminating form is characterized by the rapid appearance of beriberi signs such as loud piercing cry, cyanosis, dyspnea, vomiting, tachycardia, and cardiomegaly; the prognosis is fatal unless thiamin is administered. The aphonic form is characterized by the child's voice tone, which may vary from hoarseness to total aphonia owing to paralysis of phona-

tion nerves. The pseudomeningitic form presents with neurologic abnormalities that may include vomiting, nystagmus, purposeless movement of the extremities, and convulsion with normal cerebrospinal fluid. In the mixed form, any combination of the cardiac, aphonic, or pseudomeningitic forms can be present.[163]

In adults, thiamin deficiency may be manifested as dry beriberi, wet beriberi, or the Wernicke-Korsakoff syndrome. Dry beriberi is usually characterized by peripheral neuropathy with sensory, motor, and autonomic compromises, predominantly of the distal segments of the limbs. Wet beriberi courses with signs of congestive heart failure. Wernicke's disease is an encephalopathy of acute onset characterized by ataxia of gait and paralysis of eye movements, usually accompanied by the Korsakoff psychosis, which consists of amnesia and other mental alterations. Alcoholism is a major factor in the etiology of Wernicke-Korsakoff syndrome.

Beriberi responds to the intravenous or intramuscular administration of large daily doses (50 to 100 mg) for 1 to 2 weeks, followed by daily oral doses of 10 mg.

RIBOFLAVIN

Structure and Metabolism

Riboflavin, or vitamin B_2, was discovered as a fluorescent "yellow growth factor" in the heat-stable fraction of antipellagra extracts found by McCollum and collaborators. It was synthesized by Kuhn and Karrer in 1935, and its structure was elucidated by Warburg and Christian in 1938.[167]

All riboflavin-related compounds possess an isoalloxazine ring. Riboflavin does not have significant physiologic functions, but it is the substrate for two major coenzymes: flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD). The former contains a phosphate group, and the latter is formed by a combination of FMN with adenosine triphosphate (ATP) in the presence of FAD pyrophosphorylase. FAD can be further metabolized and bound covalently to proteins. Riboflavin is very sensitive to UV radiation[168] and can be destroyed during phototherapy of neonatal jaundice. After ingestion, riboflavin coenzyme derivatives are hydrolyzed and absorbed in the small intestine by saturable, active transport. Alcohol and antacids decrease the absorption of the vitamin, whereas dietary fiber increases it. In blood, riboflavin is transported bound to albumin or Igs.[169] Riboflavin-binding proteins have been found in sera of pregnant women[170] that may have special functions in carrying the vitamin to the fetus or facilitating conversion to FAD, acting as enzymes. Excretion of riboflavin is mainly urinary as the precursor molecule; it is increased by boric acid and chlorpromazine.[171]

Functions

Riboflavin plays a key role in the production of energy through the coenzymatic activity of FAD in the respiratory chain. Many other reactions that involve oxidation and reduction are also catalyzed by flavin coenzymes. Regeneration of glutathione in the glutathione peroxidase antioxidant system requires FAD; thus, antioxidant defense against free radicals may be compromised during riboflavin deficiency. Results from observational and supplementation studies suggest that riboflavin deficiency may be protective against malaria.[172] Given that FAD is a coenzyme for the methyltetrahydrofolate reductase enzyme, it has been postulated that riboflavin status may play a role in homocysteine metabolism and is therefore related to the pathophysiology of cardiovascular disease.[167] No epidemiologic evidence is available to support this hypothesis.

Several signs and symptoms have been related to riboflavin deficiency in humans, including stomatitis, glossitis, dermatitis, keratitis, anemia, and neurologic dysfunction. However, there is not one specific clinical syndrome characteristic of deficiency as it occurs usually in the context of multiple nutrient deficiencies. In addition to suboptimal dietary intake, riboflavin deficiency may also be the consequence of thyroid or adrenal insufficiency or negative interactions with alcohol and some psychotropic, chemotherapeutic, and antimalarial medications. These drugs include chlorpromazine, imipramine, amitriptyline, doxorubicin, and quinacrine. Deficiency of vitamin B_2 may impair the absorption of iron and the conversion of vitamin B_6 to its active coenzymatic metabolite.

NIACIN

Structure and Metabolism

Pellagra, the manifestation of niacin deficiency in humans, was first described in 1735 in Spain as a disease primarily affecting the very poor. The disorder was soon recognized throughout southern and eastern Europe as well as Egypt, where corn became the major food crop. The disease was also common in the United States in the early twentieth century, where it affected hundreds of thousands of people, with up to 7,000 reported deaths annually.[173] Nicotinic acid, one chemical form of niacin, was first isolated in 1867, but it was not until the work by Goldberger starting in 1914 that pointed to pellagra being a nutritional deficiency disease. In 1937, nicotinic acid was shown to cure the manifestation of pellagra in dogs and humans.[174]

The term niacin refers to nicotinic acid (pyridine-3-carboxylic acid), nicotinamide (nicotinic acid amide), and functional derivatives of nicotinamide. The two coenzyme forms of niacin, nicotinamide adenine dinucleotide (NAD) and NAD phosphate (NADP), participate in the catalysis of oxidation and reduction (redox) reactions. In addition, NAD exhibits several nonredox functions.

Absorption of nicotinic acid and nicotinamide in the stomach and intestine occurs via facilitated diffusion at low niacin concentrations and passive diffusion at higher concentrations. The major food forms of niacin, NAD and NADP, are converted by enzymatic action in the gut mucosa to nicotinamide. Nicotinamide constitutes the major form of niacin in the blood and serves in the tissue synthesis of NAD when needed. However, both NAD and NADP can be synthesized in all tissues of the body from nicotinic acid or nicotinamide. Excess niacin is excreted in the urine, mainly in the forms of N^1-methylnicotinamide and 2-pyridone. Measurement of these two urinary metabolites serves to assess niacin status.

Niacin is unique among the B vitamins in that it can be synthesized from a precursor molecule. The essential amino acid tryptophan can be converted to NAD via the formation of quinolinic acid and nicotinic acid ribonucleotide. An average conversion ratio of 60 mg tryptophan to 1 mg niacin has been proposed, but such a summary figure fails to account for variation introduced by other nutritional and hormonal factors (see below).

Functions

The metabolically active forms of niacin are NAD and NADP. These active forms participate in a wealth of redox reactions in which they serve as coenzymes for oxidoreductase enzymes. The niacin coenzymes transfer two electrons at a time without the formation of one-electron intermediates. NAD cycles between the oxidized form NAD+ and the reduced form NADH + H^+. Similarly, NADP cycles between $NADP^+$ and NADPH + H^+. The coenzyme function of niacin is a key component of a variety of metabolic pathways affecting carbohydrate, lipid, and amino acid metabolism.

NAD generally functions as an electron acceptor in catabolic reactions that produce energy (eg, the citric acid cycle). NADP tends to participate in biosynthetic pathways such as fatty acid synthesis, cholesterol synthesis, and the pentose phosphate pathway. NAD also participates as a substrate for enzymes in nonredox pathways that catalyze the transfer of adenosine diphosphate (ADP)-ribose moieties.[175] The enzymes mono-ADP-ribosyltransferases and poly-ADP-ribose polymerase (PARP) catalyze the donation of ADP-ribose to acceptor proteins and the enzyme ADP-ribosyl cyclase catalyzes the synthesis of cyclic ADP-ribose.[176] In prokaryotic cells, mono-ADP-ribosyltransferases produce substances acting as toxins (eg, diphtheria and cholera toxins), whereas in eukaryotic cells, they are thought to participate in signal transduction by modulating G protein activity.[177] PARP activity is augmented during cell growth and differentiation and was shown to control the repair of DNA in human cell extracts.[178] However, more research is needed to determine the role of PARP in the prevention of carcinogenesis. Via the synthesis of cyclic ADP-ribose, ADP-ribosyl cyclase triggers the release of calcium ions from an internal storage site, which is important in cell signaling.[176]

The classic symptoms of the niacin deficiency disease pellagra can be summarized as dermatitis, diarrhea, dementia, and potentially death (often called "the four Ds"). Pellagra develops when dietary niacin and tryptophan are insufficient to meet niacin requirements. Human experiments indicate that pellagra develops after 50 to 60 days on a corn diet, which is low in both bioavailable niacin and tryptophan.[177] Other dietary factors may contribute to the development of pellagra by inhibiting the conversion of tryptophan to niacin. They are excessive intake of the amino acid leucine and inadequate intakes of iron, riboflavin, or vitamin B_6. Pellagra-like symptoms in humans have also been reported after prolonged isoniazid treatment, during malignant carcinoid syndrome, and in Hartnup disease. On the other hand, there is evidence that the conversion of tryptophan to niacin is augmented considerably among pregnant women and women taking oral contraceptives.[179]

Pharmacologic doses of nicotinic acid (but not nicotinamide) in the range of 1.5 to 4 g/day have proven effective at reducing the risk of atherosclerotic heart disease.[180] This risk reduction is brought about by an improvement in the blood lipid profiles of at-risk patients, such as reduction of total cholesterol, LDLs, and triglycerides and increases in HDLs.[180]

VITAMIN B6

Structure and Metabolism

The term vitamin B_6 encompasses a group of compounds that are metabolically interchangeable and that in their free form are named pyridoxine (an alcohol), pyridoxal (an aldehyde), and pyridoxamine (an amine). The vitamin also exists in phosphorylated versions of these forms, namely as pyridoxine phosphate, pyridoxal phosphate (PLP), and pyridoxamine phosphate (PMP). Vitamin B_6 was discovered in 1934 while investigating the etiology of the niacin deficiency disease pellagra, and its structure was determined in 1939.

The major forms of the vitamin B_6 in foods are pyridoxine, PLP, and PMP. Pyridoxine is the form used in vitamin supplements. Vitamin B_6 is absorbed by passive diffusion in the small intestine. Because only free forms of the vitamin can enter the intestinal mucosa, the phosphate ester forms of the vitamin first have to be hydrolyzed to yield the free absorbable forms. PLP is the major form of the vitamin in plasma and is the major coenzyme expressing vitamin B_6 activity. The formation of PLP requires the riboflavin-dependent coenzyme FMN.[181] Phosphorylation of free forms of the vitamin to yield functional PLP occurs in most tissues of the body but to the greatest degree in the liver. About three-quarters of the body's vitamin B_6 pool are present in muscle. This pool is resistant to depletion even after prolonged intake of a vitamin B_6–deficient diet, which indicates that muscle vitamin B_6 is not a storage form of the vitamin that can be drawn on in times of inadequate vitamin B_6 intakes.[182] Catabolism of vitamin B_6 occurs mostly in the liver and excretion of the vitamin occurs in the urine, predominantly as pyridoxic acid.[183]

Functions

Vitamin B_6, via its main cofactor form PLP, features prominently in the metabolism of amino acids. PLP facilitates the transfer of amino groups and is thus critical for the production of nonessential amino acids. For example, PLP is a cofactor for the enzyme glutamate-oxaloacetate aminotransferase, which catalyzes the formation of aspartic acid from glutamate. PLP acts as a cofactor in the conversion of the amino acid tryptophan to active niacin and to the neurotransmitter serotonin. It is also involved in the synthesis of other neurotransmitters, such as epinephrine, norepinephrine, and γ-aminobutyrate. In the transsulfuration pathway from homocysteine to cysteine, PLP acts in concert with cystathione synthase to convert homocysteine to cystathione. In the breakdown of glycogen, PLP aids to liberate glucose-1-phosphate and is also part of nucleic acid biosynthesis stimulating 1-carbon metabolism. Other functions include the synthesis of carnitine and the production of compounds necessary for phospholipid biosynthesis.

Vitamin B_6 deficiency is first evidenced by decreases in plasma PLP levels and lowered amounts of the excretory product 4-pyridoxic acid in the urine. Continued vitamin B_6 deficiency leads to seborrheic dermatitis and decreased synthesis of neurotransmitters, resulting in depression, confusion, and abnormal brain wave patterns as indicated by abnormal electroencephalograms. Infants fed vitamin B_6–deficient formula are also at risk of developing convulsions.[184] Hematologic features of vitamin B_6 deficiency may include microcytic anemia, decreased lymphocyte levels, and impaired blood clotting. Levels of vitamin B_6 in breast milk are dependent on maternal intakes of the vitamin, and there is evidence that lactating mothers who consume inadequate levels of vitamin B_6 pass on deficient amounts of the vitamin to the infant.[185]

Vitamin B_6 deficiency in humans most commonly occurs in the elderly, alcoholics, individuals consuming vitamin B_6 antagonists such as penicillamine, and several inborn errors in vitamin B_6 function. Impairments resulting from genetic conditions have been shown to respond to high doses of supplemental vitamin B_6.[186]

FOLATE

Structure and Metabolism

Folate is a generic term for a family of compounds that have nutritional properties of the simplest form of the vitamin, folic acid. Clinical folate deficiency was first described in 1931 as a tropical "macrocytic anemia" that was distinct from the signs of pernicious anemia, which is an autoimmune disease leading to vitamin B_{12} deficiency.[187] The structure of folic acid was elucidated in 1945, and the understanding of its biochemical functions has rapidly grown since then. In recent years, folate has received considerable attention in the prevention of cardiovascular disease, cancer, and neural tube defects.[188]

Folic acid (pteroylglutamic acid) consists of a pteridine bicyclic ring system linked to p-aminobenzoic acid, which is connected by a peptide bond to glutamic acid. Folic acid is the chemical form used in synthetic folate supplements but does not occur in appreciable amounts in foods. Rather, most folates in nature occur as polyglutamates, with five to eight glutamate residues joined to the first glutamate. Next to modifications of the length of the glutamate chain, the vitamin may be modified by reduction of the pteridine ring system to generate dihydrofolic acid and tetrahydrofolic acid (THF). The N-5 and N-10 positions of THF, either individually or in concert, can carry 1-C units, including methyl (–CH3), formyl (–HCO), methylene (–CH2), formyl (–CH = O), or formimino (–CH = NH) groups. THF is the biologically active coenzyme and accounts for the 1-C transfer characteristic of folate-requiring reactions.

Naturally occurring folylpolyglutamates need to undergo hydrolysis for efficient absorption of dietary folate to occur. In the enterocyte, the membrane-bound enzyme γ-glutamylhydrolase catalyzes the hydrolysis of folylpolyglutamates to folylmonoglutamates. Transport across the brush border membrane of folylmonoglutamates occurs by a pH-dependent carrier-mediated mechanism.[189] At high intraluminal concentrations (> 10 μmol/L), a nonsaturable ion-mediated transport mechanism dominates folate absorption.[190] In the bloodstream, the predominant form of the vitamin is 5-methyl-THF-monoglutamate. After cellular uptake, folylmonoglutamates are converted back to folylpolyglutamates to retain the vitamin in the cell, strengthen the binding of the vitamin to folate-dependent enzymes, and allow for channeling reactions to occur.[191] Excess folate is excreted in the form of cleavage products in the urine. Fecal losses of folate occur as well but are difficult to quantify.

Functions

Folate, in the form of its primary coenzyme form THF, functions in the transfer of 1-C compounds needed in the metabolism of amino acids, purine and pyrimidine synthesis, and the *S*-adenosylmethionine (SAM) (Figure 7-3). In the metabolism of amino acids, serine can transfer a methylene group to THF to form glycine and 5-10-methylene-THF. The latter can be reduced to 5-methyl-THF, which functions in the methylation of the amino acid homocysteine to methionine using vitamin B_{12} as a cofactor.

5-10-Methylene-THF can also donate a methyl group for the formation of the pyrimidine thymidylate, a necessary precursor of DNA synthesis and erythrocyte formation. Action of the enzyme C1-THF synthetase converts 5-10-methylene THF to 10-formyl THF, which is necessary for the de novo synthesis of the purines adenine and guanine. Folate donates a methyl group to methionine to generate the methyl donor SAM, whose methyl donation is involved in more than 100 physiologic reactions. Examples include the methylation of DNA, ribonucleic acid, and membrane phospholipids.

The first manifestation of folate deficiency is a decline in serum folate levels, occurring approximately after 2 weeks of consumption of a folate-deficient diet. Hyperpigmentation of neutrophils and a rise in homocysteine levels can be noted, and abnormally nucleated erythrocytes start to appear in the bone marrow. If folate deficiency continues, megaloblastic anemia can occur. It should be noted that such hematologic changes can also be induced by diseases other than folate deficiency. Owing to the rapidly dividing nature of cells lining the gastrointestinal tract and the unmet need for folate for DNA synthesis, gastrointestinal symptoms are common in folate deficiency. Elevated plasma homocysteine concentrations, as occurring during folate deficiency, have been associated with increased risk of atherosclerotic vascular disease in adult life.[192,193] Folate supplementation has been shown to reduce homocysteine levels, and research is under way to examine the effect of folate supplementation on cardiovascular disease.[194] Poor folate status has also been associated with increased risk of cancer, especially colon cancer. This may be explained by folate's role in normal synthesis and methylation of DNA.[195]

Adequate folate status early in pregnancy greatly decreases the risk of neural tube defects, the most common major congenital abnormality in many countries.[196]

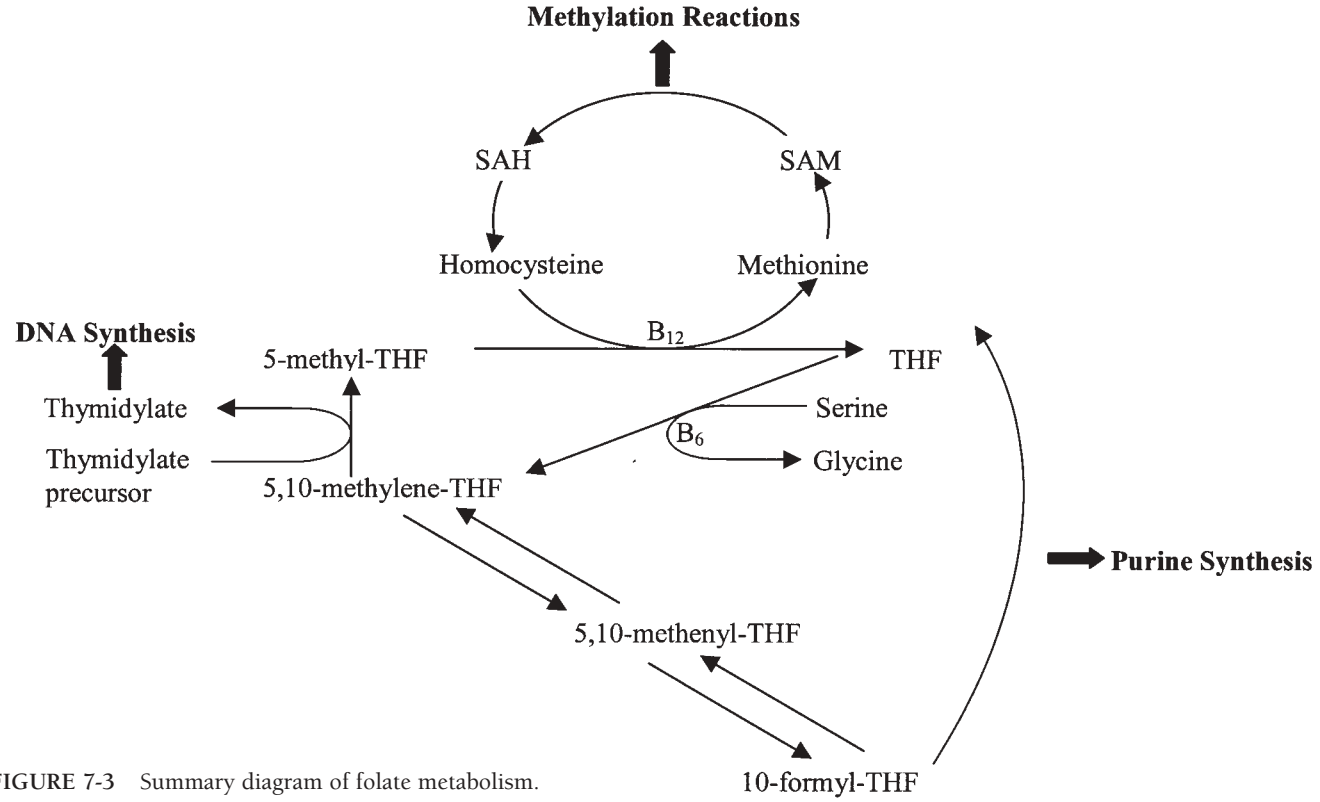

FIGURE 7-3 Summary diagram of folate metabolism.

For this reason, folic acid has been added to enriched grains and mixed food items containing these grains in the United States since 1998 at levels of 0.14 mg/100 g flour.[197] Fortified grains have thus become a good source of folate, and there is evidence that the folate status of the general population has increased as a result of this fortification program. Benefits of this fortification program are possible for disorders other than neural tube defects, such as cardiovascular disease.[198]

Folate requirements increase during pregnancy owing to the requirements of the growing fetus and related tissues. Folate secreted in milk also increases requirements during lactation. Folate deficiency during infancy may result from inadequate intakes of the vitamin, such as in infants fed on goat's milk, which is a poor source of folate. Deficiencies may also occur owing to impaired absorption of the vitamin and after intake of a range of medications, including methotrexate, anticonvulsants, and anticancer drugs that have antifolate activity.

VITAMIN B_{12}

Structure and Metabolism

The symptoms of the vitamin B_{12} deficiency disorder pernicious anemia were first described in the mid-nineteenth century. In 1926, large quantities of liver were shown to normalize the hematologic symptoms of pernicious anemia. Vitamin B_{12} was first successfully isolated in 1948 and chemically synthesized in 1973.

Vitamin B_{12} is a large molecule similar to porphyrin that has a complex ring structure (corrin ring). At its center, it possesses a cobalt molecule. Its chemical name is cobalamin, and it is solely synthesized by microorganisms. Animals consuming the vitamin conserve it in the liver in the chemical forms methylcobalamin, adenosylcobalamin, and hydroxocobalamin. Supplemental forms of vitamin B_{12} are generally in the form of cyanocobalamin, but hydroxocobalamin has also been used as a supplemental form.

In vitamin B_{12} absorption, parietal cells of the gastric mucosa secrete intrinsic factor, which is a highly specific glycoprotein for the vitamin. Absorption of the vitamin takes place at receptor sites in the distal ileum. The main serum transport protein for vitamin B_{12} is transcobalamin II (TCII). However, the vitamin B_{12} bound to TCII accounts for only 20% of the vitamin in serum. Cellular uptake of the TCII-B_{12} complex proceeds via receptor-mediated endocytosis, and cyanocobalamin is subsequently released in the lysosome. Cyanocobalamin is readily converted in the body to the two active coenzyme forms methylcobalamin and 5-deoxyadenosylcobalamin. Vitamin B_{12} is stored in the liver bound to TCI. Liver storage makes vitamin B_{12} unique among the water-soluble vitamins. Vitamin B_{12} is continuously secreted into bile, yet the majority of the secreted vitamin is reabsorbed in the process of enterohepatic circulation. Excess vitamin B_{12} is excreted in the urine, and losses also occur by the fecal route.

Functions

Vitamin B_{12} is required by all DNA-synthesizing cells, including those of the hematopoietic and nervous system. Its function is closely tied with that of folate in methyl

transfer reactions and synthesis of purines and DNA. Vitamin B_{12}, in its methylated form methylcobalamin, is required by methionine synthase for the methyl transfer from 5-methyl-THF to homocysteine to yield the end products methionine and THF (see Figure 7-3). In the absence of vitamin B_{12}, folate becomes trapped in its inactive form, 5-methyl-THF, DNA synthesis is impaired, and megaloblastic anemia develops. This type of anemia is indistinguishable to that induced by folate deficiency. Vitamin B_{12} is also a cofactor for leucine aminomutase, yet this enzyme is not vitally important in metabolism.[191–199]

In the form of its second active coenzyme form 5-adenosylcobalamin, vitamin B_{12} is required for the enzyme L-methylmalonyl-CoA mutase to convert L-methylmalonyl-CoA to succinyl-CoA in an isomerization reaction. Lack of production of succinyl-CoA by this pathway in the presence of vitamin B_{12} deficiency is unlikely to have serious metabolic consequences as succinyl-CoA is abundantly derived from fats and carbohydrates. However, accumulation of L-methylmalonyl-CoA in the cell can lead to increased production of odd-chain and branched-chain fatty acids through a sequence of reactions. Such fatty acids may be abnormally incorporated into nerve cell membranes, and it is hypothesized that they may account for neurologic symptoms owing to degeneration of myelin nerve sheaths.[191] Such neurologic symptoms may include tingling and numbness sensations in the extremities, motor disturbances, and cognitive changes such as loss of concentration and dementia. In extreme cases, the degeneration of peripheral nerves may progress to irreversible paralysis. Neurologic complications may in some cases present without hematologic symptoms. In fact, there is evidence of an inverse association between the prominence of neurologic complications and the severity of anemia, that is, more prominent neurologic complications tend to occur in individuals who are less anemic.[200,201] It should be noted that folate deficiency cannot induce neurologic complications.

Vitamin B_{12} deficiency is commonly attributable to poor absorption and less as a result of inadequate intake. Infants and children with diseases or resection of the terminal ileum (eg, Crohn's disease, short-bowel syndrome) are at risk of vitamin B_{12} deficiency. Malabsorption can also be attributable to pernicious anemia, a chronic atrophic gastritis that is characterized by the presence of autoantibodies to parietal cells, which causes loss of these intrinsic factor–producing cells. Autoantibodies to intrinsic factor have also been demonstrated.[202] Pernicious anemia in children is generally the result of a genetically determined defect in secretion of intrinsic factor or the secretion of a defective intrinsic factor.[203,204] The vitamin deficiency can be corrected by large monthly injections of vitamin B_{12}.

Vegan mothers, who are at risk of vitamin B_{12} deficiency and who may have depressed vitamin B_{12} in their breast milk, are advised to supplement their infants with vitamin B_{12} supplements from birth. Vitamin B_{12} can be effectively diagnosed by a variety of tests (see Table 7-2).

BIOTIN

Structure and Metabolism

Biotin was first isolated in 1935 from dried egg yolk, and its structure was established in 1942.[205,206] The total synthesis of the vitamin was achieved shortly thereafter. Biotin is an imidazole derivative widely distributed in foods, where it is mostly bound to proteins. Digestion of dietary protein releases biotinyl peptides, and intestinal biotinidases further hydrolyze biotinyl peptides to biotin. At low luminal biotin concentrations, the vitamin is absorbed by a sodium-dependent saturable process, whereas a nonsaturable process dominates at higher luminal biotin concentrations. Intestinal transport of biotin is faster in the jejunum than in the ileum and is very low in the colon. Biotin-producing microorganisms exist in the colon and may contribute to biotin requirements. Information on the transport mechanism of biotin to the liver and other tissues is scarce, but it is known that the liver contains significant amounts of the vitamin. Urinary losses are the major excretory route, but some losses also occur through the biliary route.

Functions

Biotin acts as a component of four ATP-dependent multisubunit enzymes that catalyze carboxylase reactions needed in energy metabolism, fatty acid synthesis, and amino acid metabolism. As a cofactor for pyruvate carboxylase, biotin aids in gluconeogenesis and replenishment of oxaloacetate for the citric acid cycle. As part of propionyl-CoA carboxylase, it helps convert propionate to succinate, which also participates in the citric acid cycle. The biotin-dependent enzyme acetyl-CoA carboxylase catalyzes the production of malonyl-CoA necessary for fatty acid synthesis, and with biotin as a cofactor, β-methylcrotonyl-CoA carboxylase metabolizes the amino acid leucine.

Human biotin deficiency is extremely rare. First, symptoms of biotin deficiency are depressed levels of the vitamin in urine, and other deficiency symptoms include nausea, vomiting, depression, dry, scaly dermatitis, glossitis, and hair loss. The egg protein avidin binds biotin tightly and prevents absorption of the vitamin; however, avidin is heat labile, and biotin deficiency can occur only in people who eat large amounts of raw eggs over many months.[191] The vitamin is synthesized by the intestinal microflora and colonic absorption occurs; controversy persists, however, over how much synthesized biotin can contribute to meet human requirements.[207]

Several genetic defects can induce potent biotin deficiency. Infants with a genetic defect in the enzyme biotidinase fail to recycle biotin and lose large amounts of biotin metabolites in the urine. Symptoms generally occur after the first week of life but before age 1 year and include poor feeding; vomiting; rash around the eyes, nose, and mouth; and neurologic symptoms such as muscle pain, lethargy, and numbness. Biotidinase deficiency is rare, with an incidence of about 1 in 120,000.[208] Genetic defects may also induce deficiencies in individual and multiple carboxy-

lases, which cause biotin deficiency symptoms and accumulation of substrates. Pharmacologic doses of oral biotin restore normal function.[209]

PANTOTHENIC ACID

Structure and Metabolism

Pantothenic acid was discovered in the 1930s as a growth factor for yeast. The structure of the vitamin was established in 1938, and its essentiality for human nutrition was first reported in 1954.[210] Pantothenic acid is formed by combination of pantoic acid and β-alanine. In food, the vitamin is present as CoA or as 4′-phosphopantetheine (Ppant). Hydrolysis of CoA and Ppant in the intestinal lumen renders the vitamin readily absorbable. After absorption, the vitamin is transported in the bloodstream to various tissues, where synthesis of CoA occurs from pantothenic acid, ATP, and cysteine. Pantothenic acid is not directly involved in the synthesis of the cofactor Ppant as the reaction proceeds from CoA as substrate. Excretion of the vitamin occurs in the urine, primarily as pantothenic acid.

Functions

As a constituent of CoA, pantothenic acid plays a key role in the metabolism of carbohydrates, proteins, and fats. CoA functions in the transfer of an acetyl group in many vital reactions, such as in the citric acid cycle, the synthesis of cholesterol, hormones, neurotransmitters, phospholipids, and antibodies. CoA is also involved in the metabolism of drugs, such as sulfonamides. Ppant is a cofactor of fatty acid synthase, to which it is covalently bound.

Pantothenic acid deficiency in humans is rare. Historically, it has been implicated in the "burning feet" syndrome, a condition noted among malnourished prisoners of war during World War II. Experimental states of pantothenic acid deficiency have been created by feeding synthetic diets devoid of pantothenic acid or by administering pantothenic acid antagonists.[211,212] Manifestations of deficiency may include neurologic symptoms such as listlessness, fatigue, headaches, tingling sensations in arms and legs, and gastrointestinal symptoms such as vomiting, abdominal cramps, and flatulence.

CONCLUSION

This chapter highlighted the main functions of vitamins and stressed the importance that adequate vitamin status plays in the well-being of infants and children. Our understanding of the functions of individual vitamins has grown considerably in the last five decades. However, a lot remains to be learned about interactions between vitamins and other nutrients. A heightened awareness of such interactions is likely to translate into improved pediatric care because deficient and excess intakes of nutrients generally occur in concert and because the metabolic pathways of many nutrients are interrelated. More research is also needed to accommodate the special needs of infants born prematurely or with low birth weight, those receiving parenteral nutrition, and those suffering from infections. During adolescence, vitamin malnutrition is still a problem in the United States and deserves particular attention. Data from US national surveys indicate that a significant proportion of adolescents consume inadequate amounts (< 75% RDA) of vitamins A, B_6, C, and E.[213] The high prevalence of inadequate intakes was present despite reported supplement intakes in one-third of the adolescents surveyed, which may indicate that those at nutritional risk are less likely to consume supplemental doses.[210] Vitamin nutrition needs to be improved on a scientific level, that is, to establish recommendations taking into consideration possible nutrient interactions and particular physiologic and disease states, as well as on a policy and programmatic level, to help children attain existing levels of recommended intakes.

CHAPTER 8

THE PRUDENT DIET: PREVENTIVE NUTRITION

Linda G. Snetselaar, RD, PhD, Ronald M. Lauer, MD

CONCERNS FOR LEVELS OF BLOOD CHOLESTEROL IN CHILDREN AND ADOLESCENTS

Atherosclerosis begins in childhood and progresses into adulthood, at which time it leads frequently to coronary heart disease (CHD), the major cause of death in the United States.[1,2] The disease is responsible for more than 500,000 deaths annually. Estimates of the annual cost of CHD range less than $74 billion.[3] Hospital discharges for acute CHD are often for premature disease (ie, in patients under 55 years of age) because of familial factors. Many of these adults have children who may have CHD risk factors needing treatment.

Elevated cholesterol levels early in life play a role in the development of adult atherosclerosis; eating patterns and genetics affect blood cholesterol levels and CHD risk.[3] Risk factors for atherosclerosis and CHD may originate early in life and should be addressed. Specifically, cigarette smoking should be discouraged, hypertension should be identified and treated, obesity should be avoided or reduced, regular aerobic exercise should be encouraged, and diabetes mellitus should be diagnosed and treated.

Diet, Blood Cholesterol, and Coronary Heart Disease

Research provides evidence linking diet, blood cholesterol levels, and CHD. Most human studies have been conducted in adults because overt, clinical CHD does not usually occur until adulthood. However, data now available support the view that atherosclerosis begins in childhood and is related to cholesterol levels and thus to nutritional factors.

Lipoprotein Metabolism

Lipoproteins play a distinctive role in cholesterol transport and apparently in atherogenesis. Research shows that low-density lipoproteins (LDLs) are atherogenic, whereas high-density lipoproteins (HDLs) may provide protection against atherosclerosis.[3–8]

Studies in laboratory animals demonstrate that high blood cholesterol levels promote atherosclerosis.[9] Diets that raise total cholesterol and LDL cholesterol levels result in atherosclerosis in many species. Hypercholesterolemic animals develop intimal lesions that progress from fatty streaks to complicated ulcerated plaques.[10,11] Studies in adolescent, nonhuman primates show that they also develop fatty streaks and fibrous plaques after a diet high in cholesterol and saturated fatty acid (SFA), similar to but less extensive than adults in that study.[12,13] Severe atherosclerosis in monkeys regresses when blood cholesterol is lowered substantially for an extended period by diet or drugs.[9,14,15] These studies support the view that there is a causal relationship between LDL cholesterol and atherosclerosis and suggest that atherosclerosis may be reversible.

Several human genetic dyslipidemias have in common raised concentrations of cholesterol-rich lipoproteins, resulting from specific gene mutations. These disorders are characterized by severe atherosclerosis and often by the occurrence of CHD at a young age. The most striking example is familial hypercholesterolemia, either in its more common heterozygous form (prevalence 1 in 500) or in its rare but much more severe homozygous form (prevalence 1 in 1 million).[3] Other examples are familial dysbetalipoproteinemia[16] and familial combined hyperlipidemia.[17]

Many epidemiologic studies target LDL cholesterol levels as one of several major risk factors for CHD in men and women. The Framingham Heart Study, the Honolulu Heart Program, the British Regional Heart Study, and studies of men screened for the Multiple Risk Factor Intervention Trial (MRFIT) show that blood cholesterol levels are a powerful and independent predictor of CHD; on average, each 1% rise in cholesterol is associated with an approximate 2% increase in CHD risk.[18–24] Recently, Davis and colleagues suggested that this relationship was underestimated because of failure to take into account intraindividual variations in cholesterol levels.[25] In fact, each 1% rise in blood cholesterol is associated with an approximate 3% increase in risk. The level of HDL cholesterol, in contrast, is inversely and independently related to CHD in both sexes and at all ages (Table 8-1).[26]

In countries where CHD mortality is highest, children's cholesterol levels are higher than in countries where CHD mortality is lower.

Recommendations for a comprehensive program of blood cholesterol lowering are based on clinical trial evidence that cholesterol lowering is effective and safe in reducing CHD risk in adults.

Clinical trials in adults show that cholesterol lowering reduces coronary risk. In the Coronary Primary Prevention Trial (CPPT), cholestyramine-induced cholesterol lowering in hypercholesterolemic middle-aged men produced an average 19% reduction in definite fatal and/or nonfatal myocardial infarction over 7 years. Men who took the full dose of resin lowered their cholesterol levels by more than 25% and reduced their risk of CHD by half.[27,28] The Helsinki Heart Study compared gemfibrozil therapy with use of a placebo in hypercholesterolemic, middle-aged men, producing a moderate reduction in LDL and a moderate increase in HDL, with a reduction of 34% in fatal and nonfatal myocardial infarction.[29] A follow-up of patients with a prior history of myocardial infarction, who had received nicotinic acid for 5 years in the Coronary Drug Project, resulted in reduced total and cardiovascular mortality in the nicotinic acid group when compared with the control group.[30] Both the Stockholm Ischaemic Heart Disease Secondary Prevention Study and the Oslo Study Diet and Antismoking Trial reported beneficial outcomes, including reduced total mortality, with reduction of cholesterol levels.[31,32] Follow-up of the MRFIT showed that lowering blood cholesterol level, drug treatment of hypertension, and counseling to achieve smoking cessation in high-risk men resulted, 10.5 years later, in a 10.6% reduction in deaths from acute myocardial infarction and a 7.7% reduction in total mortality compared with a control group.[24] Aggregate analysis of these and many other clinical trials shows that cholesterol lowering, whether induced by diet or by various drugs, in the context of either primary or secondary prevention, reduces fatal and nonfatal myocardial infarction.[33]

Initially, there had been some controversy about the cholesterol hypothesis because a number of these trials did not find a significant reduction in total mortality following cholesterol-lowering treatment.[9] These findings may be related, in part, to relatively small sample sizes or trials of relatively short duration. A number of studies (Coronary Drug Project, Stockholm Ischaemic Heart Disease Secondary Prevention Study, and Oslo Study Diet and Antismoking Trial) have demonstrated clear reductions in total mortality as well as CHD mortality, and a fourth, the Program on the Surgical Control of the Hyperlipidemias (POSCH), showed a trend in this direction.[30–32,34,35]

Several angiographic studies report the beneficial effects of lowering cholesterol. Following the National Heart, Lung, and Blood Institute (NHLBI) type II trial, the results suggested that lesions can be stabilized and progression can be slowed.[36] The 1987 results of the Cholesterol Lowering Atherosclerosis Study further indicated that regression of existing lesions can be obtained in a proportion of patients.[37] Other studies show more regression in the treated groups than in control groups, and the conclusion now seems inescapable that definite regression can be expected in 16 to 47% of patients provided that large decreases in LDL cholesterol (of the order of 34 to 48%) are induced for a period of 2 to 5 years.[35,38–40]

In summary, many studies demonstrate that lowering elevated blood cholesterol levels in adults by diet or drug treatment, or both, favorably affects development, progression, and even regression of atherosclerotic plaques. No studies provide direct proof that lowering blood cholesterol levels in children and adolescents will reduce their risk of CHD in adulthood. Such studies may never be possible because they would involve large numbers of children over several decades. Because no available evidence exists in children's diet, the available adult evidence strongly suggests that the benefit of reducing cholesterol levels in childhood will be realized in adulthood, and conclusions drawn from adult studies support the belief that long-term benefit can be expected from lowering cholesterol levels in childhood. The safety, efficacy, and acceptability of a lower total fat, saturated fat, and cholesterol dietary intake have been shown in the Dietary Intervention Study in Children (DISC) and the STRIP Baby Project.[41–43]

TABLE 8-1 Dietary Saturated Fat and Cholesterol Intake, and Serum Total Cholesterol in Boys Ages 7–9 in Six Countries

	Dietary Intake		*Serum Total Cholesterol*
Country	*Saturated Fat (% of energy)*	*Cholesterol (mg/1,000 calories)*	*(mg/dL)*
Philippines	9.3	97	147
Italy	10.4	159	159
Ghana	10.5	48	128
United States	13.5	151	167
Netherlands	15.1	142	174
Finland	17.7	157	190

Adapted from Knuiman JT et al[86] and from United States dietary data from NHANES-II[87] and serum cholesterol data from NHANES-I.[88]

Pathology of Atherosclerosis in Young People

The arterial lesions of atherosclerosis have their origin in childhood. In the aorta, fatty streaks occur in early childhood regardless of ethnic background, gender, or geographic location. In the coronary arteries, fatty streaks occur in many individuals during the second decade of life, and fibrous plaques, the lesions that begin to narrow the arteries, appear in the coronary arteries of some young persons in the United States as early as the second decade. After age 20, fibrous plaques occur in significant numbers of people.[44]

Enos and colleagues and Strong described the high frequency of advanced coronary artery lesions in young American soldiers killed in the Korean War.[45,46] Similar evidence is provided by a study of soldiers in the Vietnam War.[47] Also, investigators in the United States and abroad have documented the importance of the early development of atherosclerosis, particularly in the aorta.[48–52]

Holman and colleagues emphasized and documented the childhood origin of atherosclerosis.[53] In this study, all individuals 3 years of age and older had at least minimal fatty streaks in the aorta, and the extent of intimal surface

involved with fatty streaks progressed dramatically in the second decade of life. Strong and McGill assessed the prevalence and extent of atherosclerotic lesions in the coronary arteries of deceased subjects ages 1 to 69 years in New Orleans.[54] They showed important differences in the prevalence and extent of coronary artery lesions in population subgroups developed early in life and at least 20 years before the onset of manifest clinical disease.

The International Atherosclerosis Project (IAP) undertook an extensive study of the geographic pathology of atherosclerosis in over 23,000 sets of aortas and coronary arteries collected from autopsies in 14 countries and systematically evaluated by a group of cooperative pathologists.[55] Reports from the IAP strongly support the view that fatty streaks progress to fibrous plaques and more complicated atherosclerotic lesions based on topographic and microscopic studies.[56,57]

Strong and McGill investigated aortic and coronary lesions in 4,737 younger subjects included in the IAP, ranging in age from 10 to 39 years and belonging to six geographic-ethnic groups.[44] By age 10, most aortas from all groups had aortic fatty streaks. Coronary fatty streaks, although not as frequent as aortic fatty streaks, occurred in some cases from each geographic-ethnic location group, even in the 10- to 14-year age group. Fatty streaks were present in the coronary arteries of all persons over age 20 in New Orleans and of approximately 90% of persons in the other groups by age 30.

To assess the earliest microscopic changes of atherosclerosis, Stary systematically studied, by light and electron microscopy, unopened, pressure perfusion–fixed, left coronary arteries of 691 male and female subjects dying between full-term birth and 39 years of age.[58,59] More than 50% of children aged 10 to 14 years had lesions characterized by accumulations of macrophage foam cells, lipid-containing smooth muscle cells, and thinly scattered extracellular lipid, these changes representing the microscopic counterpart of fatty streaks. Approximately 8% of subjects 10 to 14 years of age had more advanced lesions with larger accumulations of extracellular lipid, representing lesions that either were in transition or had features of atherosclerotic plaques associated with clinical disease in adults. These microscopic studies clearly indicate a progression from fatty streaks through intermediate or transitional lesions to atheromatous lesions (comparable to fibrous plaques by gross classification) in a defined segment of the left anterior coronary artery predisposed to clinically significant lesions.

The Bogalusa Heart Study showed a significant relationship between LDL cholesterol and coronary artery fatty streaks, with significant relationships between LDL cholesterol levels and the prevalence of both aortic and coronary fibrous plaques.[60] The PDAY Study (Pathobiological Determinants of Atherosclerosis in Youth) has shown a relationship between the earliest lesions and the postmortem levels of LDL, very LDL, and HDL cholesterol and serum thiocyanate concentrations.[2] These data highlight the origin of atherosclerosis in young persons and its relationship to circulating lipids and lipoproteins and to smoking behavior.

Childhood and Adolescent Levels of Lipids

Several studies provide distributions of lipid and lipoprotein levels in American children and adolescents.[61–66] The National Cholesterol Education Program has suggested the acceptable borderline and high levels of total, LDL, and HDL cholesterol levels (Table 8-2).

Tracking

Several studies show that childhood rank order of cholesterol is maintained over time ("tracking"), although not as consistently as rank order of height and weight is maintained.[67–71]

Studies relate childhood cholesterol levels to later young adult levels.[71–73] One study examined data on children 5 to 18 years of age whose cholesterol levels were greater than the 90th percentile at a single measurement.[73] At 20 to 30 years of age, 43% of these individuals had levels greater than the 90th percentile (about four times the percentage expected), 62% greater than the 75th percentile (about two to three times the percentage expected), and 81% greater than the 50th percentile (about 1.5 times the percentage expected).[73] Of children whose cholesterol levels were greater than the 90th percentile on two occasions, 75% had higher than desirable levels (> 200 mg/dL) and 25% had desirable levels (< 200 mg/dL) at ages 20 to 25 years.[74] Because 200 mg/dL is approximately the 75th percentile for adults in their twenties, this percentage of individuals with levels at or above 200 mg/dL is about three times the percentage expected for the general population.

THE PRUDENT DIET

An approach to lowering cholesterol levels in children and adolescents is the population approach, which aims to lower the average population levels of blood cholesterol by encouraging the adoption of a low-SFA, low-cholesterol eating pattern. Even though this approach results in a relatively small reduction in mean total and LDL cholesterol levels in children and adolescents, if carried into adulthood, it could substantially decrease the incidence of CHD. It would also reduce the number of adults who have high-risk cholesterol levels.[62,75]

In the population approach, the nutrition recommendations are to lower average population levels of blood cholesterol in children and adolescents to reduce the incidence of adult CHD. These recommendations, generally to

TABLE 8-2 Classification of Total and LDL Cholesterol Levels in Children and Adolescents from Families with Hypercholesterolemia or Premature Cardiovascular Disease

Category	*Total Cholesterol (mg/dL)*	*LDL-Cholesterol (mg/dL)*	*HDL-Cholesterol (mg/dL)*
Acceptable	< 170	< 110	≥ 35
Borderline	170–199	110–129	
High	≥ 200	≥ 130	
Low			< 35

Adapted from National Cholesterol Education Program.[3]

improve health, were defined for all children and adolescents by the Expert Panel on Blood Cholesterol Levels in Children and Adolescents of the National Cholesterol Education Program.[3]

The following nutrient intakes are for healthy children and adolescents. With the introduction of solid foods in infants who have no history of allergies, fruits and vegetables can be introduced with first solids. This may induce preferences in later life for these foods. As toddlers over 2 years of age begin to eat with the family, they may safely make the transition to this eating pattern over a period of 3 to 4 years. Because food intake varies from day to day, these recommendations are meant to represent an average of nutrient intake over several days:

1. Nutritional adequacy should be achieved by eating a wide variety of foods.
2. Energy (calories) should be adequate to support growth and development and to reach or maintain desirable body weight.
3. The following pattern of nutrient intake is recommended:
   a. Saturated fatty acids—less than 10% of total calories
   b. Total fat—an average of no more than 30% of total calories
   c. Dietary cholesterol—less than 300 mg per day

No single food item provides all of the essential nutrients in the amounts needed. Choosing a wide variety of foods from all of the food groups is the best way to ensure an adequate diet.

Adequate Energy (Calories)

Children require sufficient calories for growth as well as maintenance of body functions, and their energy needs depend on height, weight, rate of growth, and level of physical activity. Younger children require a higher caloric intake per unit of body weight than older children and adolescents. Some children and adolescents may need more calories than indicated by the Recommended Dietary Allowances, particularly adolescents who participate in athletic activities.[76] An eating pattern that contains about 30% of calories from fat can readily provide adequate calories for children over 2 years of age. Excessive calories can lead to obesity and should be avoided.

Saturated Fatty Acid

SFA raises blood cholesterol levels[4]; therefore, a major dietary emphasis should be on reducing SFA intake. Thus, it has been recommended that less than 10% of calories from SFA should be consumed.

Total Fat

The percentage of calories from total fat intake, independent of the relative content of the individual fatty acids, does not affect the level of blood cholesterol. A sufficiently low SFA intake can be achieved with a fat intake of about 30% of calories. A lower fat intake is usually not necessary and, for some children and adolescents, may make it difficult to provide enough calories and minerals for optimal growth and development. The recommended target of no more than 30% of calories from fat is a practical approach to controlling SFA intake yet provides sufficient fat for essential fatty acids and absorption of fat-soluble vitamins and contributes calories for normal growth and development.

Unsaturated fatty acids do not increase blood cholesterol levels. The two major types of unsaturated fatty acids are polyunsaturated and monounsaturated. The panel recommends that up to 10% of total calories come from polyunsaturated fatty acids; this includes omega-6 and omega-3 fatty acids (largely derived from vegetable oils and fish, respectively). Monounsaturated fatty acids should provide the remaining 10 to 15% of calories from fat.

Dietary Cholesterol

It has been estimated that, with a 2,500-calorie diet, blood cholesterol will decrease by about 4 mg/dL for every 100 mg/day decrease in dietary cholesterol.[77] This response holds even at low intakes of cholesterol; thus, the lower the dietary cholesterol, the lower the blood cholesterol on the average. There appears to be considerable interindividual variability in the response of blood cholesterol to dietary cholesterol.

Carbohydrate

With the reduction in fat intake, consumption of complex carbohydrates can be increased. This level can be achieved primarily by increasing foods high in carbohydrates, such as pastas, potatoes, many vegetables, legumes, and cereals and breads, especially whole grain. These foods, as well as fruits, which are sources of simple carbohydrates, are generally low in fat and are good sources of dietary fiber, vitamins, and minerals.

Protein

Protein is vital to growth and development. Given the above recommendations for fat and carbohydrate, protein should provide about 15 to 20% of caloric intake. Protein from low-fat animal sources (meat, poultry, fish, eggs, and many dairy products) contains all of the essential amino acids in proportions needed for human growth and tissue repair. Plant proteins (from legumes, bread, cereal, pasta, and grain products) are typically low in one or more of the essential amino acids. Incomplete protein foods can be combined (eg, brown beans with rice) to achieve a balanced mixture of essential amino acids. These combinations of plant proteins are quite low in SFA and total fat.

Fiber

Foods naturally high in fiber provide energy and a variety of nutrients and are low in SFA, total fat, and cholesterol. These foods—such as fruits, vegetables, and grains, including oat and wheat cereals—are not a panacea for high blood cholesterol but are nutritious and useful components of a low-SFA, low-fat, and low-cholesterol eating pattern.

Vitamin E

Vitamin E was once widely advocated for prevention and treatment of CHD.[78] Early studies supporting these claims were marred by a lack of controls and doubtful diagnosis of CHD, and subsequent studies have failed to confirm the results.[79] Children who eat a wide variety of foods do not require supplemental vitamins.[80,81]

Eating Patterns

To meet the recommendations for nutrient intake for healthy children and adolescents, families should adopt eating patterns that include lower amounts of SFA, total fat, and cholesterol. To accomplish this, the following nutritional changes have been recommended:

1. Maximize the quantity and variety of fruits, vegetables, grains, breads, cereals, and legumes.
2. Substitute low-fat dairy products such as skim or low-fat milk and skim or low-fat milk products for those high in fat.
3. Eat moderate amounts of trimmed, lean red meat, poultry without skin, or fish in place of choices high in SFA.
4. Eat egg yolks only in moderation.
5. Use oils, margarines, and shortenings with vegetable oils containing primarily unsaturated fatty acids instead of SFA.
6. Choose prepared baked goods that have been made with unsaturated vegetable oils and, at most, small amounts of egg yolk.
7. Choose "convenience foods" that are low in SFA, total fat, and cholesterol.
8. In fast-food and other restaurants, select menu items that are low in SFA, total fat, and cholesterol as well as cooked foods that are baked, boiled, or broiled without fat.

An option is to use a system of monitoring grams of saturated fat. This system eliminates rules forbidding certain foods and focuses on personal preferences and saturated fat "budgeting."

Figure A-24 in Appendix 2 shows the US Department of Agriculture (USDA) Food Guide Pyramid for children.[82] Five major food groups replace the former USDA recommendations for a well-balanced diet.

If a vegetarian diet is chosen, consultation with a registered dietitian or other qualified nutrition professional can be helpful. Well-planned vegetarian diets have potential nutritional and health benefits, according to the American Dietetic Association.[83,84] Individuals following vegetarian plans have been shown to have lower average serum cholesterol levels and blood pressures than nonvegetarians. These findings may be related to the reductions in dietary fat and SFA and lower body weights in vegetarians rather than vegetarianism per se.[85]

Vegetarian diets for children and adolescents require careful attention. Diets must be planned to include adequate calories, protein, iron, calcium, and vitamins B_{12} and D.[83,84] Inadequate intakes of calories and nutrients from poorly planned vegetarian diets have caused growth retardation, rickets, vitamin B_{12} deficiencies, and hypocalcemia.[85] Dietary deficiencies are most common in vegan diets, which do not include dairy products or eggs. Lactovegetarian and lacto-ovovegetarian diets provide greater opportunities to include calories, protein, and other nutrients needed for growth.

Safety of the Prudent Diet

The DISC provides evidence that cholesterol-lowering diets in children are safe.[41] This study's objective is to assess the efficacy and safety of lowering dietary intake of total fat, saturated fat, and cholesterol to decrease LDL cholesterol levels in children.

This study was a six-center randomized controlled clinical trial with prepubertal boys (n = 362) and girls (n = 301), age 8 to 10 years, with LDL cholesterol ≥ 80th and < 98th percentiles for age and sex. They were randomized into an intervention group (n = 334) and a usual care group (n = 329). Intervention involved behavioral change to promote adherence to a diet providing 28% of energy from total fat, less than 8% from saturated fat, up to 9% from polyunsaturated fat, and less than 75 mg/1,000 kcal per day of cholesterol (not to exceed 150 mg/day).

Main outcome measures involved a mean LDL cholesterol at 3 years with primary safety measures of mean height and serum ferritin levels at 3 years. Secondary efficacy outcomes were mean LDL cholesterol at 1 year and mean total cholesterol at 1 and 3 years. Secondary safety outcomes included red blood cell folate; serum zinc, retinol, and albumin; serum HDL cholesterol, LDL-to-HDL cholesterol ratio, total triglycerides; sexual maturation; and psychosocial health.

At 3 years, dietary total fat (28.6% kcal), saturated fat (10.2% kcal), and cholesterol (95 mg/1,000 kcal) decreased significantly in the intervention compared with the usual care group. LDL cholesterol fell to a greater degree ($p < .001$) in the intervention group (–15.3 mg/dL) compared with the usual care group (–11.9 mg/dL). There were no significant differences between the groups in adjusted mean height or serum ferritin ($p > .05$) or other safety outcomes.

The DISC showed that dietary intervention is effective in achieving modest lowering of LDL cholesterol over 3 years while maintaining adequate growth, iron stores, nutritional adequacy, and psychological well-being during the critical growth period of adolescence. An important public health message from this study is that current dietary recommendations for healthy children, which are less restricted in total fat than the DISC diet, can be prescribed safely with surveillance of growth and development on a consistent basis.

CONCLUSIONS

Dietary changes in children are effective in lowering LDL cholesterol levels while maintaining nutritional adequacy, iron stores, and psychological well-being. Although diet changes result in modest LDL lowering, when these

changes occur in large numbers of children, they have the potential to result in a large public benefit by impeding the atherosclerotic process.

CHAPTER 9.1

COMMUNITY NUTRITION AND ITS IMPACT ON CHILDREN: DEVELOPED COUNTRIES

Johanna Dwyer, DSc, RD, Melanie A. Stuart, MS, RD, Kristy Hendricks, DSc, RD

If the future of a society is to be shaped by its children, then a strong national commitment is needed to develop their bodies, minds, and spirits. Good nutrition plays a role in growth, development and later health, prevention, control and treatment of disease, and improvement of quality of life. Community efforts are key to making this happen.

REASONS FOR CONCERN

Nutrition is an important component of health care for infants, children, and adolescents. Infants grow rapidly and have requirements for protein, energy, and other essential nutrients that are higher per unit of body weight than at any other time in childhood, making them vulnerable to dietary deficiencies and growth failure. Dietary habits of toddlers and preschoolers are important in shaping their later health and may play a role in increasing or decreasing obesity, high blood pressure, high serum cholesterol, and dental caries later in life. Adolescence, a time of emotional, physical, social, biologic, and educational transitions, is a period with particular susceptibility to weight concerns, eating disorders, alcohol abuse, and other poor dietary habits. Children with special health care needs at all ages, because of a variety of disabilities, handicaps, and chronic illnesses and conditions they may have, often need special complex and involved care and require particular attention to enable them to achieve their maximum potential.

Eating patterns begin to develop early in childhood and can profoundly affect health throughout life. In childhood, the immediate effects of improper diet are most apparent in such conditions as failure to thrive, obesity, the dietary deficiency diseases, and fetal alcohol effects. Later, chronic degenerative disease risks increase. The leading causes of death and disability for adults today include cancer, heart disease, stroke, osteoporosis, and alcoholism. Each involves risks associated with dietary patterns, as well as other preventable factors. Programs for the family and community must be designed to accommodate all of these diet-related problems.

COMMUNITY NUTRITION AND CHILDREN TODAY

The current status of some key national indicators of child well-being in the United States today has recently been summarized.[1] In the year 2000, there were 70.4 million children under age 18 in the United States, about 25% of the population. America's children are racially and ethnically diverse. In 2000, 65% of US children were white non-Hispanic, 16% were white Hispanic, 15% were black non-Hispanic, 4% were Asian or Pacific Islanders, and 1% were American Indians and Native Americans. From birth to kindergarten age, fully 61% of children received child care on a regular basis from a caretaker who was not their parent.

For many socioeconomic and health indicators, gains have been impressive over the past decade. For example, with respect to poverty, the rate for children living with their families is now 16%, which is lower than it has been for decades. In 2000, 0.8% of children lived in households reporting child hunger and 18% lived in households reporting any level of food insecurity, rates that were lower than in prior years. But problems still exist. For example, children in families below the poverty line were nearly three times more likely to experience food insecurity and hunger than their peers in families above the poverty line. According to the Healthy Eating Index, 27% of children 2 to 5 years have "good" scores, whereas only about 15% of those 6 to 9 years of age do. Children in families living in poverty were less likely than those from higher-income families to have a dietary pattern rated as "good." They also tend to be in poorer health than their more affluent counterparts. Therefore, many health and nutritional problems remain. Ways of ameliorating them by community-wide interventions are the focus of this chapter.

As a nation, we have made great strides in nutrition over the past century. The situation today differs dramatically from that in 1900, when dietary deficiency disease and undernutrition were the major problems.[2] Then

undernutrition and food insecurity were major societal problems. Now there are still some individuals who suffer from these problems. But today there are new faces to malnutrition. Overnutrition and obesity are increasing. Sometimes they coexist in the same individuals who suffer from deficiencies in other respects. Although malnutrition, starvation, and nutritional deficiency diseases will probably continue to be problems in some areas in the United States in the future, more prevalent nutrition problems involving overconsumption and imbalances in the types and amounts of food consumed and excesses of certain nutrients are also challenges.[2] Social and economic changes, such as altered family structures with more single parents, increasing ethnic diversity, a predominantly urban maternal and child population, high rates of poverty among children and their families, and more eating outside of the home, are some key variables in explaining the new forms of malnutrition we see today.[3,4]

THE FUTURE

There will be more children and a greater percentage of children in the population by the year 2010 than there are today.[1] For this reason alone, continued efforts to improve child health at the community level are necessary. Whether America's children will be healthier than ever before in the future will depend on sustained efforts on the part of parents and caretakers as well as the larger community. Systems for tracking health promotion and disease prevention objectives that include nutrition and other aspects of child and family health are now available that permit us to monitor our progress and to make corrections to improve health when they are necessary.

DEFINITIONS

Public Health

Public health is "the science and art of preventing disease, prolonging life, and promoting health and efficiency through organized community effort, so organizing these benefits as to enable every citizen to realize his birthright of health and longevity."[5] The goal of public health is to attain the highest level of physical, mental, and social well-being and longevity consistent with available knowledge and resources at a given time and place.[6] It accomplishes these objectives by focusing on the community or on large population groups rather than on individuals, on planning and monitoring rather than on delivering services.

Community Nutrition

Communities are groups of individuals or families living in a defined geographic area who live and work together, hold similar values, are influenced by the same environment, and share a number of common concerns. An understanding of the influences of society and of the community is necessary for planning effective nutrition interventions. Community nutrition applies scientific knowledge in food, nutrition, and health to a specific group of people to improve their health and welfare. To be successful, it must take into consideration the wide range of societal influences and constraints.

The community nutritionist must take into account an individual's cultural eating habits, ethnic background, income, health history, clinical assessment, dietary intake, and use of community nutrition programs to screen, assess needs, and intervene effectively.

The objectives of community nutrition are to promote health; prevent nutrient deficiencies, excesses, and imbalances; prevent diet-related diseases or conditions; and rehabilitate those suffering from nutrition-related problems. This is done by promoting healthful eating habits, ensuring access to food, and integrating nutrition into primary, secondary, and tertiary health care services.[2] Thus, it represents the traditional public health concerns (such as mass prevention and intervention measures) as well as a personal health services focus to ensure that high-risk, high-priority children especially receive health and other services they need. In this respect, community nutrition represents a fusion of both the personal health service's focus on individuals and the public health focus on the entire population.

GOALS OF COMMUNITY NUTRITION

The US Department of Health and Human Services' (DHHS) Healthy People 2010 plan singles out nutrition as essential to promote optimal health and prevent disease and provides nutrition goals for children and adolescents, which are listed in Table 9.1-1.[7] This chapter focuses on needs and meeting these goals at the community level.

The goals of child nutrition programs are to optimize growth and decrease the risk of all diet-related diseases. Strategies to accomplish the goals in the community must include consideration of the child's family; the efforts of the child, the family, and many members of the health care team; and contributions by institutions as well as economic resources in the health, food, education, and welfare sectors of the community. A supportive physical environment is also important.

In the community setting, strategies should focus on health promotion, early intervention, and prevention of diet-related diseases in groups of children and their families. In addition, community-level efforts must focus on ensuring that preventive and curative health services are in place.

Federal and state governments have been committed to promoting child health since early in this century.[8] However, the many programs they have instituted are useless unless communities make them available and families take advantage of them. Both states and communities exhibit considerable variation in the extent to which they provide supportive services and extra funds for reaching nutrition objectives. Detailed advice is available for discovering and mobilizing community nutrition resources.[9]

In the clinical setting, community nutrition–related strategies should focus on providing anticipatory guidance, preventive activities, and control of clinical problems

TABLE 9.1-1 Healthy People 2010 Nutrition-Related Goals for Children and Adolescents

- Increase abstinence from alcohol use by pregnant women.
- Increase to at least 80% those women of childbearing age who take a vitamin with the recommended 0.4 mg folic acid daily.
- Reduce low birth weight to no more than 5% of live births and very low birth weight to 1% or less.
- Increase to 75% mothers who breast-feed their babies in the early postpartum period, to at least 50% those who breast-feed until their infants are 6 months old, and to at least 25% those who breast-feed until their infants are 1 year old.
- Reduce growth retardation among low-income children aged 5 and younger to 5% or less.
- Reduce to 5% or less the prevalence of overweight and obesity (defined as at or above the sex- and age-specific 95th percentile of BMI from the NCHS/CDC growth charts) in children aged 6–11 and adolescents 12–19 years.
- In those 2 years of age and older, increase to at least
  - 75% those who meet the Dietary Guidelines' average daily goal of no more than 30% of calories from fat
  - 75% those who meet the Dietary Guidelines' average daily goal of less than 10% of calories from saturated fat
  - 75% those who meet the Dietary Guidelines' minimum average daily goal of at least five servings of vegetables and fruits
  - 80% those who meet the Dietary Guidelines' minimum average daily goal of at least 6 servings of grain products
  - 90% those who meet dietary recommendations for calcium
  - 65% those who meet the Daily Value of 2,400 mg or less of sodium consistent with the Dietary Guidelines
- Reduce iron deficiency to 5% or less among children 1–2 years, to less than 1% among children 3–4 years.
- Increase the proportion of children and adolescents 6–19 years whose intake of meals and snacks at school from all sources contributes proportionally to good overall dietary quality.
- Increase the proportion of the nation's public and private elementary schools that teach all essential nutrition education topics to their students in at least 3 different grades and the proportion of middle/junior high and high schools that teach all essential nutrition education topics in at least one required course.
- Increase the prevalence of food security among US households to at least 94% of all households.

Adapted from US Department of Health and Human Services.
BMI = body mass index; CDC = Centers for Disease Control and Prevention; NCHS = National Center for Health Statistics.

involving both primary and secondary malnutrition in all children but particularly in high-risk children.

All health care team members need to understand the importance of community nutrition, know what programs are (or should be) available, know how to obtain them for patients and clients, and know how to advocate their extension. Otherwise, those who provide direct care to children may fail to meet all of their nutrition needs.

HISTORY OF COMMUNITY NUTRITION AND HEALTH

Only in the twentieth century did the federal government begin to play a role in ensuring and safeguarding the health of American children. The Children's Bureau was established in the Department of Labor in 1912 to "investigate and report…upon all matters pertaining to the welfare of children and child life among all classes of our people."[8] It was the forerunner of efforts now centered in the Maternal and Child Health Bureau (MCHB) of the DHHS. The first federal grants-in-aid to the states for planning to improve infant and maternal health were authorized by the Sheppard-Towner Act of 1921. This legislation was first administered by the Children's Bureau in the Labor Department, but since the 1960s, the US Public Health Service in the DHHS has administered such programs.

Title V of the Social Security Act of 1935 initiated the federal and state partnership for maternal and child health that served as the major impetus for the development of public health nutrition services for mothers and children. The states used these federal funds for planning and developing a wide range of programs to improve the health of mothers and children. In 1981, Title V changed with the creation of the Maternal and Child Health Service Block Grant, which provided monies with fewer specific requirements and more state discretion within the general realm of maternal and child health needs. Fifty-nine states and jurisdictions now receive funding. The federal government also provides small amounts of federal set-aside funds to support special projects of regional or national significance. Other categorical programs for specific purposes are funded from the DHHS, the US Department of Agriculture (USDA), and other branches of government. With these funds and their own matching resources, the states provide a variety of services. However, access to health care remains an unresolved issue today.[10,11] Lack of access to medical nutrition therapy and other health services is a major problem for children who have health problems that cannot be solved by community nutrition or public health efforts. Community efforts supplement, but are not substitutes for, individual health services.[12]

Today more than 2,000 public health nutritionists are employed in federal, state, and local public health agencies. They also serve as members of health care teams, where they have the responsibility of assessing community nutrition needs as well as planning and directing programs of nutrition services for individuals. Many other health professionals, including over 60,000 registered dietitians, devote some of their time and effort beyond the scope of individual counseling to community programs and also play a role in ensuring that community nutrition needs are met.

NUTRITION SCREENING, ASSESSMENT, AND INTERVENTION

Nutrition screening, assessment, and intervention are important at both the level of the individual patient and that of population groups. A systematic approach and an integrated structure for screening, assessing, and intervening are needed to deal with nutrition problems in both health and social service settings.[13] The approach is summarized in Table 9.1-2. Details on how nutrition screening and assessment apply to individuals are provided elsewhere in this book.

The first step in developing an appropriate care plan for a community is nutrition screening of the entire maternal and child population to identify major problems. This may

involve examination of relevant statistics and resources of actual surveys. Next, the specific subpopulation of interest must be considered. Screening aims both to increase nutrition awareness among communities, families, and health professionals and to identify factors increasing nutritional risks in target groups. In the community nutrition context, the screening process might involve review of health indicators, such as the prevalence of low birth weight, with further delineation of high-risk groups using income, ethnicity, age, and other characteristics of parents or infants. Those groups who are found to be at risk are then further assessed.

The second step in care planning is a comprehensive nutritional assessment of the community in which the children live. Nutrition screening and assessment should be used in an effort to find groups at especially high nutritional risk. Some nutritional issues can be easily assessed and remedied by the health and social service systems. Others require further medical or social assessment before the causes of the malnutrition can be assessed. The process of setting priorities for intervention among the groups found to be in need of services and allocating resources appropriately to these efforts depends on the individual initiative and political will of the group's providers.

The final step in care planning is intervention, which may be at either the individual or the community level. This may involve nutritional measures such as food or counseling or other interventions that improve nutritional status more indirectly, such as oral health, pharmacy, social, and mental health services. The ultimate goal is to prevent, control, or ameliorate nutrition-related problems. The end result should always be to improve or ameliorate children's health.

TABLE 9.1-2 Pediatric Nutrition Screening, Assessment, and Intervention in the Community

Screen for Risk: Identify individuals and groups in the community needing further assessment for potential health problems with nutritional implications.	Look for the following "*DETERMINE*" risk factors: • *D*isease • *E*ating disorders • *T*ooth decay • *E*conomic hardship • *R*educed nutrition education • *M*ulticultural issues • *I*nadequate food intake • *N*utrient deficiencies • *E*levated or reduced body weight
Screen and Assess Community Resources	Determine whether nutrition resources are adequate, which groups are at high risk, and extent to which community nutrition needs are being met by existing programs. Tools include demographics, socioeconomic stratification, health statistics, local health resources, cultural factors, housing, food supply, child nutrition programs, social welfare programs, education, occupational data, etc.
Assess Child: Confirm that diet-related problems are present and whether growth and nutrition are inadequate owing to dietary deficiency, excess, or imbalance or secondary to disease.	Follow the *ABCDEF*s of assessing nutritional status: • *A*nthropometrics: height, weight, triceps skinfold, arm circumference • *B*iochemical: hemoglobin/hematocrit, albumin, transferrin • *C*linical: skin, tongue, hair • *D*ietary intake: by 24-h recall, food frequency, food record • *E*mpathy • *F*unctional status at all levels: physical, mental, emotional
Intervene at Individual and Community Levels	Identify and use community and individual health care resources, using the mnemonic SOMe Meds and Nutrition: • *S*ocial services • *O*ral health • *M*ental health • *Med*ical care and medications • *Nutrition* counseling, education, and support

NUTRITIONAL MONITORING AND SURVEILLANCE AT THE STATE AND NATIONAL LEVELS

Monitoring and surveillance are analogous to repeated screening and evaluation efforts at the individual level. Monitoring is the periodic measurement of factors that indicate that changes in nutritional status have occurred. It applies to specific individuals, communities, and the general population. Surveillance is the continuous and regular collection of data that are compiled to detect warning signs of problems at the community level early enough to provide feedback for health care team members.

The purpose of monitoring and surveillance is to provide continuous, reliable information on a community's nutritional status and the factors that influence it to find ways to improve it.

National nutrition monitoring involves measurement of health status, food supply, food consumption and composition, and dietary knowledge and attitudes.[14] At the federal level today, nutrition monitoring and surveillance are conducted by several different government agencies. Within the DHHS, the National Center for Health Statistics of the Centers for Disease Control and Prevention (CDC) conducts the National Health and Nutrition Examination Survey (NHANES). NHANES is a periodic, population-based survey providing national data on specific health status measures, including dietary intake, eating habits, and biochemical and anthropometric indices related to nutrition. NHANESs are now continuously in the field. The NHANES data provide useful benchmarks for the health of these groups. However, the number of children and adolescents surveyed is small, and not all relevant problems can be examined in each survey. Therefore, occasionally, special surveys have been conducted that oversample these groups.

In 1999, the USDA's CSFII (Continuous Survey of Food Intake of Individuals) was merged with the NHANES. Both the USDA and the CDC's National Center for Health Statistics now partner on the dietary portion of the survey, which

is called "What We Eat in America." The combined survey is now in the field, and the results should be available in 2004.

The USDA monitors food security in the United States through an annual survey of 40,000 US households conducted as a supplement to the US Census Bureau's nationally representative Current Population Survey. The most recent food security survey revealed that 89.5% of US households were food secure. The remaining 10.5% were food insecure; at some time during the prior year, these households were uncertain about having or were unable to acquire enough food to meet the basic needs of all household members because they had insufficient money or other resources.[14] Single mothers with children had the highest levels of food stress. Minority group black and Hispanic households also had rates of food insecurity and hunger above the national average.

The USDA also provides funds for grants and contracts to universities and nonprofit organizations to perform analysis and research in support of improving food consumption practices. These include rating food intakes of various portions of the population from national survey data using a new tool, the Healthy Eating Index,[15] and program-specific analyses, such as studies of the National School Lunch and Breakfast Programs.[16]

The CDC of the DHHS conducts ongoing state-based nutritional monitoring activities. The database consists of data collected on children and pregnant women enrolled in health department clinics, the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC), and the Head Start programs at the state and local levels. Programs include the Pediatric Nutrition Surveillance System (PedNSS), the Pregnancy Surveillance System (PNSS), and the Severe Pediatric Undernutrition Surveillance Systems (SPUN). These surveys are not necessarily representative of the entire population but provide much useful data on groups at special risk.[17]

DIVISION OF LABOR: MANAGEMENT OF COMMUNITY NUTRITION SERVICES

The management process consists of planning, organizing, implementing, directing, controlling, and monitoring. The dynamic aspects of the process of community nutrition service management are illustrated in Figure 9.1-1 and occur on two levels. First, there is program management at the indirect service level, which includes macrolevel planning, administration, supervision, consultation, and training, as well as screening and assessment of problems at the community level. Program management and evaluation efforts generally occur at this level. Second, direct service delivery may be provided to both groups and individuals, and this includes screening, assessment, intervention, and follow-up. Both levels must focus on the child and his/her family if the programs are ultimately to be effective.

Planning

Planning is a process of devising a course of action to reduce uncertainty and to anticipate and initiate change. Community nutrition planning involves analyzing subjective and objective data, writing mission statements, setting goals and objectives, and activating means of achieving objectives. Nutrition planning is influenced by the internal culture and capabilities of each organization involved, as well as by the public agenda, state of scientific knowledge, wants and needs of the families, and advocacy of experts, parents, and professional groups.

Community nutritionists should participate in the planning processes of the agency, study the agency or community health plans, know those who participate in the planning group, get involved, and involve others. Planning goes beyond administrators, leaders, and program managers and should include those who will be responsible for implementation and those who will be recipients of services.[18]

Planning for high-priority nutrition problems can be aided by forming alliances with related constituencies in the service network. Some examples are collaborative planning by nutrition service providers, advocates, and patients. This sort of collaboration may build political support and bridge organizational and ideologic boundaries, identify mutual goals, and build cohesion and capacity to act together if potential adversaries are approached, coopted, and included in the process. In some instances, it may assist in making difficult decisions about using limited resources.

Implementing

Planning identifies what to do. Implementation begins the process of doing. Effective community nutrition program implementation requires administrative support (budget, staff, space, equipment); commitment of staff to program goals, objectives, and interventions; and support and respect of a target population who is also convinced of the benefits of the program and willing to commit time and effort to participate.

Screening and assessment at the community level are the responsibilities of the community nutritionist, who ensures that systems are in place in community programs and encourages their institution in personal health services. Nutrition screening and assessment also occur at the direct service delivery level, where they are usually administered by health or social welfare care team members such as dietitians, physicians, nurses, social workers, and physical therapists.

The role of the community nutritionist in implementing programs varies. Depending on the health and nutritional problems found, children and/or families are referred to different community and personal health services for interventions including nutritional counseling, food, welfare education, and health programs or to private physicians.

Monitoring and Evaluation

Community nutrition program implementation must be systematically monitored by the collection and analysis of appropriate data to provide the continuous feedback needed to assess performance. Evaluation involves the systematic measurement of results by comparing the data collected with pre-established standards or controls to decide whether to continue, expand, redesign, or terminate the program.

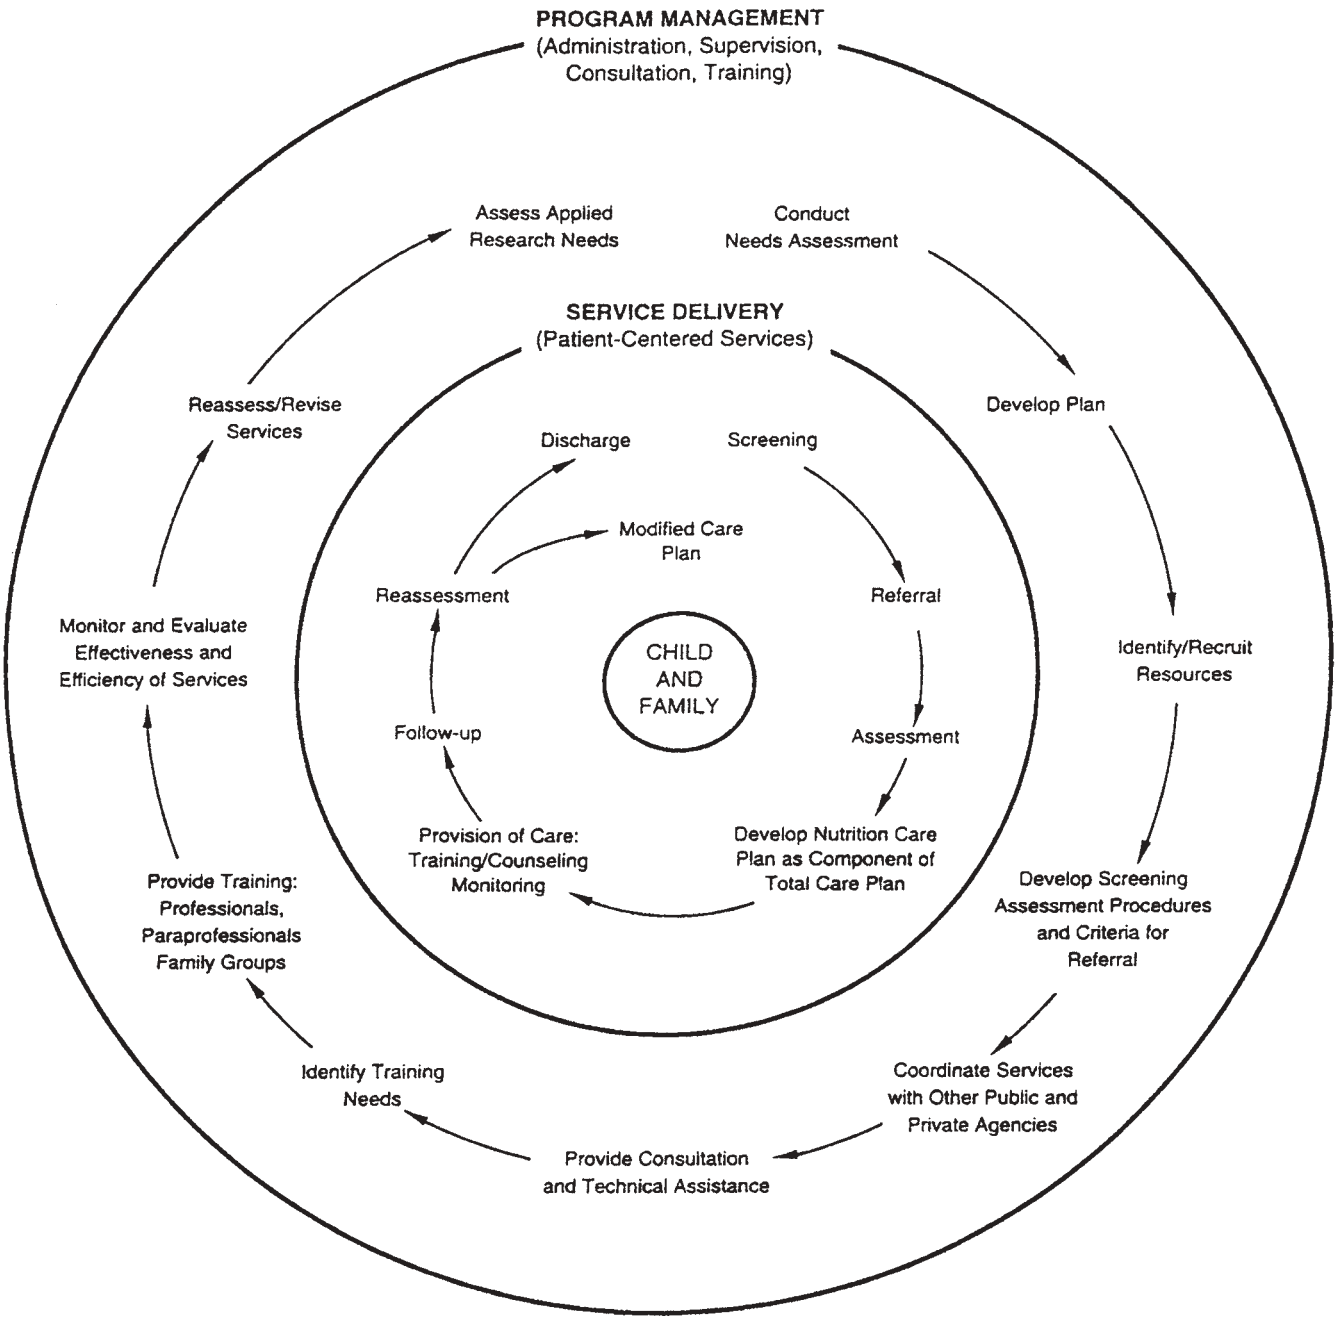

FIGURE 9.1-1 System for nutrition services. Adapted from Baer MT, editor. Nutrition services for children with handicaps: a manual for state Title V programs. Los Angeles: University Affiliated Program, Center for Child Development and Developmental Disorders; 1982.

Monitoring must also be accomplished at both direct and indirect service levels. At the direct personal health service delivery level, the health care team evaluates program impact on a population or community by observing improvements in health. At the indirect level, the management of the community nutrition program may also evaluate effectiveness, efficiency, and cost through cost-effectiveness analysis to determine whether the program's benefits are sufficient to offset its cost. One current effort of this type is the Preventive Health Services Task Force. Its publications on health services that are viewed as effective are increasingly being used as a guide for services.[19] Another key document for monitoring progress at the community level is the tracking system for the Healthy People 2010 objectives.[20]

CURRENT NUTRITIONAL STATUS OF INFANTS, CHILDREN, AND ADOLESCENTS

This section summarizes the major problems of different age groups today and some diet-related risk factors. It provides recommendations needing incorporation in both community nutrition programs and personal health and social services for children.

Some nutrition problems such as iron deficiency anemia, growth retardation, dental caries, obesity, and possibly diet-related decreased resistance to infection affect some children at all ages and are matters of concern across the entire developmental period.[21] Others, as described below, affect specific age groups.

Pregnant Women and Infants

Community concern about good nutrition should start before birth. Nutritional needs in pregnancy and lactation at both the individual and community levels have recently been summarized.[21–23] High-risk women who are poor need to be enrolled in the WIC and provided with nutrition counseling, food education, and other specialized health services.

Adequate nutrition is vital for premature, small-for-date, and other low birth weight infants who are at risk of developmental disadvantage. (See other chapters in this volume for more details.) Early intervention programs to encourage and promote good nutrition among those infants most in need are of particular concern.

The March of Dimes recently published a report that summarizes interventions that are needed to deal with the new faces of nutritional problems that confront Americans today, particularly those that affect those in the childbearing years.[24] These include not only undernutrition and food insecurity but also nutritional imbalances and excesses. The report emphasizes prevention, not only in one-on-one health visits but also by social marketing and health communications to create healthier environments in the larger community. The importance of prevention particularly targeting childhood and preconceptional females is highlighted. Some of the key recommendations of the report that have implications for community nutrition include the following:

1. *Early nutrition matters*. Attending to early nutrition of infants and children under 2 years is critical. Steps include promoting and supporting exclusive breast-feeding for 6 months and continued breast-feeding with complementary foods up to 12 months of age or longer. The special needs of nutritionally at-risk infants, including preterm and/or low birth weight infants, must be ensured. Promotion and support of programs to ensure adequate intakes in pregnant and lactating mothers and the introduction of safe, nutritionally adequate, and developmentally appropriate complementary foods are needed.
2. *Healthy weight matters*. It is important to increase awareness of healthy weight throughout the life cycle to improve health, including good pregnancy outcomes. Those who are at risk of pregnancy with body mass indices under 18.5 or over 25 should reduce them to more healthful levels. Increasing the average age at first pregnancy will permit full maturation before childbearing. Women who are pregnant need assistance to gain a healthful amount of weight during pregnancy and also may need help in achieving a healthy weight after birth.
3. *Nutritious, safe food and diet quality matter.* Food-based dietary guidelines must address the nutritional requirements of periconceptional, pregnant, and lactating women and very young children. When it is not possible to meet all of their needs through available food sources, including fortified foods, appropriate specific vitamin and mineral supplements for women of childbearing age, infants, and young children should be provided.

Nutrition is especially critical in the first year of life.[25] Nutrient needs are high because growth and development are more rapid in infancy than at any other time after birth. Weight usually triples and height doubles in the first year. Approximately a third of calories consumed is used for growth during the first 4 months. This rapid growth in the healthy term infant during the first 4 months of life requires more energy, protein, and other essential nutrients per unit of body weight than at any other time in infancy or childhood. Feeding nourishing foods to infants promotes adequate growth and good health.

The gastrointestinal tract of the newborn infant is well developed but immature. All of the secretions of the digestive tract contain enzymes especially suited to the digestion of human milk. The ability to handle foods other than human milk or formula depends on the physiologic development of the infant. Thus, it is important to encourage breast-feeding and to feed infants age-appropriate foods selected on the basis of their developmental readiness.[25] Not only will this help to prevent complications, it will also help to build positive attitudes about food and eating.

Attention to feeding the appropriate type and amount of food is essential. All parents and caretakers need appropriate advice and guidance. For the poor at high risk, WIC, which provides food, health services, and education, may be in order. For the ill, Title V and Medicaid-supported health services, as well as special services for those with especially severe handicapping conditions, may be in order.

Some of the common nutritional and health problems and related risk factors in infants that need attention by community nutritionists are summarized in Table 9.1-3. Table 9.1-4 provides recommendations for promoting good nutritional status during this period.

Preschool and School-Aged Children

Table 9.1-5 outlines some of the current nutritional concerns and Table 9.1-6 provides recommendations on promoting good nutrition after infancy in the preschool and school years.

In late infancy, children begin to learn to feed themselves independently. They progress from eating with their hands to using utensils. Children need to be independent and able to try new skills to help them develop positive attitudes about food and eating.

Children's growth rates slow considerably after the first year of age, resulting in decreased appetite and food intake. This normal phenomenon is often mistaken for poor appetite, although it is not. In spite of the slower growth rates, appropriate nutrition is vital to provide needed nutrients and energy to maintain resistance to infections, materials needed to build new tissues as growth proceeds, and adequate nutrient stores.

TABLE 9.1-3 Current Nutritional Issues and Recommendations for Infants

Current Health Problems	*Related Nutrition Risk Factors*
Growth retardation, underweight	Dietary inadequacies, low birth weight, inappropriate introduction of foods
Dental caries	Excessive, frequent consumption of sweets that are retained in the mouth, baby bottle tooth decay, lack of fluoride
Iron deficiency anemia	Early introduction of cow's milk, malnutrition, inadequate dietary iron intake
Other nutrient deficiencies	Inadequate intake of certain nutrients, lack of appropriate supplements
Infections	Malnutrition, lack of breast-feeding

What Needs to Be Done?

- Improve nutrition training of health professionals
- Increase nutrition counseling and education of parents and caretakers
- Strengthen breast-feeding support
- Develop nutrition and feeding guidelines for agencies responsible for the administration of health, social welfare, and related program services
- Enhance the research base for current issues in infant nutrition
- Prevent or treat inappropriate weight gain

TABLE 9.1-4 Recommendations for Enhancing the Nutritional Status of Infants

Early infancy (0–6 mo)

- Breast-feed until 4–6 mo of age
- If breast milk is not provided, feed with a hygienic, nutritionally adequate source of heat-treated formula until 4–6 mo of age
- Supplement with vitamin D and iron if the infant is solely breast-fed for the first 6 mo of life or if these are not provided in formula
- Supplement with fluoride if the water or formula is devoid in the nutrient
- Avoid unsuitable feedings (solids, cow's milk, and skim milk) under 6 mo of age and encourage breast-feeding and adequate supplementation
- Ensure that the infant receives enough food by monitoring growth
- Use proper feeding techniques to avoid gas, aspiration, and other problems
- Delay introduction of solid foods until age 5–6 mo, when the infant is developmentally ready to deal with them
- Avoid foods commonly causing allergies, intolerances, or hypersensitivities
- Ensure that water intakes are adequate
- If family resources are inadequate, obtain assistance from federally sponsored food programs for infants and children
- Obtain relevant anticipatory guidance on feeding and health

Later infancy (6–12 mo)

- Use iron-fortified formulas, iron supplements, and iron-fortified cereals
- Ensure a gradual transition to family diets rather than attempting to wean suddenly
- Introduce solid foods sequentially after 4 to 6 mo when the child is developmentally ready and needs supplementary feedings
- Take common problems in stride. Temporary refusals of solid foods at weaning and failures to switch over from pureed or baby foods to foods that must be chewed are normal setbacks
- Consult health providers if feeding problems persist
- Health and encourage self-feeding
- Realize that some decrease in appetite in late infancy is to be expected as growth slows and that it is no cause for alarm
- Avoid struggles and battles of will with the child about food
- Keep environments safe (especially with respect to lead and common household chemicals, which are poisonous) and begin to teach child to shun mouthing and eating nonfood objects
- Begin oral hygiene measures

Good nutrition is important to sustain growth and permit development. It is especially important in the weaning period to prevent the risks of iron deficiency anemia, dental caries, and obesity and diet-related risks that may contribute to later hyperlipidemia and hypertension.

Obesity is increasing in Americans, with estimates of obesity in 10 to 30% of school-aged children.[26,27] Therefore, attention to nutrition must not be neglected in the preschool, primary, and middle school years. The US Surgeon General recently called for immediate action on obesity, particularly in children and adolescents.[28] His report concluded that in 1999, approximately 61% of American adults were overweight, along with 13% of children and adolescents. Overweight among adolescents has tripled since 1980, and obesity among adults has doubled. Also, associated conditions such as asthma and type 2 diabetes are rising among children, and diet-related chronic disease risks linked to obesity are also on the rise. Minorities and low-income families often are particularly afflicted. Therefore, there is a need for immediate action. Strategies that communities can use in helping to address overweight and obesity especially in children and adolescents involve "CARE": communication of the problem and steps to correct it, actions, research, and evaluation. These action options include the following:

1. *Physical activity.* Require daily, quality physical education at all school grades. Currently, the only state requiring physical education for kindergarten to grade 12 is Illinois. Today only about one in four teenagers nationwide take part in some form of physical education. It is also important to provide safe and accessible facilities for the recreation of people of all ages. Community facilities should be available for physical activity for all people, including on the weekends, and there should be more opportunities for physical activity at work sites. At the same time, it is important to reduce the time people spend in watching television and in other sedentary behaviors. In 1999, 43% of high school students reported watching 2 or more hours of television a day.
2. *Food options.* Ensure the availability of more food options that are low in fat and calories, as well as fruits, vegetables, whole grains, and low-fat or nonfat dairy products, on school campuses and at school events. It is important to enforce existing USDA regulations that prohibit serving foods of minimal nutritional value during mealtimes in school food-service areas, including vending machines.
3. *Communications.* Change the perception of obesity so that health, and not simply personal appearance, becomes the chief concern. This means providing

TABLE 9.1-5 Current Nutritional Issues and Recommendations for Children

Current Health Problems	*Related Nutrition Risk Factors*
Obesity	Caloric consumption exceeds caloric need
Failure to thrive	Dietary inadequacies
Iron deficiency anemia	Malnutrition, inadequate dietary iron intake
Dental caries	Excessive, frequent consumption of foods high in sugar and starch with poor oral hygiene
High blood pressure	Overweight, high sodium intake
High blood cholesterol	Excessive intakes of saturated fat and cholesterol

What Needs to Be Done?

- Achieve adequate nutrition services in daycare programs and early childhood education (Head Start)
- Increase participation in and coverage of child nutrition programs (School Lunch and Breakfast)
- Increase parent and community nutrition education
- Improve nutrition training of health professionals
- Enhance the research base to answer existing questions in child nutrition
- Change policy to integrate nutrition services into all aspects of child health care

TABLE 9.1-6 Recommendations for Enhancing Nutritional Status in Children

Preschool years

- Ensure that levels of physical activity and rest suffice to maintain normal growth and development and a good appetite
- Provide nutritious food in the home and in other settings in which the child eats to encourage good food choices
- Teach the child to choose and eat nutritious foods for meals and snacks
- Avoid sugary starchy snacks that are retained in the mouth and encourage oral hygiene practices to promote good dental health
- Foster appropriate eating behaviors by providing suitable role models, by permitting the child to choose food portions, by giving some latitude in food preferences, by exposing him/her to new foods, by fostering table manners appropriate to his/her developmental level, and by keeping meals as times for social interchange
- Recognize and deal with feeding problems early before they become well established
- Handle struggles over food reasonably to avoid the development of feeding problems
- Feed and hydrate children appropriately during illness
- Help the child grow out of fatness by encouraging physical activity
- Ensure that iron needs are met by wise food choices
- Ensure that the child learns to distinguish food and nonfood objects

School years

- Monitor growth in height to ensure that nutritional status is satisfactory
- Provide good examples and guidance to instill healthful habits and attitudes about foods and eating
- Establish consistent guidelines and follow them to ensure that the child's diet is nutritionally adequate
- Promote eating and physical activity habits that will foster normal body fatness
- If excessive fatness is a problem, encourage child to increase physical activity and help him/her to cut energy intakes slightly so that the child can grow out of his/her fatness
- Ensure that diet-related risks of dental caries are minimized
- Help the child to distinguish between reliable sources of information on food choices and promotional messages, which may be unreliable
- Ensure dietary moderation with respect to dietary fat, cholesterol, sugar, and sodium
- Ensure that diets are adequate in fiber
- Ensure that iron needs are met by wise food choices

appropriate education in schools and communities and in the training of health professionals about healthful eating habits and regular physical activity, based on the Dietary Guidelines for Americans, for people of all ages.

4. *Growth monitoring.* New growth charts are now available for children and adolescents to evaluate their size and growth.[28,29] They need to be used on a continuing basis.

Adolescents

Puberty is a unique and complex developmental period marking the transition from childhood to adulthood. It is accompanied by a series of physical, physiologic, biochemical, hormonal, social, and psychological changes. Adolescence is a nutritionally vulnerable period for several reasons. A dramatic increase in physical growth occurs during puberty. The growth spurt is highly sensitive to nutrient deprivation. Inadequate nutrition during this time may delay or stunt linear growth.[30] Alterations in body composition in puberty and during the consolidation that occurs in later adolescence, as maturity is reached, increase nutrient and energy needs. During the second decade of life, children gain about 20% of their adult height and 50% of their adult weight.[31] After puberty, although linear growth ceases, changes continue until maturity is reached.

The larger body requires increased amounts of nutrients. Calcium is a nutrient of particular concern because bone growth and bone mass accumulate rapidly during this time of life. Osteoporosis is a disease that afflicts mostly the elderly, but just as is the case with atherosclerosis, its seeds are sown in childhood. One of the most effective ways to prevent osteoporosis is to build a strong, dense skeleton during the growing years to act as a reserve later in life. Moreover, changes in individual behaviors and lifestyle preferences in younger children may last through adolescence and into adulthood, again contributing a lifetime of optimal bone health. Increasing attention is being paid to school programs that will increase bone accretion and muscular strength in children starting in early elementary school, aged 5 to 7 years of age, and continuing into adolescence. The interventions now being tested include weight-loading physical activity and calcium-rich snacks for children as well as age-appropriate, behaviorally focused active learning to promote skill building and self-competence while building bone quality and bone strength.

Growing independence, the need for peer acceptability, concern with appearance, and active lifestyles of adolescents often affect eating habits, food choices, nutrient intake, and thus nutrition status. Adolescents are seeking to establish their identity and are susceptible to peer pressure and mass media. They are also preoccupied with physical appearance and body shape and size. Desires to be lean and to have an attractive body, societal pressures, and an abundance of food in the environment can lead to inappropriate weight reduc-

tion, dietary aberrations, and nutrient deficiencies.[32] Chronic dieters are at high risk for inadequate diets. In adolescent females, such behavior may lead to eating disorders, such as anorexia nervosa and bulimia nervosa.[33,34]

Common nutritional problems in adolescents are provided in Table 9.1-7. They include obesity, hyperlipidemia, dental caries, and hypertension.[35,36] These problems of dietary imbalance and excesses may coexist with undernutrition with respect to iron, energy, and other nutrients in some individuals. Dietary factors increasing the later risk for chronic diseases such as osteoporosis (inadequate intakes of calcium and vitamin D), heart disease (excessive intake of saturated fat and cholesterol, low intake of fiber), and some types of cancer may be present.[36] Table 9.1-8 provides recommendations to enhance nutritional status during adolescence.

Pregnancy and lactation in adolescence also increase nutrition risk because the young female needs a supply of nutrients to support her own growth as well as the growth of the fetus and nutrition of the suckling infant.[37] Nutritional needs of pregnancy and lactation are discussed elsewhere in this book.

TABLE 9.1-7 Current Nutritional Issues and Recommendations for Adolescents

Current Health Problems	*Related Nutrition Risk Factors*
Hypertension	Overweight, excessive sodium intake, low potassium intake
Underweight	Undernutrition, anorexia nervosa, bulimia nervosa
Obesity	Caloric consumption exceeds caloric need, sedentary lifestyle
Dental caries	Excessive, frequent consumption of sugary starchy foods that are retained in the mouth, lack of oral hygiene
Iron deficiency anemia	Malnutrition, inadequate dietary iron intake, pregnancy without iron supplementation
Elevated serum cholesterol	Excessive saturated fat and cholesterol intake
Nutrient deficiencies	Inadequate nutrient intakes, extended periods of dieting
Eating disorders	Societal pressure to be thin, peer pressure, diet fads
Alcohol abuse	Underage alcohol use

What Needs to Be Done?

- Include nutrition in comprehensive health education in schools
- Develop national guidelines for school-based nutrition education programs
- Increase nutrition education to parents and communities
- Increase School Lunch and Breakfast participation
- Improve training and continuing education for all health care providers in the area of nutrition
- Integrate nutrition screening, education, and intervention services into health services aimed at teenagers
- Expand school-based health clinics especially for teenagers who have no primary physician
- Expand research on nutritional needs of adolescents

NUTRITION FOR CHILDREN WITH SPECIAL NEEDS

Some of the most common nutritional issues of children with special needs are outlined in Table 9.1-9. Children with special health care needs make up approximately 10 to 20% of the pediatric population, depending on the definition used.[38] The term special needs describes a group of infants, children, and youth with or at risk for physical or developmental disability or with a chronic medical condition caused by or associated with genetic/metabolic disorders, birth defects, prematurity, trauma, or infection (including human immunodeficiency virus [HIV] infection). They present a particular challenge to community nutritionists today because many special needs children who were formerly institutionalized now dwell with their families in the community.

Table 9.1-10 provides some recommendations for enhancing the nutritional status of special needs children. Some of the nutrition needs of children with special health care needs are unique (eg, the child with a metabolic disorder controllable only by diet), but in most aspects, their nutritional needs are similar to those of other children. The "special needs" child in the family is first of all a child who has the same nutrient needs for optimal health, growth, and development as any other child. Superimposed on these needs, however, may be multiple risks, ranging from social/environmental factors, such as decreased access to food because of limited finances, to factors involving disorders, such as feeding problems or the need for chronic medication.[39] These factors may place a child at risk for inadequate nutrient intake, impaired nutrient absorption or use, or increased nutrient excretion. Such insults, if they are severe and/or prolonged, and especially if they occur early in life, can have lasting effects on the child's growth and cognitive development. Various handicapping conditions have different nutrition-related problems and needs.[40]

TABLE 9.1-8 Recommendations for Enhancing Nutritional Status in Adolescents

- Maintain desirable weights. Avoid obesity and eating disorders by developing healthful attitudes toward food, appropriate energy intakes, and a physically active lifestyle, including both aerobic and strength-building exercise
- Abstain from self-induced vomiting, bulimia, and laxative abuse
- Eat a variety of foods to ensure dietary sufficiency of protective nutrients, including protein, vitamin, minerals, and fiber
- Avoid dietary imbalances, stressing moderation with respect to fat, saturated fat, cholesterol, sugars, and salt by moderation in intakes of foods high in these and low in protective nutrients
- Find ways to eat that fulfill the teenager's individual needs, philosophies, wants, and schedules without doing violence to nutritional status
- Identify and alter eating habits that are not conducive to good nutrition, including long-standing poor dietary intakes, irregular or unplanned food intakes, and excessive intakes of fat, cholesterol, sodium, sugar, and alcohol
- Avoid alcohol use
- Provide assistance for special problems such as teenage pregnancy, diets for competitive athletes, diets for those with allergies and disease
- Ensure adequate intakes of calcium and vitamin D to maximize bone density

TABLE 9.1-9 Current Nutritional Issues and Recommendations for Children with Special Needs

Current Health Problems	*Related Nutrition Risk Factors*
Growth retardation, underweight	Increased needs; inadequate intake caused by mechanical difficulties with chewing, swallowing, or feeding oneself; malabsorption
Obesity	Reduced resting metabolism, decreased energy expenditure, excessive calorie intake
Gastrointestinal complications	Diet not adequate in fiber and water
Nutrient deficiencies	Inadequate intake of certain nutrients, lack of supplementation, increased needs, drug–nutrient interactions
Infections	Malnutrition

What Needs to Be Done?

- Ensure that community programs for special needs children are in place to screen and assess nutrition problems
- Implement use of standardized screening and referral tools for service providers
- Improve nutrition training of health professionals
- Increase nutrition counseling and education for families
- Develop nutrition and feeding guidelines for agencies responsible for the administration of health, social welfare, and related program services
- Enhance the research base for current issues in nutrition for children with special needs

TABLE 9.1-10 Recommendations for Enhancing Nutritional Status in Children with Special Needs

- Recognize that expectations for growth may be different; use appropriate standards when available
- Provide adequate nutrition to achieve optimal growth potential
- Consider the extra or lessened energy needs owing to the child's condition and adjust intake accordingly
- Use vitamin and mineral supplements if directed by physician
- Frequently evaluate adequacy of child's diet
- Ensure adequate intake of fluid and fiber
- Consult an interdisciplinary team and develop a care plan that includes realistic expectations regarding the child's potential, understanding of feeding skill progression and recognition of developmental readiness for next steps, and enrolment in early intervention programs as needed
- If warranted, adjust feign positioning to allow for adequate food intake, use appropriate nipples and feeding devices for children unable to use standard equipment, and adjust pace of feeding appropriately
- Determine family's need for food assistance, support with home and money management, diet information, and emotional support

These are represented schematically in Figure 9.1-2 and are discussed in more detail in another chapter.

An amendment (PL 99-457) to the Federal Education for the Handicapped Act gives nutrition professionals the opportunity to have a voice in establishing nutrition policy and standards of care for young handicapped and high-risk children. Preventive services now extend to children as young as 3 years of age, and Part H of the law provides financial incentives for states to provide services to children with special health care needs from birth to 2 years of age. Nutrition should be included in these services.

EXISTING PROGRAMS

Federal Programs

Either the USDA or the DHHS administers most federally funded food and/or nutrition programs for mothers and children. The programs are administered on the state level by the Department of Welfare, Department of Education, or Department of Health depending on their particular focus. One type of federal support is through benefits or cash assistance that goes directly to eligible recipients (such as the Food Stamp program, which provides food vouchers, or the School Lunch program, which provides inexpensive or free meals). Another type is in-kind services (such as the USDA's Expanded Food and Nutrition Education Program [EFNEP], which provides nutrition education to low-income families).

Means-tested programs require assessment of means or income before one qualifies for them. They are special cash or in-kind services targeted to provide a safety net to protect children in low-income families. Eligibility for such programs, such as Food Stamps, Medicaid, general relief payments, funded child health services, or free school lunch and breakfast, is assessed by review of family incomes. These programs are valuable contributions for maintaining or improving the nutritional status of low-income families. Such families may have limited access or resources available to buy food, and those who are particularly vulnerable from the physiologic standpoint include infants, young children, and pregnant and lactating women.

Community nutrition services for families and children are also available as part of other health and social services, such as intensive infant care programs, services for handicapped children, dental health programs, family planning service, school health, and teenage pregnancy/parenting programs.

The federal government also provides grants for planning and service provisions to states for program development to provide food assistance, nutrition education, and counseling to eligible families at the local level through health centers, school systems, and community action agencies.

Health care providers need to know about the many food and nutrition programs available in their local areas and how and when to refer their patients to them.

USDA Programs The USDA provides various public health programs at the community level. These include Food Stamps, School Lunch and Breakfast, Special Milk Program for Children, Child Care Food Program, Summer Food Service Program for Children, WIC, EFNEP, and Commodity Supplemental Food Program (CSFP). These programs served an estimated one in six Americans at some point during 2001.[41] Food pantries and soup kitchens are also available for some families that lack food. Surplus foods, both dry and perishable, are distributed to food pantries and soup kitchens. Table 9.1-11 presents a summary of current expenditures on these programs.

DISORDER	PREVALENCE ESTIMATES PER 1,000 (AND RANGE)	EXAMPLE OF NUTRITION PROBLEMS AND FACTORS CONTRIBUTING TO HIGH NUTRITIONAL RISK: Child-related: Altered nutrient needs	Altered energy needs/intake	Problems with oral cavity	Nutrient deficiencies	Constipation/diarrhea	Poor appetite	Delayed feeding skills	Malabsorption	Nutrient-drug interactions	Maladaptive behaviors	Lack of knowledge	Caregiver-related: Difficulty understanding diet	Does not limit intake	Inappropriate feeding practices
Asthma	38 (20–53)		●		●		●			●					
Moderate to Severe	10 (8–15)														
Visual Impairment	30 (20–35)														
Impaired Visual Acuity	20							●			●

Gastrointestinal Disorders	< 1.0	●			●	●	●		●						

FIGURE 9.1-2 Prevalence of certain chronic conditions with associated nutrition-related problems.

Food Stamp Program ***What It Is.*** This is the largest and most far-reaching food assistance program for low-income families in the United States to help them buy the food they need for a nutritionally adequate diet. The amount provided is based on the USDA's Thrifty Food Plan, a market basket of suggested amounts of food that make up a nutritious diet and that can be purchased at a relatively low cost. The federal government pays for all benefits issued through the program and shares administrative costs with the states. Puerto Rico, American Samoa, and the Marianas receive cash grants instead under the Nutrition Assistance Program that permits them to provide food assistance programs for their low-income residents. Food Stamps is a means-tested entitlement program; any household that meets program eligibility requirements may receive them. Households participating in the program actually receive their benefits by an electronic benefits transfer card system rather than by stamps or coupons, as in days gone by. Benefits can be used to buy food but not alcohol, tobacco, or nonfood items such as soap or paper supplies. Nationally, the majority of all Food Stamp recipients are children, and the preponderance of Food Stamp benefits is paid to families with children.

Who Qualifies. For families with children, the principal eligibility requirement is that gross household income is below 130% of the federal poverty level and that net income, after various deductions, is at or below 100% of the poverty level. The value of a household's assets (eg, cash on hand, checking or savings accounts, stocks and bonds, recreational boats and vehicles, some cars, and land that is owned but not inhabited by the household) is also accounted for in determining eligibility.

How to Enrol. Contact the state or local welfare office and obtain an application.

Child Care Food Program ***What It Is.*** This program provides cash reimbursement and/or commodities for the provision of meals and snacks to institutions such as child care centers and family and group daycare homes providing nonresidential child care to children from low-income families. This program funds the meals provided in Head Start. This is not an entitlement program. Subsidies are

TABLE 9.1-11 Food Assistance Program Expenditures, USDA, 2001

Food Assistance Program	*Program Costs, 2001 (Million Dollars)*
Food Stamp–related programs	19,009.5
Food Stamp Program	17,702.2
Nutrition assistance programs	1,279.4
Child nutrition programs	9,918.6
National School Lunch Program	6,454.8
School Breakfast Program	1,441.4
Child and Adult Care Food Program	1,733.6
Summer Food Service Program	272.3
Special Milk Program	15.5
Supplemental Food Programs	4,235.1
WIC	4,133.2
Commodity Supplement Food Program	102.0
Food donation programs	596.8
Food distribution on Indian reservations	68.6
Disaster Feeding Program	0.4
The Emergency Food Assistance Program	370.0
Charitable institutions and summer camps	6.0

Adapted from USDA Food and Nutrition Service, Keydata, September 2001.
WIC = Special Supplemental Nutrition Program for Women, Infants, and Children.

provided for two meals and one snack per day for children less than 12 years old. Meals must meet USDA-specified requirements. Family or group daycare homes are paid a fixed reimbursement, depending on the type of meals served. Daycare centers are reimbursed for meals at rates depending on the type of meal and eligibility of children for free, reduced-price, or paid meals.

Who Qualifies. Institutions eligible to participate include child care centers, settlement houses, neighborhood and Head Start centers, and institutions providing day care for the handicapped and their families or group daycare homes. Private daycare centers can participate only when at least 25% of their enrolled children are from low-income families receiving benefits through Title XX of the Social Services Act.

How to Enrol. Contact the local school authority or child care center.

School Lunch and School Breakfast Programs ***What They Are.*** Over 90% of all schools in the United States participate in the National School Lunch Program. They receive cash assistance to help purchase food and pay labor costs as well as direct donations of agricultural food commodities. Participating schools must agree to serve meals at a reduced price or free to children who are unable to pay the locally established full price. The federal reimbursement level is such that all meals fed to children receive some subsidies, but they are largest for the poorest children, who receive meals free. To receive a free or reduced-price meal, means tests are required. Each year, the Secretary of Agriculture issues uniform national standards for free and reduced-price eligibility based on national poverty guidelines.

To ensure that the nutrition goals of the program are met, minimum meal pattern requirements are specified, and the USDA periodically updates these. The lunch is designed to provide about one-third of the Recommended Dietary Allowances (RDAs) for age and the breakfast about one-fourth. Recent regulatory changes have provided for more flexibility in the quantities and types of foods offered in the meal pattern; for example, skimmed milk, unflavored low-fat milk, flavored whole milk, or buttermilk can be offered as a choice for those who do not wish regular whole milk. Children can now choose three of the five meal components for lunch, and the school will still be reimbursed for the whole price of the meal. This provision of offering instead of simply serving all meal components is designed to cut down on waste.

Who Qualifies. Any public or nonprofit private school of high school grade or under is eligible. Public and licensed nonprofit private residential child care institutions such as orphanages, homes for retarded children, juvenile detention centers, and temporary shelters for runaway children also are eligible.

How to Enrol. Contact the local school authority.

Special Milk Program for Children ***What It Is.*** This program reduces the cost of each half-pint of milk served to children by providing for cash reimbursement at an annually adjusted rate to public and nonprofit schools, child care centers, summer camps, and similar institutions that do not participate in any other federally assisted nutrition program. Participants can choose to provide milk free or at low cost to all children or may elect to serve free milk to children whose families are below 130% of poverty.

Who Qualifies. This program is available only to institutions that do not participate in the National School Lunch, School Breakfast, or Commodity Programs.

How to Enrol. Contact the local school authority.

Summer Food Service Program for Children ***What It Is.*** This program provides nutritious meals for preschool and school-aged children under 18 years of age in recreation centers or summer camps, during vacations in areas operating under a continuous school calendar, or in areas with poor economic conditions. Meals are served free and must meet the minimum standards established by the USDA.

Who Qualifies. Sponsors of the program must be public or private-nonprofit school food authorities; state, local municipal, or county governments; or public, private-nonprofit residential summer camps. The programs must be in areas where at least half of the children are from households with incomes at or below 185% of federal poverty guidelines; there is no income test for eligibility in these low-income areas, and any child in the program may participate. Other programs that contain at least half of children from families at or below 185% of the federal poverty guidelines may also provide food to all children in the program. Individual children in these programs may participate without regard to their family's income, and they may receive as many as two meals and two snacks per day. The USDA reimburses sponsors of the program.

How to Enrol. Contact the local school authority.

WIC ***What It Is.*** Since its inception in 1972, the WIC program has grown from $20 million to more than $4.1

billion yearly in authorized funds. The USDA provides annual cash grants to state health departments or comparable agencies on the basis of a formula that considers food costs and administrative costs. The program is very large, but it is not an entitlement program; rather, it is a grant program with funding limits that are set annually. Participation is an option for states and localities, but today it is available in virtually all parts of the country.

The WIC program differs from all other federal food assistance programs in its close association with health care services and inclusion of food, health, and nutrition education services together.[42,43] These services are defined as ongoing, routine pediatric and obstetric care. Health care itself, other than screening and limited assessment and care provided by WIC, must be supported by state, local public and private-nonprofit health or human service agencies as well as the private sector. The amount and kind of health services provided to WIC recipients vary from state to state and locally.

The benefits of the program include vouchers for the purchase of specific foods tailored to the dietary needs of infants, children, and pregnant or postpartum women. Physicians or health professionals may also prescribe special infant formulas and certain medical foods for WIC participants with special medical conditions. In addition to food, WIC also provides referrals to health and social services, including prenatal care, and nutrition counseling and education sessions. In addition, many pregnant women gain initial access to prenatal care via their WIC screening. Efforts are made to adapt the education activities to the individual participant's nutritional needs, cultural preferences, and education levels. Approximately 75% of the current participants are children ranging in age from newborn to 5 years.

Who Qualifies. Low-income pregnant and postpartum women, lactating mothers, infants, and children up to 5 years old who are determined to be at nutritional risk by a health professional are eligible if they fall below 185% of federal poverty guidelines. The criteria for nutritional risk include dietary risk, anthropometric risk (eg, overweight, underweight), biochemical risk (eg, low hematocrit), and medical risk (eg, diabetes mellitus) and other factors such as homelessness. A priority system is in place that categorizes participants on the basis of severity of potential effects and outcomes so that those at highest risk are served first. Participants must be recertified every 6 months to continue receiving benefits.

How to Enrol. To obtain WIC benefits, an individual must apply at a WIC clinic.

Commodity Supplemental Food Program ***What It Is.*** This program provides nutritious supplemental foods at no cost to infants and children up to their sixth birthday and to pregnant and postpartum women who are at or below 185% of the federal poverty level who are not served by WIC. The program provides food packages that are tailored to the needs of participants.

Who Qualifies. Those below 185% of federal poverty levels who are not served by WIC qualify. States can require that participants be nutritionally at risk to qualify for the program. It operates in parts of 18 states and the District of Columbia.

EFNEP ***What It Is.*** This program provides instruction in basic food and nutrition-related topics to low-income families and individuals and is operated through the state Cooperative Extension service. It is not an entitlement program. Its aim is to develop understanding and awareness through a variety of methods, including direct teaching by nutrition assistants in existing groups (such as employment and training programs and shelters for homeless families), cluster groups consisting of two to five participants, one-on-one home visits, mailings, telephone, and mass media efforts.

EFNEP teaches participants how to plan for daily food needs; prepare nutritious, low-cost meals that meet the daily RDAs of nutrients; select and buy food economically; and effectively use other supplemental programs available, such as Food Stamps, WIC, School Meal Programs, and CSFP.

Who Qualifies. Families with children under 19 years of age, pregnant women, and individuals who are responsible for purchasing and preparing foods (such as special needs adults, teens living independently) are eligible. To qualify, applicants must have income at or below 185% of federal poverty guidelines and be at nutritional risk as determined by an EFNEP nutritionist.

How to Enrol. Call the national EFNEP office at 202-720-8855. A coordinator will refer the applicant to an EFNEP office in his/her area.

CSFP ***What It Is.*** This in-kind program provides food and is available at local option in several states. Providing commodity supplemental foods and nutrition education to participants, the CSFP is designed to supplement their diets with nutritious foods. The foods supplied by CSFP are different from WIC foods in their variety (ie, they consist of canned meat or poultry and canned vegetables). CSFP distributes food rather than vouchers for redemption at the grocery store. Also, the provision of health care to recipients is encouraged but not mandated, unless it was already in existence prior to 1978. Simultaneous participation in WIC and CSFP is prohibited. The supplemental foods (usually surplus agricultural commodities) are distributed to state agencies, Indian tribes, or groups responsible for administering the program. Each state selects local, private, nonprofit agencies to administer the program at the local level. Local agencies determine the eligibility of applicants, distribute the supplemental foods, and provide nutrition education. Federal funds provide for some of the administrative costs such as outreach, warehousing of food, and transportation to obtain food if necessary.

Who Qualifies. Low-income pregnant, lactating, and postpartum women, infants, and children to age 6 years are eligible.

How to Enrol. Contact state or local public or private-nonprofit health agencies.

Food Distribution Program on Indian Reservations ***What It Is.*** This program provides commodities to low-

income households on participating reservations and to Native American families living in designated areas near reservations. This is an alternative to the Food Stamp program for American Indians who do not have easy access to food stores. Participants receive a monthly food package containing a variety of foods to meet their health needs and preferences.

Who Qualifies. Program eligibility is based on a person's household income, assets, and residence on or near a reservation.

The Emergency Food Assistance Program (TEFAP) ***What It Is.*** First started as a way to reduce inventories and storage costs of surplus commodities by distributing them to needy households, it now also includes funds appropriated by Congress to purchase additional commodities. The USDA buys the food, processes and packages it, and ships it to the states based on a formula that takes into account the number of people below the poverty level and the number unemployed.

Who Qualifies. States set their own eligibility criteria and select emergency feeding organizations such as soup kitchens, food recovery organizations, and food banks to distribute the food.

Charitable Institutions and Summer Camp Food Distribution Program ***What It Is.*** The USDA donates food to nonprofit charitable institutions serving meals on a regular basis to summer camps for children, orphanages, soup kitchens, temporary shelters, and church-operated community kitchens for the homeless. The amount of food donated depends on the amount of surplus and price support commodities that are available.

Who Qualifies. Institutions participating in the Summer Food Service Program are not eligible.

DHHS The DHHS provides a wide variety of public health programs at the community level, as well as payments for health services. The public health programs include the Head Start and Early Intervention (EI) programs and the Aid to Families with Dependent Children (AFDC) program. In addition, limited monies are provided for nutrition services such as assessment and counseling. Title V of the Social Security Act of 1935 authorized grants to states to plan for provision of comprehensive health services to mothers and children. In subsequent years, funding of categorical programs provided monies for planning and provision of special services, such as lead poisoning prevention, services for handicapped children, and family planning. Monies for planning such programs are provided from federal funds by the DHHS. Demonstration grant funds have also been available on an increasingly limited basis over the past few decades for high-risk communities and groups. The comprehensive services include medical and dental care, nursing, nutrition, and social work.

Head Start ***What It Is.*** This program is particularly well known for its multifaceted approach to child health and development, including social and educational development. Administered by DHHS and funded directly to local agencies, Head Start provides low-income preschoolers and their families with day care, access to medical care and social services, and nutrition services, including meals, nutrition education, and staff training.[44]

Head Start programs are funded through grants from the Administration for Children, Youth and Families regional offices and the Native American Migrant Program branches. These grants are awarded to a variety of local public agencies, private-nonprofit organizations, and public school systems. The program is very large but not an entitlement. It is at the discretion of states and localities and serves primarily children from poor families.

Head Start programs serve a multiracial, multiethnic group of low-income children and families. Each program must offer four major components: education, social services, parent involvement, and health services. With the goal of meeting each child's individual needs, the program offers a wide variety of learning experiences aimed at fostering intellectual, social, and emotional growth. Head Start also aims to meet the ethnic and cultural characteristics of the communities served.

Head Start's nutrition program is part of the health component offered and provides nutritious meals from the Child Care Food Program, as well as nutrition education for children, staff, and parents.

Who Qualifies. To be eligible for Head Start, a child must be between 3 and 5 years of age and come from a low-income family whose total annual income does not exceed 100% of the federal poverty guideline or who is receiving public assistance from programs such as AFDC or SSI.

How to Enrol. Contact the Head Start Bureau, which is located in the Administration for Children, Youth and Families, Office of Human Development Services, DHHS.

Head Start for Children with Special Needs ***What It Is.*** Head Start is the largest provider in this country of services for preschool children with handicapping conditions.

Who Qualifies. It is mandated to serve preschool children who have a broad range of handicaps. Children with severe or multiple handicaps present additional challenges to Head Start staff in the planning and provision of individual services. Program requirements call for individualized plans for special education, treatment, and related services for all handicapped children served by Head Start. These plans must be based on the child's specific handicapping conditions, as well as the unique needs arising from those conditions.

How to Enrol. Contact the Head Start Bureau, which is located in the Administration for Children, Youth and Families, Office of Human Development Services, DHHS.

EI Programs and Services ***What It Is and Who Qualifies.*** EI programs and services for infants, toddlers, and their families have existed in many areas of the United States for more than 25 years. These services are organized to address the developmental needs of young children between birth and 3 years of age who may be at risk for

poor developmental outcome because of an identified disability or because of biologic or environmental risk factors.[45,46] Although all of these programs share the common goal of optimal infant development, they approach it in different ways. That is why collaboration is essential in the development of an Individual Family Service Plan (IFSP), which addresses all of the child's needs that must be met for the child's potential to be reached. Some EI programs are home-based models, others are center-based models, and others are a combination of those two approaches. Intervention programs also differ with respect to their program philosophy and goals, the population that is served, team composition, program content, and program evaluation. Services are generally multidisciplinary, in recognition of the interrelationship of development in various domains, and may include input by developmental educators, occupational and physical therapists, speech pathologists, psychologists, nurses, dietitians, and social workers.

Federal law significantly influences the development of EI programs. The most applicable law, enacted in 1986, is Title I, Part H, Handicapped Infants and Toddlers, of PL 99-457, Education of the Handicapped Amendments of 1986. That law extends public education to children 3 years old and older and provides incentives to states to serve children with special needs from birth onward. It includes nutrition as one of eight disciplines to be included on the team providing services to these handicapped infants and their families.

Part H of PL 99-457 requires that services designed for children from birth through 36 months meet their developmental needs. It mandates psychological services, parent and family training and counseling, transition services, diagnostic medical services, case management, and health services that will enable the child to benefit from other early interventions. The eight disciplines specified by PL 99-457 include special education, nursing, nutrition, psychology, physical therapy, occupational therapy, speech-language pathology, and social work. This law provides great opportunities for nutrition intervention in preschool children with handicapping conditions and their families. To date, however, most states have done little to develop community-wide networks to provide EI services that include nutrition.

How to Enrol. Contact the state Maternal and Child Health Department.

Personal Responsibility and Work Opportunity Reconciliation Act ***What It Is.*** In 1996, under the Personal Responsibility and Work Opportunity Reconciliation Act, the basic cash assistance program AFDC was eliminated and replaced with Temporary Assistance for Needy Families (TANF).[47] The 1996 welfare legislation provides block grants to states for time-limited cash assistance and made other program changes (Food Stamps, SSI for children and others). How these programs develop will have a profound effect on families living in poverty in the United States and the potential to significantly impact the nutritional status of children. The overall effects of welfare reform on child health and nutrition need to be closely monitored.

Who Qualifies. States have much more control over the money block granted including time limits, sanctions, and categorical restrictions. Although there are advantages to this (flexibility), there are no assurances that the funds will be spent where most needed, and the program may lack focus.

How to Enrol. Contact the local Department of Public Health.

State and Local Programs

There is a great deal of variability between states and localities in the extent to which they supplement federal nutrition funds or provide additional in-kind resources, such as health services. These variations make it essential for community nutritionists to know the specifics of state and local programs in their areas..

WEB-BASED RESOURCES FOR COMMUNITY NUTRITION

The DHHS has developed a number of Web-based resources that may be helpful in planning community nutrition efforts. Many nutrition resources not specified below are listed at this Web site: <http://www.nutrition.gov>. The gateway to reliable consumer health information on the Internet is provided at <http://www.healthfinder.gov>. Healthy People 2010–related materials include a general description of the initiative at <http://www.health.gov/healthypeople>, a community-planning guide using Healthy People 2010, entitled *Healthy People in Healthy Communities*, at <http://www.health.gov/healthypeople/publications/HealthyCommunities2001>. Information on TANF is available at http://www.neighborhoodlaw.org/aprimer.htm. A "toolkit" for planning at the state level is at this Web site: <http://www.health.gov/healthypeople/state/toolkit>. The CDC's planned approach to community health (PATCH) is provided at <http://www.cdc.gov/nccdphp/patch/index.htm>.

Several Web sites focus on physical activity and health. These include the Surgeon General's report on this topic at <http://www.cdc.gov/nccdphp/sgr/sgr.htm>. The President's Council on Physical Fitness and Sports is available at <http://www.fitness.gov>. Tips for promoting better health for young people through physical activity and sports are provided at <http://www.cdc.gov/nccdphp/dash/presphysactrpt/index.htm>.

The USDA provides several Web sites to improve access to food stamp and food program–related nutrition resources for assisting community nutrition efforts.

All USDA Web sites are available at the National Agricultural Library's homepage: <http:/www.nal.usda.gov>. Some specific Web sites include the following:

- The Food and Nutrition Information Center is a large, Web-based information center backed up with trained nutritionists who can help in locating information and borrowing additional resources from the collection of the National Agricultural Library. Access it at <http://www.nal.usda.gov/fnic>.

- The Food Stamp Nutrition Connection has a training center with a collection of social marketing and programming resources on food stamps, a resource library providing ready-to-use educational materials, information on hot topics, contacts at the state and national levels, and program facts. These are available at <http://www.nal.usda.gov/foodstamp>.
- The WIC program has a Web site that summarizes recent studies on WIC and provides other educational materials. It is located at <http://www.fns.usda.gov/oae/menu/published/wic/wic.htm>.
- A special Web site for child care nutrition resources focuses on food programs for children in child care. It is located at <www.nal.usda.gov/childcare>.
- The Healthy School Meals Resource System is a searchable Web site that provides information to persons working in USDA's child nutrition programs. It includes materials to assist nutrition educators both in the classroom and in the school cafeteria. Access it at <http://www.schoolmeals.usda.gov/8001>.
- The Dietary Guidelines for Americans are available on the Web at <http://www.health.gov/dietaryguidelines>.

LESSONS LEARNED FROM COMMUNITY NUTRITION EFFORTS

Community Investments in Child Health and Nutrition Make Sense

As early as the fourth century BC, the philosopher Plato stressed the importance of investing in children from an early age. Several millennia later, numerous studies confirm Plato's suppositions about the importance of investing in our children.[48] For example, supplementing the diets of pregnant women and infants and immunizing children against early childhood diseases save lives and improve health. It is to be hoped that, in the future, programs such as Head Start, EI, and WIC, with demonstrated success in strengthening the bodies and minds of children, will reach more of their target populations. Also, special attention must be paid to nutrition for children with special needs and other chronic health problems. Current programs do not cover them adequately.

Table 9.1-11 shows current federal spending for a number of key health and food programs involving children.

Community Health and Children's Health Care Must Be Equal Partners

Community health and nutrition efforts expand the traditional focus of direct health services. Both are necessary to ensure child and family health. Also, broader economic factors that affect food insecurity must be dealt with.[49] The distinctions between traditional public health and personal health services are slowly blurring in this country. In the future, community nutrition concerns will need to be incorporated into both systems. There is the danger that nutrition will "fall through the cracks" because there are other pressing needs. Thus, it behooves all of those who are interested in the health of children to pay attention to ensuring that federal, state, and local governments employ nutritionists to look after community needs in nutrition. These professionals must work with others in health, welfare, education, and food agencies in the public and private sectors to ensure that all children are well nourished. At the same time, dietary concerns must be increasingly incorporated into personal health services. Only when these steps are taken will community nutrition realize its potential to have a positive impact on children.

Child Nutrition and Physical Activity Are Inextricably Linked, Like Siamese Twins

Both physical activity and sound nutrition in the community help to keep children healthy and ready to learn and also prevent later chronic disease risk.[50] Long-term community efforts at the school, family, and individual levels are necessary to yield the benefits of lower health risks over the long term. Community leaders, experts in health and education, and parents themselves must be involved in school-based and other prevention-oriented programs.

School-Based Programs Offer Much Potential for Health Promotion and Primary Prevention of Diet- and Physical Activity–Related Risk Factors if Supplemented by Parent, Family, and Community-Wide Efforts

School-based programs are excellent sites for these efforts. However, changes in the curriculum alone are not sufficient to bring about alterations in risk factors for cardiovascular disease or obesity; changes in school meals and alterations in physical education programs are also needed. More attention to physical training components that increase strength may be important in preventing later osteoporosis risk. Thus, multiple risk factors need to be targeted. Also, community efforts to reinforce these efforts are needed.[51]

In addition to school-based efforts, family and community efforts are also required. Children do not spend all of their waking hours in school. The microenvironment of the family is an important milieu for enhancing and carrying forward school-based health promotion and physical education efforts. The macroenvironment of the community must also be conducive to healthy lifestyles.

Healthful Eating Patterns for the Whole Family Are Critical

Foods must be eaten to be nutritious, and overall diets are the most important. Children and their families eat foods, not individual nutrients. There is often a gap in teaching about the merits and demerits of individual foods, and broader guidance on healthful diets or eating patterns is needed. Existing scientific evidence shows that overall eating patterns and diets and not consumption of individual foods or nutrients are most closely linked to positive effects on health. Therefore, families need information about healthful, enjoyable eating patterns that provide a broad, food-based context for healthful eating and about healthful physical activity and exercise patterns. When needs cannot be met by food-based solutions alone, supplementation with vitamins and minerals may be considered.[52,53]

Information on Healthful Eating and Physical Activity Must Be Communicated More Effectively at the Community Level

Consumers and policy makers must view the Dietary Guidelines for Americans and other nutrition education guidance and programs as acceptable and actionable as well as authoritative if they are to be used. The Dietary Guidelines,[54] the USDA's Food Group Pyramid,[55] the Healthy Eating Pyramid for children (which is based on the Dietary Reference Intakes and the Dietary Guidelines), food labels, and health claims provide such guidance to the community.[56] Information about them needs to be communicated, coordinated, and harmonized to facilitate food purchases and consumption decisions, and diet-related efforts must be accompanied and reinforced by physical activity programs. This challenge is one that food producers, marketers, public policy makers, and educators face together. Intervention strategies from the social and behavioral sciences may be helpful in tailoring messages to our diverse population.[57,58]

CONCLUSION

Community efforts in this country are in line with those of the overarching goals of the World Health Organization's Health for All campaign in the twenty-first century to increase healthy life expectancy, ensure universal access to quality health care, and achieve greater equality in health status within and among countries.[59]

CHAPTER 9.2

COMMUNITY NUTRITION AND ITS IMPACT ON DEVELOPING COUNTRIES (THE CHILEAN EXPERIENCE)

Gerardo Weisstaub, MD, MSc, Magdalena Araya, MD, PhD, Ricardo Uauy, MD, PhD

NUTRITION A KEY FACTOR FOR HUMAN AND SOCIAL DEVELOPMENT

The nutritional status of children is directly related to their health condition, and both, in turn, are key determinants of the human and social development of communities around the world. Improvement of nutrition and health increases the chances of child survival and is a precondition for economic development. UNICEF has proposed a conceptual model to understand the causation of malnutrition beyond the obvious immediate determinants (Figure 9.2-1). Undoubtedly, the basic determinants relate to the social, economic, cultural, and political structures of society. These define what resources are controlled by individual families, including access to information and education, household food security, care of women and children, and access to health and a healthy environment. It is within this context that children have inadequate access to food in terms of quantity and quality; in addition, infection will further compromise nutrition by augmenting nutrient losses and increasing nutrient needs.

Nutrition has been considered a basic human right and has been expressly recognized by international human rights covenants since 1924,[1] yet this right is commonly the subject of political demagogy rather than being actively upheld, respected, protected, and promoted. The relationship between poverty and malnutrition has been well established in both directions, that is, how poverty conditions nutritional status and vice versa. Moreover, the correlation is by no means linear. There are multiple examples that illustrate how nutrition can improve despite economic limitations. Economic development is by no means sufficient to improve nutrition, especially in countries where wealth is concentrated in a few hands. The United Nations' Human Development Index illustrates how nutrition and health can be dissociated with economic status.[2] For example, Indonesia has a higher per capita gross national product than China, but malnutrition is presently rare in the latter, whereas it is frequent in the former. Brazil has experienced significant economic growth over the past decade, but malnutrition in children under 6 years of age remains high. Recent analysis of trends reveals significant reductions in malnutrition assessed by underweight or stunted linear growth except in sub-Saharan Africa and Central America. These regions have experienced protracted civil wars, and, more recently, that African region has been stricken by human immunodeficiency virus/acquired immune deficiency syndrome (HIV/AIDS) and its consequences. On the contrary, Latin America and the Caribbean combined have reduced malnutrition to about a third of the 1970 figure, despite the unchanged proportion of families living in poverty (as shown in Figure 9.2-2).[3] This concept should be stressed because health professionals frequently work under the assumption that nothing can be done in terms of prevention and control of protein-energy malnutrition (PEM) unless social conditions change and poverty reduction is achieved. Undoubtedly, both should proceed in tandem because improved nutrition will contribute to socioeconomic improvement.

The World Health Organization (WHO), UNICEF, and other international organizations concerned with malnutrition have recognized for several decades the role of malnutrition in defining infant mortality. The immediate cause of death may be diarrhea or pneumonia, but the risk of dying from these conditions is increased manifold by severe and moderate malnutrition. The work of Puffer and Serrano in the Americas and more recently Pelletier and colleagues, using data from Africa and Asia,

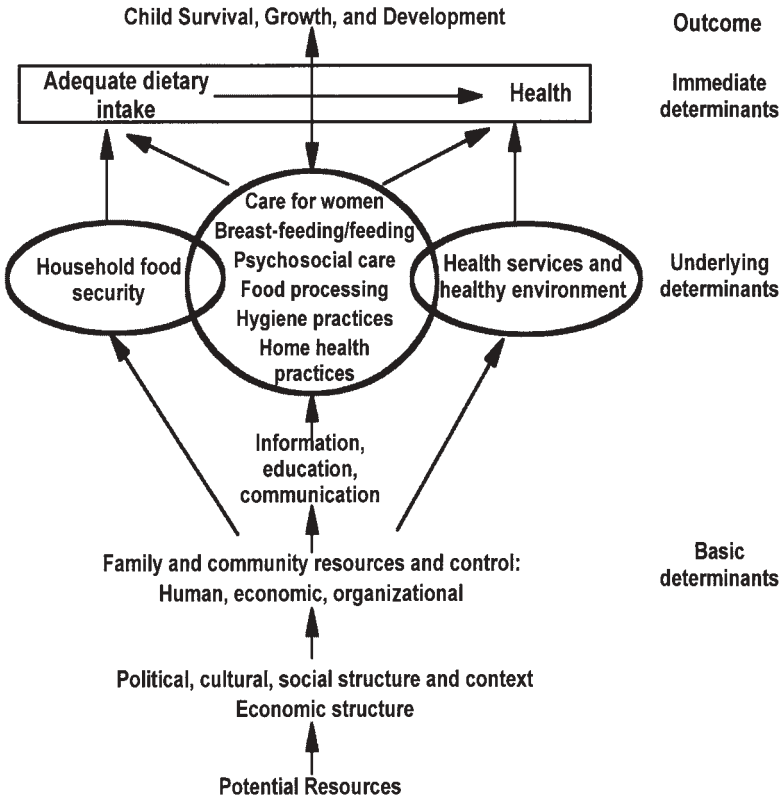

FIGURE 9.2-1 Conceptual model of child development useful in the analysis of prevention and control of malnutrition. Adapted from ACC/SCN Commission on the Nutrition Challenges of the XXI Century.[3]

has documented with precision the contribution of malnutrition to infant mortality.[4,5] The conclusion reached by both is that over half of all infant deaths are determined by malnutrition. UNICEF, in its annual report on the state of the world's children, stated that "malnutrition is directly related to over half of all infant deaths that occur worldwide."[1] Chapter 11, "International Nutrition," discusses nutrition and infection interactions as crucial factors contributing to infant death.

MALNUTRITION AS A GLOBAL PUBLIC HEALTH PROBLEM

Weight, height, and head circumference measurements have been widely used as indicators of nutritional adequacy. Malnutrition as a public health problem is assessed based on growth indices relative to those derived from a standard population. Yet most growth standards describe what may be considered normal growth based on values

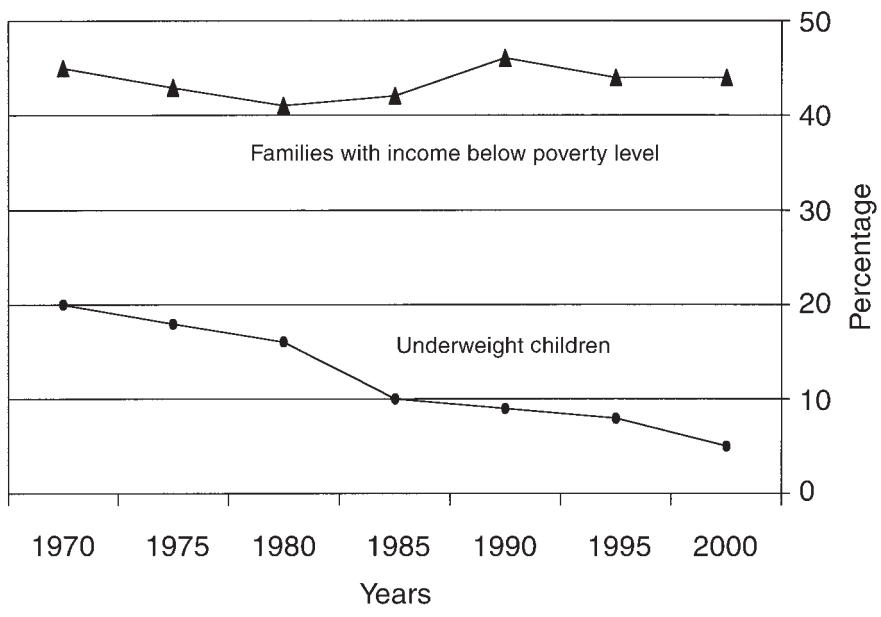

FIGURE 9.2-2 Child undernutrition in Latin America and the Caribbean: trends, reasons, and lessons. Over the past 30 years, population under the poverty line has remained stable, but malnutrition has declined significantly.

obtained in a given normative population. Normal is derived from statistical normalcy rather than based on specific health and/or quality of life outcomes related to a set of growth parameters. For example, the National Center for Health Statistics (NCHS) growth reference standard, used as the basis for the present WHO international standards for infants 0 to 36 months, is derived from children growing in a relatively affluent, predominantly artificially fed, rural community from Yellow Springs, Ohio, over 30 years ago.[6] New growth standards are being developed by WHO/United Nations University (UNU) based on the growth of infants from middle-income and well-educated families who are exclusively breast-fed for 4 to 6 months and given appropriate complementary foods after weaning. Preliminary findings indicate that infants fed according to present WHO recommendations and living in appropriate conditions grow less rapidly than the present NCHS median reference value, particularly after 4 to 6 months (unpublished). A significant discrepancy of approximately half a standard deviation in estimated height status arises around 2 years of life. The limitations in present growth standards led a WHO Expert Committee in 1995 to support the development of a new growth reference.[7] The WHO multicountry (Brazil, Norway, India, Ghana, United States, and Oman) growth reference study is presently in progress, more than 13,000 healthy infants and children are involved, and data collection is expected to be complete by the end of 2003. This new reference will provide a scientifically reliable descriptor of physiologic growth and a powerful tool for advocacy in support of good health and nutrition.[8] Another objective of the new reference is to support, based on actual evidence, the concept that human growth during the first years of life is very similar across groups of children of different ethnic backgrounds. This confirms that existing differences in growth across countries are predominantly environmentally derived and can be narrowed over time. Prevalence estimates of global malnutrition based on the new reference will clearly be affected to the extent that the new reference may differ from the current WHO norms in median values and/or distribution.

Patterns of change in prevalence of underweight (low weight for age), stunting (low length for age), and wasting (low weight for length) are being monitored systematically by WHO (241 countries) by de Onis and colleagues.[9] The evolution in prevalence of underweight and stunting reveals significant reductions for most countries over the past two decades, yet the rate of progress (0.5% per year) is insufficient to achieve the stated goal of the world summit for children. Although the prevalence of malnutrition in developing countries as a whole fell from 46.5 to 31% between 1970 and 1995, about 15 percentage points in all for this 25-year period, progress in reducing malnutrition has varied greatly from one region to another. Malnutrition has declined the fastest in South Asia (by 23 percentage points) and the slowest in sub-Saharan Africa (4 percentage points), but the rate of progress is decelerating. During 1970 to 1985, the prevalence of malnutrition fell by 0.8 percentage points per year; during 1985 to 1995, it fell by only 0.3 points. The situation is particularly troubling in sub-Saharan Africa, where the prevalence of underweight children actually increased from almost 29% in 1990 to 31% in 1995. In West and East African regions, the prevalence in underweight and stunting has actually increased over the past three decades. In Central America, there is no improvement, whereas in South America and South-Central and Southeast Asia, progress has been significant. Since 1970, the prevalence of underweight children has decreased in 35 developing countries, held steady in 15, and increased in 12, with most of the countries with increases in sub-Saharan Africa.[10]

The causes behind the insufficient progress are multiple and complex in their interactions. Political strife, government unresponsiveness to the needs of the community, stagnant economies, low status of women and unequal rights, poor education and inadequate access to health care, poor sanitation and unclean water, high prevalence of infections, and low birth weight interact in determining poor postnatal growth and high rates of malnutrition.[9]

Because most of these factors are interrelated, it becomes virtually impossible to isolate their effects from retrospective trend data or regression models. Decreases in the prevalence of malnutrition have been described in relation to improvements in household food security, supply of clean water and environmental sanitation, education of women, early treatment of diarrhea with oral rehydration solutions in the community, early treatment of respiratory infections, promotion of breast-feeding, appropriate complementary feeding, immunization, growth monitoring, and surveillance for early identification of malnutrition.

Smith and Haddad have attempted to explain the key factors responsible for the different rate of progress across regions of the world (Figure 9.2-3).[11] They examined the contribution of national food supply, women's status, and women's education and health environment based on proxy indicators from available country data. Improvements in women's education contributed by far the most, accounting for 43% of the reduction in child malnutrition between 1970 and 1995, whereas improvements in per capita food availability contributed about 26%. Comparisons between regions were quite revealing.

The overall reduction in the prevalence of child malnutrition in South Asia for the 25-year period was estimated to be 16.5 percentage points. The greatest contributions to this reduction came from increased education of women and improvements in health environments; each accounted for about 28%. Gains in the status of women accounted for about 25% of the reduction and improvements in food availability for about 20%. The total reduction for sub-Saharan Africa's malnutrition rate over the study period was only 4.2 percentage points. Most of this was explained by increases in women's education, followed by improvements in health environments. Increased education of women made strong contributions in all periods except for the late 1980s, when enrolments actually declined. Improvements in health environments have made their greatest contribution after 1985. Women's relative status, as evidenced by gender differences in life expectancy, has continually declined in the region since

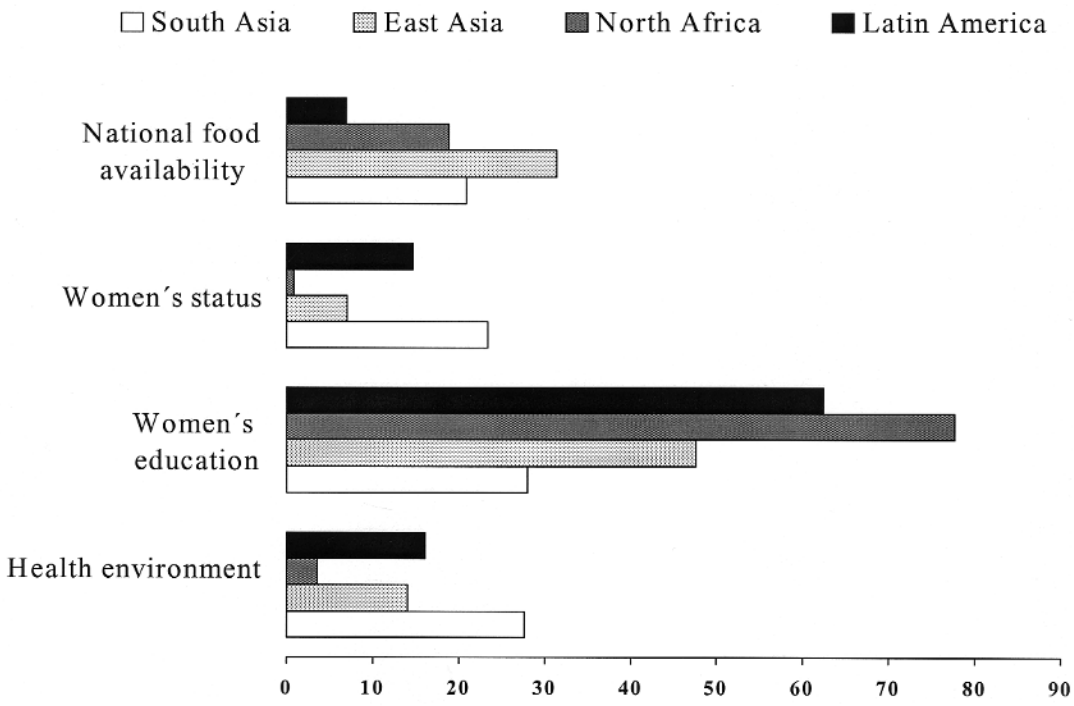

FIGURE 9.2-3 Estimated contributions of underlying determinant variables for malnutrition across regions of the world.

the 1970s, most precipitously after 1985. The consequence has been a recent worsening in prevalence of child malnutrition in the region. Changes in food availability have played a large role in both directions. Substantial improvements in the late 1980s and early 1990s were outweighed by deteriorations during the 1970 to 1985 period.

Latin America and the Caribbean experienced an estimated 11 percentage point reduction in child malnutrition over the study period, most of which took place during 1970 to 1980. Since then, reductions in child malnutrition have continued at a much slower pace. Like the other regions, the greatest contribution comes from women's education, which explained 62% of the improvement, whereas the contribution of environmental health to this improvement has steadily declined. Strong improvements in the status of women in the 1970s were followed by very small improvements in the 1980s. Food availability improved in the 1970s but declined slightly in the early 1980s.

Prevention and control of infections are clearly critical aspects of malnutrition reduction efforts. As documented in Chapter 11, infection has a definite adverse effect on nutritional status, whereas malnutrition compromises the host defenses and immune responses, increasing case fatality and disease susceptibility.[12] Relative risk (RR) of death from infection is directly correlated with severity of malnutrition: RR ± SD 8.4 ± 2.1 for severe PEM, 4.6 ± 0.9 for moderate PEM, and 2.5 ± 0.3 for mild PEM.[5] Yet because the severely malnourished represent a small proportion of the total population, mildly to moderately malnourished individuals are responsible for most of the malnutrition-related deaths. It has been estimated that close to 80% of all malnutrition infection–related deaths are attributable to moderate and mild malnutrition. Despite the obvious public health implications in terms of preventing death, given the high mortality of the severely malnourished, the cost-effectiveness of PEM treatment is greater than that of controlling moderate malnutrition.

The adequacy of breast-feeding and weaning foods also plays a key role in malnutrition prevalence, especially after 6 months of life. In most countries where malnutrition prevails, the time of onset is after 6 months; this is when breast milk is insufficient to meet infant needs and also a time when mothers have increased competition for their time/dedication to the infant. This is coupled with weaning foods that are inadequate and of low energy density and low nutrient density. Under these conditions, feeding frequency and added starch or oil to increase energy density become crucial to prevent malnutrition.[13] A study in Bangladesh examined the role of education during the weaning period, demonstrating that education on complementary feeding given to mothers was effective in enhancing weight gain despite the fact that no foods were actually provided. The authors suggest that the educational efforts on what constitutes adequate complementary feeding and on how to prevent microbial contamination of weaning foods are important as malnutrition prevention strategies.[14]

Although there are no easy answers or a magic "silver bullet" in combating malnutrition, several options can be suggested based on the success and accomplishments of some countries in malnutrition reduction. In most cases, poverty reduction efforts need to go hand in hand but should not be considered a precondition for success. Suggesting that poverty reduction is a precondition for success is simply not realistic because malnutrition is not only a determinant but also a consequence of poverty. Thus, the efforts should not be postponed until major political or

economic events improve the economic condition of the poor because reducing malnutrition contributes by itself to poverty reduction. The notion of human capital as a major determinant of economic growth has been recognized globally with the award of two Nobel Prizes in economics over the past decade.[15]

A strategy for action, based on what has worked in different settings around the world (Costa Rica, Thailand, Cuba, Chile, and Kerala-India, among others), is proposed in Figure 9.2-4. This serves to analyze the necessary interactions among the key social actors required for successful implementation of malnutrition control and prevention programs. The basic and critical component is social mobilization to establish the demands for action from the political actors; this process should lead to community actions as well as responses by government. A responsive government is one that responds to community demands; this requires some degree of participation by society in government, ideally but not necessarily a government by the people, from the people, and for the people. Communities that are so empowered and able to participate in the political process will be successful in demanding appropriate actions from governments. Malnutrition needs to become unacceptable to society to trigger the level of action required to address the issue frontally. What does it take to trigger this process? In most cases, proactive academics and/or nongovernmental organizations (NGOs) that have a strong voice, independent from government, have catalyzed the process and led the way. "Political will" does not come easily, nor is it generated from within; professionals, academics, NGOs, community leaders, and the press should act in concert to elicit action. The role of the press in generating public awareness and communicating public concern of malnutrition as a key restriction for national development is crucial. Recruiting and training select journalists will serve to generate widespread recognition of the problem and make people aware that the solutions are credible and feasible by illustrating what has worked elsewhere. Academics and professionals should propose the necessary actions that are required to implement effective programs to control and prevent malnutrition, ideally based on technical consensus rather than political considerations. They should promote a critical review of policy options based on what may work in a given setting; international organizations can assist in reaching a technical consensus by providing evidence and expert advice on successful examples of malnutrition reduction. The private industrial or business sector is usually a latecomer in this scene. Yet public private partnerships are a must for sustainable programs because industry is a key partner in the implementation of programs, for example, in nutrient supplementation, fortification, and other food-based strategies.[16] In the final analysis, unless we activate the political process and include industry, we get no action.

Governments must be committed to generate the actions necessary to solve malnutrition as a public health problem. Governments are usually restricted in meeting social demands by the available monetary resources and are not willing to commit funds unless they see a clear return on investment. Thus, it is crucial to clearly present the cost-benefit analysis of various programs for nutrition improvement. Moreover, if the community is truly aware and the issue has become a political priority, there may be a clear political benefit as well as an economic gain in terms of human capital formation. The involvement of the press in facilitating social communications is important in open societies. For example, the cost of providing half of all critical micronutrient needs per person per day for a year by fortifying a staple food has been estimated to be less than a dollar per year; this is less than a pack of cigarettes in most countries. The World Bank has estimated the benefit-to-cost ratio of micronutrient fortification to be at least 17:1. On a relative basis, not all programs are equal in terms of cost benefit or cost-effectiveness; thus, the tools of economic assessment should be used in defining policy options. As demonstrated by the International Food Policy Research Institute study, the mix of policies that will work differs in various settings (see Figure 9.2-4). The impact of maternal education has been shown to work across all regions, yet we must bear in mind that access to education by women is in itself an index of multiple social, economic, and cultural factors.

Nutrition and food policies should be integrated in the context of national development strategies. Nutritional problems are determined by economic and labor policies, health and education sector policies, and welfare policies. The integrated approach may be more difficult to implement in most settings because government structures are sectorial, yet harmonization of policies is a must to avoid duplication, wasteful use of resources, and overburdening personnel budgets.[17] Cost-effectiveness evaluation of programs should be included at the outset in the present climate of fiscal policies. Presently, program sustainability in a world of competing interests will progressively depend on the capacity to demonstrate cost-effectiveness over time. Technical considerations should prevail over political interest in defining what should be done; this is the best way to optimize chances of success. This is true at all lev-

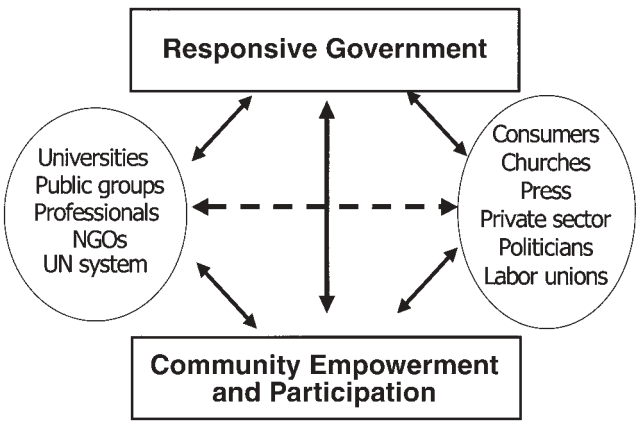

FIGURE 9.2-4 Scheme for strategic analysis of protein-energy malnutrition control and prevention. See text for details on dynamic interactions between stakeholders. NGO = nongovernmental organization.

els. National and international programs are not always guided by the best technical advice but, many times, respond to politically motivated actions.

The emerging orientation to guide nutrition and food policy by the ethical dimension and human rights concern can no longer be ignored. In a world of plenty, malnutrition can no longer be justified as a problem of the poor or a problem that affects others but not us. Globalization should be not only about business and trade but mostly about how we as humans face a common future. We cannot afford to have over a third of the people in the planet under conditions of poverty and malnutrition. Pediatricians should be concerned with the status of children worldwide. As we reflect on our own actions, our research should not ignore that we are progressively citizens of a common planet; our advocacy and our research in search for the truth should serve not only those around us but children around the world. Funding for applied research in the nutrition and health of children should be as important as the present emphasis on protection from bioterrorism and the war on terrorist activity worldwide. Providing for a better future for children across the world will do more for peace than the massive bombings that have recently taken place. Controlling and preventing malnutrition should top the list.

POTENTIAL STRATEGIES FOR THE TREATMENT AND CONTROL OF SEVERE AND MODERATE MALNUTRITION

First, we should clearly establish that prevention and treatment of malnutrition are complementary and do not contradict each other, as some would like to believe. The public health imperative of prevention is better than cure and cannot be used to negate or withhold treatment to those already affected by malnutrition. Both strategies must work in tandem to avoid malnutrition altogether and to recuperate those who are severely malnourished and at risk of death or severe disability as a consequence. The respective actions for prevention are quite different from those necessary for effective treatment but should be seen as part of the spectrum of efforts to combat malnutrition. What can we learn from experience, either success or failure, in the treatment of malnutrition?

The percentage of severely malnourished in a given population rarely exceeds 1 or 2% of children, yet their case fatality is high. Thus, they constitute an important proportion of preventable death and disease burden in most developing countries. Once they enter the hospital, up to 50% of malnourished children die depending on the quality of care they receive. A survey of the published literature reported by Schofield and Ashworth indicated that mortality from severe malnutrition ranges from 4 to 49% in 79 centers across the world.[18] The reason for this variance can be found in treatment practices. In fact, a controlled study demonstrated that even in a well-recognized high-quality center, mortality could be reduced from 20 to 5% if a standardized protocol was used.[19] Schofield and Ashworth concluded that inadequate treatment is the main reason for the high mortality and emphasized, as Chapter 10, "Protein-Energy Malnutrition: Pathophysiology, Clinical Consequences, and Treatment," does, the need to train and update health professionals responsible for the care of these children on the treatment of malnutrition. The most commonly used treatment for severe malnutrition has been care in hospitals and/or in closed nutrition recovery centers or ambulatory care in open recovery centers and/or primary health clinics. The respective actions are quite different and should be seen as part of the spectrum of efforts to combat malnutrition. We comment summarily on them in the next paragraphs:

1. *Hospital treatment.* In this case, the goal is to achieve nutritional recovery, preventing death and the sequelae related to severe malnutrition in the shortest possible time. The issue of duration of treatment is critical not only for cost-effectiveness but also to prevent risk from nosocomial infections and preserve the mother–child interaction necessary for normal growth and development.[20] For details on treatment and follow-up after discharge from hospitalization, see Chapter 10.
2. *Closed nutrition recovery centers (CNRCs).* These are institutions based in the community and established to treat moderate and severe malnutrition. Children enter the center after infections, electrolyte abnormalities, and other acute medical complications have been treated in the hospital. These centers are especially suited if there is a high prevalence of severe malnutrition in young infants and in settings where mothers have difficulties in caring for their infants. After nutritional recovery has been achieved, these children can be followed in the primary health care centers. Successful experience in using these centers has been achieved in Haiti, Costa Rica, Colombia, New Guinea, Uganda, Venezuela, Thailand, and Chile, yet in few countries has the effort been sustained sufficiently to effectively contribute to the reduction of malnutrition prevalence.

   Hospitalization is commonly considered most effective in attaining nutritional improvement over a short period of time, yet it is associated with a greater risk of hospital-acquired infections that prolong treatment and interfere with normal family life as the mother must continue taking care of the other siblings. Thanangkul and colleagues, based on their experience in Chiang Mai, Thailand, suggested that the duration of hospitalization should be as short as possible to prevent the adverse consequences of admission on mothers and children. Outpatient treatment was considered potentially equally effective and at much lower cost. The aforementioned survey suggests that hospitalized treatment under optimal conditions is very effective (up to 70% recovery) and is associated with a 5 to 7% mortality and a 1% recurrence rate.[21] However, the cost of treatment is high and sometimes unaffordable by families, thus limiting its widespread use.

   Ashworth and Khanum evaluated the cost of various treatment modalities in a controlled randomized

study in 437 Bangladeshi malnourished children aged 12 to 60 months. They were allocated to hospital admission, daycare nutrition recovery centers, and home care. The respective costs, to reach the target of 80% weight for height, in US dollar equivalents were 156, 59, and 29 per treated child, respectively. The costs of health personnel constituted the largest component for the treatments away from home. The days required to reach the target were lowest in the hospital at 18 days; 23 days in the daycare center and 35 days in the home treatment group were required. The cost per day of treatment per child was 8.6, 2.5, and 0.8 in US dollar equivalents, respectively.[22] Figure 9.2-5 summarizes these results. In the opinion of these authors, CNRCs may be more effective in nutritional recovery over time but often neglect other aspects, such as educating mothers and involving the family in the recuperation process. They propose that after initial stabilization has been achieved in the hospital over the course of a week, home treatment should be the preferred choice in terms of cost-effectiveness because it permits the treatment of more children with the same resources at an equivalent efficacy. In their study, mortality was equally low in the three groups (< 5%).[23] Moreover, when surveyed, parents indicated that they preferred either of the nonhospitalized treatment regimens, despite the higher cost to them, because they bore the cost of the complementary foods used in the nonhospitalized treatment.

3. *Daycare nutrition recovery centers and ambulatory care.* Daycare centers are also called open centers; these centers provide nutrition and related care for malnourished children during the day. They also provide education to mothers and psychomotor stimulation for the children. Mothers participate in the child's care and receive social support to enhance the chance of success of the recovery process. Various specific modalities of ambulatory care have been tested.

A community-based nutrition recovery effort was undertaken in a periurban slum area of Peru in 1988. The program included education and social support to mothers and family, growth monitoring and surveillance, management of common childhood illness, and use of low-cost complementary foods. Children under 3 years of age with moderate and severe malnutrition based on weight for age were included. Of the 54 children included, 1 died (2%) and 4 required hospitalization; after 3 months of the program, 19% remained moderately malnourished. The annual cost of the recovery program was $21 (US) per child. This program serves to illustrate the cost-effectiveness of a community-based nutrition recovery effort. The cost-effectiveness of community-based efforts in this case is over 20 times greater relative to hospitalized care.[24]

In Chile, a specific mode was foster care used in the case of malnourished children with difficult social situations that impeded home recovery efforts. If chil-

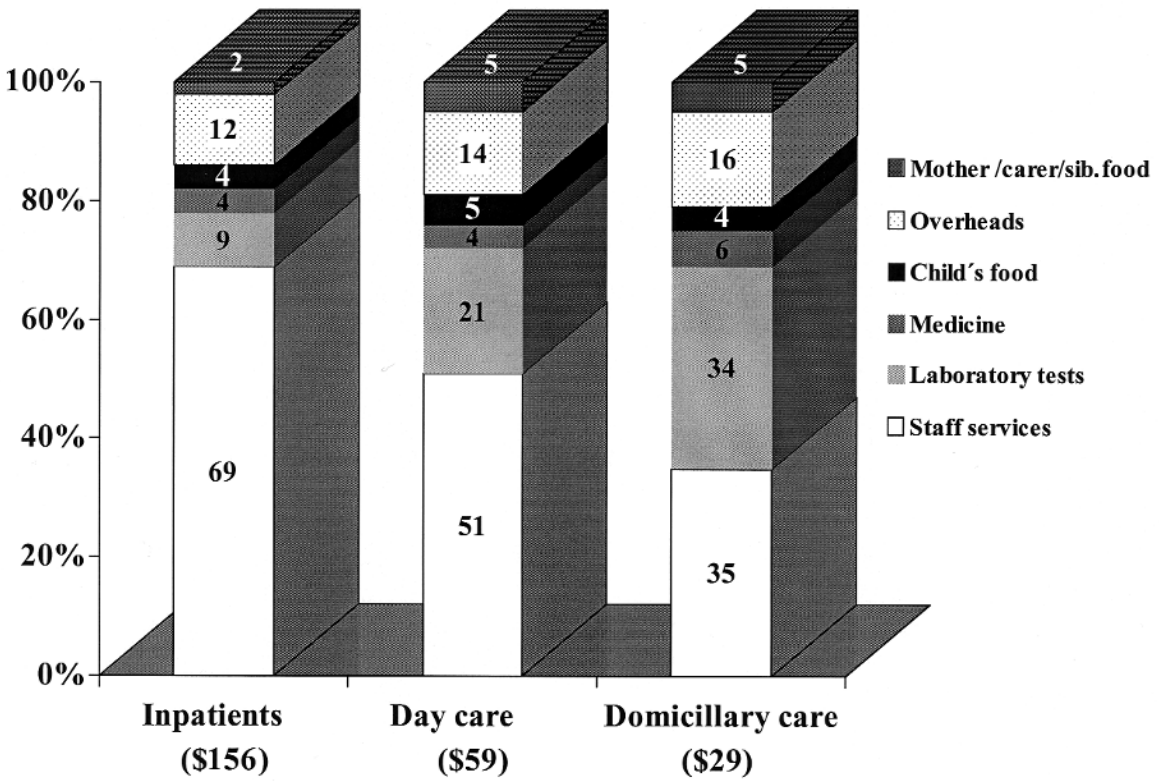

FIGURE 9.2-5 Cost-effectiveness of various treatments for severe malnutrition. Children were allocated to hospitalization (n = 173), daycare nutrition recovery center (n = 134), and ambulatory treatment (n = 130). All achieved a similar degree of recovery (weight for height 80% of World Health Organization standard). Cost is expressed in US dollars per treated child for treatment to reach the goal. The y axis represents the percentage of costs by various components detailed in the legend; the numbers in the bars correspond to the percentage of costs of each component for the three treatments.

dren could not be recovered within their home, they were placed in foster care until recovered. This program was implemented in 1983 by a multiprofessional team that included a physician, social worker, field nurse, and nutritionist. Specialized foster care was provided within the community by a specially trained caretaker; the biologic mother was able to visit the child as often as she wanted while she was receiving special training from the foster family. The evaluation of 291 children recovered under this mode of foster care revealed that the program was effective in normalizing weight for height and improved psychomotor development in 83% of the total.[25]

IMPLEMENTATION OF PROGRAMS TO PREVENT AND REDUCE MALNUTRITION AT THE NATIONAL LEVEL: THE EXPERIENCE OF CHILE

We need not only to examine the specific actions to treat severely and moderately malnourished children to understand how Chile succeeded in reducing malnutrition but also to assess the multiple programs that acted in synergy to achieve this goal. A key component was the primary health infrastructure with wide coverage and the human/material resources necessary for effective action. The capacity to identify and refer the severely malnourished to nutrition recovery centers when appropriate is vital for success. A nutrition recovery program focused on treatment of the severely malnourished working in isolation will have little or no impact unless it is coordinated with an effective primary and secondary prevention program working through the primary health system.[26]

Chile stands out among countries of Latin America and the Caribbean for the notable improvement of its health and nutrition situation, particularly in pregnant women and young children. This improvement has been achieved progressively and continuously through comprehensive health, nutrition, sanitation, education, and reproductive health strategies initiated in the 1940s. The results came 30 to 40 years later but much earlier than the considerable economic progress experienced by the country during recent decades. A key element in the success of the Chilean experience has been the uninterrupted application of programs defined based on technical consensus independent of major political, social, and economic changes. The programs remain in place and were expanded even in periods of social instability, radical political changes, and serious economic crisis. Only recently, poverty reduction has contributed to improved food security and to the improvement of the quality of life of low-income groups.

The achievements obtained in children's health can be appreciated in the declining rates of infant mortality and mortality owing to acute diarrhea and bronchopneumonia. Infant mortality dropped by approximately 90% and mortality owing to respiratory infections and acute diarrhea by over 95%. Between 1940 and 1960, total infant mortality was reduced in Chile from 193 to 120 per thousand live births. From 1960 to 1990, it fell to 17 per thousand, and over the past decade, it dropped to around 10 per thousand. See Table 9.2-1 for the degree of achievements of 2000 goals for nutrition of children and women; note the virtual eradication of malnutrition and the rise of obesity as the major diet- and nutrition-related public health problem.[27,28]

A key strategic factor in the development of nutrition programs in Chile has been the emphasis placed on the political dimension of nutritional problems. Nutrition of the population, especially its more vulnerable sectors, has been at the center of the political debate for the past 40 or 50 years. It has been transformed into a key indicator to assess social justice and equal opportunity for all. The 1970 presidential election campaign is a good example of this. All three main candidates for the presidency (one representing the conservative right, a second representing the center left [Christian Democratic], and the third representing the Socialist left) proposed the eradication of malnutrition as a key target of their respective future governments. Salvador Allende, the Socialist candidate, was elected on that occasion with the promise of providing half a liter of milk per day to every child up to 15 years of age in the country.

The community demanded access to health and food, not only to meet this basic need but also as a fundamental human right. The process initiated by academic researchers led to policy development and implementation of nutrition programs. The expansion of these programs became part of the social demands made by the population to the governments, and those politicians who satisfied these demands of providing more food to the economically vulnerable groups were elected and maintained in office. Community organizations, political parties, the Catholic Church, concerned academics, labor unions, and multiple social organizations played key roles in demanding action. Most of the nutrition programs were eventually built into the law specifying universal coverage and the respective yearly budget allocations. Any changes to the supplementary feeding programs have always been undertaken with extreme caution by governments because they are reluctant to take risks on a matter of such high political sensitivity.[27,28]

The National Supplementary Feeding Program (PNAC) is the main nutrition program for the prevention and control of malnutrition. It consists of the distribution of milk and other food products free of charge to children under 6 years of age, pregnant women, and breast-feeding mothers, with the sole condition of complying with the scheduled outpatient visits and preventive health actions determined by the Ministry of Health. In its present form, PNAC began operating in 1954 for the purpose of protecting and improving the nutritional state of pregnant women and children. Until 1974, it provided milk with variable fat content as the sole product. During the period from 1974 to 1981, studies were conducted with various milk-cereal blends for children after 2 years of age in an effort to reduce cost and to prevent the dilution of the product within the family. This alternative based on milk/wheat blends fortified with micronutrients has remained in place until now. All products are distributed in water-soluble dry powder form (except rice, which is given to families with greater need). PNAC's coverage was extended to all chil-

dren under 14 for a brief period (1971–1973), to return later to its original target population.[29]

Between 1975 and 1993, the protein-calorie malnutrition rate in the preschool population under control at the primary health care units of the National System of Health Services (SNSS) was calculated using the criterion weight for age below –1 SD of the median for age and gender (standard of reference based on the population described by Sempé and colleagues.[29a] These standard and diagnosis criteria were maintained over a period of almost 20 years. This makes it possible to appreciate the rapid reduction of malnutrition in the population under control in the public health system, which is equivalent to close to 75% of the total population of children under 6 in the country.

The National Nursery Schools Council (JUNJI), like the National Council for Students Assistance and Scholarships (JUNAEB), is an autonomous public corporation created by law in 1971 that is functionally dependent on the Ministry of Education. JUNJI plans, promotes, coordinates, provides incentives, and supervises the organization and functioning of daycare centers, which, as the name implies, provide day care for preschool children until they are old enough to start attending elementary education. JUNJI coordinates and supervises preschool education in the context of integral attention of preschool-aged children. Together with food and education in accordance with the child's age, this program also provides social assistance to the family when required.

The programs of food and social assistance to schoolchildren were initiated in 1929 with the Student Assistance and Scholarships Committees, which operated at the municipal level with local financing and some resources from the central government. In 1952, the Ministry of Education assumed, at the central level, the administration of these programs. This situation continued until 1964, when this and other responsibilities were handed over to an autonomous public corporation created by law for that purpose: the JUNAEB.

TABLE 9.2-1 Degree of Achievement of Nutritional Goals, Chile, 2000

Indicator	*Baseline 1987–1989 (%)*	*Goal 2000 (%)*	*2000* (%)*
Pregnant women with low W/H	25	15	15
Anemia in infants	30	10	5
Anemia in pregnant women	25	10	25
Newborn with low birth weight	6.9	6.0	5.0
Newborn with insufficient weight	21	15	12.5
Breast-feeding exclusively to 4 mo	44	80	60
Breast-feeding to 12 mo	20	35	34
Student grade 1 with height < – 1 SD	33	20	15.6
Under 6 yr old with W/A < – 2 SD	2.2	2.0	0.8
Food-insecure households	35	20	21
Indigent population	18	15	7
Obesity in preschool children	4.6	3	12
Obesity in children entering school	6.5	4.5	16
Obesity in pregnant women	12	8	32

Adapted from Plan Nacional de la Infancia, UNICEF, 1994.
W/A = weight/age; W/H = weight/height.
*Ministry of Health, Chile, 2001.

Conceived as a state assistance organization to support the work of the Ministry of Education, JUNAEB works on the basis of integral assistance for the purposes of providing maximum support to poor students, not only in terms of nutrition but also through programs of health, housing, educational recreation, scholarships, and so on.

JUNAEB provides orientation and plans and coordinates the execution of these social and economic assistance programs directed to students at the preschool, elementary, and high school level in order to make effective the equal opportunities in education. Program activities are aimed at providing incentives for incorporation and permanence in the educational system, preventing school desertion, and improving academic results of children in municipal and subsidized private schools. The School Feeding Program (PAE) takes up most of the institution's resources.

In 1951, fortification of wheat flour with B complex vitamins was established for the purpose of "improving the nutritional situation of the Chilean population." It included iron, calcium, thiamin, riboflavin, and niacin. Iron was added in low concentration and, owing to the presence of calcium and the type of compounds used (elemental iron), was probably of very low biovailability. In 1967, regulations on iron fortification were amended, making the process much more effective from a nutritional point of view. Bread made from wheat flour is the main source of calories in the Chilean diet. Total calorie consumption in the lowest income quintile is about 1,200 kcal/person/day, of which 40% comes from bread, whereas in the highest-income group (quintile V), with a total consumption of 2,085 kcal/person/day, only 20% is obtained from bread. Quality control is carried out by the Ministry of Health, which monitors the iron content in flour samples obtained in a regular and random manner from the mills. A study on iron content in bread obtained at commercial bakeries indicated that 87% of bakeries in the Metropolitan Region use flour without iron. Although it has been impossible to assess the efficacy of the fortification program, its impact has produced a change in the prevalence rates of iron deficiency anemia. Bread alone supplies 0.36 mg of iron per day in children 2 to 6 years of age and almost 1 mg/day in adolescents.[30] In fact, this problem has virtually disappeared in schoolchildren (7% in 1974 to less than 1% in 1994) and adolescents (5 to 1%). In contrast, the prevalence in infants remains high (approximately 23%). Iron-fortified cow's milk for infant feeding was introduced only in 1999.

Legislation establishing mandatory iodination of salt was enacted in 1959, and the Food Code of 1960 determined the obligation of salt fortification. This measure did not really become effective until 1982, when the Food Code was updated and the new version allowed the existence of both iodized and noniodized salt in the market. In 1989, the Ministry of Health established mandatory iodization, iodine added in the form of sodium or potassium iodates or iodides in a concentration of 100 ppm. A single producer supplies approximately 90% of the edible salt market and has maintained a good level of iodination. As a result, endemic goiter has been eradicated as a public

health problem. A study conducted in 1994 in four surveillance areas demonstrated that less than 10% of schoolchildren between 6 and 16 years of age showed goiter. When present, it was type Ia with high levels of urinary iodine. At present, a commission with the participation of the Pan American Health Organization (PAHO), UNICEF, the salt industry, and the Ministry of Health works to safeguard this achievement.[31,32]

In 1975, in Chile, severe malnutrition of the marasmic type was concentrated in children under 12 months of age. In fact, among the cases of severe malnutrition that were admitted to hospital, 76% were under 6 months of age. The population of these children, estimated at that time at around 15,000 at the national level, had an important effect on child mortality rates and overburdened pediatric hospital services, where their mortality, owing to intercurrent infections, was extremely high. Belonging, in general, to homes in extreme poverty, the severely malnourished infants who survived their hospital stay were discharged only partially recovered, or even with yet greater nutritional deterioration, to return to their homes where the existing poverty and marginality conditions determined their death or readmittance to hospital very shortly thereafter.

For the purpose of putting an end to this problem, in 1975 the Chilean Nutrition Foundation (CONIN) was created, a private nonprofit foundation that established throughout the country a system of 33 CNRCs with 1,400 beds provided for the integral treatment of children with severe malnutrition. This treatment includes, as basic elements, pediatric and nutritional attention; psychomotor, social, and emotional stimulation of the child; the incorporation of the mother to the child's recovery process; and integral child care training for the mother. At the same time, efforts are made to improve the socioeconomic situation of the family as well as the conditions existing in the home.

The CNRCs are directed by a pediatrician who has the collaboration of a professional team made up of a nurse, nutritionist, social worker, child care worker, nurse's aides, and a variable number of volunteer workers. CONIN provides support on technical aspects of the program through pediatricians with experience in public health and nutrition, psychologists and physical therapists who monitor the psychomotor stimulation program, and a social worker and a training unit that design strategies for education and social reinsertion of the mothers and family group of the children under treatment.

The CONIN program is to a great extent financed by funds provided by the Ministry of Health on the basis of the annual projected number of children to be treated. CONIN, through various mechanisms, generates supplementary resources. Volunteer workers play an important role in the institution, participating both in the care of the children and in the search for resources to assist the family group. In this task, CONIN centers generally count on the support of local governments.[26]

The program applied by CONIN has been successful. The reduction of malnutrition has led to the closing of many CNRCs, with only 18 remaining throughout the country. Of these, only some maintain their original objectives, although the children being treated today are, almost exclusively, suffering from moderate malnutrition owing to social deprivation and/or maternal neglect. Some other centers have destined their beds to reinforcement of the work of the Ministry of Justice with minors under socially deprived environment or maternal neglect. As primary malnutrition subsided, five of the existing centers are now concentrating their effort to the study and treatment of children with secondary malnutrition.

SELECTING THE BEST APPROACH TO TREAT SEVERELY MALNOURISHED CHILDREN

The selection of a treatment modality for malnourished children starts by defining the severity of the malnutrition. Gómez and colleagues, in the late 1940s, proposed the first classification of PEM based on weight expressed as a percentage of normal value for age. Despite the limitations of percent normal, it is still used by many because of its simplicity. First-degree or mild PEM is defined as between 75 and 90% of normal, second degree or moderate as 60 to 75%, and third degree or severe as < 60% of that expected for age.[33] Bengoa, with his functional classification in the mid-1950s, established treatment modalities based on the Gomez criteria, indicating that those with first degree should be treated in the primary health or outpatient health clinic by providing education and dietary advice and those with second degree should be treated in the daycare nutrition recovery center using complementary foods in addition to education. Finally, third-degree PEM should be treated in the hospital.[20] To a great extent, with the caveats described in the corresponding section, the Bengoa approach remains valid. Hospitalization should last strictly for the minimal time required to treat complications and stabilize the patient and then feed nutrient- and energy-dense foods as tolerated. CNRCs should be reserved to situations in which PEM is highly prevalent, particularly in young infants, and family conditions do not permit recovery at the home. The choice of treatment modality should also consider parental choice, cost-effectiveness of treatment under real-life situations, access to primary health care system, availability of health infrastructure, social support system available in the community, maternal education and overall condition, and psychosocial interactions within the family.[20]

The main barriers or impediments in control and treatment of malnutrition relate to the multiple conditioning factors presented earlier. Translating theoretic concepts into practices that lead to improved nutrition and health of children is also a challenge. Treatment norms and preventive strategies may be well known, but they are harder to establish as standards of practice. In addition, physicians commonly depart from rules to demonstrate their autonomy and status or challenge specific aspects of the norm based on anecdotal personal experience rather than on firm evidence. Health professionals often consider malnutrition as an unavoidable consequence of poverty and thus may accept it as a social problem outside the health realm. The common acceptance of malnutrition by communities and the political leadership as a chronic unsolvable prob-

lem inherent to social structure has traditionally led to passive acceptance and inaction. Physicians often define health expenditure priorities based on what is more attractive for medicine per se rather than on the impact on burden of death and disease. Some physicians are more interested in providing individual health care rather than addressing public health problems.

Physicians are weak in networking and partnership skills; they are not trained for teamwork and associate success with individual recognition. These traits prevent physicians from leading multiprofessional multidisciplinary teams such as those needed to address malnutrition effectively. The organizational environment becomes an important barrier; physician-led administration is usually centered on medical interest rather than on patients' need. Moreover, other health professionals are seen as subservient to the physician rather than team members with equal participation. Promoting new attitudes and skills, training for teamwork, active listening, and defining funding priorities based on the health needs of the community are key to establishing effective malnutrition prevention and treatment programs.

CONCLUSIONS

Presently, the world produces enough food to feed the 6 billion inhabitants of the planet. Food production increased by 25% over the last decade, reaching a daily availability of 2,750 calories and 76 g of protein per person.[9]

Yet undernutrition affects close to a billion people, and stunting and underweight affect close to 200 million children under 5 years of age, mostly found in South Asia and sub-Saharan Africa. The overall trend is toward a small decrease in the proportion of undernourished children with a minute decrease in the absolute number. Unfortunately, the goal established by the UN for the year 2000 two decades ago to reduce malnutrition by 50% was not met. The present level of progress of –0.72% per year is only half of the 1.5% decrease required to reach this goal in the next 20 years. Moreover, some regions, such as sub-Saharan Africa, show a rising prevalence of malnutrition. This situation is worse in countries affected by civil strife and drought, where famine conditions may cause the death of children at rates 20 to 40 times greater than those found in the general population. We can firmly state that malnutrition and growth failure of children remain issues that affect not only survival but also the quality of life of children in many parts of the world. Prevention is the best form of treatment. There is no doubt that sufficient knowledge exists to treat and prevent primary malnutrition in virtually all children. The condition should be considered a preventable disease, but its eradication requires full commitment by society to assign a high priority to the well-being of children. Changing the social, economic, and political forces that condition abnormal growth and development in PEM goes beyond the realm of specific medical action but requires concerted participation of physicians as advocates for children in the political process. Placing demands on political leaders is essential to ensure that children, from the time of conception throughout their various development stages, are provided with adequate nutrition to allow for the full expression of their genetic potential. Acceptance of this basic premise by the community is essential before appropriate prevention strategies can be successfully undertaken.[3]

Treatment of childhood malnutrition initiated as a response to a basic humanitarian duty to prevent death during the first half of the past century remains a problem in many regions of the developing world. Presently, the mandate is based on the right of adequate food and nutrition for all children as part of the global human and social development agenda. National and international nutrition and food programs developed over the past 50 years have been implemented as integral components of broader strategies of primary health care and education, oriented toward preventing deaths and improving the quality of life of low socioeconomic groups. Pediatricians worldwide also should be aware of malnutrition as a conditioning factor delaying recovery from illness and as a major determinant of the quality of life of children with chronic disease.[3]

The key for effective malnutrition prevention is integrating health care, household food security, and care as proposed by the UNICEF model (see Figure 9.2-1) presented at the outset. The following are some of the components of malnutrition primary prevention programs that have been developed and tested over past decades throughout the world in a variety of political and social settings:

1. Promote early contact between mother and infant to improve the chance for successful breast-feeding. Establish hospital and other health routines that support breast-feeding while in the maternity ward and later; successful early bonding and documented breast-feeding are vital. Support breast-feeding by the groups interacting with mothers (health team and others) and by legal frameworks that promote, protect, and sustain the right of working women to practice it.
2. Monitor growth and development with adequate standards (present standards are being revised based on present recommended feeding modes). Intervene only when appropriate to prevent malnutrition and specific micronutrient deficits. Mothers should be familiar with growth monitoring cards and be ready to take appropriate actions when growth faltering occurs. The degree of actions taken by the community will depend on the strength of the primary health care.
3. Introduce appropriate micronutrient-rich complementary foods and supplements at 6 months of age. If complementary foods are needed earlier, consider the risks associated with interference of breast-feeding. Ideally, these should be based on local foods that are accessible to the population. Micronutrients will be required in most cases; new developments include fortification at the household level either with tablets, sauces, or sprinkles. Food donations should be incorporated into existing programs and not depend on whether surplus exists in industrialized countries. Occasional food donations, no matter how well meaning, can have adverse consequences in the long term when they disappear.

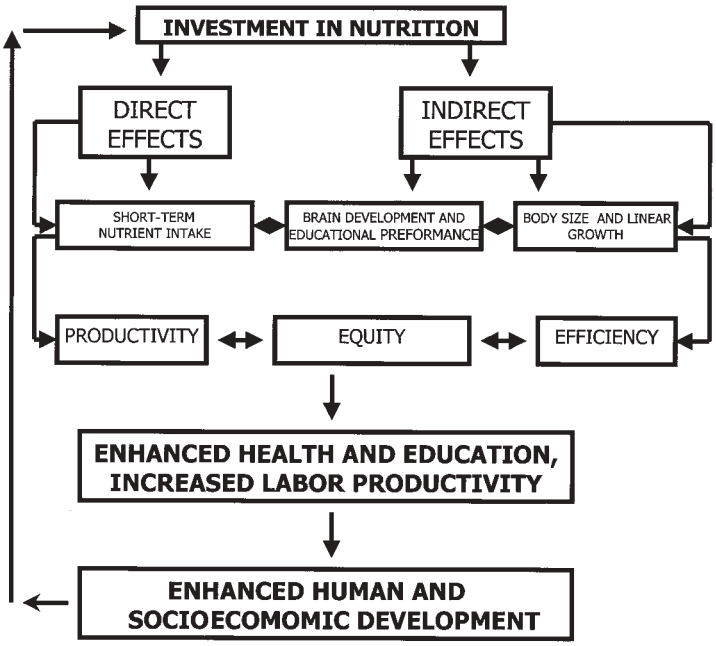

FIGURE 9.2-6 Model to explain how investment in nutrition contributes to economic growth and national development. Short-term improvement in food intake is coupled with better linear growth and enhanced mental development. These translate into better health, decreased infectious morbidity and mortality, enhanced educational performance, and increased capacity for physical work. These interactions in the appropriate social and political conditions lead to increased efficiency, productivity, and equity. The product of the investment is better health, education, and productivity, thus generating economic growth and greater human and social development. This virtuous cycle is closed as more investment in nutritional improvement takes place.

4. Identify infants at risk for malnutrition and growth failure based on biologic and social risk factors. Provide adequate social and medical support for families with children at risk. Early identification should be based on community surveillance not only of growth but also of caring practices and of critical food insecurity. Early interventions at this level are significantly more cost-effective. This area is presently receiving insufficient attention despite being at the core of the problem.
5. Educate parents and adolescent girls (who will be mothers) on how to promote growth and development through appropriate home environment, care, and stimulation. Verbal and cognitive stimulation for malnourished children results in higher growth rates than for children without such stimulation. Interactions with parents, caregivers, and other children are essential for the young child and can be improved by education of caregivers. Care initiatives should go beyond focusing on individual practices and behaviors to bring in dimensions of care for the family and the community.
6. Provide universal coverage of children for basic health care services, as well as full coverage for all children with immunizations to prevent infectious disease and avoid their adverse effects on nutritional status and provide early diagnosis and treatment of diarrheal disease at the community level using oral rehydration. Link this effort to the community-based surveillance for effective prevention and control of mild and moderate PEM. Depending on what is available in the country, the approach may not require expensive infrastructure but rather may be community based and sustained.

Treating hundreds or thousands of affected children will not solve the problem of malnutrition as a global public health problem. Unless society at large confronts this issue in its full dimension, the problem will continue. Access to adequate amounts and quality of food represents a basic human right and is a necessary precondition for health. In turn, good nutrition and health are prerequisites for human, social, and economic development (Figure 9.2–6). Physicians, especially pediatricians, should not be passive bystanders but rather activists in this process. Reducing malnutrition of infants and young children means a brighter future for humankind and will contribute to giving world peace a better chance.

CHAPTER 10

PROTEIN-ENERGY MALNUTRITION: PATHOPHYSIOLOGY, CLINICAL CONSEQUENCES, AND TREATMENT

Mary E. Penny, MB, ChB

The number of children affected by and the long-term consequences of malnutrition place it among the greatest public health problems facing the world today. The World Health Organization (WHO) estimates that malnutrition contributes to 55% of child mortality worldwide.[1] Even mild degrees of malnutrition double the risk of mortality[2,3] for both respiratory and diarrheal disease mortality[4] and malaria,[5] but this risk is greatly increased in more severe degrees of malnutrition.[2,3] Severe malnutrition, also called protein-energy malnutrition (PEM), is eminently treatable, but, sadly, this is an area where the gap between existing knowledge of successful practice and the reality of the management of most malnourished children is abysmal. Recent reports illustrate how the adoption of improved management can drastically reduce mortality even in resource-restricted circumstances.[6] The global importance of malnutrition and the long-term consequences are dealt with in Chapter 11, "International Nutrition." The public health significance, as discussed in Chapter 9.2, "Community Nutrition and Its Impact on Developing Countries (The Chilean Experience)," emphasizes the necessity for the combination of policies designed to prevent malnutrition and the treatment of children with existing malnutrition. These authors describe the success in Chile of such an approach. Malnutrition is not only a problem of developing countries. Failure to recognize malnutrition may also contribute to increased morbidity and mortality in other conditions seen in developed countries such as congenital heart disease[7] and cystic fibrosis.[8] This chapter deals with the clinical management of severe malnutrition and attempts to show how an understanding of the pathophysiology provides a basis for the treatment of the severely malnourished child. The multiple factors that contribute to the development of malnutrition are detailed elsewhere; this chapter is principally concerned with severe PEM as a clinical entity because the failure to recognize the special needs of these children contributes to the high mortality.[9]

DEFINITIONS OF MALNUTRITION

Malnutrition has many causes. In any individual, inadequate food intake, infections, psychosocial deprivation, the environment, and perhaps genetic variability contribute. The clinical manifestations in the child depend on the duration and degree of shortfall in dietary intake, the quality of the diet, host factors such as age, and the interplay with infection.

The first step in the diagnosis of malnutrition is nutrition assessment. This is an essential part of any clinical pediatric evaluation and is discussed in detail in Chapter 2, "Nutritional Status Assessment for Clinical Care." Repeated nutritional assessments of all ill children are important to prevent the insidious onset of malnutrition, which may hinder recovery. Adequate growth is an indication of health and recovery. For the individual child, the most important information is gained from serial measurements indicating the child's growth, and this provides essential information for diagnosing cause and guiding treatment. The importance of using this often available but overlooked information cannot be overstated.

Although measurements of height and weight are the usual mainstays of diagnosis, additional information on body composition can be obtained from skinfold thickness and other more sophisticated methods. Biochemical and hematologic tests may also be useful, especially in monitoring progress. PEM is often associated with micronutrient deficiency, and examination should include a specific search for Bitot's spots or xerophthalmia, manifestations of vitamin A deficiency,[10] and signs of other micronutrient deficiencies.

Sole reliance on weight and length or height can lead to failure to recognize kwashiorkor and an underestimation of the severity of the malnutrition in these children. The scheme recommended by WHO (Table 10-1) has the merit of distinguishing these two entities and is useful in clinical practice.[11] Figure 10-1 illustrates a child with marasmus and shows the characteristic muscle wasting particularly evident in the buttocks, the pinched face, and anxious demeanor. Figure 10-2 shows the same child on recovery. Figure 10-3 illustrates a child with kwashiorkor. Symmetric edema is evident, especially in the lower limbs. The hair is sparse, and the flaky paint rash is seen on the buttocks, legs, and arms. Figure 10-4 shows the typical bilateral symmetric edema of the legs.

Marasmus is generally thought to be the result of a cumulative, usually slow, inadequate energy and protein intake. The child's metabolism has adapted, producing changes that prolong survival and protect essential visceral and brain function. This is the type of PEM traditionally seen in famine, food restriction, or anorexia. Kwashiorkor is also a severe form of malnutrition. The etiology is not well understood, but the long-held view that protein deficiency in the face of adequate energy intake causes kwashiorkor cannot explain all of the evidence. Observed findings are more in keeping with an interaction between nutritional deficits and the response to injury, infection, and oxidative stress. Marasmus and kwashiorkor commonly coexist, and although a simple unified approach to clinical management can be applied successfully to both conditions,[11] the two are clinically distinct entities.

FIGURE 10-1 Child with marasmus.

PATHOPHYSIOLOGY

Metabolic Responses to Inadequate Energy Intake

PEM is the result of a chronic and cumulative failure to meet physiologic energy and nutrient requirements.[12] The manifestations of this process depend on different factors: age, concomitant infection, prior nutritional state, and the nature of the dietary restriction, to name four. Both the early classic experimental studies of food energy deprivation and starvation in animals and humans and studies of severely malnourished children on admission and during recovery have contributed to our understanding, although the situation is complicated by the multifactorial causes of malnutrition in most children. A detailed description is

TABLE 10-1 Classification of Moderate and Severe Malnutrition

	Moderate Malnutrition	*Severe Malnutrition*	
Symmetric edema?	No	Yes	Edematous malnutrition or kwashiorkor
Weight for age			
SD score	–2 to –3	< –3	Severe wasting
% Median	70–79	< 70	or marasmus
Length for age			
SD score	–2 to –3	< –3	Severe stunting
% Median	85–89	< 85	

Adapted from World Health Organization.[11]

beyond the scope of this chapter, but the interested reader is referred to excellent reviews.[13,14]

In the absence of infection, fasting results in an initial depletion of fat stores and then glycogen stores mediated by metabolic and endocrine changes that have the common goal of preserving vital functions, allowing the animal or human to survive until dietary energy can be restored. Early changes include a reduction in activity that conserves energy expenditure.[15] Growth is slowed, reducing the energy need to maintain this, and changes occur in body composition. Metabolic rate expressed in relation to height or lean body mass decreases.[14] Brain and viscera are relatively preserved (Figure 10-5),[16] resulting in the body composition typical of marasmic children.[17] There is an increase in total-body water, which is mainly extracellular but may also be intracellular.[12,13,18]

These metabolic adjustments to starvation are mediated, at least in part, by hormones. Cortisol concentration rises but remains responsive to stress.[17,19] Insulin secretion falls, and there is a reduction in plasma levels, a reduced response to glucose, and peripheral insulin resistance.[20,21] Growth hormone is generally high, and the normal suppression by glucose load is lost, although exceptions occur in marasmus.[22] There is low activity of insulin-like growth factor 1, the metabolic effector of the growth promoting the effect of growth hormone.[17] The net effects of these hormonal changes are mobilization of fat, degradation of

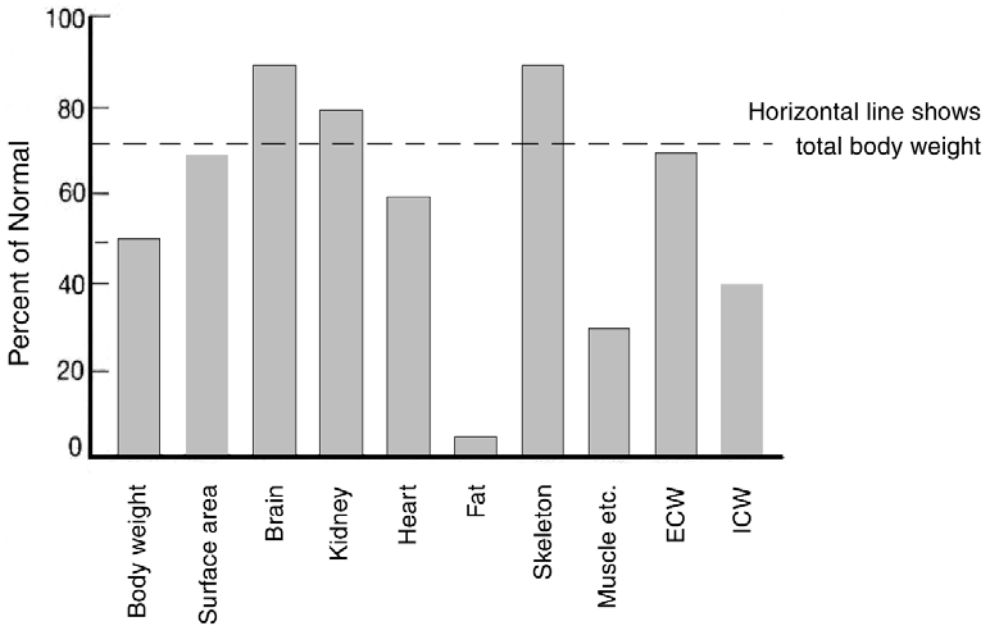

FIGURE 10-5 Weights of organs at death in atrophic children as percentages of normal age controls. ECW = extracellular water; ICW = intracellular water.

muscle protein, and reduction in basal metabolic rate. Increased aldosterone contributes to potassium loss already compromised by the effects of energy restriction and reduced adenosine triphosphate synthesis on the sodium pump.[23]

Adaptation to Reduced Protein Intake

During protein deprivation, skeletal muscle is lost as structural protein is recycled to conserve essential enzymes and provide energy for metabolic processes. There is both a fall in muscle protein synthesis and an increase in breakdown, which provides essential amino acids to the liver for protein synthesis and gluconeogenesis.[17] Within the liver, there is a shift in the rates of synthesis of different proteins; synthesis of albumin, transferrin, and apolipoprotein B are decreased, but the synthesis of other proteins is protected.[24]

Changes in Electrolytes

Changes in chemical composition of the body that occur during malnutrition have important consequences for treatment. Sodium, potassium, and phosphate merit special mention, but changes in other electrolytes, such as magnesium and calcium, are probably important but have been less studied.

The vast proportion of total-body potassium is intracellular, in contrast to sodium, which is actively removed from cells by the sodium pump. In both marasmus and kwashiorkor, sodium retention occurs, resulting in an increase in whole-body sodium, even though serum levels may be low, reflecting an increase in extracellular water. There is a decrease in total-body potassium,[25] although serum potassium may remain normal. Alleyne and colleagues described how potassium kinetics are altered during recovery.[26] There was an initial acute repletion of potassium when hypokalemia and whole-body deficiency improved, followed by a longer phase of cell membrane recovery and reestablishment of the normal Na/K gradients. A third phase occurred when rapid growth of skeletal muscle increased potassium requirements.[27,28] Nichols and colleagues calculated from balance studies that 7.0 mmol/kg of potassium was needed in the first week or acute phase of recovery, an amount similar to the level of supplement giving best results in a clinical trial in Malawi.[29,30]

The inconsistencies between serum and total-body potassium are explained by events at the cell membrane. In marasmus, there is a decrease in the activity of the ouabain-sensitive energy-dependent sodium pump, resulting in increased intracellular sodium and reduced potassium.[31] These cell membrane changes are associated with intracellular changes, with relatively low intracellular K and relatively high sodium. Different mechanisms operate in kwashiorkor, in which there is an increase in cell membrane leakiness. Sodium, responding to the electrolyte gradient, enters the cell, stimulating increased activity of the sodium pump but not enough to prevent Na increase and K loss.[31,32] Similar differences between marasmus and kwashiorkor were reported by Kaplay in India.[33] Forrester and colleagues found that these electrolyte changes could be reproduced in in vitro erythrocytes if glutathione was artificially reduced, resembling the situation in kwashiorkor.[34] Increased intracellular sodium is accompanied by increased cell water, which may be one of the explanations for edema in kwashiorkor.[35] Hypoinsulinemia is implicated in this process.[36] These electrolyte changes are the basis for the recommendations of dietary restriction of sodium, the use of low-sodium oral rehydration solutions (ORSs), and potassium supplementation in all severely malnourished children.

Hypophosphatemia has been shown to occur in malnourished children and is associated with high mortality. In a South African study, 10 of 60 patients died, all but one with very low serum phosphates.[37] The lowest levels of serum phosphate were associated with diarrhea and dehydration. A more recent study from Malawi supports the association of hypophosphatemia and increased mortality.[38] However, it is difficult to distinguish the effects of low phosphate from hypokalemia, which also causes hypotonia and sudden death. In Jamaica, serum phosphate levels were generally higher than those recorded in Africa and although correlated with edema were not associated with mortality. Repletion, even on a milk diet, took 2 to 3 weeks.[39] In India, severe hypophosphatemia was not seen.[40]

Interaction with Infection

Infection and nutrition are mutually interlocked in a vicious cycle that operates at many levels, from social cultural interrelations to intracellular metabolism. Environmental conditions that give rise to inadequate energy and protein intakes are also associated with conditions in which bacterial and other microbial contamination is often rife.[41] In addition, in famine or poverty, children's diets tend to consist largely of carbohydrate staples with little or no animal products or fat.[42] Animal products such as red meat, poultry, offal, fish, milk, and eggs are important bioavailable sources of minerals and other micronutrients that have an essential role in combating infections.[43] Fat, needed to provide essential fatty acid (EFA) and facilitate the absorption of fat-soluble vitamins such as E, D, and A, which also protect against infections, is also often low in these diets.

During infection, there are metabolic changes that concentrate body energy resources on production of acute-phase proteins in the liver and are often the opposite of those seen in starvation.[44] The production of acute-phase proteins and the metabolic consequences of infection are mediated by protein cytokines, lipid-derived factors that include prostaglandins, leukotrienes, and platelet activation factor. Endocrine changes also play a role; the concentration of catabolic hormones such as glucocorticoids, glucagons, and epinephrine increases. The cytokine interleukin (IL)-6 increases norepinephrine, cortisol, and glucagon and is the main stimulus for the mobilization of acute-phase proteins in the liver. Cytokines also enhance the effect of stress-related hormones on the production of acute-phase proteins.[45] Because of the interaction between food restriction and infection in the pathogenesis of malnutrition, any integrated approach to explaining the pathophysiology has to take both into account. The differences between kwashiorkor and marasmus may be partially explained by an increased shift toward the metabolic con-

sequences of infection in children with kwashiorkor. In addition, preceding nutritional status may modify the metabolic effects of infection. An example is the increased rate of breakdown and synthesis of protein in response to infection in children with marasmus but not those with kwashiorkor[46] and the slower recovery from infectious diarrhea.

Cytokines

Because of the fundamental role of cytokines in infection and the interaction with malnutrition, a brief summary of their action is necessary. For more detail, readers are referred to more detailed reviews.[45,47,48] Cytokines are small, nonstructural proteins that can be produced by nearly all nucleated cells in very small amounts, have local and systemic effects, and are involved in the primary response to infection. Synthesis of cytokines is rapidly induced in response to infection, trauma, ischemia, and other events. Cytokines are also involved in mediating the changes in protein metabolism and muscle function that accompany infections, fasting, and cancer cachexia. The family of tumor necrosis factors (TNFs), IL-1, and IL-6 are all proinflammatory cytokines. The proinflammatory cytokines mediate the local inflammatory response, which includes local heat, redness, pain, swelling, and systemic effects such as fever and anorexia. To avoid self-injury during the inflammatory response, the induction and synthesis of cytokines are controlled in a complex interactive process full of checks and balances. This tightly controlled system is disturbed in malnutrition. Children with severe malnutrition often have a reduced inflammatory reaction and blunted febrile response. In keeping with this, reduced levels of in vitro production of IL-1 and TNF by circulating monocytes have been reported in malnutrition.[49] In contrast, high concentrations of cytokine IL-6 and TNF have been reported in the serum of malnourished children without current infection.[50] Further studies are needed to sort out the role of these inflammatory mediators in malnutrition, but the consequence of a reduced inflammatory response to infections has important clinical management consequences as the usual manifestations of infection may be absent in PEM.

Acute-Phase Proteins

Cytokines modulate the production of acute-phase proteins. C-reactive protein, α_1-antitrypsin, and α-macroglobulin are examples of positive acute-phase proteins, so called because their synthesis by the liver increases in response to stresses, including infection.[44] Serum concentration of the so-called negative acute-phase proteins (albumin, prealbumin, fibronectin, retinol binding protein) is reduced in children with malnutrition[49,51] despite an overall net increase in hepatic protein synthesis. Low levels of fibronectin have been reported to be a useful early indicator of malnutrition.[52] Positive acute-phase proteins are an essential part of the defense against infections, but uncontrolled inflammation has been linked to adverse consequences, for instance, in inflammatory bowel disease, rheumatoid arthritis, and perhaps kwashiorkor. Studies are complicated by the coexistence of infection and malnutrition and the limitations of interpreting serum levels, which represent a balance between synthesis and catabolism. Studies in Ghana on children without sign of infection found raised concentrations of C-reactive protein in kwashiorkor and to a lesser extent in marasmus.[53] Alpha-1 acid glycoprotein levels were raised in kwashiorkor in Thai children.[51] On the other hand, Ekanem and colleagues,[54] studying children, 75% of whom had kwashiorkor, documented only slight increases in C-reactive protein in children without infection and large increases in infected children, indicating apparent preservation of the acute-phase response to infection in this population of children. This is in contrast to findings in Jamaica[55] of normal levels of C-reactive protein and serum amyloid A with a blunted response in the expected acute-phase response to diphtheria-pertussis-tetanus vaccination. Elegant recent studies in Jamaica using stable isotopes, in this case in mainly marasmatic children, with infections showed that the increase in plasma levels of acute-phase proteins was attributable to a reduction in catabolism rather than an increase in synthesis of the proteins, in contrast to the situation in normally nourished infected children.[56] Further studies such as these using labeled amino acids are needed to clarify the role of disturbances in the synthesis and catabolism of acute-phase proteins in the pathophysiology of severe malnutrition.

Kwashiorkor

Kwashiorkor has historically been attributed to a diet lacking in protein, and the edema was thought to be explained by low albumin. In consequence, children were treated with high-protein diets. However, several observations cast doubt on this hypothesis.[57] Kwashiorkor often follows infections such as measles and dysentery and has been reported in breast-fed babies, who presumably are ensured adequate protein intake, and children in the same community on very similar diets may develop kwashiorkor or marasmus. Edema has been shown to improve independently of albumin.[58] Golden demonstrated that recovery was possible with relatively low-protein diets and was dependent on energy intake and not protein.[59] It seems unlikely that simple protein deficiency is the cause of kwashiorkor.

Free Radicals

Excess free radical production has been suggested as the fundamental explanation of the clinical findings in kwashiorkor.[60] The acute inflammatory cells that form the first line of defense against infections respond with a respiratory burst during which free radicals are produced. This response to infection or cell injury relies on these free radicals for the destruction of bacteria. The free radicals are characterized by one or more unpaired electrons, which makes them highly reactive and unstable.[61] Reactive oxygen species include oxygen radicals such as singlet oxygen and nonradicals such as hydrogen peroxide; reactive nitrogen species include nitric oxide. The most potent free radicals include the hydroxyl radical and iron free radicals, which occur when unbound iron is present during free radical production. Free radicals are produced in normal metabolism, and a certain level of these radicals is required for normal functioning. However, this amount is kept to a

minimum by a number of scavenging mechanisms, which detoxify the radicals. Free radical production is increased by stresses, which include inflammation, infections, and environmental stresses.[62] Oxidative stress is a process in which the normal balance between pro-oxidants and antioxidants is shifted toward the oxidant side, resulting in an increase in free radicals that cause biologic damage.[63] Increased oxidative stress has been demonstrated in kwashiorkor.[64] The damage caused by free radicals includes disrupting enzymes and nucleic acids and the peroxidation of lipoproteins and EFAs in cell membranes by hydrogen peroxide. Dietary antioxidants protect from oxidant damage either directly by scavenging free radicals or because they are required for enzymes, which neutralize free radicals such as superoxide dismutase (copper, zinc dependent) or glutathione peroxidase (selenium dependent) and catalase. Many studies show low concentrations of antioxidants in the serum and red cells of children with malnutrition, especially kwashiorkor.[64–66] Blood cell concentrations of glutathione, vitamin E, and the vitamin E-to-cholesterol ratio are reduced,[50] resulting in diminished resistance to oxidative stress.

The hypothesis proposes that the balance between production and quenching of free radicals is perturbed in kwashiorkor, resulting in oxidative stress. This is attributable to low levels of dietary antioxidants, with possibly increased free radicals as a consequence of the disturbance in the acute-phase response to infections and other environmental stresses.

Lipid Metabolism, Polyunsaturated Fatty Acids, and Free Radicals

Recent research investigating the role of lipids in malnutrition lends support to the theory of oxidant stress as a cause of kwashiorkor. It has been known for a long time that there are changes in the lipid profile of red cell membranes and plasma in malnutrition.[67–69] Recent interest has focused on these EFAs and their metabolites as these have protean functions, which include maintaining the integrity of cell membranes and involvement in the synthesis of immunologically active elements such as prostaglandins and leukotrienes.[70] A low proportion of arachidonic acid, one of the EFAs, in the lipid profile of cell membranes and low concentrations in the plasma of children with severe malnutrition have been reported.[71] These changes in EFAs are not owing to dietary deficiency alone and are more likely a result of shifts in the metabolism of these EFAs. In particular, desaturation, which is subject to endocrine influence, is reduced, and low desaturase activity has been reported in PEM.[72] There may also be peroxidative degradation of EFAs in cell membranes. Levels of antioxidants are consistently reduced in PEM, and this increases the peroxidation of membrane long-chain polyunsaturated fatty acids (PUFAs).[73,74]

Leukotrienes are a family of mediators involved in the inflammatory response. The EFA arachidonic acid mentioned above is a precursor of the leukotrienes. Glutathione is also needed for the synthesis of leukotrienes from arachidonic acids, and several studies have documented low levels of whole-blood glutathione and low urinary excretion in kwashiorkor and marasmus patients,[66,75,76] suggesting that synthesis of the leukotrienes might be compromised in severe malnutrition. However, it seems that different leukotrienes are affected in different ways because concentrations of the cysteinyl leukotrienes LTE_4 and LTC_4, which mediate vascular damage and edema, have been found to be increased in the red cells of children with kwashiorkor but not marasmus, whereas LTB_4, which stimulates chemotaxis, was much reduced.[77] Cysteine supplementation improved the erythrocyte synthesis rate in children with kwashiorkor.[78]

The changes in sodium and potassium fluxes across cell membranes characteristic of kwashiorkor may also be explained in this model of reduced antioxidants. In an in vitro model, red cells depleted of glutathione showed increased leakiness to sodium and potassium, mimicking the findings seen in kwashiorkor.[66] The active transport of sodium out of the cell was increased but could not compensate for the increased permeability, resulting in the low K, high Na typical of malnutrition.

In summary, much remains to be learned about the pathophysiology of kwashiorkor. At present, it seems that the syndrome results from the interplay of nutrient deprivation and infectious or environmental stresses, which leads to a disturbed balance in the normal physiologic response to these insults. The syndrome may be predisposed by a specific pattern of nutrient deficiencies, which include protein, antioxidants, trace elements, sulfur amino acids, and probably others. In kwashiorkor, there is evidence of low antioxidants and increased oxidative stress, resulting in changes of free radical damage, increased sodium/K flux across membranes, triglyceride accumulation in the liver, low albumin, changes in n-6 PUFAs, and altered leukotriene production. The role, cause, or effect of changes in the acute-phase reaction, including the cytokine inflammatory response, remains to be elucidated.

Alternative theories to explain kwashiorkor have not been supported by more recent evidence. The postulated association with the hepatic toxin aflatoxin may be an example of one environmental trigger with a role in some geographic areas where fungal contamination of staple foods is common,[79] but this hypothesis has not been supported by absence of aflatoxins in liver samples from kwashiorkor, even in areas where aflatoxins are common.[57]

Changes in Organs and Systems in Malnutrition

In addition to the myriad cellular manifestations of PEM, widespread alterations in organ and system function occur, many of which are relevant to clinical management.

Endocrine System Endocrine changes mediate the metabolic adaptation to starvation and have been mentioned. These changes have important consequences on the clinical management of severely malnourished child. Pancreatic atrophy is a common finding in marasmus,[80] and the consistent findings in severe malnutrition of a reduction in serum insulin levels and impaired insulin response to a glucose load, glucagons, and arginine[12,20] explain the vulnerability of the child to delays in starting feeding and the need for fre-

quent small feeds. Hypokalemia contributes to this effect,[81] hence the importance of potassium supplements. There is also a reduction in insulin receptor affinity.[21] These hormonal effects rapidly reverse on refeeding, with weight gain.[82]

Studies in malnutrition have generally reported raised concentrations of growth hormone on admission,[22] but these concentrations reduce in those gaining weight on dietary treatment. Cortisol concentrations rise, especially in kwashiorkor, and the circadian rhythm is abolished, but the response to adrenocorticotropic hormone is preserved.[12,83] Cortisol levels also rise with infection; 80% of children with kwashiorkor showed a rise in cortisol in response to infection compared with only 50% of those with marasmus.[12] This reduced response in marasmus may explain why these children are so susceptible to hypoglycemia. High levels of adrenaline are reported early in hospitalization, especially in kwashiorkor.[12] Both the plasma concentration and the secretion rate of aldosterone are high.[23]

Thyroid gland function is altered in malnutrition.[84,85] During nutrition deprivation, at first thyroxine (T_4) increases, but as malnutrition becomes more severe, and especially if kwashiorkor develops, total T_4 decreases. There is also a decrease in thyroid binding proteins, but this does not account for all of the reduction in T_4 and suggests a primary effect on synthesis.[86] Increased thyroid-stimulating hormone secretion heralds recovery.[87] There is also a reduction in deiodination of T_4 to triiodothyronine (T_3), resulting in reduced T_3.

Immune System Children with severe malnutrition are very susceptible to infection, especially with gram-negative organisms, and deaths are often attributable to sepsis. The subject has been extensively reviewed by Chandra and others[88–92] and is dealt with in more detail in Chapter 20, "Malnutrition and Host Defenses." In summary, there are profound changes in cell-mediated immunity, the complement system, and function of polymorphonuclear cells and fewer reported effects on humoral immunity.

Cell-Mediated Immunity. Cell-mediated immunity is altered in severe malnutrition.[90] The thymus, necessary for normal differentiation of T cells, is consistently reduced in size,[93] and the production of thymic hormones is reduced.[91,92] Evidence of T-cell functional impairment also comes from the observation of reduced cutaneous tests to recalled antigens, for instance, the tuberculin test[94,95]; however, studies differ in reports of numbers of circulating T cells and the ratio and effect on T-cell subsets. In general, it appears that T4 cells are relatively reduced, and T8 cells are affected to a lesser degree. At the gastrointestinal level, atrophy of gut-associated lymphoid aggregates as a prominent feature of malnutrition has been reported.[96]

Humoral Immunity. Immune globulin production by B cells has been reported to be normal or raised,[90] and immunoglobulin (Ig)G seroconversion in response to several vaccines is preserved.[97] Increased IgA has been reported, but there was a reduced response of secretory IgA in nasopharyngeal secretions to measles vaccine,[98] and children with severe malnutrition in Brazil were found to have lower secretory IgA in urine, which increased on rehabilitation.[99]

The complement system shows consistent abnormalities with decreased C3 level.[100,101] This seems to be related to protein metabolism.[53] Some studies report particularly low concentrations of C3 in kwashiorkor. However, Ekanem and colleagues found that C3 levels, although low, rose significantly in the presence of infection.[54] C4 levels seem to be increased or unaffected by nutritional status.

Other potentially important disturbances in the immune system include impaired phagocytic activity by polymorphonuclear cells.[89]

The consequence of these various effects is a reduced capacity of the malnourished child to respond to and combat infections, leading to an increased risk of sepsis, one of the main reasons for mortality in malnourished children.

Liver In the liver, there is a shift from the production of carrier proteins and a relative increase in the production of acute inflammatory proteins, indices of response to injury or infection. This is particularly marked in kwashiorkor. The liver in kwashiorkor is often enlarged and shows a fatty infiltrate owing to accumulation of triglycerides.[102,103] These changes improve on clinical recovery, and there is no evidence that kwashiorkor per se results in long-term liver damage or cirrhosis.[104]

Cardiac System Cardiac output is reduced in children with acute PEM compared with cardiac output on recovery.[17] Cardiac muscle, however, shows only nonspecific changes, and muscle contractility is normal. Sinus bradycardia may be present, as well as mild hypotension. Concomitant deficiencies such as hypokalemia, anemia, and vitamin deficiencies may affect the heart. Pericardial effusion may be present in edematous malnutrition. During recovery, the heart size increases rapidly owing to chamber enlargement, and left ventricle musculature increases in proportion to increasing weight.[105] However, if dietary repletion is rapid, especially if there is also a high sodium load, heart failure may develop and sudden death occur. Prompt action to reduce hyperalimentation, restrict sodium intake, and administer diuretics can reverse the heart failure, but because this condition may not be recognized or is confused with sepsis, this complication is responsible for unnecessary deaths. This cardiac pathology is not considered primary to the heart but is more probably part of the refeeding syndrome described later.[17,105]

Respiratory System The reduction in muscle mass that occurs in severe malnutrition affects respiratory muscle, including the diaphragm; this leads to reduced muscular function, which influences vital capacity and maximal inspiration and inspiratory pressures.[106] This weakness may be exacerbated by electrolyte abnormalites such as low phosphate[107] and hypokalemia. The ventilatory response to hypoxia is blunted, but not the response to hypercapnia.[108] Despite these alterations, tachypnea and subcostal retraction remain useful signs in diagnosing pneumonia in malnutrition.[109]

Gastrointestinal Tract Diarrhea and malnutrition often occur together. Malnutrition increases the risk of more pro-

longed episodes of diarrhea,[110] and the combination of persistent diarrhea (more than 14 days of diarrhea) and malnutrition carries an especially high mortality.[111] Diarrhea and malnutrition so often coexist that it is difficult to determine the extent to which each contributes to pathology. Nevertheless, both animal and human studies suggest that severe malnutrition per se affects the intestinal tract with reduced gastric acid production, thinning of the small intestinal mucosa, and flattening or disappearance of the villi with relative sparing of the crypts.[17,112] There is increased cellularity of the lamina propia, especially in children with kwashiorkor.[112] These anatomic changes are reflected in impaired mucosal function, increased permeability as demonstrated by the double sugar technique,[113,114] and malabsorption as shown by nutrient absorption studies.[115] The mucosa seems to be particularly affected in kwashiorkor. In children with PEM in Malawi, kwashiorkor was associated with abnormal results, and persistent diarrhea was not an independent risk factor for altered permeability.[114] Loss of the villous architecture of the small intestine for any reason reduces disaccharide activity because the disaccharides, especially lactase, are found at the villous tips. Thus, lactose malabsorption is a common finding in both infectious diarrhea and in PEM.[116] Fat malabsorption is also seen in both persistent diarrhea[117] and PEM.[118] As well as the mucosal changes, bacterial overgrowth in the upper small intestine has been described in PEM and may lead to bile salt conjugation, further impairing fat absorption.[119] On the other hand, the human intestine has remarkable reserve capacity, and the clinical consequences of the demonstrated pathology need to be put into context. In the first place, the intestinal mucosa receives nutrients directly from the lumen, and enteral feeding is necessary for recuperation of intestinal health. We now know that even the damaged intestine benefits from food. Even in the face of malabsorption, diets can be designed to capitalize on remaining function. Carbohydrates are well absorbed in the small intestine until disaccharidase capacity is overwhelmed, at which point, the unabsorbed sugars cause osmolar diarrhea and the risk of dehydration. Presenting a mixture of different carbohydrates in small frequent feeds in presentations with relatively slow gastric emptying, such as milk, allows even lactose to be tolerated. Studies in children with persistent diarrhea, many of whom were malnourished, demonstrated that locally prepared diets with less than 3 g/kg body weight/day as lactose were well tolerated and led to prompt recovery.[120] In contrast to carbohydrate, fractional fat absorption remains constant over a wide range of intake,[121] so more fat in the diet results in more fat absorbed, and in practice, the increased fat loss is of little clinical consequence.[118] This is of considerable practical importance because the high energy density of fat means that more calories can be given in smaller volume, which is essential when feeding PEM children, who are usually anorexic. Although we lack randomized clinical controlled trials of early feeding in PEM, such as those that provided conclusive evidence for continued feeding in acute diarrhea,[122] cumulated experience demonstrates the success of this strategy. Early initiation of oral feeding was one of the major management changes associated with the introduction of a specific protocol for PEM in Bangladesh that halved mortality. Specifically, deaths from hypoglycemia were reduced.[6] Further aspects of gut function are discussed in Chapter 19, "Immunophysiology and Nutrition of the Gut."

Hematology: Anemia Anemia is common in severe malnutrition and may be attributable either to iron deficiency and/or reduced red cell production in adaptation to a smaller lean body mass.[123] Despite the fact that most children will have been consuming a diet deficient in bioavailable iron, in kwashiorkor, there is elevated hepatic iron, and bone marrow iron shows stainable iron in half of children. This is an unusual finding in marasmus.[124] Iron is tightly bound to proteins during storage and transport to prevent free iron forming the extremely damaging hydroxyl radical. In kwashiorkor, the reduced plasma levels of transferrin mean that iron binding capacity is reduced and the concentration of free iron may increase.[125] Low transferrins have been associated with increased risk of mortality in hospitalized children with PEM.[126] It has been suggested that this free iron causes or contributes to the etiology of kwashiorkor,[127,128] although not all children with kwashiorkor have raised indices of free iron. The homeostatic control of intestinal iron absorption is maintained in children with kwashiorkor.[129] Those with high serum ferritin and percent saturation of transferrin were found to absorb less oral iron than those with low serum ferritins.[129] The iron issue is important not only because of its possible role in the etiology of kwashiorkor but also because iron supplements might actually increase mortality in acute PEM. Smith and colleagues, in a small nonrandomized study in Nigeria, found higher mortality; 10 of 31 children given iron supplements at admission or day 3 died compared with 2 of 12 nonsupplemented children.[130] Whatever the role of iron supplements during the acute phase of malnutrition, during recovery, with its accompanying increase in lean body and red cell mass, iron is required, and stores are quickly exhausted so that classic iron deficiency features occur.[131] Iron supplements should be given during this stage.

Little is known about the relative role of other micronutrient deficiencies in contributing to the anemia of malnutrition. In studies in South Africa and Egypt, there was no evidence of vitamin B_{12} deficiency, but serum folic acid levels were low.[132,133] In Cairo, low serum folate levels correlated with megaloblastic findings on bone marrow and with improvement in these parameters following treatment with injected folic acid, but in South Africa, serum folate was unrelated to hemoglobin levels, which improved without folic acid supplements. Copper, riboflavin, and vitamin E deficiencies may contribute to the anemia of PEM.

Skin and Hair In marasmus, the dry wrinkled loose skin is a result of almost total loss of subcutaneous fat. This leads to a relative increase in surface area, reduced protection from ambient temperature, and therefore increased susceptibility to hypothermia. Hair is thin, grows slowly, and falls out readily, and on microscopy, there is a lack of hair root

bulbs and a shift to the resting state of hair growth.[134] In kwashiorkor, skin changes may be florid and show the characteristic signs described earlier, or they may be absent. Some changes are similar to those seen in acrodermatitis enteropathica, and improvement may occur with zinc ointments, suggesting that concomitant zinc deficiency may be implicated.[135] Other nutrient deficiencies, such as EFA deficiency, the B vitamins, and amino acid deficiencies, also cause skin changes and may contribute. Hair is also affected; depigmentation is a classic sign. Hair follicles show fewer and abnormal growing bulbs, showing atrophy and shaft constriction with depletion of pigment.[134]

Brain Function and Development Most child malnutrition occurs at a time of rapid development, so any insult at this time may have far-reaching consequences. In addition to primary effects on neuronal tissue, there may be secondary effects owing to anemia, micronutrient deficiencies, apathy, and reduced activity. The environment in which most malnourished children live often fails to provide the stimulation and support that the developing child needs to realize his/her potential. The clinically recovered child usually returns to this same environment, thus making it difficult to determine the impact of malnutrition per se on long-term development. Early studies comparing the outcome of children recovered from severe malnutrition who either returned home or were adopted into families with more resources suggested that environmental influences outweighed the sequelae of the malnutrition.[136] The randomized trials conducted by Grantham-McGregor in Jamaica and others have contributed greatly to our understanding of the importance of stimulation as well as dietary therapy in reversing developmental delay.[137,138] This important subject is further addressed in Chapter 21, "Brain Development."

Bones

Children with severe malnutrition often remain stunted after recovery. Branca and colleagues used pyridinoline and deoxypyridinoline, cross-linking amino acids of collagen that are excreted in the urine in proportion to skeletal turnover, to study bone turnover in severe malnutrition.[139] They found low rates of bone turnover during the acute phase of malnutrition and much higher levels during recovery. Age, severity of wasting on admission, and cross-link excretion accounted for 44% of the variability in height velocity during recovery.[139–141] Bone demineralization has also been reported and may be attributable to phosphate deficiency.[142] Concomitant nutrient deficiencies such as vitamin D deficiency causing rickets and osteomalacia, scurvy caused by vitamin C deficiency, and bone changes typical of copper deficiency may also be present.

CLINICAL MANAGEMENT

Treatment regimens for the clinical management of severe malnutrition have been developed by a limited number of specialist centers across the world. These regimens tend to be experience rather than evidence based, and there is a need for clinical trials to clarify many different management issues. Nevertheless, the WHO, in consultation with experts from many parts of the world, has recently formulated recommendations, and this clear, didactic protocol is now available for centers wherever malnourished children are treated.[11] The following discussion of management adheres in general to the WHO guidelines.

Clinical Assessment and Triage

When malnourished children first present, health personnel are usually faced with a question about whether hospitalization is advisable. This is often a tricky decision and deserves some discussion. Risk factors for mortality in a series of studies include severity of malnutrition, young age, pneumonia, severe diarrhea (more than six stools a day, dehydration), signs of sepsis, hypothermia, fever, and electrolyte abnormalities.[143–145] Children with these risk factors should be admitted urgently. Table 10-2 lists factors to be taken into consideration when deciding on admission.

Hospital versus Community Rehabilitation

Hospitalization is usually required for the severely ill child with PEM, but once the acute conditions have been treated, other alternatives include rehabilitation centers or community care. The relative merits of these different options are discussed in Chapter 9.2.

Phases of Treatment

The child admitted with PEM should be treated according to a locally developed protocol based on the WHO guidelines. The use of such protocols has been shown to reduce mortality.[6] The management of malnutrition is a team activity, and all staff who come into contact with the child or the child's caretaker in any way should be aware of the management plan.

Treatment can be divided into three phases:

1. The initial or acute phase (2 to 10 days) when the child is being treated for complications such as dehydration, hypoglycemia, and infections. Dietary therapy starts.
2. The second phase of recovery or rehabilitation (2 to 6 weeks) when the child will increase dietary intake and gain weight.
3. The follow-up phase (6 to 26 weeks), which may be after discharge.

Phase 1: Examination and Emergency Treatment A full clinical history should be obtained; symptoms suggestive of infection and diarrhea are particularly relevant. Birth history is important because low birth weight may explain the infant's low weight, and it is essential to review any growth data that may be available. A developmental history and past medical problems may reveal concomitant conditions that cause or contribute to the malnutrition. Most children will have been chronically ill, and information on medication and therapies, including traditional healers, may be relevant. It will be essential to have information on the child's diet history, including breast-feeding, family diet, food constraints, and access to food programs, as well as a full social and family history, but this information may be

TABLE 10-2 Factors to Consider When Admitting Children with Protein-Energy Malnutrition

Child Factors	
Severity of the malnutrition	The more severe the malnutrition, the greater the need for specialized refeeding, monitoring, and intervention to treat complications such as infection, electrolyte abnormalities, hypothermia, and hypoglycemia
Edema	Children with edematous malnutrition may not appear to be ill and do not induce the same shock horror response as a child with marasmus. Their edematous weight masks the severity of their condition.
Presence of infection	Malnourished children should be regarded as immunodeficient so that infections are more likely to need parenteral antibiotic treatment and close monitoring, which is difficult to do at home. Persistent diarrhea may present special problems and usually quickly improves with a clean diet and appropriate therapy in hospital.[120]
Presence of other conditions	Malnutrition is not always a consequence of primary energy and protein deprivation. The presence of other conditions such as congenital heart disease, cystic fibrosis, and tuberculosis may determine where these children will be best managed. Therapeutic malnutrition units may not be best able to cope with these pediatric emergencies.
Family Circumstances	
Social circumstances	The ability of carers to follow treatment schedules at home, who looks after the child, conflicting work and other family constraints on outpatient attendance, nearness to health facilities, availability of backup services and nutritional support in the community are all factors to be taken into consideration
Previous treatment	Previous attempts at treatment should be taken into account. A child who is worsening despite being in an outpatient or community care program should not have to wait to reach a specific degree of severity to be admitted once the alternatives have failed.
Home social circumstances	These include the nearness to health facilities able to deal with emergencies or monitor the child and the presence of community support with or without food supplements. Children treated in well-organized programs may avoid hospitalization, although there needs to be provision for those who deteriorate, and this may occur suddenly and catastrophically.
Economic considerations	Inevitably, economic considerations will influence decisions and sadly often are the deciding factor, although not in the interest of the child. However, it is very important that health professionals do not add to financial burden with unnecessary tests that do not change management or expensive versions of medicines or medicines of no proven efficacy that compete in the household budget for the food that the child needs or dissuade parents from seeking help for their children.
Hospital Facilities	
Infection risk	Children with severe malnutrition are vulnerable. If admission to hospital means being on a general ward with children with measles and diarrhea, then they may be safer at home, despite the severity of their condition. Obviously, the best option is to provide isolation facilities and hand washing, but this may not always be the case in practice.
Feeding arrangements	Children with malnutrition require frequent feeding. Emergency departments may not have provisions for feeding; even on the ward, provision of food may depend on parents, and this may present an additional complication for caretakers if their time is split between home and hospital. Families may have to buy or prepare the food for their child.

better obtained once the acute phase is completed and is part of building up a relationship with the family.

A detailed clinical examination is essential, but care should be taken not to stress the patient and to protect him/her from cold. Table 10-3 shows some signs and symptoms of particular importance and their management.

Management of Diarrhea and Dehydration. The principles of management, rehydration, and continued feeding are no different in the malnourished child. Signs of dehydration and their management are shown in Table 10-4. Particular attention has to be paid to the volume of fluid given and electrolyte management.

Most children with dehydration can be managed with oral rehydration therapy. In moderate dehydration (WHO plan B), 70 to 100 mL/kg of ORS should be given over 8 to 12 hours, starting frequently (5 mL/kg every 30 minutes). ReSoMal is the preferred option (Table 10-5). The child's clinical state should be monitored at least hourly. If vomiting occurs, then rehydration can be detained 30 to 60 minutes and then resumed. If the child refuses to drink or becomes very tired by the effort of drinking, a nasogastric tube should be used. If the child drinks avidly, then only small amounts should be offered by spoon, never by bottle, as taking a large amount at a time may provoke vomiting. If the child does not show signs of recovery (improved general condition, passing urine), consider sepsis. If diarrhea is ongoing, estimate diarrhea losses and increase the rehydration fluid volume accordingly. A diarrheal stool in a child less than 2 years can be estimated as 50 to 100 mL and 100 to 200 mL in an older child or in very severe diarrhea. Once the child has clinically recovered and signs of dehydration have improved, the child can be started on diet, even though the programmed amount of ORS has not yet been completed or diarrhea continues. Alternate ORS and diet.

Intravenous Therapy. Intravenous infusions should be avoided as far as possible. If unavoidable, for instance in shock, the volume of intravenous therapy should be kept to a minimum, and particular attention should be paid to protecting the site of intravenous access from infection. If antibiotics are to be given intravenously, a heparinized cannula, rather than a continuous infusion, is safer to avoid fluid overload. It may be difficult to establish venous access in malnourished children, especially those with edema, but prolonged attempts and "cut-downs" performed without anesthesia and with little attention to sterility place the malnourished child at risk of hypoglycemia, hypothermia, sepsis, and stress, which increase mortality. Sometimes an intravenous line is started because it is a "routine in all sick children" or "in case it is needed later." Such practices should be avoided in children with PEM. The only absolute indications are circulatory col-

TABLE 10-3 Identification and Management of Complications of Protein-Energy Malnutrition

Sign or Symptom	*Findings*	*Management*
Edema	Usually symmetric and positional; pretibial edema may be evident only on pressing on the shin with a finger and looking for the indentation. The presence of edema also means that gross weight underestimates the child's degree of malnutrition	Edema indicates kwashiorkor and is an indication of severity. Dietary guidelines for kwashiorkor should be applied.
Odd facies, palmar creases, heart murmurs, cyanosis, signs of congenital abnormalities	Chromosomal and congenital disorders may contribute to malnutrition	These children should receive the same treatment for their malnutrition, but concomitant conditions will affect outcome and long-term management
Developmental assessment	An adequate developmental assessment is not possible in a sick or malnourished child, but signs such as increased tone and contractures may point to cerebral palsy and degenerative neurologic disorders may be discernable	
Infection	Malnourished children may not mount a full-blown inflammatory response to infection, so signs may be attenuated and diagnostic tests misleading. The febrile response is reduced.[146]	WHO recommends starting all children with severe malnutrition on a broad-spectrum antibiotic such as cotrimoxazole (sulfamethoxazole 25 mg plus trimethoprim 5 mg) even in the absence of signs of infection
Sepsis	Difficult to distinguish from dehydration. Recent apathy, reduced level of consciousness, jaundice, abdominal distention (babies), fever or hypothermia, hypoglycemia, petechiae, and poor peripheral perfusion are all indicators of possible sepsis.	If there is any doubt, the child should be treated as septic and intravenous antibiotics used. These should be broad-spectrum and cover gram-negative bacteria. Combinations of aminoglycosides such as gentamicin (7.5 mg/kg IM daily) with ampicillin (50 mg/kg 6 hourly) or amoxicillin or third-generation cephalosporins such as ceftriaxone are recommended.
Focal infections	Pneumonia is very common,[147] but cough may be absent. Tachypnea and subcostal recession are preserved. In otitis media, the tympanum may not appear red, and infections may present with perforation and otic discharge. Urine should be examined for urinary tract infections, but false positives owing to dehydration mean that it is better to obtain nonurgent samples after rehydration. The skin should be carefully examined all over.	Infections should be treated as in well-nourished children, using appropriate antibiotics preferably based on local sensitivity patterns. Because of the depressed immunity, disturbed gut function, which might reduce absorption of oral preparations,[148,149] and limited muscle bulk for frequent intramuscular injection, intravenous antibiotics should be used for all serious infections.
HIV/AIDs	In many parts of the world, a large proportion of children presenting with severe malnutrition will have HIV/AIDS	The same management principles apply and the malnutrition should be treated actively. Improving the malnutrition will improve the child's quality of life.
Tuberculosis	Clinical manifestations may be absent. Radiographic changes may be seen only when the child starts to recover from malnutrition. Tuberculin skin tests are usually negative.[94] A positive family history should be sought.	Tuberculosis therapy should be started once tracheal aspirate or gastric cultures have been collected. A trial of therapy is sometimes needed in children in whom there is a suspicion of tuberculosis.
Diarrhea and dehydration	Diarrhea is common, and signs of dehydration should be sought (see Table 10-4)	Diarrhea is not a contraindication to starting diet. Dehydration should be managed as indicated below.
Electrolyte disorders	All malnourished children should be considered to have sodium retention and potassium depletion. Measurement of serum electrolytes is useful to guide management, but low serum sodium is not an indication for administering sodium. Children with kwashiorkor may urinate infrequently and in small volume; neither this nor normal serum potassium should deter the administration of potassium supplements. Hypotonia may be a manifestation of hypokalemia.	Severely malnourished children are best managed with relatively low sodium oral rehydration solutions. The old standard WHO oral rehydration solution (90 mmol sodium) is not recommended. A solution with 60 mmol sodium was found to be superior and to speed recovery.[150] WHO recommends ReSoMal (see Table 10-5), but if not available, the new standard 75 mmol oral rehydration solution could be used. Potassium at 40 mmol/L is recommended. Treatment schedules are given below.
Hypoglycemia	Blood sugar < 54 mg/dL or 3 mmol/L. Floppiness, unresponsiveness, hypothermia, convulsions, and coma are signs of hypoglycemia. If the child is convulsing, hypoglycemia should be assumed and treatment started empirically even before procedures such as lumbar puncture to exclude meningitis.	If the child is conscious, oral glucose (50 mL of 10% solution) may be given, by nasogastric tube if necessary. Follow with milk or diet as soon as possible. If in coma, an intravenous infusion of 10% glucose (5 mL/kg) should be given and followed by oral glucose or diet. Children with hypoglycemia should be considered septic and treated with antibiotics.
Hypothermia	Rectal temperature is more accurate, and, ideally, a low reading thermometer should be available. Rectal temperature < 35.5˚C is diagnostic. Axillary temperature < 35˚C is suggestive.	The child should be warmed gradually either by wrapping in blankets, warming the room, or using the skin to skin kangaroo technique. If the child is hypothermic, assume sepsis.
Anemia	Malnourished children are often anemic, but in nonmalarial areas, severe anemia, < 8 g/dL, should not be assumed owing to nutritional deficiency, and other reasons should be sought.	Intestinal parasites, especially hookworm, may be present and should be treated. Anemia is usually chronic and only needs immediate treatment if there are signs of cardiac failure or hemoglobin < 5 g/dL. In this case, transfusion should be given with great care as discussed with intravenous therapy.

TABLE 10-4 Signs of Dehydration and Interpretation in Severe Malnutrition

Sign	*Plan A*	*Mild or Absent* *Plan B*	*Moderate* *Plan C*	*Severe (with shock)* *Comment*
Conscious level	Normal/alert	Agitated/ irritable	Lethargic/comatose	Agitation is typical. Infection and hypoglycemia also give lethargy.
Eyes	Normal	Sunken	Very sunken	Ask mother about eyes
Tears	Present	Absent	Absent	Tears often absent
Buccal mucosa	Moist	Dry	Very dry	Mouth breathing may cause dryness
Skin pinch	Returns quickly	Returns slowly < 2 s	Returns very slowly > 2 s	More difficult in PEM
Thirst	Drinks normally	Drinks avidly	Unable to drink	If avid, useful

PEM = protein-energy malnutrition.

lapse caused by severe dehydration or septic shock. In this case, solutions with low sodium, such as half-strength Darrow's solution, Ringer's lactate, or half-normal 0.45% saline, all with 5% glucose, should be used. Potassium chloride should be added to provide 20 mmol/L, infused at 15 mL/kg per hour, preferably using a programmable pump. The child's hydration status, pulse, and respiratory rate should be reviewed at least hourly. If the child was dehydrated, improvement should be obvious; if not, septic shock is likely, and parenteral antibiotics should be started, if not already given, and blood transfusion considered. If blood is not available, plasma is an alternative. Transfusion should be given slowly (10 mg/kg over 3 hours) with close monitoring of jugular veins and respiration rate as malnourished children are at high risk of congestive heart failure. Diuretics such as furosemide 1 mg/kg may be given if there is any suggestion of heart failure.

Parasites and Gut Flora. Parasites should be treated if identified in the stools. If *Giardia lamblia* is present, metronidazole is recommended. A lower than usual dose, 12.9 mg/kg/day, has been suggested on the basis of pharmacokinetic studies.[149] Bacterial contamination of the small intestine has been described in children with PEM, but the functional significance of this is not clear.[151] Children admitted to the hospital from highly contaminated home environments were found to have bacterial contamination of duodenal fluid regardless of nutritional or diarrheal status.[152] The bacterial flora reduced within days of eating a clean diet and without antibiotic therapy.[117] The need to treat all children with PEM for bacterial overgrowth remains controversial, and randomized controlled trials are needed.

General Care of the Malnourished Child. Sadly, the mortality rate for children hospitalized for severe malnutrition is often high,[9,153–156] and some of these deaths are a consequence of hospital practices, such as long waits without food, indiscriminate use of intravenous fluids, and the dangers of admission to a high-risk environment. Adoption of recommended guidelines and the use of protocols that facilitate a team approach have resulted in spectacular reductions in mortality rates.[6] An important aspect of these improvements is the organization of services with a view to preventing complications. Early deaths, within the first day, are often attributable to hypoglycemia and/or failure to recognize and treat infections adequately. Later deaths may be owing to overwhelming infections, but sudden unexpected deaths after a few days may be caused by cardiac failure associated with the refeeding syndrome.

Prevention of Hypoglycemia. It is important to give thought to how to prevent hypoglycemia. Travel to the hospital and waits to be seen in the emergency or outpatient department can place the child at risk, and this may be exacerbated by hospital policies such as "nil by mouth" until the child is reviewed and reluctance to start any "treatment" until experts are consulted or test results are available. Mothers should be encouraged to breast-feed their babies while waiting, and a triage system that quickly identifies children with severe malnutrition and directs them into a protocol providing immediate feeding will reduce the risk of hypoglycemia and the attendant mortality. Frequent feeds every 2 to 4 hours are needed at first. Nighttime, when staffing levels are reduced, often provides a challenge, and health facilities should have a plan to cope with this. This might involve having prepared diets or

ingredients always available in the emergency department or on the ward and using nasogastric tube feeds if staff or family are not available for the time-consuming process of encouraging the malnourished child to eat frequent feeds. Monitoring is very important. If the mother is accompanying the child, she should have access to refreshments; otherwise, she may be tempted to share the child's ration.

Prevention of Hypothermia. Children with PEM, especially those with marasmus, have less insulating fat and a relatively large surface area, so that body temperature tends to reflect ambient temperature, and they are very vulnerable to hypothermia.[157,158] Prevention requires planning to avoid having the child unclothed for long periods, for instance, while having radiographs or during medical examination, and providing an ambient temperature that is warm, 25°C to 30°C, and without draughts. Washing should be kept to a minimum, and the child should be dried and wrapped immediately. At night, temperatures often fall, so additional precautions may be necessary.

Dietary Management. Dietary therapy must be started rapidly, and this requires a protocol. The health care professional should specify dietary therapy when the child is first seen. The exact diet to be used will depend on local circumstances. In some cases, it may be easiest to have infant formula available when the diet kitchen or daytime nursing is not available, even though it is too expensive to continue. When families are expected to provide food for patients, a special diet will need to be prescribed and made available until family food can take over. This might be the WHO-recommended F75 and F100 (Table 10-6), which have been designed and tested in malnutrition treatment centers.[11] The F75 is designed for the initial phase and F100 for the rehabilitation phase, but many centers use F100 from the start, especially in marasmic children. Alternative local diets have been used successfully; an example used at the Instituto de Investigacion Nutricional, Lima, is given in Table 10-7. Whatever diet is chosen, this should have an energy density of 75 to 100 kcal/100 mL, the osmolarity should be lower than 350 to 400 mOsmol/L,[159] and 6 to 12% of the calories should come from protein[159,160] and at least some of this from an animal source (milk, chicken meat, or egg). Techniques such as fermentation and the combination of complementary vegetable proteins can improve the protein quality and may add valuable vitamins.[161] Although diets based on vegetable protein have been used successfully, nitrogen retention is usually less than that seen with milk diets (Table 10-8).[162,163] At least 50% or more of calories can come from fat; higher fat results in higher overall energy absorption.[164] Diets should be liquid if nasogastric tube feeding is to be used; they should not thicken on standing, a problem of higher proportions of carbohydrate, and they should be palatable. Sodium should not exceed 2 mmol/kg/day, and potassium should be added to give 5 to 7 mmol/kg/day. Additional vitamins and minerals should be added to provide one to two times the daily requirement. A local vitamin supplement can be used, but it is often harder to find a mineral source, and WHO provides a recipe for a mineral mix that can be made in a local pharmacy or biochemistry department.[11] An exciting new advance is the recent development of high-fat solid rehabilitation diets resistant to bacterial contamination and with excellent preservation of micronutrients.[165]

TABLE 10-7 Preparation of Rice Milk Diet

Ingredients	*Energy 1 kcal/cc*		*Household Measures for 100 cc*
Full-fat dried milk (g)	76	7.6	5 heaped spoonfuls
Rice (g)	74	7.4	5 heaped spoonfuls
Vegetable oil (cc)	33	3.3	1 ounce or measure with syringe
Sugar (g)	27	2.7	2 heaped spoonfuls
Kalium (cc)	9	0.9	Measure with syringe
Water to total volume (cc)	1,000	100	

Diet used at the Instituto de Investigacion Nutricional, Lima.

Children should receive 80 to 100 kcal/kg/day; < 80 kcal/kg is insufficient to maintain metabolic needs, and > 100 kcal may put the child at risk of the refeeding syndrome discussed below. Feeds should be given every 2 to 4 hours at first. The amount actually consumed should be monitored by direct observation. Continuing or developing diarrhea does not necessarily mean that the diet should be changed. Only if diarrhea becomes worse, for instance more than six voluminous liquid stools per day, or dehydration occurs is it necessary to change to a low-lactose diet with the same calorie content. Oral rehydration fluid should be given between meals to compensate for stool losses. An algorithm illustrating the dietary management in the acute phase is shown in Figure 10-6.

Breast-fed Children. The mothers of breast-fed children should be encouraged to nurse as breast milk continues to provide important nutritional support even through the second year of life.[42] Breast-feeding should be encouraged in the hospital whenever the child is strong enough to suck; if possible, breast milk may be extracted to add to the diet, and this may help the mother feel involved and important.

Younger exclusively breast-fed babies may occasionally present with PEM, and it is not reasonable to assume that a baby who has become severely malnourished on the breast will improve if no action is taken. These babies need additional food. Improving breast-feeding technique and

TABLE 10-8 Composition of Mineral Mix Solution

Substance	*Amount*
Potassium chloride	89.5 g
Tripotassium citrate	32.4 g
Magnesium chloride ($MgCl_2.6H_2O$)	30.5 g
Zinc acetate	3.3 g
Copper sulfate	0.56 g
Sodium selenate*	10 mg
Potassium iodide*	5 mg
Water to make	1,000 mL

If it is not possible to weigh very small amounts accurately, this substance may be omitted.
Adapted from World Health Organization.[11]

relactation may be tried to increase breast milk supply once the baby is improving but are not suitable for the initial phase of management. For babies under 4 months of age, a modified cow's milk formula is the recommended food; for infants older than 4 months, a cereal milk diet can be given. The youngest babies present a problem when infant formulas are beyond the resources of parents or the hospital, but priority should be given to obtaining milk formula for babies under 4 months. Complementing with another woman's breast milk is possible only if a safe sterile supply is available.

Mineral and Vitamin Supplements. Micronutrient deficiencies are common in malnutrition. Regardless of signs of vitamin A deficiency, this should be assumed and retinol palmitate given orally on admission, 50,000 IU for children < 6 months age, 100,000 IU for children age 6 to 12 months, and 200,000 IU for older children. A repeat dose should be given the next day and a third dose after 2 weeks or on discharge, whichever is sooner. A single oral dose of 5 mg folic acid on admission is recommended followed by 1 mg daily. Other vitamins and minerals are best given with the diet or as a daily supplement during recovery.

Zinc supplementation of malnourished children has been shown to improve weight gain[166,167] and improve immunologic outcomes, and 1 mL/kg/day of a 1.5% zinc acetate solution daily is recommended. Care should be taken not to provide too much zinc as mortality was increased in Bangladeshi children receiving 6 mg/kg/day.[168]

Copper deficiency has been reported in malnourished children,[169] and copper sulfate should be added to the diet if not included in the mineral mix.

Iron supplements are not recommended during the acute phase because of the risk of producing iron free radicals, as described earlier in the chapter.[125] However, iron supplements are essential once growth and rehabilitation start and muscle and blood are being synthesized.[170] Ferrous sulfate or fumarate syrup may be given 4 mg elemental iron/kg body weight.[171]

As mentioned earlier, electrolyte disturbance is part of the pathophysiology of malnutrition. A triad of interrelated electrolyte deficiencies, potassium, magnesium, and phosphate, occurs. Deficiency of these elements may become especially critical once treatment is instigated and recovery starts. Potassium should be added to the diet to ensure a total of at least 5 mmol/kg/day or more. Magnesium is needed for potassium to enter cells, and magnesium supplements should be added to the diet and, if possible, mineral ORS used(ReSoMal). If not given in the diet or ORS on the first day, an alternative is to give magnesium sulfate 50% solution, 0.3 mL/kg intramuscularly (maximum 2 mL) once, and then include it in the diet. Hypophosphatemia is associated with increased risk of dying and should be included in the diet. Milk provides an excellent source.

Refeeding Syndrome. The refeeding syndrome is a potentially lethal complication of an increase in calorie intake following starvation. Sudden onset of lethal cardiac failure occurring during refeeding was first reported in the classic studies of experimental starvation in adults in Minnesota and later in starved Japanese prisoners of war, the survivors of concentration camps, and following the wartime famine in the Netherlands, when, following starvation, there was sudden access to unlimited food.[172,173] This syndrome also occurs in severely malnourished children and may be responsible for considerable mortality, although the precise incidence is difficult to know as, clinically, the syndrome may

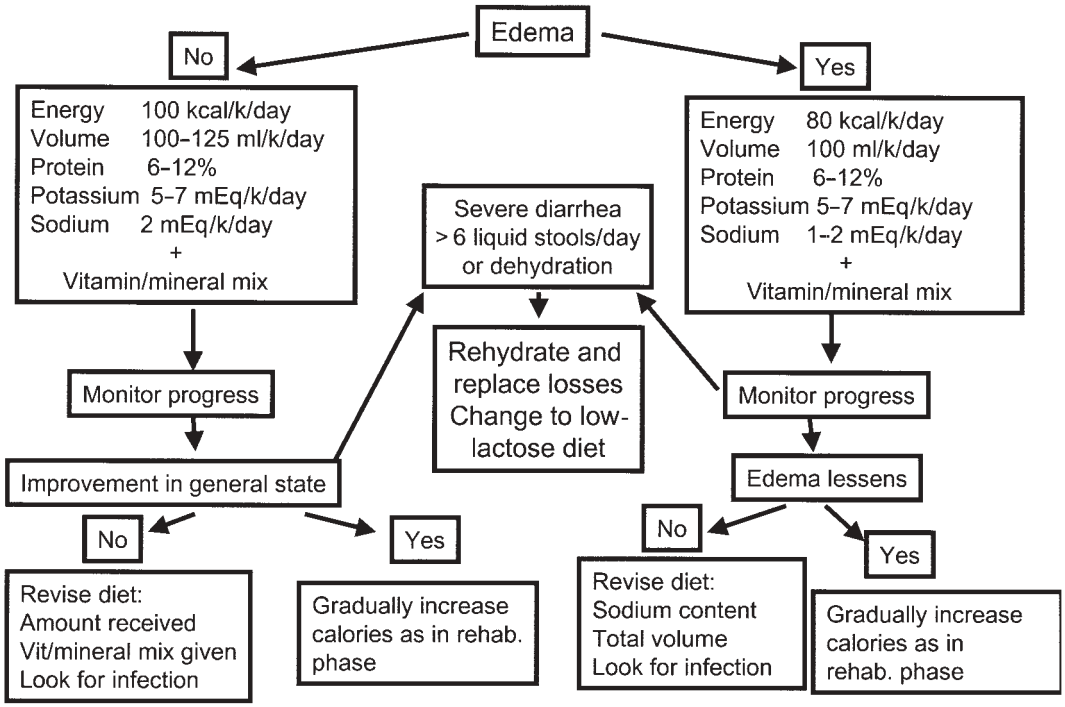

FIGURE 10-6 Phase 1: Nutritional Management.

be difficult to distinguish from pneumonia and sepsis deaths. Sudden death shortly after refeeding has started in a child who seemed to be doing well is suspicious. The syndrome also occurs with parenteral and enteral feeding.

When glucose becomes available during refeeding, gluconeogenesis is inhibited, and there is a rise in plasma glucose and insulin excretion. Rebound hyperglycemia may occur with polyuria and dehydration. There is a flux of glucose, potassium, magnesium, and phosphate into cells, which may result in rapid lowering of serum levels. The sudden reduction of serum levels of these three electrolytes is thought to explain most of the consequences of the refeeding syndrome. Phosphate depletion results in anorexia, adverse neuromuscular effects (eg, diaphragmatic weakness and respiratory insufficiency), and a reduction in myocardial contractility.[174] Cell membrane electrolyte fluxes are perturbed, and there is an intracellular accumulation of calcium, sodium chloride, and water, which may result in edema and is probably one of the mechanisms that explain recurring edema when children with kwashiorkor are refed too rapidly. There is also a derangement of phospholipids in cell membranes.[175] When refeeding with high-carbohydrate diets occurs, there is an increased need for phosphate for phosphorylation and protein synthesis and a shift of available phosphate into cells. Although hypophosphatemia was thought to be the main cause of the refeeding syndrome, the clinical effects of potassium and magnesium deficiency are similar, and it is likely that all three electrolyte disturbances contribute to a certain extent. Thiamin deficiency may also be important and has been reported in refeeding alcoholics and following starvation treatment of obesity. Its role in the refeeding of malnourished infants is not known. Thiamin is an essential cofactor for various enzymes, and carbohydrate refeeding causes increased thiamin use.

The key to prevention of the refeeding syndrome is the avoidance of rapid refeeding, especially with high-carbohydrate diets, whether intravenous or enteral, and the replenishment with potassium, magnesium, and phosphate and restricted sodium intake. The safest way to correct phosphate deficiency is with milk diets because oral phosphate salts are laxatives and may well exacerbate diarrhea. Milk is also useful as a good source of magnesium, as well as protein and energy, but needs to be mixed with a cereal such as rice or sugar to reduce the sodium and protein and lactose load. If intravenous treatment is unavoidable and oral feeding is delayed, phosphate can be given intravenously with care and should be included in parenteral feeding regimens. If children are dehydrated, magnesium and potassium can be added to oral rehydration therapy as in the ReSoMal recommended by WHO. Vitamins, including thiamin, should be added to the diet from the start. The reader is referred to several recent reviews of this subject.[173,176,177]

Skin and Eye Care. The skin lesions of kwashiorkor improve with dietary therapy but, in the initial phase, may become infected and are a potential source of pathogens causing sepsis. Care should be taken to avoid pressure on affected areas and the skin should be kept clean and dry; 1% potassium permanganate solution may be applied to the worst areas. If possible, the perineum and buttocks should be left uncovered and carefully cleaned and dried immediately after defecation.

Special care should be taken of the eyes of children with signs of vitamin A deficiency (xerophthalmia). Retinol supplements should be given immediately in the same doses noted above,[10,171] and the eyes should be protected with pads soaked in saline. Atropine and antibiotic eye drops should be applied at least four times daily until there is no sign of inflammation.[10,171]

Phase 2: Rehabilitation The initial phase of management lasts while metabolic and electrolyte abnormalities are corrected and infections treated. This phase may last from 1 to 7 days, sometimes longer, if infection is difficult to treat and edema slow to resolve. The recognition of recovery is subjective but usually obvious to staff. There is a general improvement in the child's condition. The return of appetite, reduction in apathy, and return of smiling are encouraging signs indicating improvement. Weight gain may not occur at this stage, and in kwashiorkor, there is usually a brisk weight loss as edema disappears. If the child does not seem to be recovering and edema continues without obvious cause, suspect occult infection, for instance, tuberculosis, inadequate potassium repletion, and phosphate deficiency. An algorithm for the dietary management of the child during this phase is shown in Figure 10-7.

If the child shows signs of improvement, the rehabilitation phase can start. In this phase, emphasis is on intensive feeding to restore lost weight and emotional and physical stimulation to optimize recovery. For long-term successful recovery and to prevent relapse, the clinical unit needs to work closely with the family during this phase. Ideally, this phase should be 2 to 6 weeks to give the child, especially his/her immune system, the best chance to recover before being challenged by the home environment. A reasonable goal is for the child to reach –1 SD (90%) of the median weight for length[178] before discharge. In some settings, it is very difficult to retain the child in the hospital for this time, and when children are exposed to other ill children, the hospital may not be the safest place.[179] An alternative is to seek out or establish rehabilitation care in the community, and several successful models have been reported. Too early discharge in the absence of follow-up rehabilitation leads to very high postdischarge mortality.[180]

Diet. During the rehabilitation phase, the dietary calorie intake should be increased. This should be gradual, for instance, an additional 25 kcal/kg/day every other day,[159] to avoid the refeeding syndrome and should be guided by the child's appetite and general condition. Diets are calculated based on body weight, so correction will need to be made for the child's changing weight. Most children will reach intakes of between 150 and 250 kcal/kg/day, and rapid weight gain at this stage is desirable as it is associated with the same body composition as lower weight gains.[181] The same diet started in the initial phase may be continued; if F75 was used, then F100 should be substituted. Readers are referred to a review of the criteria for rehabilitation diets

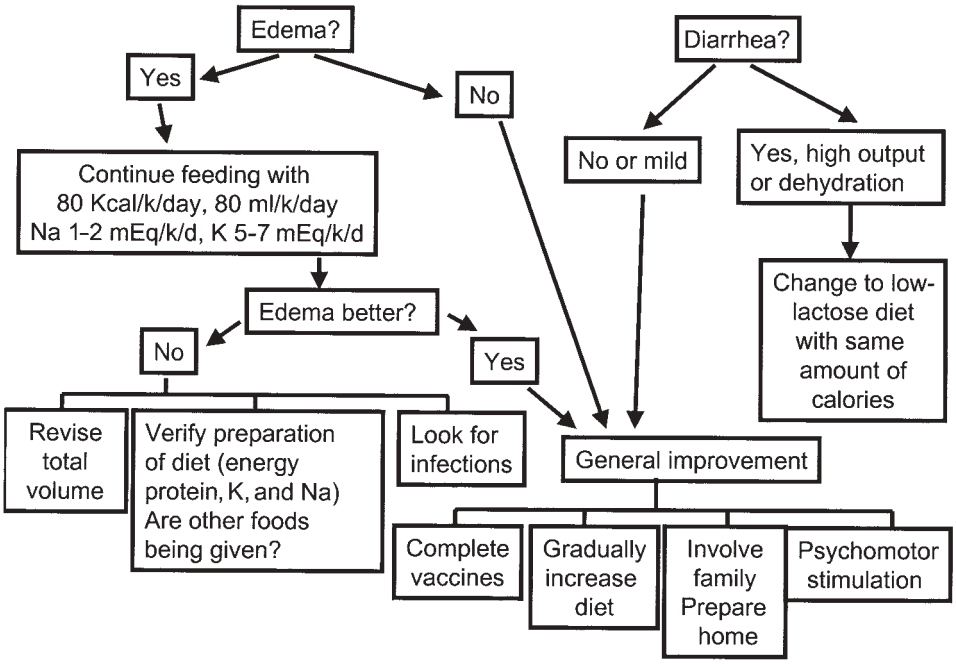

FIGURE 10-7 Rehabilitation phase.

and guidance on practical aspects.[159,182,183] At first, it is useful to continue a set diet as it is easier to calculate intakes, but as the child improves, the diet should be varied, and the child should be encouraged to eat a variety of locally available solid foods. Wherever possible, mothers not only should be taught about diets based on nutrient-dense local weaning foods but should prepare and feed these preparations in the hospital or rehabilitation unit.

During this phase, iron supplements should be started at 3 to 4 mg elemental iron/kg/day and other micronutrient supplements should be continued.

Physical and Emotional Stimulation. Early physical and emotional stimulation are very important. Even during the initial phase, mothers can be encouraged to talk to and hold their children. They can be taught to massage their children, which has been shown to increase growth recovery. Children should de provided with a visually interesting environment. As soon as possible, play therapy should be instigated. The WHO manual provides examples of easy-to-make toys.[11] Studies in Jamaica and India showed that an early stimulation program improved growth, complementing micronutrient supplements.[137,138]

Phase 3: Follow-up Before the child is discharged, arrangements should be made for follow-up in the community or in the outpatients department. Recently recovered malnourished children often relapse, and children have a high mortality rate after discharge.[180] Families should have easy and rapid access to medical care, ideally on the unit where the child is known. The choice of follow-up, like the length of hospital stay, will depend on the availability of services. The availability of a well-designed follow-up program can make all the difference to subsequent risk of dying.[184] Studies following children treated for severe malnutrition have shown variable recovery of nutritional status and intellectual development.[185,186] Sustained recovery of nutritional status is possible, although stunting usually remains.[187] Growth following rehabilitation depends on the favorable home circumstances.[136] When family circumstances remain unchanged, the outlook is poor.[188] A study in Lima comparing children returning home with those who had to be adopted and were integrated into families with few resource constraints showed both the importance of follow-up care but also the potential for recovery of these children.[136] Children should be followed up for at least 6 months to ensure successful rehabilitation.

CONCLUSIONS

The last few years have brought exciting advances in management of severe malnutrition. Lessons learned in the past are now being applied in hospitals and rehabilitation centers all over the world, although much more needs to be done to ensure that this information reaches and changes practice in all of the situations in which severe PEM is treated. Greater understanding of the pathophysiology of PEM has contributed to more rational therapy, and some clinical trials of therapies, new diet possibilities, and management strategies are being reported. Nevertheless, there is a great need for more research. The pathophysiology of kwashiorkor is still unclear, and the complicated interplay between infection and nutrition in PEM and its consequences are not resolved. Many of the recommendations for management have never been properly assessed.

The long-term goal, of course, is to prevent PEM. Some aspects could be relatively easily achieved. Medical practices, for instance, that deprive children of food while they are ill, especially with diarrhea, have been unequivocally

shown to be unnecessary and harmful, but the use of diluted diets or "resting the gut" continue. Attention is now being given to early enteral feeding of critically ill children, which reduces malnutrition and mortality.[189] Great strides have been made in understanding the importance of exclusive breast-feeding and the requirements for adequate complementary feeding practices, but much work is still needed to change complementary feeding practices in many countries and overcome the restraints on food security. Infections, which are very common among the most deprived populations, contribute to malnutrition. Whereas children with access to sufficient food of high nutritional value experience only transient effects, those on marginal diets are caught in a cycle of infection, exacerbating malnutrition and vice versa. Interventions that reduce the burden of disease will reduce malnutrition in these populations. Measles was once a common precursor to kwashiorkor and severe vitamin A deficiency but, with vaccination, has now disappeared in many countries. Other vaccines against diarrheal diseases could make important contributions. Severe PEM is an entirely preventable disease, but it will continue to kill and contribute to the deaths of millions of children while war and natural and man-made disasters continue to affect large parts of the world.

CHAPTER 11

INTERNATIONAL NUTRITION

Benjamin Caballero, MD, PhD, Asim Maqbool, MD

The implications of global health issues for the medical practitioner have become increasingly apparent over the past decade. The acquired immune deficiency syndrome (AIDS) epidemic, the emergence of new communicable diseases, and the global epidemic of obesity are examples of major domestic public health issues closely linked to the global situation. In addition, the dramatic expansion in travel and communications and the globalization of the economy are weakening cultural and geographic barriers and exposing a variety of populations to similar dietary and lifestyle factors affecting the risk of disease.

The field of international nutrition attempts to identify and study the health consequences of these global changes. In this chapter, we focus on how the current situation impacts on survival, growth, and well-being of infants and children.

CHILD SURVIVAL AND GROWTH: GLOBAL TRENDS

Mortality

Estimates indicate that malnutrition is associated with as much as 60% of deaths during the first 5 years of life (Figure 11-1). Protein-energy malnutrition (PEM) and micronutrient deficiencies (such as vitamin A and zinc) are major contributors to the higher mortality rates from illnesses and diseases such as pneumonia, malaria, diarrhea, and measles in the developing world.

Over the past 40 years, global child mortality rates for children under 5 years of age have declined by half.[1] Figures for United Nations (UN) regions and worldwide rates are presented in Table 11-1. Rates exhibit a wide range, from 5 per 1,000 live births in Scandinavian countries to 334 in 1,000 live births in Niger.[1] Declining trends in mortality have been, as expected, more pronounced in countries with initially high rates, ranking the West Africa region as the most pronounced, followed by Latin America, North Africa/Near East, and Asia. Minor increases in mortality rates over the past decade occurred in East and Southern African regions.[2–4]

Mortality is the end result of a complex interaction of health, nutritional, and environmental factors. The relative contribution of each of these is still a matter of intense study and debate, but it seems clear that among these, current dietary intake and prior nutritional status are paramount.[2–4] Stunting and wasting are both significant contributors to mortality rates for a number of primary diseases, particularly infectious diseases. Of the dietary factors, breast-feeding duration and timing of introduction of complementary foods are prominent.[5,6] Other determinants include access to and use of prenatal care, immunizations, maternal education, and access to electricity.

The phenomenon of decline in mortality rates observed in developing countries over the past five decades has been somewhat independent of changes in socioeconomic status. Major factors are likely to be mass immunization, widespread use of oral rehydration therapy, and promotion of breast-feeding.[7] Integrated programs that combine promotion of breast-feeding with immunizations and micronutrient supplementation are also important contributors on the prevention side, as are programs aimed at improving case management, such as the World Health Organization's (WHO) Integrated Management of Childhood Illnesses program. Improvements in the availability of health services, particularly for pregnant women, were also important contributors.[8] However, trends toward reduction in mortality were partially offset in some cases by economic decline and social and political instability.[3,9] In any case, sustainability of many of these programs is frequently uncertain, depending in large part on political decisions at the level of countries or regions.

Growth

Stunting is the term used to define chronic malnutrition, in which a child's weight is proportional to his/her height, but height is below the reference standards for age (< 5th height-for-age percentile). This type of growth delay usually results from frequent acute episodes of growth deceleration, most commonly related to infectious episodes.[10–12] Current (1995–2000) data on the prevalence of the different forms of PEM are presented in Table 11-2.

Over the past two decades, a consistent decline in stunting has been documented. In 1980, 41% of children under 5 years of age had some degree of growth retardation for their age. At present rates, it is projected that that figure will fall to 32.5% by 2005, equivalent to a reduction of 40 million in the number of stunted children.[7] Encouraging as these data may be, it is sobering that this positive

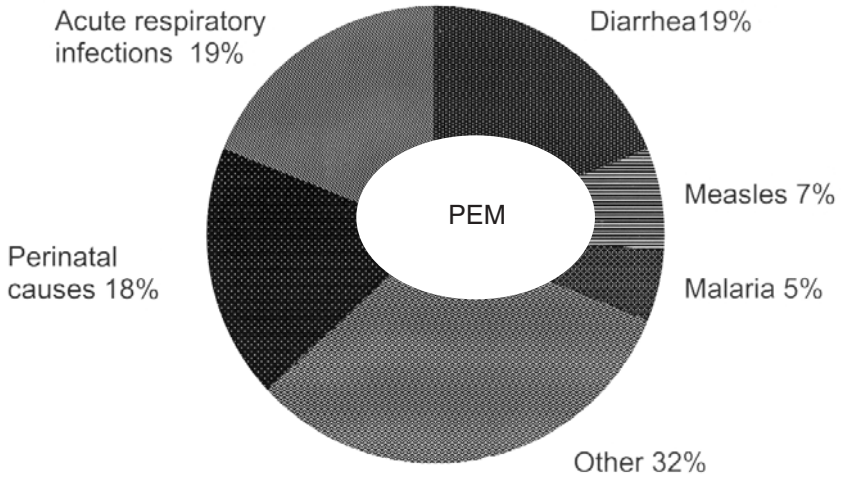

FIGURE 11-1 Major global causes of death among children under 5. Adapted from The Global Burden of Disease 2000 Project: aims, methods, and data sources. Global Programme on Evidence for Health (EIP) Policy Dicussion Paper #36. Geneva: World Health Organization; 2001.

trend would still leave about 192 million children with inadequate growth.

The geographic prevalence of stunting is far from uniform. Whereas one-third of children in the developing world are currently defined as stunted, 70% of these children live in Asia (61% of the total number reside in South Asia), 26% in Africa, and the remaining 4% in Latin America and the Caribbean. Similarly, whereas the overall trend is in decline, rates are actually increasing in sub-Saharan Africa, at a rate of 0.08%/year.[7] Figure 11-2 depicts trends in stunting in UN regions from 1980 through projections for 2005.[1,2,7]

Several studies have demonstrated an inverse correlation between stunting, cognitive and physical development in young children, and consequently lower intelligence levels in older children and functional impairment in adulthood, both in terms of intellectual and physical aspects, impairing work capacity. Stunting also increases obstetric risk in women and also has a transgenerational effect, leading to the perpetuation of suboptimal growth in the population as a whole.[13]

Wasting, usually measured by weight for height, is an indicator of acute malnutrition. A low weight for height can occur in a previously healthy child, but more commonly it affects populations of children who are already suffering from chronic malnutrition (stunting). Acute weight loss may be linked to inadequate dietary intake owing to illness or simply to unavailability of food, such as in natural or man-made disasters that suddenly displace populations from their natural habitat. Values 2 standard deviations below the median value are considered moderate wasting, with < 3 standard deviations defining severe wasting. Wasting can also be estimated using the mid-upper arm circumference (MUAC), a more rapid assessment method frequently used in refugee camps to triage emergency assistance.[14,15] Severely wasted children would have lost most of their subcutaneous fat, as well as some of their muscle mass, resulting in a very low MUAC.

Recent analysis of available global data for the period 1995 to 2000 indicates that about 9% of children are moderately to severely wasted (see Table 11-2). Wasting has a low to moderate prevalence in Latin America and the Caribbean and a high prevalence in South Asia. In Africa, prevalence shows substantial variability across countries, with an increasing trend from West to East. Sub-Saharan Africa, which has the highest rate of stunting in the world, shows only low-to-moderate rates of wasting.[2]

Whereas stunting has long-term implications for adult health and productivity, wasting is closely linked to child mortality.[16,17] By increasing the frequency and severity of infectious diseases, acute malnutrition significantly increases mortality from communicable diseases.[18–20]

Fetal Growth and Birth Weight

Birth weight is a potent indicator of infant growth, response to environmental stimuli, and ultimately to infant survival. Low birth weight (LBW: < 2,500 g) carries a 10-fold higher risk of neonatal mortality compared with newborns weighing 3 to 3.5 kg.[21,22] Twenty-one of the 25 million LBW infants born every year are in the developing world. The distribution of LBW by region of the developing world is shown in Figure 11-3. Whereas prematurity

is the main contributor to LBW in the developed world, the vast majority of LBW infants born in the developing world are born at term but of small size for their gestational age, that is, with intrauterine growth retardation (IUGR). The prevalence of LBW in the developing world ranges from 26% of live births in South Asia to 12% in sub-Saharan Africa.[21]

IUGR has two distinct patterns: asymmetric versus symmetric. Asymmetric IUGR is usually associated with energy restriction during the second and third trimesters, as well as with prematurity, preeclampsia, and tobacco smoking. Asymmetric IUGR carries a higher risk of death during the neonatal period than symmetric IUGR.[23] The more common type of IUGR in the developing world is symmetric IUGR, reflecting a sustained energy restriction throughout pregnancy. Hypoglycemia, hyperviscosity, hypothermia, perinatal asphyxia, and aspiration are more frequent in the wasted neonate. These findings persist despite correction for both birth weight and gestational age.[24]

In the developing world, maternal prepregnancy weight is strongly correlated with birth weight. A maternal prepregnancy body mass index (BMI) of < 18.5 is associated with higher morbidity and mortality for both mother and fetus.[19] Thus, there is an intergenerational effect of stunting because stunted girls reaching their reproductive age will have an increased risk of producing LBW babies. Maternal behaviors and cultural factors determining level of physical activity and food intake also influence energy balance during pregnancy.[19]

In addition to dietary energy, micronutrient deficiencies can significantly affect fetal growth, as well as impact on obstetric mortality. Vitamin A deficiency appears to have a significant effect on maternal mortality, as suggested by studies in Nepal in which vitamin A supplementation reduced mortality by 30%.[25] Whereas maternal zinc supplementation has not yielded a demonstrable effect on birth weight, duration of gestation, or postnatal mental development,[26] significant positive effects on fetal neurobehavioral development have been reported.[27,28] Zinc supplementation may act by other mechanisms enhancing neonatal survival, such as by augmenting the acquisition of natural immunity.[27] Additional maternal factors increasing the risk of LBW are low maternal age (< 18 years), chronic infections such as malaria, gastrointestinal parasites, sexually transmitted diseases, and first-time births, the latter also seen in the industrialized world.[21]

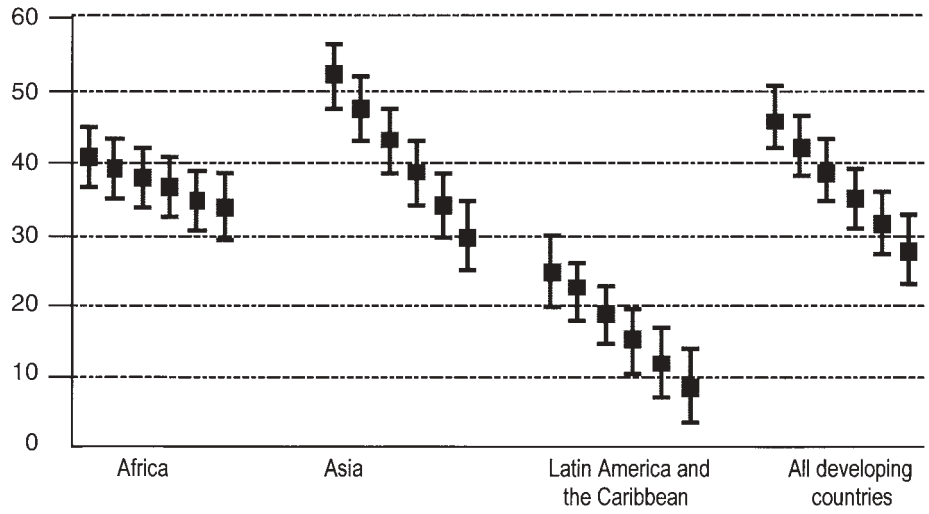

FIGURE 11-2 Trends in chronic childhood malnutrition (stunting) by region, from 1980 to 2005. Box-whisker plots are at 5-year intervals, depicting 95% confidence interval. Reproduced with permission from de Onis M et al.[7]

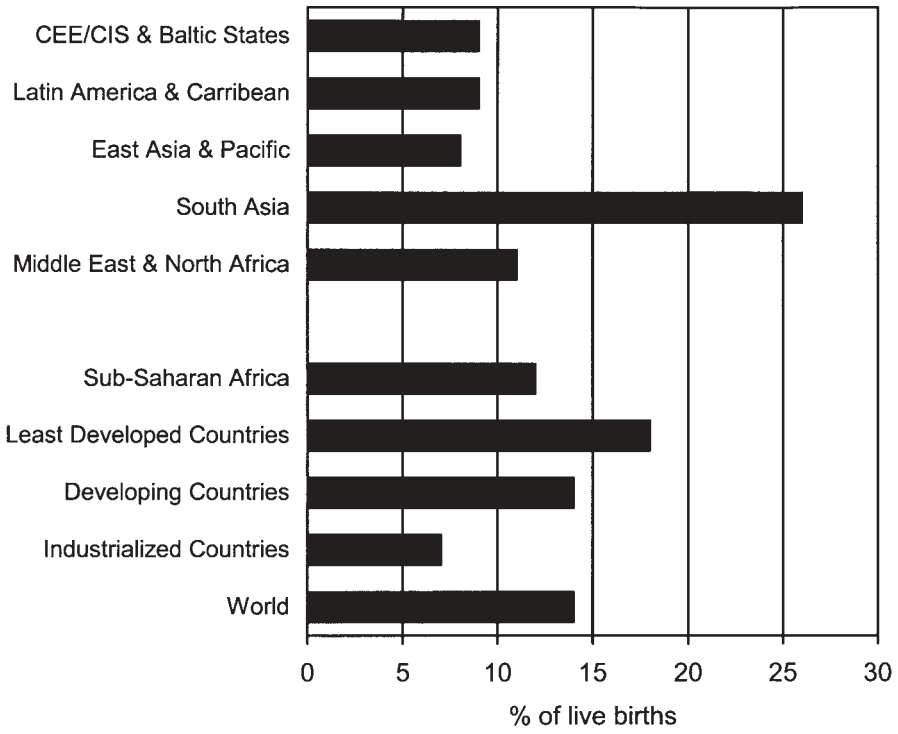

FIGURE 11-3 Rates of low birth weight (≤ 2,500 g), expressed as a percentage of live births, by region. CEE = Central and Eastern Europe; CIS = Commonwealth of Independent States. Adapted from UNICEF.[2]

The implications of IUGR extend beyond those of anthropometrics and growth. Studies in the developing world have reported lower Bayley scores and lower mental development index scores in LBW infants. These findings, however, are associated with environmental factors as well, such as standard of living, housing, and parental education. The trends in these studies would suggest that cognitive development and deficits change over time, and many of the conclusions drawn depend on the age at which they are actually followed up and may actually be transient.[29–31]

The Guatemala longitudinal study documented some degree of catch-up growth of infants with IUGR during the first 2 years of life, with subsequent stabilization at the centiles achieved by that age.[12] Body weight and height deficits in 17 to 19 year olds were evident, averaging 5 kg and 5 cm below non-IUGR children.[32,33]

Different approaches for the prevention of IUGR have been evaluated over the past decades.[34] These include macronutrient or micronutrient supplementation during pregnancy, interventions targeting nonpregnant women of reproductive age, management of obstetric disorders, increasing access to primary health care, and others.[34–36] Other important components of IUGR prevention include tetanus immunization, malaria prevention and treatment, reduction of tobacco exposure during pregnancy, and increasing prenatal care and peer counseling.

INTERACTION OF NUTRITION AND INFECTION

The vicious circle of PEM, impaired immune response, increased infections, and decreased food intake has been well recognized since the seminal work of Scrimshaw and colleagues.[37] Several of the essential host defenses against infection, including epithelial and mucosal integrity, mucociliary clearance, gastric acid production, immunoglobulin synthesis, and lymphocyte differentiation, are impaired to variable degrees in PEM.[20,38,39] In addition, specific micronutrient deficiencies, particularly hypovitaminosis A, have a significant effect on immune function. Zinc deficiency is also associated with thymic impairment and is commonly seen in the tropics and in response to diarrheal disease. Zinc deficiency states impair gastrointestinal mucosal integrity, alter taste perception, and promote anorexia, which in itself can contribute to decreased oral intake.[40–44]

Other effects of PEM on the immune system include impaired differentiation and functioning of CD4+ cells and natural killer cells, reduced complement activity, and intracellular killing of bacteria. In response to stimuli, immunoglobulin A responses may be impaired as well, in terms of both magnitude of response and antibody affinity.[45]

The cumulative effect of mild but repeated infectious episodes on child growth has been well documented in a variety of settings in the developing world.[10,46–49] Figure 11-4 depicts the growth pattern of a child in the village of Santa Maria Cauque, Guatemala. Decreased dietary intake owing to anorexia or withholding of food by caregivers, excess nutrient losses, and increased nutrient requirements are the usual mechanisms by which infection aggravates nutritional status. In addition, the immune response to infection induces a catabolic state that may persist beyond the clinical course of the infectious episode, as shown by the pioneering studies of Beisel.[38] A novel mechanism for the nutrition–infection interaction was recently described in mice, consisting of mutation of the viral genome by sele-

nium deficiency in the host, resulting in enhanced or newly acquired virulence.[50]

The vicious circle of infection-impaired nutrition infection results in a significantly higher morbidity and mortality when an infection affects a malnourished host. This increase in mortality is more or less proportional to the severity of the underlying PEM. It is estimated that an impaired nutritional status contributes to 56% of deaths owing to infectious diseases in children.[18]

EARLY GROWTH PATTERNS AND ADULT DISEASES

The long-term health effects of transient nutritional events that occur at critical periods of development are receiving much attention. This phenomenon was first documented by Widdowson, who showed that a short-term food restriction in rats had dramatically different effects depending on when it occurred in the life cycle of the animal.[51] An early restriction caused a permanent change in food intake and thus in growth rate, whereas a restriction after weaning was quickly compensated by transient overeating and catch-up growth. The notion that early metabolic events can affect risk of disease much later in life has been termed "metabolic programming" and "imprinting" and is also known as the "Barker hypothesis." This British investigator presented a series of descriptive epidemiologic evidence linking respiratory, cardiovascular, and metabolic diseases in the adult with birth weight, indicating that lower birth weights increased the risk of acquiring those diseases in adulthood (Figure 11-5).[52–54] In spite of the descriptive nature of these studies, they inspired further research, most of them confirmatory of an effect of early nutrition status on the risk of disease in adulthood.[55–59] Most of these data were obtained in developed countries. Although there are few comparable studies in developing countries, some recent results seem to confirm that these conclusions are also valid in developing countries.[60] Nevertheless, the potential implications are clear, given the high proportion of LBW that exists in most developing countries.

One central proposition of the "fetal origins" hypothesis is that fetal adaptation to a limited energy supply (commonly owing to maternal malnutrition or placental dysfunction) is achieved at the expense of selective differentiation of certain metabolic pathways and physiologic functions. This differentiation, although it may have short-term benefits for survival, may become detrimental to health later in life, when energy supply is plentiful.[61] An

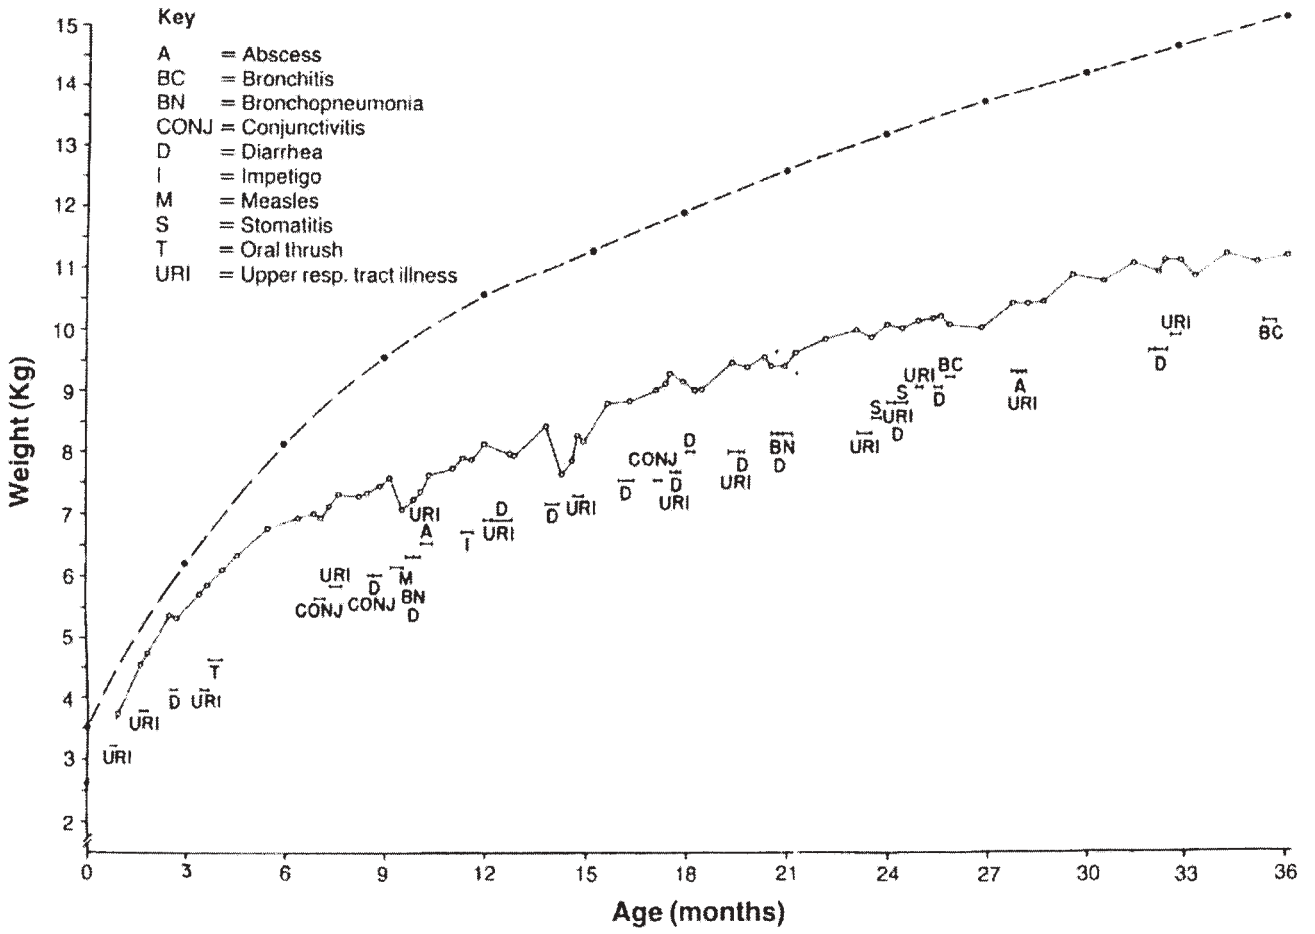

FIGURE 11-4 The impact of repeated infections on growth of a child in rural Guatemala. The *solid line* represents the weight of the child; the *broken line* is the 50th percentile of reference weight standards (Institute of Nutrition of Central America and Panama, 1956). *Horizontal lines* above disease codes indicate duration of each infectious episode. Reproduced with permission from Mata L.[10]

example would be the maximization of energy conservation pathways when there is a deficient maternal energy supply. This response, if irreversible, may result in an increased risk of obesity later in life, particularly in the face of unrestricted dietary energy availability.[59,62–65] Similar explanations have been put forth to explain hypertension risk based on restricted placental blood flow and diabetes risk based on impaired glucose supply,[66–71] as illustrated in Figure 11-5.[72]

Chronic maternal nutrient deprivation and fetal nutritional stress seen in children born in the developing world usually result in symmetric/proportional growth retardation. These may have a significantly different impact on the development of organ systems, lean tissue mass, subcutaneous fat deposition, and thus different health consequences.

There is evidence suggesting that the type and timing of feeding during the first 12 months of life may have an impact on the risk of adult disease. One study among Pima Indians, who exhibit widespread obesity as adults, showed that breast-feeding during 2 to 4 months significantly reduced the risk of obesity and of type 2 diabetes in adulthood.[73] Similarly, a cross-sectional study conducted in Germany by Von Kries and colleagues found a lower prevalence of obesity at age 5 years in children who had been breast-fed: 2.8% versus 4.5% in non–breast-fed infants.[74] Further analysis of the data suggested a dose-response relationship in breast-fed children, according to duration of breast-feeding.[74]

MICRONUTRIENT MALNUTRITION

Single- and multiple-nutrient deficiencies are widespread, affecting over 2 billion persons worldwide, mostly but not only in developing countries. Iron deficiency is considered the most prevalent single-nutrient deficiency, affecting more than 1 billion persons, followed by hypovitaminosis A and iodine. The global prevalence of deficiencies for vitamin A, iodine, and iron is presented in Table 11-3. Much less is known about the global prevalence of zinc, calcium, and folate deficiencies, but they are receiving increasing attention as potentially significant problems. Although multiple vitamin and mineral deficiencies are usually part of the malnutrition syndrome, the identification and treatment of individual micronutrient deficits are appealing because of their cost-effectiveness.[75]

Infectious diseases are an important contributor to micronutrient deficiencies. They increase gastrointestinal losses and may impair effective use of dietary sources as well. Conversely, micronutrient deficiencies may increase susceptibility to infection, as noted above.[76,77]

Vitamin A deficiency is one of the major single-nutrient deficiencies in the world. Every year there are about 10 million new cases of xerophthalmia in children. Indirect estimates indicate that vitamin A deficiency affects 130 million preschool-aged children worldwide, with 1 to 2 million dying each year.[78] Among the many factors contributing to this deficiency are low consumption of animal protein sources, reduced bioavailability and bioconversion of dietary provitamin A (betacarotene), and excess losses during episodes of acute infection.

Traditionally linked to blindness, the role of vitamin A deficiency on child mortality was demonstrated by the landmark studies of Sommer and colleagues in the early 1980s, showing that a single large dose of vitamin A resulted in a 30% reduction in child mortality.[79] Numerous subsequent trials in different countries have confirmed those findings, yielding, on average, a reduction of about 20% in mortality.[80–84] Supplementation is now national policy in several countries with endemic hypovitaminosis A. The effect of vitamin A on mortality is likely attributable to its positive effects on the integrity of epithelia, cell differentiation, and the immune system, thus reducing the severity of many infectious diseases, particularly gastrointestinal and respiratory.[82,85]

It has been postulated that micronutrient content of breast milk depends on maternal intake for some micronutrients but is independent of others. Vitamin A, B complex vitamins, and iodine are expressed in lower concentrations in the case of relative maternal deficiency but increase in response to maternal supplementation. Vitamin D, folate, zinc, iron, and calcium are maintained at relatively stable concentrations in breast milk, even in maternal deficiency states. The former category has been labeled as priority I, with the latter as priority II in the literature. The data to date on these findings are limited and are contradicted across different studies.

Multiple-nutrient deficiency is receiving increasing attention, particularly during reproductive age. The role of folic acid on pregnancy is well recognized in developed countries, but there is less information for developing countries, where populations are likely to present it combined with other micronutrient deficiencies. Several multiple micronutrient trials are currently under way, with fetal-neonatal growth and development and maternal mortality as major outcome variables.

As a corollary of the early clinical trials, in which micronutrient supplements (usually as capsules) were distributed in the study population, several countries have implemented distribution programs at the regional or national level. These can be mass distributions or can target at-risk groups. Although, in some cases, this has resulted in significant reductions in child mortality, supplement distribution is regarded as a temporary

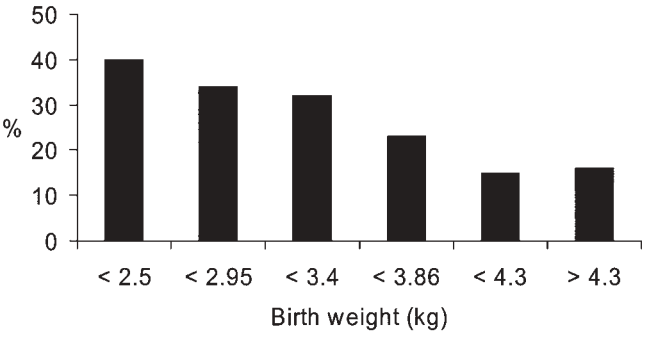

FIGURE 11-5 Association of birth weight with risk of impaired glucose tolerance and non–insulin-dependent diabetes in adulthood. Adapted from Phipps K.[72]

*With and without anemia.

approach.[75,86] The ultimate goal would be to ensure the availability of foods of enough quality and quantity to supply the requirements for all micronutrients. Nevertheless, given the complexity of factors affecting food availability and intake in different populations, micronutrient supplementation will continue to be a cost-effective temporary strategy for the immediate future.

Food fortification is a powerful approach to combat micronutrient malnutrition. Although its implementation and sustainability are more complex than for supplement distribution, it can take advantage of the market forces and food distribution channels, requiring little direct involvement from the target population. A successful fortification program depends on a variety of conditions. First, the food item to be fortified should already be consumed by the majority of the population. Second, the fortification process should not change the properties of the original product to avoid rejection by consumers. Third, the fortified item should not be priced significantly higher than the original product. Finally, an inexpensive and effective monitoring and quality control mechanism should be available.[86] A number of countries have implemented fortification programs with varied degrees of success. Perhaps one of the generally successful programs is salt iodization. This intervention has reduced the incidence and prevalence of iodine deficiency–related diseases, including cognitive and mental impairment, growth failure, and cretinism on a global scale. Impediments to the use of iodinated salt may occur when in direct competition with local salt production, as in mountainous regions, and when smaller markets and more remote populations impair distribution. The choice of a preferred approach for the control of micronutrient deficiencies depends on several factors. These include the severity and extent of the problem, cultural factors, and linkage to existing health programs and resources.

On the government level, agricultural policies can provide incentive to rotate crops and to enhance the diversity and yield of foods grown and available. Agricultural technology, selective crop breeding, and transfer of technology may aid in increasing the micronutrient content of particular foods. Subsidization of certain seed types and of fertilizers may aid in encouraging the horticulture of certain crops as well. Development of appropriate preservation modalities and transportation infrastructure is also key to public policy.

The emergence of subsistence horticulture has also received much attention and allows for considerable food quantities for individual household consumption and its control, as well as providing a potential source for income supplementation through sales of surplus. Successful implementation of this approach in Taiwan is encouraging.[75]

Food-based strategies need to consider economic sustainability, which is linked to cost and effectiveness. Sustainability is also reliant on the education of the population and to eventual behavior change to accommodate changes in dietary intake into their lifestyle. Initial political commitment is required to effect mass public awareness and education campaigns, which in themselves need to be multifaceted in their approach to ensure success. Technical adaptability, both to short-term seasonal and climactic changes and to long-term predictable/eventual issues in water supply, waterlogging, and salinity, must be taken into account in the initial planning stages. Integration of these approaches and establishment of food security can aid in effecting behavior change in a population and render it somewhat resistant to political changes/instability from a health perspective.

NUTRITION TRANSITION

The dramatic advances in communications and transportation and the globalization of economic markets are promoting rapid changes in diet and lifestyle in developing countries. This phenomenon, often termed the nutrition transition, is a key factor in the changing disease patterns for developing countries. Projections from data for the past decade indicate that by the year 2020, chronic, noncommunicable diseases will account for 70% of the disease burden in these transitional countries.[87] This, in turn, will impose tremendous demands on the health care system of these countries, currently geared predominantly toward maternal and child care. A detailed analysis of the nutrition transition can be found in a recent book by Caballero and Popkin.[26]

Urbanization, which occurs at a faster pace in the developing world, is having a profound effect on dietary patterns and lifestyle. The UN predicts that almost 90% of the projected population growth for the next 20 years will

occur in urban areas of the developing world (Figure 11-6). This, the absolute number of persons whose diet and lifestyle will be modulated by the urban environment, will increase dramatically.

The urban environment has two major effects on disease risk. First, consumption of processed foods, usually having a higher fat content, increases substantially. Second, daily energy expenditure decreases significantly: intense physical labor of field work is replaced by sedentary, low-energy work of service jobs or automated manufacturing.[88] Television viewing is also a well-documented factor in increasing sedentary time in adults and adolescents. Thus, an increased energy intake and a reduced energy output are likely to result in weight gain and obesity. In addition, sedentary lifestyle per se carries an increased risk for cardiovascular diseases.[89] The impact of urban dwelling on obesity prevalence has been documented for several regions in the developing world. Figure 11-7 presents obesity data for several Latin American countries reported by Martorell and colleagues.[90]

In spite of the recognized diversity of the transition in different countries, some general trends can be suggested. In most cases, the diet tends to increase in its animal protein, saturated fat, and total fat content. Consumption of processed foods also increases.[91] Unlike developed countries, food price exhibits strong elasticity, thus linking dietary patterns to market forces and socioeconomic status.[89]

A few countries have begun to consider the long-term implications of their socioeconomic changes on the health of the population. Most notably, Brazil has pioneered the linking of federal subsidies to diet quality, particularly in schools. It has also launched a program to increase physical activity throughout the day, Agita Sao Paulo, which has become a model for a WHO initiative.[92,93] Other countries, such as China, are testing regional programs to promote healthful eating and lifestyle, particularly in the urban population. There are some comprehensive experiences in preventive interventions in developed countries that can provide insight into effective approaches. Among these, the North Karelia study is well recognized as a successful model of integration of public and private efforts to use market forces, the media, and consumer education to improve dietary patterns.[94]

CONCLUSIONS

This chapter has summarized current global trends in child survival and health, emphasizing their close links with nutritional status. Positive trends in child survival are certainly encouraging, but there is still much to be done to ensure that those children who survive past their first year of life have adequate access to food, are protected from infections, and have the opportunity to grow and develop into healthy adults. This task is certainly more challenging and complex than preventing early death: they require lifelong health care interventions and important improvements in social and economic equity. In spite of these challenges, the success of several programs aimed at reducing malnutrition, controlling micronutrient deficiencies, improving food security, and expanding immunization coverage is encouraging. Community involvement, empowerment of women, and recognition of unique local social, cultural, and economic conditions all seem to be key ingredients for success.

CHAPTER 12

NUTRITIONAL EPIDEMIOLOGY

Carine M. Lenders, MD, MS, Walter Willett, MD, DrPH

Nutritional epidemiology is the study of relationships between diet and disease. Although the effects of nutritional deficiencies have been recognized for centuries, the chemical structures of compounds responsible for these deficiencies have been determined only this past century. Globally, the four most commonly recognized deficiencies in children include protein-calorie malnutrition and iron, iodine, and vitamin A deficiencies. The importance of folate deficiency has also become apparent in the past two decades. Interventions have evolved beyond the treatment of deficiencies to the reduction of disease risk (eg, food fortification with iodine, iron, and folate; zinc and vitamin A supplementation programs; and breastfeeding campaigns). More recently, the relationship between nutrition and disease has been expanded from that of deficiency to that of excess; the concept of *nutrition transition* has been developed. Countries undergoing modernization and westernization are faced with diseases associated with both under- and overnutrition. Globally, overnutrition and related complications have become the most important nutritional problem.

In contrast to those of most adults, children's needs vary with time as they grow and mature; therefore, assessment of pediatric diet, nutrition, and associated diseases is more challenging than that of adults. The dietary choices of children depend on their food preferences and on parental choice and control, food availability and cost, peer pressure, and advertising. Young children's ability to report their dietary intake is limited; thus, dietary assessment often requires a surrogate reporter. Despite these differences in approaches to assessment, current national surveys conducted in the United States have shown overall similar dietary trends in adults and children aged 2 to 18 years.

The development of techniques to assess diet and breastfeeding, the refinement of anthropometric methods, and the identification of biochemical indicators of diet (biomarkers) specific to population groups have greatly facilitated the field of nutritional epidemiology. Information from basic research has been used at the population level, and new questions in epidemiologic studies have been brought to the laboratory bench and the clinical setting. Methods used to investigate the relationships among diet, nutrition, and diseases include descriptive, analytic, and experimental studies. The development of hypotheses often comes from ecologic observations, and prevalence rates and diet–biochemical relationships are typically based on cross-sectional studies. The assessment of etiologic relationships is usually performed using case-control studies and prospective studies, which are typically expensive and of long duration. Each type of study has its own benefits and pitfalls. Although the best evidence for causation comes from experimental studies such as randomized, double-blind trials, in many situations it is not feasible to randomly assign subjects to diet for long periods of time.

In this overview of nutritional epidemiology, we briefly describe issues and approaches for assessing dietary intake and nutritional status, the application of different study designs, and considerations in the analysis and interpretation of data. Because of its vital importance to child health, we use the relationship between folate intake and incidence of neural tube defects to illustrate various approaches in nutritional epidemiology.

ASSESSMENT OF DIETARY INTAKE

Diet exposure can be measured either in terms of foods or as nutrient and nonnutrient components. The power to detect an association between diet and disease is usually greater when using nutrients (from all foods) rather than one food or food group to represent diet, and interpretation of associations is easier to explain biologically. However, food analyses are used frequently because people eat foods, not nutrients, and food can reflect the combined effects of multiple nutrients and differences in bioavailability of nutrients. Each dietary representation has its benefits and weaknesses, and the use of both methods provides the greatest insight.

An association between a food and disease can lead to the identification of a substance that is responsible for disease or its prevention. A classic example is that of scurvy. As recorded by Hippocrates, symptoms of scurvy were already recognized in ancient Egypt, Greece, and Rome. Later, a tree extract provided by North American Natives cured scurvy among members of an expedition led by Cartier in the sixteenth century. Lind, in his *Treatise of the Scurvy* (1753),[1] documented that lemons and oranges also cured subjects with scurvy. However, the relationship between scurvy and vitamin C deficiency was made much later. Celiac disease

provides another example.[2] Although descriptions of symptoms compatible with celiac disease were recorded in antiquity, Samuel Gee (1888) defined the classic symptoms of celiac disease in the mid-nineteenth century. These symptoms included chronic diarrhea, abdominal distention, and poor weight gain several months after the introduction of solid foods. The relationship between certain types of cereals and celiac disease was determined when the typical symptoms of pediatric celiac disease disappeared during the food shortages of World War II and relapsed after cereal supplies were restored.[3] Gluten, the major component of cereal proteins, was implicated.[4]

Intake of nutrients or foods is typically interrelated, which can result in difficulties in interpreting findings. For example, an inverse relationship exists between dietary fat and fiber intake among children.[5] Therefore, associations between food and disease could be attributable to foods either high in fiber or low in fat, or both. Sometimes multivariate analysis can be used to disentangle these associations. To minimize interrelations, investigators sometimes use food groups or account for the contributions of nutrient intake from various food groups. Also, "pattern analysis,"[6] based on factor or cluster analysis, groups together subjects with similar intakes of food. These patterns can then be evaluated in relation to disease risk.

Dietary Assessment Methods

Methods to measure dietary intake include 24-hour recall, food records, food frequency questionnaires (FFQs), diet histories, and observation (Table 12-1) The validity and the reliability of dietary intake methods among 2- to 18-year-old children and adolescents from industrialized countries have been reviewed elsewhere.[7–9] Most validation studies have used observation, diet records, or repeated 24-hour recalls as reference standards. Assuming energy balance, the doubly labeled water method is considered the best method for validation of energy intake using traditional dietary assessment methods.

The doubly labeled water method is the first truly noninvasive means to measure total daily energy expenditure accurately in free-living humans and is based on measurement of CO_2 using a nonradioactive isotope. The technique was introduced in the 1950s, but applications started being made among adults in the 1980s. The total energy expenditure obtained from the doubly labeled water method can be accurate,[10] but large interlaboratory variability has been found in a blinded evaluation of multiple laboratories.[11] Also, the reproducibility of this method at an interval of several months or more has not been evaluated in free-living populations. Overall, studies show that current dietary assessment methods provide better estimates for the composition of the diet—after adjusting for energy intake—rather than absolute intake of nutrients or energy and for a group rather than individuals.[12,13]

24-Hour Recall The 24-hour recall method is based on an interview, typically conducted by a trained dietary interviewer. It provides appropriate mean estimations for groups but not for individuals because of large day-to-day variation in individual intakes. Surrogate reporters are required for children who are young (preteen),[9,14] mentally retarded, or too sick to respond by themselves. Reporting problems can arise if parents spend less time with their children, for example, when they work outside of the household or have a large family.[13]

Twenty-four-hour recalls by children aged 2 to 18 years, or by surrogate reporters, have been compared to reference standards (observations, food records, and food chemical analysis) and summarized elsewhere.[8] In their review, McPherson and colleagues showed correlation coefficients (r values) of .2 to .9 for energy intake and .4 to .6 for most nutrients compared with the standard methods.[8] The correlation coefficients for nutrients improved after adjusting for energy intake. Compared with the standard method, recalls tended to either over- or underestimate energy intake.[8] The extent of underreporting was greater in adolescents than in all other age groups.[15,16] Food eaten varied from 68 to 84% when diet recall was compared with the validation standard.[8] The validity of the dietary recall improved when individual meals were compared rather than using 24-hour periods. Baxter and colleagues found that the accuracy of dietary recall did not vary with gender or ethnicity.[17]

The number of days for which dietary recording is necessary to accurately identify specific nutrient intakes in children has been calculated by determining the day-to-day intraindividual variation in dietary intake data for infants 4 to 6 months of age[18] and preschool children.[19] Quandt obtained dietary information using 24-hour recall among 28 mothers for their infants' diets on four random days over approximately 1 month.[18] In contrast to what is the case with adults, investigators found no effect of day of the week on nutrient variation in this age group. Interindi-

TABLE 12-1 Advantages and Disadvantages of Dietary Assessment Methods

Method	*Recording Time*	*Period*	*Interviewer Training*	*Subject Literacy*	*Affects Diet Intake*	*Memory Based*	*Subject Burden*	*Food Description*	*Automated Procedure*	*Budget*
Recall	Short	Defined	High	No	No	Yes	No	Yes	Yes	Expensive
Food record	Defined	Defined	High	Yes	Yes	No	Yes	Yes	Yes	Expensive
Food frequency	Short	Long	None	Yes	No	Yes	Yes	No (ranks)	Yes	Relatively inexpensive
Histories	Long	Imprecise	High	No	No	Yes	Yes	Yes	No	Expensive
Observation	Long	Defined	High	No	No	No	No	Yes	No	Expensive

vidual variation exceeded intraindividual variation for all nutrients except vitamin C.

Stein and colleagues measured intraindividual day-to-day variation and tracking of nutrient intakes in a longitudinal study of 181 preschool children (93% Hispanic) aged 45 to 60 months recruited through a hospital-based pediatrics practice in New York.[19] In that study, 24-hour dietary recalls were administered four times in the first year and three times in the third year to children's mothers. Although the reliability of estimates (intraclass correlation coefficients) of energy and nine nutrients obtained from a single administration of the dietary recall ranged from .15 to .38, the authors were able to show substantial tracking of underlying diets among preschool children over a 19-month period, despite day-to-day variation.

Fisher and colleagues showed that body weight also influenced the accuracy of dietary reports made by children and their parents in a sample of 146 children aged 4 to 11 years using the doubly labeled water method to validate the energy intake measured using 24-hour recalls.[20]

Food Record The food record method consists of a detailed diary of foods consumed over one or more days.[21] It provides appropriate mean values for groups but not for individuals, unless the number of days is substantial. The information is collected at the time of consumption so that memory is not a limitation. However, assessment is imprecise when dining out and can interfere with dietary intake. McPherson and colleagues pointed out that there were no specific validation studies of portion size collection and none of the studies reviewed presented results on validity in reporting food items.[8] Underreporting in children's adult-assisted food records increased with age (9 to 12 years old) when energy expenditure was measured with doubly labeled water.[22] In that study, the investigators found differences in reporting by race but not by gender. African American children were significantly more likely to underreport energy intake than were white children.

Black and colleagues studied the day-to-day variation in energy intake of 48 breast-fed infants using 4-day diet records at monthly intervals from age 1.5 to 7.5 months and of 37 fully weaned infants studied at 10, 12, 15, and 18 months of age.[23] Dietary variation was lowest in fully breast-fed infants, increased as solids were introduced, and approached values found for adults in the 18-month-old infants. Nelson and colleagues showed that with the exception of ascorbic acid, intakes were the lowest in the youngest age groups (less than 36 months of age) and rose through childhood to peak in adolescence and young adulthood.[23] In contrast to the homogeneity of the intragroup coefficient of variation (CV_w) of specific nutrients among children and adults, the intergroup coefficient of variation (CV_b) varied largely by age group and gender, resulting in variance ratios that were relatively low for toddlers, high for children aged 5 to 17 years, and intermediate for adults. These authors found that up to 4 years of age, 7 days were adequate to estimate all macronutrients except type of fat. For animal protein, the number of days required to achieve a level of accuracy of ranking at and above .9 was 18 days (Table 12-2).

As determined by the doubly labeled water method, underreporting of energy intakes on children's assisted food records increased with age.[8,24] Using that same reference method, other investigators have also shown that estimations by food record can be made at the group, but not individual, level. O'Connor compared measurements of energy intake from diet records and total energy expenditure using the doubly labeled water method in 47 children aged 6 to 9 years.[25] Although the mean energy intake and the total energy expenditure were not significantly different, the authors showed no significant correlation between energy intake and total energy expenditure. Findings of this study confirm the notion that energy intake assessed by diet records is not representative of total energy expenditure at the individual level but that 3-day food records could be used to estimate energy intake at the population level. Even longer periods of dietary records (eg, 7 days) compared to the doubly labeled water method can underestimate energy intake, especially in overweight adolescents.[26]

Food Frequency Questionnaire In contrast to food records and 24-hour recalls, food frequency questionnaires are relatively inexpensive and aim to represent long-term intake. The food frequency method relies on a food list, and participants are asked to report the frequency of consumption of each food item; the design of these questionnaires is described in detail elsewhere.[13,9] FFQs can be used to rank respondents by levels of intake. The period of time covered by the FFQ can be weeks, months, or years, and the questionnaires can be classified as quantitative (ie, food models shown for usual portion size), semiquantitative (ie, standard serving size used), or nonquantitative (only frequency assessed). Overestimation of intakes of energy and other nutrients was observed in studies using a validation standard (diet record or repeated 24-hour recall) when adults' rather than children's portion size were used in children studies.[8]

When multiple 24-hour recalls, rather than just one, were used as the validation standard, investigators observed similar estimates for energy intake obtained with the 24-hour recalls and the FFQ, referred to as the Youth-Adolescent Food Frequency Questionnaire.[9] In that study,

TABLE 12-2 Number of Days Dietary Records Are Required for a Correlation Coefficient of .9 between Observed and True Intakes

	Days for Children 1 to 4 Years Old	*Days for Boys 5 to 15 Years Old*	*Days for Girls 5 to 15 Years Old*
Protein	5	6	15
Animal protein	6	7	18
Fat	7	8	12
Saturated	8	6	12
Polyunsaturated	15	18	28
Monounsaturated	11	9	14
Cholesterol	27	18	21
Carbohydrate	6	10	9
Folate	6	9	22

Adapted from Nelson M et al.[23]

further adjustment for intraindividual variation in recalls improved the nutrient correlation coefficients. Inner-city sixth and seventh grade students demonstrated the ability to provide valid estimates of intake of calories and a variety of nutrients over 1 year. However, children in the fourth and fifth grades in inner-city schools experienced difficulties in completing the same FFQ.[27] This finding shows that surrogates are needed in older children from disadvantaged populations. Blum and colleagues recently also validated the use of a shortened version of the Youth-Adolescent FFQ in Caucasian and Native American children ages 1 to 5 years, with a parent or guardian filling out the questionnaire.[28] The average correlation was similar to that found in validation studies among adolescents and adults.

In contrast to the accuracy of repeated 24-hour recalls[29] and weighed diet records,[16] when the doubly labeled water method was used as a standard, energy intake was overestimated by 50% in infants when FFQs were used.[30] Using the same doubly labeled water method as a standard in a group of older children (9 to 16 years old), energy intake obtained from the Youth-Adolescent FFQ was underestimated. However, the authors showed that despite a wide range of variability in reporting accuracy across adiposity status and gender, this method estimated the mean energy intake of a group with appropriate accuracy.[31]

Diet History Diet history provides information on typical meals, food intakes, and preparation of food using a questionnaire, an interview, or both. This method is more qualitative than FFQs; the interview can take between 1 and 2 hours. Studies in children have shown overestimation of nutrients and energy intakes in the first interview compared with overestimations in subsequent interviews.[32] In addition, Livingstone and colleagues validated the energy intake assessed by 7-day weighted food records and diet histories with that obtained using the doubly labeled water method in 78 subjects aged 3 to 18 years.[16] Food records underestimated energy intake, whereas diet histories tended to overestimate energy intake in most age groups if it is assumed that the results from the doubly labeled water method were without error.[11]

Observation Trained personnel can observe patients in a variety of settings, especially schools. Food intake can be measured once or multiple times. The method is intrusive and is impractical in large studies. However, this method is often used as a validation standard for school-aged children and is reliable.[33]

Special Case for Dietary Assessment: Breast-Feeding

Studies relating breastfeeding to illness are difficult to evaluate because of the use of a variety of definitions for breastfeeding,[34,35] selection bias,[36,37] confounding,[38] and reverse causality.[37] As reviewed below, few studies have addressed the reproducibility and validity of breastfeeding assessment methods. Several techniques have been used to evaluate the intake of breast milk among breastfeeding children. The doubly labeled water method is considered the gold standard for evaluating energy intake in breast-fed children.[39,40] Other techniques include test weighing and the evaluation of the duration and frequency of breastfeeding using observation, recall, and record studies.

Doubly Labeled Water Technique The use of doubly labeled water has been validated against periodic open circuit respiratory gas exchange in infants.[41] Prentice and colleagues first showed that the energy requirements of infants were lower than recommended intakes, based on the combination of energy deposited during growth and total energy expenditure obtained by the doubly labeled water technique in 355 healthy infants aged up to 3 years.[42] Butte and colleagues conducted a validation study of conventional weighing techniques to estimate milk intake in breast-fed and formula-fed infants using the doubly labeled water method.[40] They found a mean difference between methods of 14% (106 g/day) in breast-fed infants and 8% (70 g/day) in formula-fed infants. Based on this method, these researchers also showed that energy requirements of infants and toddlers were 80% of current recommendations and were lower in breast-fed than in formula-fed infants.[39]

Test-Weighing Techniques Conventional test-weighing techniques include weighing either infants or mothers before and after a known or unknown amount of breast milk intake. Brown and colleagues conducted validation studies of different test-weighing techniques among 64 infants before and after the consumption of a known amount of milk.[43] The measured bottle weight corresponded to 94.9 ± 13.2% of the estimated change in weight of the infant. These techniques allowed good estimates of breast milk consumption to be made, noting that the average amount of breast milk received declined with time from 632 g/day for the 5 to 12 month olds to 368 g/day for the 24 to 30 month olds.[44] Because of the intrusive nature of test weighing, it generally will not be directly useful in epidemiologic studies, but it could serve as a standard in validation studies of other methods.

Observation, Recalls, and Questionnaires Piwoz and colleagues conducted a validation study of breastfeeding recall using observation as the reference standard.[45] He obtained 1,574 single-day dietary intakes (12-hour observations plus 12-hour recall) and mothers' monthly reports of usual feeding practices. They demonstrated that single-day studies produced a different view of feeding practices compared to the mothers' reports. Exclusive breastfeeding was observed 25% more frequently among infants younger than 4 months than was self-reported. In contrast, self-reported formula consumption was 30% more frequent compared to observation data. Differences between reported and observed practices were related to mothers' age and education, number of children younger than 5 years in the home, and infant age and disease on the observation day. The investigators concluded that consumption of breast milk or formula during the past 24 hours should not be used alone as the basis for classifying infant feeding practices in surveys.

Most epidemiologic studies have used recalled or observed data to provide information on breastfeeding. Investigators have used information on the duration, frequency, and minutes of breastfeeding rather than test-weighting or isotopic methods to evaluate the relationship between breastfeeding and outcome (ie, growth and disease), and some, but not all, studies have gathered information on additional sources of foods beside breastfeeding. For example, Zeitlin and Ahmed examined the relationship among breastfeeding, total energy intake, and growth of infants in Bangladesh using observation (minutes of breastfeeding) and 24-hour recall to estimate breast milk and other food intake in infants and children aged 5 to 23 months.[46] Beaudry and colleagues used a self-administered standardized questionnaire mailed to every mother 1 week before infants reached 6 months of age to evaluate past breastfeeding and weaning behaviors.[47] Some authors suggested that clarification of the intensity and duration of breastfeeding might help detect dose-response effects of breastfeeding.[35]

ASSESSMENT OF GROWTH AND BODY COMPOSITION

The focus of many studies in nutritional epidemiology is body weight, but recent techniques have evolved to better characterize changes in body weight in terms of body composition. Chapter 4, "Body Composition and Growth," describes the theory and practice of many of these techniques, as well as what is known about developmental changes in body composition.

Because nutritional epidemiologic studies in pediatrics often employ a variety of body composition techniques, the relationships among them are of interest. Densitometry is typically considered the gold standard for a two-compartment model of fat and nonfatty tissue in adults and depends on measurements of total body density. Despite the lack of data on fat and fat-free mass densities in children,[48] densitometry has been compared with anthropometric measurements involving weight, height, and skinfold thickness measurements (Table 12-3). Likewise, anthropometric data based on weight and height indices have been compared with skinfold thickness measurements (Table 12-4).

Data on weight and height were also compared more recently not only to measurement of skinfold thickness but also to dual-energy x-ray absorptiometry (DXA) among children aged 2 to 19 years.[49] Compared to weight for height and the Röhrer's index (Wt/Ht^3), the Quetelet index, or body mass index (BMI; Wt/Ht^2), was identified as the better predictor of overweight (but not underweight) when average skinfold thickness measurements were used as standard. BMI was also shown to perform better than the Röhrer index when the standard for percent body fat or total fat mass was estimated using DXA in children aged 3 to 19 years. No differences were found between BMI and weight for height in detecting overweight or underweight.

As reported in Table 12-5, anthropometric measurements and bioelectric impedance are most useful in large-scale studies. Although BMI does not directly measure body fat, it is typically used to evaluate adiposity in adults and has been recognized as a useful predictor of adiposity in children and adolescents, which, in turn, also predicts risks for present or future medical complications of obesity.[50] The weight indices are considered adequate when the correlation with percent body fat is high and the correlation with height is low. Although there is no perfect weight index of over- and underweight—irrespective of height and width—BMI turned out to be a reasonable index from childhood to adulthood.[51] Transformation of weight and height is also discussed in Gasser and colleagues' review.[51] Frontini and colleagues further demonstrated that the association of weight to height index was not superior to BMI as an indicator of adiposity compared to skinfold thickness measurements as reference standards and related cardiovascular risk factors during childhood in the Bogalusa Study.[52]

Self-reported weight and height among adults is frequently used in nutritional epidemiology. In contrast to the findings in adult studies, results from adolescents aged 12 to 17 years in the Third National Health and Nutrition Examination Survey (NHANES III) showed that self-reported weights were missing in 40% of 12 year olds and 25% of 13 year olds. Based on their findings, the investigators did not recommend the use of self-reported weight and height as proxy measures of weight and height among adolescents aged less than 14 years.[53] In contrast to these findings, Strauss considered that the *available* self-reported weights and heights among 12 to 16 year olds in NHANES III were reliable (n = 1,657 of 1,932).[54] In that study, correlations between self-reported weight and actual weight ranged between .87 and .94, depending on gender or race. Another recent study of first and fourth grade students in Japan showed that the child's weight and height obtained from parents was accurate.[55] The renewed interest in body composition, combined with the awareness of the growing obesity epidemic, has resulted in the need for improved reference data for body composition (see Chapter 55, "Obesity").

BIOMARKERS OF DIETARY INTAKE

Biochemical indicators (biomarkers) of dietary intake—blood, urine, stool, and tissue nutrients—can reflect nutrient intake. Biomarkers are important in epidemiology because they can be used as surrogates for dietary intake when the nutrient content in a food varies greatly. They can also be useful as determinants of disease, even if they reflect intake poorly; serum cholesterol provides a good example. Biomarkers can also be used to validate nutrient intake assessed by dietary assessment methods. When biomarkers need to represent the intake of a specific nutrient in an epidemiologic study, the most important requirements are its sensitivity to changes in dietary intake and its ability to reflect the cumulative average intake over an extended period of time.[13]

Sensitivity of a Biomarker

The sensitivity of a biomarker depends on how well the biomarker reflects true nutrient intake, which can vary with the chemical form of the nutrient. For example, the bioavailability is lower for dietary folate than for supplemental folate, so serum levels will differ with the form of folate. Serum sodium is an example of a biochemical measure biomarker that is not

*The relationship between body density and triceps skinfold for the nonobese adolescents was [body density = 1.128 – .78 log triceps skinfold].
†Arm circumference had the highest correlation with both weight (r = .90) and bone density (r = – .63). The authors showed body densities for their subjects similar to those shown by previous authors estimated from skinfold thickness measures [bone density = 1.1516 – .09256 log triceps skinfold] and comparable to real body density measurements.
‡Total skinfolds provided (at least 12 sites from the chin to the knee). Overall, correlation for triceps was – .79 and – .72 for subscapular.
Of note, the correlation coefficients between predictors of adiposity and total body densitometry tend to be positive when authors have transformed body density measurements using an equation to estimate fat (as in Maynard or Roche) but tend to be negative when using direct measurements of hydrodensitometry (as in Horsha). In the Bogalusa Study, the authors used W/H^p rather than W/H^3. They calculated the optimal "p" for each category of gender, race, and age because they wanted to obtain an index that was independent of H during growth and early life development [log(W) = a + p log(H) + e].

sensitive to intake because it is tightly regulated to remain within a specific range. The 24-hour urinary measurement of 3-methylhistidine is an example of a good biomarker for animal protein intake (r = .77).[56]

Period covered by a biomarker

Studies of chronic diseases require biomarkers that are less susceptible to short-term fluctuations. For example, serum folate is sensitive to changes in intake and modestly sensi-

tive to temporary changes in folate metabolism. Data from the Framingham Study demonstrated a strong inverse correlation between plasma homocysteine and folate intake over long periods, assessed using FFQs.[57] Another example is that of plasma amino acids. There is evidence that plasma amino acids are indicators of dietary amino acids if they are measured within 2 hours of a protein meal.[58] Plasma amino acid measurements in the postabsorptive state (at least 8 hours without food consumption) are an indicator of dietary intake of amino acids when similar protein meals have been consumed for at least 2 weeks.[59]

Source of Biomarker Measurements

Sources of biomarkers in humans include direct measurements of nutrients, enzyme activity, products of the metabolic pathway, and challenge (tolerance) tests. The biomarker can be measured directly in body fluids or tissues such as plasma, serum, erythrocytes, adipose tissue, muscle, urine, stool, hair, and nails. For example, mean population intakes of iodine and sodium can be estimated by casual urine samples.[60] Enzyme activity can be used to evaluate specific dietary nutrients (eg, alkaline phosphatase for zinc, glutathione peroxidase for selenium, and erythrocyte transketolase for thiamin).

Plasma homocysteine is a sensitive, but not a specific, marker of folate, and 1,25-dihydroxyvitamin D is a good marker for vitamin D deficiency. Although serum ferritin is a sensitive test of iron status and continues to be the leading single determination for individual iron status, it is not recommended in inflammatory states because it is an acute-phase reactant. Serum transferrin receptor is a promising alternative because it is more specific than ferritin. Another example of a nutrient that can be confounded by inflammation is serum betacarotene.[61] Finally, by-products of nutrients can be related to disease, such as protein carbonyl content, which is the most widely used marker of oxidative modification of proteins.[62]

Factors Influencing Biomarker Measurements

The relationship between dietary nutrients and biomarkers can be influenced by sample collection, storage techniques, seasonal timing, time of day, study design, contamination (eg, zinc collected in ethylenediaminetetraacetic acid tubes), stability, storage temperature, and freeze-thaw cycles, as well as level of quality control.[13]

Biomarkers to Validate Dietary Assessment Methods

Biomarkers can be useful for validating other methods of dietary assessment such as FFQs, diet records, or recalls. A major advantage is that the source of error in the biochemical measure and intake assessment should be independent. For example, good correlations between folate intake and serum or red cell folic acid provided important documentation about the assessment of dietary folate, despite concerns about bioavailability and stability in food processing.

TRACKING DIETARY INTAKE

For adults, year-to-year dietary intakes, assessed by FFQs, show correlations of .6 to .7,[13] with decreasing correlations over longer intervals,[63] but diet tracking varies according to age category among children. Although parents have a dramatic influence on their children's dietary intakes, young children's preferences are not necessarily similar to those of their parents; however, as children grow older, their preferences become more similar.[64] Energy-density manipulation studies show that children are able to adjust their daily energy intake when they focus on their own hunger and satiety cues rather than on their parents asking them to "clean their plates."[64]

There was substantial tracking of underlying diets in a study of preschool children (45 to 60 months old) over a 19-month period.[19] After correction for intraindividual variation, the correlations ranged between .2 and .6. The correlation between nutrient intake at age 2 and at age 4 was examined in the Bogalusa Study cohort of children aged 6 months to 4 years.[65] Total protein, animal protein, total sugar, sucrose, starch, total fat, saturated fatty acids, polyunsaturated fatty acids, and cholesterol showed correlations of .5 to .6 in children aged 2 years compared with children aged 4 years. At 2 years of age, 47 to 65% of children in the top tertile for total fat, saturated fat, and cholesterol intake remained in the top tertile by age 4.

Tracking of diets has also been studied in older children and adolescents. Tracking of fruit and vegetable intakes (food records) among children in third grade showed correlations of .4 to .5 over 2 years.[66] Calcium and dairy intake (diet histories) from adolescence into adulthood (13 to 27 years old) showed a correlation of .4.[67] Using three 24-hour recalls per survey, a longitudinal study of 984 children aged 6 to 13 years tracked nutrient intakes over a 6-year period in China.[68] The authors concluded that even under conditions of rapid socioeconomic change, children were likely to maintain their dietary intake patterns from childhood into adolescence. The correlations between dietary intakes measured at a 6-year interval ranged between .28 and .51 for macronutrients and major food groups (vegetable and fruit, meat, and edible oils).

TRACKING OF NUTRIENTS AND BIOMARKERS

Using 3-day dietary records, participants in the Penn State Young Women's Health Study showed weaker tracking of nutrients over a 6-year period among subjects who were 12 years of age at initiation of the study until they reached 18 years.[69] Although the year-to-year correlation coefficient for body weight over the 6-year period of that study was .9, rank and correlation analyses showed low tracking among nutrients examined (fat, sugar, iron, and vitamin C). Another longitudinal study of tracking between 13 and 33 years of age in Amsterdam showed that tracking of nutrient intakes showed relatively low but significant stability coefficients for all macro- and micronutrients (.28 to .52).[70] Overall, most nutrient tracking studies have shown that patterns of dietary intake are already present by 2 years of age. Although tracking varies with age, most studies show a low to modest correlation over time. Possible reasons for conflicting results of tracking could include study design, age groups under study, dietary instrument used to assess diet, socioeconomic background, and prevalence of overweight, among others.

Studies of tracking of diet and disease using biomarkers in pediatrics are few, except for those of cardiovascular disease. One example is that of diet and cardiovascular disease risk factors in the Bogalusa Study, carried out in Louisiana.[71] Dietary cholesterol changes correlated significantly with serum total cholesterol changes (r = .42) and low-density lipoprotein cholesterol (r = .50) from 6 months to 4 years of age. The correlation between dietary intake and subscapular skinfold thickness measurements was .3 to .4 for total protein, total fat, starch, and energy.[71,72] In another longitudinal study from birth to 5 years of age, tracking of serum cholesterol was similar to that in older children and adolescents once the weaning process was completed.[73] The composition of fatty acids in blood has been shown to reflect the quality of dietary fat. Therefore, the long-term stability (tracking) of the serum (and hence dietary) fatty acid composition of serum cholesteryl ester fatty acids were analyzed in a randomly selected population sample of 1,029 Finnish boys and girls aged 3, 6, 9, 12, 15, and 18 years and again 3 years later. The correlations were high for all fatty acids; both linoleate and arachidonate had correlations of .6.[74]

EVALUATION OF DIET–DISEASE RELATIONSHIPS

The ability to detect an association between a dietary variable and disease requires adequate interindividual variation in that dietary factor.[13,75] This implies that the likelihood of detecting a risk associated with a specific food or nutrient among homogeneous populations who are characterized by little variation in the food or nutrient studied will be low. Dietary intake can vary with cultural background (eg, among religious groups), type of foods consumed (eg, vegetarianism), type of soil (eg, soil with little selenium or iodine), food preparation (eg, manioc with cyanide), and disease state (eg, lactose intolerance, heart disease). The detection of an association between food and disease or nutrient and disease can also be limited by errors in measuring dietary intake. Variation in diet over time can be considered to be an error if long-term average intake for an individual is etiologically important. Specific data collection and statistical procedures can be applied to minimize the effects of error.

Adjustment for Energy Intake

The major components of energy intake have been reviewed elsewhere[13,76] and include body size, growth, physical activity and fidgeting, and metabolic efficiency. Most of the variation in energy intake among subjects is attributable to differences in body size and physical activity. Although metabolic efficiency and fidgeting also vary among subjects, they are not measured in nutritional epidemiology because of the lack of practical measures. In addition, a large proportion of the variation in nutrient intake is attributable to total energy intake. Adjusting for total energy intake can be viewed as a measure of nutrient composition rather than as a measure of absolute intake. Even though the association between nutrients and predictors of total energy intake is complex, failure to adjust for energy intake can result in misleading conclusions. Thus, and for the same reasons that animal studies of nutrient effects are conducted under isocaloric conditions, taking total energy intake into consideration when evaluating the relationships between diet and disease is usually important. An exception could be when the outcome being eval-

uated is growth or weight gain. Because adjusting for total energy is important in nutritional epidemiology, especially when energy intake is related to disease, models have been proposed and are reviewed elsewhere (Table 12-6).[13,77]

Residual Model Nutrient residuals are computed using a regression model with the absolute nutrient as the dependent variable and calories as the independent variable and then entered into a regression model with disease as the dependent variable. This model is comparable to isocaloric metabolic studies, in which total energy intake is constant, except for the modification in one nutrient. In the case of macronutrient calories, this model can also be viewed as the caloric substitution of one macronutrient for a similar number of calories from other sources.

To make the interpretation of actual nutrient intake easier, a constant (typically the mean nutrient intake of the study population) is added to the residual values, which have a mean of zero and include negative values. When total energy intake is an important predictor of disease, total energy intake is added to the model, which already includes the nutrient-adjusted variable, as summarized in the second equation in the first model in Table 12-6. However, the magnitude of the relationship between total energy intake and disease can vary among studies because the contribution of foods to total energy intake can be different.

Standard Multivariate Model In the standard multivariate model, both absolute nutrient intake and calories are considered independent variables in a regression model. Although the nutrient is adjusted for total energy intake in this model, the meaning has changed to calories independent of the nutrient. If we consider that total energy intake includes only protein, fat, and carbohydrate calories and the nutrient studied is protein, then energy intake corresponds to carbohydrate and fat calories. Although the meaning of total energy intake has changed, the coefficient of the nutrient studied is the same as that of the second residual model presented in Table 12-6. Some authors have concerns about this type of model, in which variables can be strongly correlated. McGee and colleagues have shown that results can vary widely when using highly correlated variables.[78] They suggest that variables with coefficient correlations of approximately .6 should not be included in the same model.

Energy Partition Model The energy partition model is very different from the two preceding models. This is not an isocaloric model. Using the same example of total energy intake being equivalent to calories from protein, carbohydrate, and fat, this model implies that we examine the relationship between disease and increasing amount of protein in the diet, while keeping term for other calories (including fat and carbohydrate) constant. Therefore, the relationship between nutrient and disease can still be confounded by total energy intake and could erroneously indicate an effect of protein on disease.

Multivariate Nutrient Density Model In the multivariate nutrient density model, the nutrient density is calculated as the nutrient divided by the total energy intake in a regression model, in which a term for calories is added as a second independent variable. This is an isocaloric model. This model can be interpreted as the relationship between the nutrient composition of the diet with disease when total energy intake is constant. Because nutrient densities are not highly correlated with total energy intake, the calories will retain their meaning of total energy intake.

Unlike in the residual model with calories and the standard multivariate model, in which the effect of the nutrient is considered similar in subjects consuming high- or low-energy diets, the nutrient density model can be useful when body size (and therefore total energy intake) varies widely among subjects. However, nutrient densities can result in an erroneous relationship. For example, when a nutrient has a weak correlation with total energy intake or a low variability and is subsequently divided by total energy intake, the nutrient can become highly correlated to total energy intake. Therefore, dividing by another variable does not necessarily mean that its effect is removed. As for absolute nutrient, nutrient densities can result in erroneous conclusions when total energy intake is associated with disease. Given the inclusion of the inverse of total energy intake in nutrient densities, nutrient densities tend to be associated with disease in the direction opposite that of total energy intake.

It is clear from this discussion that the interpretation of energy intake depends on the other variables added in the models. Therefore, the addition of predictors of energy intake to a model will also modify its interpretation. For example, if we assume energy balance, the interpretation of total energy intake in a model in which physical activity and body size were included would be that of metabolic efficiency. In another example, when residuals of weight on height (remove the effect of height on weight) and residuals of height on weight (remove the effect of weight on height) are included in a model with energy intake, height represents lean body mass, weight represents fat, and energy intake represents both physical activity and metabolic efficiency.[13]

The relationships between dietary intake and disease are complex. Although the interpretation of energy intake varies with the analytic method, the association between absolute nutrient intakes and disease should take into account total

TABLE 12-6 Possible Models That Account for Total Energy Intake in Epidemiologic Studies

1. *Residual model*
   Disease = nutrient residual
   Disease = nutrient residual + calories
2. *Standard multivariate model*
   Disease = calories + nutrient
3. *Energy partition model*
   Disease = $\text{calories}_{(\text{nutrient})^*}$ + $\text{calories}_{(\text{other})^\dagger}$
4. *Multivariate nutrient density model*
   Disease = (nutrient/calories) + calories

Adapted from Willett W. [13]
*$\text{Calories}_{(\text{Nutrient})}$ corresponds to caloric intake from a specific nutrient.
†$\text{Calories}_{(\text{other})}$ corresponds to calories from other nutrients than those under study.

energy intake because the observed association can simply reflect that of total energy intake and disease. The presentation of various analytic approaches could further strengthen the findings of an association between diet and disease.

Type of Studies

The case of the relationship between folate deficiency and neural tube defects (NTDs) will be used to illustrate the contribution of a variety of study designs to the determination of a causal relationship between nutrient intake and an important health outcome. In addition, this example shows how the knowledge of a relationship between a nutrient and an outcome might not be sufficient to develop prevention interventions. Finally, it also demonstrates the value of nutritional epidemiology in establishing and evaluating public health policies.

Descriptive Epidemiology The description of variation in rates of disease among different populations and locations, and over time, is generally called descriptive epidemiology. An environmental role in the development of NTDs was suspected from ecologic (differences in rates among geographic areas) and migration studies. The frequency of NTDs was higher in the northern United Kingdom and decreased when populations moved from high-prevalence areas in the United Kingdom to the United States. High prevalence of NTDs seemed to plague disadvantaged populations. For example, an epidemic of NTDs was observed during the Great Depression in Boston.[79] Another example comes from the decreasing rates of NTDs in Ireland over one decade concurrent with the use of fortified breakfast cereals.[80]

Clinical Observations and Intervention Studies Clinical observations often provide important leads for further study. The finding of a relationship between socioeconomic background and NTDs resulted in a study of mother's and children's folate status in the United Kingdom. Smithells and colleagues performed blood tests to study micronutrients and found that folate, among others, was low among mothers whose infants had NTDs.[81] It was also observed that drugs interfering with folate metabolism were associated with the risk of NTDs.[82]

Risk of recurrence was examined in a nonrandomized prevention trial of multivitamin and mineral supplementation in England and suggested a beneficial effect of supplementation.[83,84] Supplementation started at entry to prenatal care for all women. Women who received supplements before 6 weeks of gestation (which corresponds to the cutoff point for neural tube closure) were further compared with women who received supplements later. Other smaller intervention studies showed nonsignificant lower risk of NTDs among supplemented women. Overall, intervention studies showed a fourfold decrease in risk of NTDs among women taking a multivitamin, but the studies have been criticized because many of the data were from nonrandomized trials.

Case-Control and Cohort Studies of Vitamin Supplements In case-control studies, previous diet or use of supplements by cases (or, in this example, mother of the case) is compared with that of controls. In cohort studies, nutrient data are collected before the occurrence or recurrence of disease; thus, these studies tend to take longer and are more expensive. However, cohort studies are less subject to methodologic bias.

Only four studies examined folate intake from the diet; others used information on supplements containing folic acid. Mulinare and colleagues used a birth defects registry to identify children born with NTDs and retrospectively asked about periconceptional multivitamin use (a period of up to 14 years before the interview).[85] The risk of NTDs was approximately 60% lower for women who reported taking supplements. In contrast, Mills and colleagues did not find a significant relationship between folate and NTDs.[86] Shaw and colleagues found a similar reduction in NTD risk when folate supplementation was started after 3 months of gestation, raising concerns about the causality between folate and NTDs.[87] Milunsky and colleagues conducted a prospective cohort study of multivitamin use and NTDs by telephoning mothers at the end of the first trimester of pregnancy to inquire about the type of supplement taken.[88] Findings showed a strong inverse relationship between multivitamin intake during the first 6 weeks of pregnancy and protection against NTDs.

In summary, all case-control and cohort studies except one supported a protective effect of periconceptional multivitamin use. It was unlikely that results observed in most studies were attributable solely to chance because of the variety of design and the choice of controls. However, confounding factors could have led to these findings. For example, NTDs occurred more often in populations of lower socioeconomic background, so that, in principle, socioeconomic background could have been a confounding factor. Also, the association between folate and NTDs might have been attributable to other vitamins in the multivitamin preparation.

Case-Control and Cohort Studies of Serum Folate Daly and colleagues collected blood samples prospectively from more than 50,000 women attending their first antenatal clinic in Dublin maternity hospitals from 1986 to 1990.[89] They used a nested case-control design (sample from all cases and a matched sample of mothers who did not develop an NTD pregnancy) comparing early pregnancy blood folate concentrations in 81 women with pregnancies subsequently affected by NTDs and in a systematic sample of 247 control pregnancies. Folate levels were found to be lower for mothers who later had children who developed NTDs. The same authors found that a woman's risk of having a child with an NTD was associated with early pregnancy red cell folate concentrations in a continuous dose-response relationship.[89] However, in the absence of double-blind randomization, the social and reproductive differences between mothers who took the supplement and those who were considered part of the control group (mothers received supplements after the periconceptional period or refused to take the supplement) led to uncertainty as to the significance of the results.

Randomized Trials The evidence for the relationship between folate intake and NTDs from randomized trials

comes from two studies. One was on the *recurrence* of NTDs (history of previous pregnancy resulting in an NTD) conducted by the Medical Research Council (MRC) Vitamin Study Research Group. This was a randomized trial conducted in five European countries, Israel, and Canada.[90] The other trial was on the *occurrence* of NTDs (first pregnancy resulting in an NTD), conducted in Hungary.[91] In the MRC study of recurrence, women were randomized in a 2×2 factorial design to 4 mg of folate versus placebo or to other vitamins typically contained in multivitamins versus placebo. The trial was stopped early because of the findings of a 72% protection rate for folate. The Hungarian study used a multivitamin with trace elements and folate versus trace elements and vitamin C. This trial was also stopped because of a high occurrence of NTDs in the placebo group.

Implications The findings from these studies led to policy responses that were controversial and unclear. A variety of strategies could have been used to improve the folate status of the population: (1) increase intakes of foods rich in folate, (2) recommend routine use of supplements, or (3) suggest the fortification of foods.

Although increasing intakes of fruits and vegetables rich in folate would be beneficial in many respects, its effect on occurrence of disease would be minimal. Not only would large amounts of folate be necessary to increase plasma levels, but national programs to increase fruit and vegetable intake have not been particularly successful in the past. In addition, the bioavailability of folate in foods is not as good as that of supplemental folate.[92] Cuskelly and colleagues conducted a randomized trial of strategies to provide a daily intake of 0.4 mg of folate through either supplementation, food fortification, free provision of folate-rich foods or dietary advice regarding folate-rich foods compared with a control group over a 3-month period.[93] Concentration of folate in red cells increased significantly only in the groups receiving folate supplements or folate-fortified foods. This study reinforces the concern of the effectiveness of dietary interventions in view of social and economic barriers.

The strategy that consisted of recommending folate supplementation to women during their reproductive years was supported by most epidemiologic studies and was endorsed by the Centers for Disease Control and Prevention (CDC) in 1992. The CDC recommended the use of 0.4 mg of folate daily in women who planned a pregnancy and 4 mg for those who had a history of NTD pregnancies. Although multivitamin consumption was affordable for most, the timing of supplementation and compliance were of concern. Many institutions supported the notion of informing women about folate supplementation; failure to provide this information was considered negligent. Targeting supplementation to a population at risk was difficult because there were no clear affordable screening tools available to identify subjects at risk and the population as a whole seemed to be at risk, based on Daly and colleagues' study.[89]

Finally, the strategy of fortifying the food supply had been used long before with success in many countries (eg, with iron and iodine). Fortification of the food supply would have an impact on the entire population and would not require ongoing educational campaigns. Nevertheless, the level of fortification and the type of foods to be fortified were the center of intense debate. The main concern was the masking of vitamin B_{12} deficiency. However, given that about 25% of the population of the United States consumed multivitamins with 0.4 mg of folate, the rare report of neurologic complications associated with vitamin B_{12} was reassuring. Nevertheless, the US Food and Drug Administration (FDA) considered that levels of folate consumption from food and supplements above 1 mg of folate daily were concerning.

Although flour was a good candidate for fortification because it is consumed by most subjects in the population, the amount of consumption varies in the population. Therefore, simulations of food fortification of specific foods were performed by artificially increasing the folate content of products made of flour in existing food intake databases. Results from these simulations showed that folate intakes higher than 0.4 mg would have to be tolerated to increase folate intake of the entire population. Using this method, Oakley and colleagues showed that fortification with 0.35 mg of folate in 100 g of flour would increase the average intake by 0.25 mg, but 30% of women would still have a total folate intake below the recommended 0.4 mg and 15% of the women would have an intake above 1 mg per day (for most multivitamin users). Fortification with 0.14 mg of folate in 100 g of flour would result in an average increase of only 0.1 mg per day.[94] The FDA recommended the use of 0.14 mg of folate in 100 g of flour; this was implemented in 1998.

The demonstration that folic acid plays a major role in the prevention of *recurrence and occurrence* of NTDs stimulated further research on the possible mechanisms underlying the relationship and a possible nutrient–gene relationship. The association of a polymorphism in a folic acid metabolizing gene with the risk of NTD strongly supports the role of folate in the etiology of NTDs and could indicate a group with a higher folate requirement. A polymorphism in the 5,10-methylenetetrahydrofolate reductase gene is associated with a reduction of activity of that specific enzyme. An increase in the prevalence of this polymorphism was observed in infants born with NTDs and in their parents compared with controls.[95] The possible role of vitamin B_{12} in NTDs is still unclear, as reviewed elsewhere.[96]

Findings on folate and the risk of NTDs have given credibility to the search for other examples in which suboptimal intakes of nutrients could lead to high risk of chronic disease. The case of folate and NTDs was resolved in a relatively short time, in part because of the short interval (first 6 weeks of pregnancy) of exposure during which a nutritional imbalance could result in detrimental effects. In addition, the period between exposure and outcome was relatively short, the exposure could be evaluated by dietary assessment techniques and biomarkers, safe randomized trials could be conducted, and the strength of the relationship was large. Although a causal relationship is typically based on randomized clinical trials, the case of folate and NTDs suggests that a combination of study approaches can provide sufficient evidence when randomized studies cannot be easily performed.

SUMMARY

Nutritional epidemiology can potentially contribute substantially to our understanding of disease in children and to the relationship between diet during childhood and risk of chronic diseases and cancer. The latency period between dietary exposure and disease can be years rather than weeks. Support for the long-term effects of diet comes from studies of diabetes and cardiovascular disorders[97] that led to the Barker hypothesis of fetal origin of chronic disease, as well as from studies of cancer.[98] A variety of approaches will provide the best evidence on these relationships, particularly when used in conjunction with clinical, biochemical, and molecular data.

CHAPTER 13

FOOD SAFETY

Catherine E. Woteki, PhD, RD, Brian D. Kineman, MS

Safe food and water supplies are prerequisites for good nutrition and the overall health of a population, especially for infants and children whose immune systems are immature and therefore more vulnerable to foodborne infections. Foodborne hazards encompass microbiologic, chemical, and physical agents that can cause injury and disease when ingested. Microbiologic agents include pathogens and parasites that are either present in food when purchased or introduced into food by cross-contamination during preparation or eating. Chemical hazards are substances that are naturally occurring toxicants or that are introduced into food intentionally (such as pesticide residues or food coloring or preserving additives) or through environmental contamination. Physical hazards include pebbles, glass, metal, wood, or plastic shards that can cause physical injury or choking when ingested.

Infants and young children are among the most vulnerable to foodborne infections because of their lower body weight and immature immune systems. A dose of foodborne pathogen that may cause no illness or only mild illness in an adult can cause severe illness in a young child. Therefore, extra care needs to be taken in preparing food for young children to minimize the chance of cross-contamination.

FOODBORNE DISEASE

The terms "foodborne disease or illness" and "food poisoning" are often used interchangeably to describe general symptoms associated with consuming a contaminated food. Specifically, food poisoning refers to all forms of serious injury from gastroenteritis, whereas foodborne disease can be more broadly interpreted as encompassing all injury or illness associated with eating foods contaminated with pathogenic chemical or physical agents. In addition, the term foodborne disease can include all chronic sequelae, such as arthritis, associated with foodborne pathogens.

Agents of foodborne illness can be classified into one of three categories: biologic, chemical, or physical. Biologic pathogens include bacteria, fungi, parasites, viruses, and prions. Pathogenic chemical agents linked to foodborne illness include pesticides, herbicides, naturally occurring toxins produced by bacteria or mushrooms, mycotoxins produced by fungi, radioisotopes, and toxic heavy metals, such as copper, arsenic, and zinc. Glass, dirt, rocks, and plastic are examples of physical agents that can be introduced into the food supply and, when ingested, cause injury. Some agents associated with foodborne illness, notably bacteria and fungi, are capable of rapidly multiplying and producing toxins in foods. Foods, on the other hand, merely serve as vehicles of infection for viruses and parasites.

This chapter focuses on some of the key agents associated with foodborne illness and provides background information on how to protect infants and children from foodborne illness. Only the most serious or common agents associated with foodborne illness in children are profiled, including a general description of the agent, high-risk foods, modes of transmission, and notable symptoms of illness, including incubation periods (time between consumption of agent and onset of illness) and, where relevant, infectious dose (the amount generally required to cause illness in a "healthy" individual) and recent outbreaks, to further illustrate the nature of the agent being discussed.

BACTERIAL FOODBORNE PATHOGENS

Bacteria are small, single-celled organisms that possess no distinct nucleus. They are probably the most adaptable organisms on earth and are known to exist in all environments—in the air, in soil, and on rocky surfaces. Bacteria can be found in extreme climates, from the Arctic cold to the scorching temperatures of geysers, and have evolved to survive and thrive at high acid and high salt concentrations. Many environmental bacteria form spores—resistant, dormant structures within the cell—that protect the organism from adverse conditions, such as when adequate nutrition or moisture is lacking. Such bacteria are capable of staying in a dormant state for a couple of months, until optimal conditions are restored. With such abilities to adapt to various stresses and the capability of thriving in practically all environments, it is no wonder that bacteria exist in a wide variety of foods.

Bacteria are classified on the bases of shape (spherical [cocci], rod [bacilli], or spiral), group orientation (some bacteria such as *Bacillus* sp are noted for lining up into "chains," for instance), oxygen tolerance (aerobe,

microaerobe, facultative anaerobe, and anaerobe), cell wall structure (gram positive or gram negative), the capability to form spores, motility (possession of a flagellum), ability to ferment different sugars, and the presence of certain surface antigens, to name just a few characteristics. Most of these organisms exist as free living, but a few have ecologic niches in the external, mucosal, and other surfaces of humans and other creatures. Bacteria, for the most part, are harmless and perform beneficial roles to the environment and their human or animal host. A tiny minority, however, possess certain characteristics, such as the ability to produce toxins, that give them the capacity to threaten their host. Over 200 different species are considered to be pathogenic toward humans, many of which are associated with foodborne illness. The Centers for Disease Control and Prevention (CDC) recently estimated the number of foodborne illnesses associated with various pathogens.[1] The top seven bacteria in the analysis, including estimated foodborne illness and hospitalizations, are listed in Table 13-1. A brief review of some of these bacterial pathogens, as well as additional agents that are responsible for foodborne illness in children, is explored in this section. Emphasis is placed on organisms with higher rates of hospitalization, not necessarily those associated with higher estimated rates of illness

TABLE 13-1 Estimated Number of Foodborne Illnesses and Foodborne Hospitalizations from 7 Bacterial Pathogens

Bacteria	*Estimated Foodborne Illnesses*	*Estimated Foodborne Hospitalizations*
Campylobacter spp	1,963,141	10,539
Salmonella, nontyphoidal	1,341,873	15,608
Clostridium perfringens	248,520	41
Staphylococcus food poisoning	185,060	1,753
Shigella spp	89,648	1,246
Yersinia enterocolitica	86,731	1,105
Escherichia coli O157:H7	62,458	1,843

Adapted from Mead PS et al.[1]

Campylobacter jejuni

Campylobacteriosis is the leading cause of diarrhea in the developed world, with the number of cases exceeding those of salmonellosis and shigellosis.[2] *C. jejuni*, the bacterial agent responsible for the illness, is a gram-negative, slender, curved rod. It grows under microaerophilic conditions (in an atmosphere of approximately 5% oxygen) and has the unusual property of having an optimal temperature for growth of 42°C instead of the more typical 37°C, which is associated with most human pathogens. *C. jejuni* is found in the normal gastrointestinal and genitourinary flora of many animals, including sheep, cattle, chickens, wild birds, and domestic dogs.

C. jejuni, when ingested, colonizes the intestinal mucosa, but the exact mechanism behind its pathogenesis has yet to be fully elucidated. It is postulated that gastrointestinal illness from *C. jejuni* infection results from toxin production and bacterial invasion and proliferation with the intestinal mucosa.[3] The infectious dose, as indicated by volunteer human feeding studies, appears to be very low—around 100 organisms.[4] Onset of illness typically occurs 2 to 5 days after consumption, with symptoms consisting of severe abdominal pain, fever, and bloody diarrhea with nausea; vomiting is not commonly associated with *C. jejuni* food poisoning. Symptoms are usually self-limiting, lasting for several days to more than 1 week. *C. jejuni,* in extreme cases, can result in acute and chronic sequelae such as bacteremia, urinary tract infection, meningitis, endocarditis, peritonitis, and reactive arthritis. *C. jejuni* has also been linked to being the potential cause of Guillain-Barré syndrome (GBS), an autoimmune disorder of the peripheral nervous system, which is characterized by limb paralysis. *C. jejuni* is the most common microorganism identified in patients with GBS.[5] Nevertheless, fatalities from *C. jejuni* are very rare.

Because a number of animals serve as reservoirs for *C. jejuni*, many foods can be associated with *C. jejuni* contamination. Undercooked meat and chicken are typical sources of *C. jejuni* infection. Unpasteurized milk and nonchlorinated water can also harbor the organism. *C. jejuni* is very susceptible to heat and low pH, so typical cooking temperatures and acid washes, when applied properly, can kill the organism. But, owing to its low infectious dose, it is still a very difficult organism to control. Cross-contamination during food processing in the factory or food preparation in the kitchen can be a real problem with any organism with such a potent pathogenicity.

C. jejuni accounts for a large number of sporadic cases of illness throughout the summer months; large outbreaks are rare. Most outbreaks are attributed to the consumption of contaminated milk. One such outbreak occurred in 1986, when 172 students at an elementary school were infected from improperly pasteurized milk. The dairy supplying milk to the school did not vat pasteurize the milk at a high enough temperature or for the required length of time.[4]

Salmonella spp

Salmonella spp are gram-negative, facultative anaerobic, non–spore-forming bacilli that are widely distributed in nature. They reside in the intestinal tracts of animals and humans. The bacteria are excreted in the feces, where they can contaminate virtually any object that comes into contact with the feces. Over 2,000 distinct antigenic variants of *Salmonella* have been identified based on analysis of cell wall, capsular, and flagellar antigens. Human infection is linked to only a few of these serotypes, however.

The symptom of illness greatly depends on the type of *Salmonella* involved. *S. typhi* is the most serious of the *Salmonella* spp, being the agent responsible for enteric (typhoid) fever. *S. typhi* can penetrate the intestine and enter the bloodstream. There the organism has the ability to evade the initial immune response by entering macrophages and multiplying. Illness occurs 7 to 28 days after exposure, with symptoms that include high fever, headache, vomiting, and diarrhea.

Symptoms of nontyphoid salmonellosis are similar to those associated with enteric fever, only milder. The bacte-

ria, following ingestion, pass through the stomach and adhere to the epithelial cells lining the small intestine, causing inflammation. Ingestion of 10,000 or more bacilli is required to cause illness in healthy individuals; in children and immunocompromised individuals, the required dose is much smaller.[4] Clinical manifestations of salmonellosis, following a broad incubation period of 6 to 72 hours, include nausea and vomiting followed by nonbloody diarrhea and abdominal cramps. Diarrhea persists as the major symptom for 3 to 4 days. The illness is usually self-limiting after about 7 days. Occasionally, the microorganisms can enter the blood and cause sepsis. Once in the bloodstream, the bacteria can cause a number of problems by invading tissue. Arthritis, aneurisms, and meningitis are just a few of the chronic sequelae that can result from salmonellosis.

Raw meats, fish, poultry, eggs, and milk and dairy products are the typical risk foods for *Salmonella* spp contamination. Outbreaks associated with orange juice, tomatoes, cantaloupe, cilantro, and alfalfa sprouts have also been reported.[6–10] Thorough cooking of foods can control the organism because they are susceptible to heat (71.7°C for 15 seconds has been shown to be effective in destroying the bacteria). *Salmonella* spp are also susceptible to acidic conditions (pH 4.0) but are resistant to both freezing and drying.[11]

Salmonella spp account for a large number of reported outbreaks. A large salmonellosis outbreak in US history, involving 16,284 confirmed cases, occurred in 1985. The cause of the outbreak was believed to be pasteurized milk, which had been cross-contaminated with raw milk.[12] The largest US outbreak of salmonellosis occurred in 1994 when 224,000 people, nationwide, became ill from ice cream contaminated with *S. enteritidis*.[13] Surprisingly, the cause was not linked to an egg product in the ice cream but resulted from an unsanitized truck in which some of the product had been transported. The truck had previously hauled nonpasteurized liquid eggs containing the pathogen.

Escherichia coli

Of all of the members of the family Enterobacteriaceae, *E. coli* is the largest colonizer of the intestine of humans and animals. *E. coli* probably holds the honor of being the most feared bacterial pathogen among the general public owing to recent dramatic reports of outbreaks associated with *E. coli* O157:H7. Most strains of *E. coli* perform a beneficial role for the host, aiding in the digestion of foods, the destruction of other pathogenic bacteria, and the production of vitamins. However, a few strains are capable of producing harmful toxins that can cause a variety of conditions, ranging from mild diarrhea to death.

E. coli is a gram-negative, rod-shaped organism. It is classified as a facultative anaerobe and is a typical coliform—an enteric bacterium that ferments lactose to acid end products. Transmission of the bacteria occurs through fecal contamination. In nature, the organism can survive readily with minimum nutrients. *E. coli* can also colonize the skin as well as the female genital tract.

Pathogenic *E. coli* that causes gastroenteritis is classified in accordance with its virulence properties. The four types of diarrhea causing *E. coli* are enterohemorrhagic (EHEC), enteroinvasive (EIEC), enteropathogenic (EPEC), and enterotoxigenic (ETEC). EIEC, as the name implies, invades and proliferates within epithelial cells of the intestine, causing a mild form of bacillary dysentery. ETEC adheres to the mucous layer of the small intestine and produces toxins that result in watery diarrhea. EIEC and ETEC are uncommon agents of foodborne illness in developed nations; therefore, they will not be discussed in any more detail in this section.

EPEC is a very common cause of infant diarrhea. EPEC cells form small clumps by binding tightly to the enterocytes of the small intestine, causing the lining cells to disrupt. Resulting symptoms can include bloody or watery diarrhea. The infectious dose for infants is believed to be very low, although no exact figures are reported. In healthy adults, a dose of 10^6 cells is probably required for associated illness to occur.[4]

EHEC includes *E. coli* O157:H7, a recent emerging pathogen that was identified in 1982 as the cause of two major outbreaks of hemolytic colitis in Oregon and Michigan attributed to hamburgers.[14] *E. coli* O157:H7 produces a very powerful toxin similar to the one associated with *Shigella dysenteriae*, a bacterium that causes a severe form of bacteria dysentery. The incubation period is somewhere in the range of 3 to 9 days. Characteristic symptoms of infection include intense abdominal pain and nonbloody diarrhea, which progresses within 1 to 2 days to bloody diarrhea that can become quite severe. Vomiting and low-grade fever can occur as well. Illness usually persists for about 8 days and then subsides. *E. coli* O157:H7 is also a major cause of renal failure (hemolytic uremic syndrome [HUS]) in humans and the leading cause in children.[15] About 10% of cases progress into HUS.[16] The infective dose of *E. coli* O157:H7 is unknown but is believed to be very low—less than 10 organisms.[4]

The majority of reported *E. coli* O157:H7 outbreaks are linked to undercooked ground beef, but associations with raw milk, vegetables (including sprouts), cheese, water, juice, and fruit have been reported. Many foods can account for EPEC illness. As with *E. coli* O157:H7, raw beef and chicken are the primary risk foods. More importantly, contaminated water is probably the number one vehicle for EPEC transmission.

E. coli O157:H7 is sensitive to heat (grows poorly at 45°C) but has an unusual resistance to acid. Studies have demonstrated that the organism can survive in apple cider with a pH of 3.6.[17, 18]

There are numerous reports in recent years of outbreaks associated with *E. coli* O157:H7. The largest outbreak in the United States occurred in 1993 throughout the Pacific Northwest (Washington, Idaho, California, and Nevada).[19] In all, over 700 cases were confirmed; 178 people were hospitalized and 4 children died. Contaminated hamburgers from a fast-food chain were determined to be the cause of the outbreak. The largest outbreak in world history occurred in 1996 in Japan.[20] Radish sprouts contaminated with the organism were responsible for over 10,000 illnesses, a vast number of them being school-aged children. Unpasteurized, commercially sold apple juice

was the source of an unusual 1996 outbreak in the United States. The reported median age of the 45 victims was 5 years, with 12 persons being diagnosed with HUS.[21]

Fecal to oral transmission is also a common cause of outbreaks with *E. coli* O157:H7. This is especially true for daycare centers. An example of this was reported in Minnesota, where 68 cases of *E. coli* O157:H7 infection were identified over an 18-month period, involving nine daycare facilities.[22] In addition, younger children have been reported to shed the organisms for longer periods after resolution of symptoms compared with adults, which makes the risk factor of daycare centers even greater than once suspected.[23] *E. coli* O157:H7 transmission via the fecal-oral route also can occur by swimming in contaminated waters, as was demonstrated in an outbreak involving 12 individuals, ages 2 to 12 years, in 1995.[24]

Listeria monocytogenes

To avoid the possible misconception that only gram-negative bacteria are responsible for foodborne illness, *L. monocytogenes* is a small, gram-positive bacillus that is also a very important foodborne pathogen. It is found everywhere in nature—in the soil and water, for example. The bacterium also colonizes the intestine of humans and animals, primarily ruminants (ie, cattle, sheep, goats, deer, and elk). It is one of the few environmental gram-positive bacilli that do not form spores. Owing to its omnipresence, foods can easily become contaminated with *L. monocytogenes* through fecal or environmental transmission.

Listeriosis rarely occurs in healthy adults; however, it is a grave threat to the immunocompromised populations (human immunodeficiency virus [HIV]-positive individuals, patients subjected to chemotherapy, etc), the elderly, infants, and pregnant women. The symptoms of listeriosis are highly variable, depending on the host and particular strain of infection. In healthy individuals, symptoms are typically very mild and go unnoticed. As an opportunistic infection, symptoms may include nausea, vomiting, and abdominal pain, followed by fever. Pregnant women may also suffer flu-like symptoms. The onset of illness, like the symptoms, varies greatly, spanning from as short as 1 day to as long as 3 weeks after consumption. The very serious clinical features of listeriosis include meningitis, septicemia, and encephalitis. Listeriosis in pregnant women can lead to spontaneous abortion or stillbirth. Additionally, mothers can contaminate the skin and respiratory tract of their newborns by transmitting the organism from their gastrointestinal tract and perianal region if they are carriers.

The infectious dose of *L. monocytogenes* is unknown, but in susceptible people, fewer than 1,000 organisms can probably cause disease.[4] *L. monocytogenes* produces a hemolysin that, in conjunction with other factors, allows the organism to evade macrophages. In this respect, the organism is able to spread, avoiding much of the immune response. This is the reason that the strength of the immune system is extremely crucial in the ability of the body to adequately defend against the organism.

Beef, pork, ready-to-eat foods, soft cheeses, foods purchased at delicatessen counters, milk, poultry, fruits, and vegetables are all examples of reported sources of contamination.[25,26] *L. monocytogenes* is extremely hardy for an organism that does not form spores. The organism has the ability to grow at refrigeration temperatures (3°C) and is resistant to acid pH and salt treatments that are often used to ensure food safety. However, cooking or pasteurizing foods can effectively eliminate the risk of foodborne listeriosis in foods that can be cooked.[27]

Listeriosis occurs sporadically, but, from time to time, outbreaks of *L. monocytogenes* do occur, associated most typically with contaminated cheese or milk. Southern California was the scene of a mass outbreak in 1995, in which 142 people became ill from consuming Mexican-style soft cheese contaminated with *L. monocytogenes*.[28] There were 48 deaths, of which 10 were neonatal and 20 fetal. Hot dogs and delicatessen meats contaminated with a rare strain of *L. monocytogenes* were the culprits in a large multistate outbreak in late 1998 and early 1999 that resulted in 20 deaths.[29]

Chocolate milk, contaminated from a tank drain at the dairy, was the vehicle of *Listeria* transmission at a picnic in Illinois, which resulted in 45 cases.[30]

Clostridium perfringens

C. perfringens is a large, anaerobic, spore-forming, gram-positive rod that is widely distributed in nature, residing in the soil. The organism can be harbored in the intestine of humans and many animals, where it is passed in the feces. *C. perfringens* is the agent responsible for a common form of food poisoning as well as gas gangrene, anaerobic puerperal sepsis, and anaerobic cellulites.

Food poisoning resulting from *C. perfringens* is typically a mild illness. The illness has an incubation period of 8 to 24 hours, followed by nausea, abdominal pain, and diarrhea. Fever is not associated with illness; vomiting is rare. The illness usually self-resolves within 24 hours. In fact, the illness is often mistaken for a case of the "24-hour stomach flu." The infectious dose required for onset of associated symptoms is quite large—10^8 vegetative cells.[4] After ingestion, the bacteria release an endotoxin into the upper gastrointestinal tract, which is responsible for the clinical manifestations of infection.

The spores of *C. perfringens* are very resistant to heat, being able to withstand temperatures of 100°C for more than 1 hour. Foods associated with *C. perfringens* illness include meats, meat products, and gravy.

Outbreaks associated with *C. perfringens* are very common, even though many cases go undetected or unreported, owing to the mild symptoms associated with the illness. Two outbreaks of *C. perfringens* following St. Patrick's Day meals occurred in 1993.[31] Over 200 people became ill in two states after consuming contaminated corned beef. In one state, the delicatessen that had served the meat initially boiled it for 3 hours and allowed it to cool to room temperature before refrigeration. The corned beef was then heated to 120°F (48.8°C), sliced, and served to the public. Some of the product, which was made for catering, was allowed to stand at room temperature for several hours before serving. It was recommended by the state health department, after the outbreak, that the meat, not served directly after cooking, be

divided into small pieces, placed in shallow pans, and chilled rapidly on ice before refrigeration. Before reserving, it was further recommended that the meat be rapidly heated so that the internal temperature of the meat would reach at least 165°F (74°C).

An unusual outbreak occurred in 1990 at a conference for cake decorators.[32] Thirty-two of the 42 attendees became ill after consuming contaminated minestrone soup. The soup, which consisted of chicken, fresh vegetables, canned tomatoes, chicken base, navy beans, and peas, was heated under boiling (a temperature too low to destroy vegetative cells). Also, it was determined that the chicken stock used in the soup was not chilled before preparation and the leftover soup was held at room temperature for too long before reheating.

Clostridium botulinum

C. botulinum is a gram-positive, anaerobic, endospore-forming bacillus that is widely found in the soil. *C. botulinum* produces seven different types of a very potent toxin, referred to as types A, B, C, D, E, F, and G. Humans are susceptible to types A, B, and E and animals to types C and D. Because of its potency, botulinum toxin is an agent associated with biologic warfare because only a few nanograms of it can cause death.

The toxins produced by *C. botulinum* are responsible for causing three types of botulism: foodborne, infant, and wound. Wound botulism is quite rare and occurs when the organism is introduced into the body through a wound. Foodborne botulism results from the ingestion of the toxin through a food source. Symptoms for foodborne botulism begin to develop between 12 and 36 hours after the toxin is introduced into the body. The botulism toxin works by binding to the neuromuscular junction of nerves, preventing the release of acetylcholine, which results in muscle paralysis. Dizziness, weakness of limbs, blurred vision, general fatigue, and difficulty in swallowing are all early characteristics of infection. Vomiting, nausea, and diarrhea may occur also but usually are not accompanied by fever. Antitoxin serums and respiratory support systems are often required treatment in more severe cases. Death is usually caused by paralysis of the diaphragm, leading to asphyxiation.

Infant botulism occurs when the ingested spores of *C. botulinum* germinate and colonize the child's gastrointestinal tract. The defining symptom of infant botulism is a severe loss of head control. Other symptoms include constipation, weakness, and poor feeding. Most cases require mechanical ventilation. A 12-year case study at one tertiary care hospital revealed that 68% of its infant patients were mechanically ventilated during the course of their illness.[33]

Any food that has a low acidity and salt concentration and supports an anaerobic environment for the organism is a high-risk food. Foods that are sources of foodborne botulism include canned and bottled foods (especially home-canned foods) and foods that are submerged in oil or fat. Honey is the primary food of concern for infant botulism. It is reported that 25% of honey products have been found to contain spores.[34]

Although *C. botulinum* spores are very resistant to heat, the toxin itself is very susceptible to heat. Certain processing conditions have to be met to ensure safety from botulism, especially in the canning industry. Food processors exploit the fact that the organism is very sensitive to acidic conditions to achieve this. *C. botulinum* is not capable of producing the toxin in such conditions.

Because of dramatic changes in food safety practices in the canning industry, outbreaks of foodborne botulism are not as common as they once were. When they do occur, it is usually the result of an isolated flaw in production, such as a leak in a can. Occasionally, ethnic foods cause an outbreak of foodborne botulism. Eight individuals in the United States and Israel became ill after eating a salted fish known as *ribyetz*, a Russian food, contaminated with type E botulism.[35]

Infant botulism occurs sporadically. A typical case resulting from the consumption of honey contaminated with spores is described in a recent report in which an 11-week-old child was admitted to a hospital with infant botulism:

> "The child was initially admitted with the sole symptom of vomiting. Soon she progressively became weak and noticeably floppy in appearance. She had poor head control, decreased limb tone, and a "frog-like" leg posture. The baby required intubation and artificial ventilation for 18 days. She was treated with cefotaxime and ampicillin for 48 hours and was discharged after 33 days. She was readmitted after 4 days owing to respiratory difficulty. After another stay of 12 days, this time not requiring respiratory assistance, she was discharged. A history examination revealed that the mother had dipped the infant's pacifier in commercial honey.[36]

OTHER BACTERIAL FOODBORNE PATHOGENS

There are numerous bacterial agents that are capable of contaminating our food system and causing some form of illness. The focus of this chapter does not allow for full coverage of all of the important agents; a clinical microbiology text could easily do more justice to the subject. Instead, the brief profiles are included as a quick reference point for a more detailed study. Some of the other microorganisms that are frequently associated with foodborne illness include *Shigella* sp, a group of bacteria that consists of some strains that produce toxins similar to *E. coli* O157:H7, and *Yersinia enterocolitica*, an organism whose infection can produce intense abdominal pain, similar to appendicitis. *Bacillus cereus* and *Staphylococcus aureus* are both gram-positive, toxin-producing bacteria that can contaminate food. The toxin associated with *B. cereus,* a common soil bacterium, produces symptoms almost identical to that of *C. perfringens* infection. *S. aureus* is a bacteria that is harbored in the nose and throat and on the hair and skin of humans, which links the organism to a number of foods. Its toxin is fairly potent and results in a quick onset of illness, with symptoms that include abdominal cramping, nausea, and vomiting.

VIRAL FOODBORNE PATHOGENS

Foodborne viruses infect through ingestion and are passed through the feces. With very few known exceptions, trans-

mission of viruses occurs via the fecal-oral route or through contaminated water or food. Viruses are thought to be the major causes of unexplained foodborne outbreaks because, unlike bacteria, very few specific foodborne viruses have been identified. Children are a high-risk group for foodborne viral infections because many such illnesses are associated with schools and daycare centers.

Rotavirus

Rotavirus is the most common diarrheal pathogen in the world and infects an estimated 2.7 million children in the United States each year.[37] The *Rotavirus* virus particle is a spherical, "wheel-shaped" structure (65 to 75 nm in diameter) that contains a genome consisting of 11 segments of double-stranded ribonucleic acid (RNA), surrounded by a double-shelled outer capsid. Different serogroups of the virus exist, based on the variety of antigens present on the outer capsid. Transmission of the virus occurs via the fecal-oral route.

The majority of infections are asymptomatic in neonates and adults.[38] Onset of symptomatic illness occurs 1 to 3 days after ingestion of the virus particles, with the initial symptom of vomiting followed, within hours, by watery diarrhea that is characterized by brown, copious stools. Low-grade fever may also be present. In severe cases, the diarrhea becomes clear. The illness is usually self-limiting, with vomiting lasting for 1 to 3 days and diarrhea for 5 to 8 days. Death rarely occurs, but when it does, it is typically in the elderly and infant populations. The virus is especially contagious because so few particles are required for infection (10 to 100), yet so many are excreted in the feces (up to 1,000 particles/mL feces).[4]

Foods that are eaten raw such as salads and fruits can serve as good vehicles for the virus. The virus is fairly resistant to low pH and low temperature (it can survive at a pH of 2.8 and a temperature of 4°C for 3 days) but is susceptible to heat; a temperature of 60°C for 10 minutes will destroy it.[39] Thorough cooking and reheating of potentially contaminated foods should be effective in eliminating the virus. The peak time of year for infections is in the winter months, probably because this is when people are in close proximity to each other, allowing for the easy transmission of the organism. Group A *Rotavirus*, although it is the most important serotype of *Rotavirus*, is rarely associated with foodborne or waterborne outbreaks. Group B *Rotavirus* has been found only in China, and group C *Rotavirus* is rarely detected owing to a lack of adequate diagnostic methods.[40]

Hepatitis A

The hepatitis A virus is an unenveloped, small molecule (27 nm diameter) that consists of a single strand of RNA surrounded by a protein capsid. There are at least five different hepatitis viruses, of which hepatitis A and E are associated with foodborne illness. Hepatitis A and E are transmitted through the fecal-oral route. Hepatitis E infection is usually acquired from contaminated water, whereas A is commonly transmitted through food and water.

The hepatitis A virus replicates in the gut mucosa and spreads to the liver. Necrosis of the liver parenchymal cells is the determining factor in the severity of the disease. Infection is associated with a very long incubation period (14 to 40 days). Symptoms at the onset include fever, nausea, abdominal pain, and anorexia, followed in several days by jaundice. The infectious dose is believed to be in the range of 10 to 100 particles.[4] Age and previous exposure are important factors on the infection-to-disease ratio. This is one of the rare pathogens in which adults are at greater risk of suffering clinical disease from the infection than children. Once infected, most people develop a lifelong immunity to the virus. Currently, no treatment exists for hepatitis A infection, but, owing to the mild nature of the illness, adequate nutrition and rest are sufficient.

A number of foods can be contaminated by the virus—lettuce, delicatessen meats, fruits, juices, milk, vegetables, raw seafood, and iced tea—because the virus is stable at cold temperatures (–20°C) and low pH.

Outbreaks are usually associated with conditions of crowding such as hospitals, restaurants, and schools. In 1997, frozen strawberries, imported from Mexico, were responsible for an outbreak in three different school districts in Calhoun County, Michigan.[41]

Norwalk Virus

The Norwalk virus is the leading reported cause of viral gastroenteritis in adults and older children in the United States and the most commonly identified cause of illness, along with *Salmonella*, in school-related outbreaks.[42,43] A member of the Calicivirus family of viruses, Norwalk virus particles are 27 to 38 nm in diameter and consist of a single positive strain of RNA. The organism is transmitted from person to person through the fecal-oral route.

Infection has an incubation period of 10 to 51 hours. Symptoms are very similar to *Rotavirus*, consisting of vomiting, nausea, abdominal pain, and diarrhea. The nature of the illness is mild and self-resolves in about 1 to 2 days. The inoculation dose is unknown but believed to be very small.

Norwalk virus is very hardy and can remain active after exposure to acid (pH 2.7) and heat (60 minutes at 60°C).[44] Foods that have been reported in outbreaks include salads, fruits, eggs, coleslaw, and raw shellfish. Outbreaks are usually associated with public food facilities, such as cafeterias and restaurants. An example of this occurred recently at a Texas university, where 23 students were treated for acute gastroenteritis at a local hospital. Reverse transcriptase polymerase chain reaction methods were employed to determine that the vehicle was delicatessen-served foods, at the university cafeteria, that were contaminated with the Norwalk-like virus.[45] A food handler denied having the illness but quit her job instead of submitting a stool specimen for confirmation.

PARASITES

In developed nations, foodborne parasitic infection is not a common problem. Globally, however, the burden of such infection is tremendous. The two parasites discussed in detail in this section, *Cryptosporidium parvum* and *Toxoplasma gondii*, are protozoa. Other protozoa that are sig-

nificant foodborne pathogens include *Entamoeba histolytica,* which causes amebic dysentery, and *Giardia lamblia*. Both of these organisms are transmitted in a very similar manner, through fecally contaminated water or food, and cause illness when an individual consumes cysts that contain the organism larvae. There are several helminths that are associated with foodborne disease because they use an animal as a host during some stage of their life cycle. Tapeworms, flukes, and roundworms are different groups of helminths that are of concern to human health and are notable for being associated with eating raw or undercooked meats and fish.

Cryptosporidium parvum

C. parvum is a protozoan that accounts for a significant number of diarrheal illnesses in children. The life cycle of the organism consists of an egg (cysts), which is ingested by a human or an animal. Sporozoites are released from the cysts in the small intestine. Several stages of the life cycle occur in the cell membrane of the small intestine, where the organism reproduces, before new cysts are shed in the feces. Transmission of the cysts to humans can occur through contaminated food, water, animals, or other humans.

In individuals with healthy immune systems, symptoms include severe, watery diarrhea that can last 2 to 14 days and can result in dehydration. The infection dose is very low, about 10 organisms.[4] Onset of illness occurs 1 to 2 weeks after exposure. *C. parvum* is also a very important opportunistic pathogen. Illness from *C. parvum* infection in the immunocompromised host can result in severe, prolonged diarrhea that can lead to death.

Because the cysts are transmitted through fecal contamination, virtually all foods can be potential sources of contamination. Oocysts are susceptible to freezing and high temperatures. For this reason, foods that are considered low risk include frozen, pasteurized, or processed canned foods.

Large outbreaks are usually associated with contaminated water. The largest outbreak of cryptosporidiosis in US history occurred in Milwaukee, Wisconsin, in 1993 in which 403,000 people contracted the illness from a contaminated public water supply.[46]

Daycare centers are very common settings for cryptosporidiosis outbreaks, where diaper changing close to food preparation areas can contaminate food or formula. An outbreak at a daycare center was reported in Georgia in 1989, and stool samples from 39 children and 3 staff members were found to contain the organism.[47] Diarrhea in some children resolved only to reappear again later on, indicating the potential for reinfection under conditions of poor hygiene.

Toxoplasma gondii

Toxoplasma gondii is an opportunistic pathogen and a concern for pregnant women. It is a two-host parasite that uses the domestic cat as the definitive host and warm-blooded mammals as intermediate hosts. Humans can become infected with the organism either by ingesting sporulated oocyst in contaminated meat or water or by consuming cysts in undercooked, contaminated meats. Domestic cats pass unsporulated oocysts in their feces, which can be easily introduced into a food or water source through fecal contamination. The rate of placental transmission is reported to be between 17 and 25%, although infection of the fetus occurs only if the woman has no prior exposure to the organism.[48] When this occurs, abortion and stillbirth can result. An estimated 1 child per 1,000 to 10,000 is born with toxoplasmosis each year in the United States.[49]

In healthy adults, *T. gondii* infections are often asymptomatic. Antibody data suggest that 30 to 60% of the US adult population has been infected with the organism at one point or another.[48] In liveborn children with toxoplasmosis, symptoms may not appear for months or years later and may result in such chronic sequelae as epilepsy, palsies, slight deafness, and retardation.[50] Ocular toxoplasmosis occurs when cysts rupture in the retina of the eye, resulting in vision impairment.

A number of meats can be associated with *T. gondii* contamination, including pork, lamb, and beef. The biggest risk factor, however, is the presence of cats in the household. Pregnant women should avoid contact with cat feces and soil and wash their hands before eating and after handling raw meat.[48] Cooking meat at a temperature of 61°C or higher for at least 3.6 minutes has been demonstrated to be sufficient in inactivating cysts.[51]

To date, no outbreaks of toxoplasmosis have been reported in the United States. Occasional small outbreaks occur worldwide. Two separate outbreaks of human toxoplasmosis occurred in Korea in late 1994 and early 1995.[52] All three infected individuals in the first incident suffered vision loss and all five in the second one had lymphadenopathy. In both cases, eating undercooked pork was linked to infection.

FUNGI

Fungi are a broad class of microorganisms that require organic compounds for energy and carbon. They share the characteristic of being eukaryotes that possess an outer cell wall. Fungi exist everywhere in nature, and some are parasites on humans and animals. For the most part, they perform a beneficial role by contributing to the decomposition of matter and recycling of nutrients. A small number cause illness in humans, however. Of the over 100,000 species of fungi that exist, only about 100 have been identified as being pathogenic toward humans.[53]

The fungi kingdom consists of molds and yeasts. Yeasts are nonfilamentous, unicellular organisms, whereas molds are multicellular and have hyphae (long filaments of cells joined together). Several species of yeast, such as *Candida albicans* and *Cryptococcus neoformans,* are pathogenic in humans and account for a considerable number of illnesses among the immunocompromised. Although yeast can cause spoilage in foods, only molds produce toxins that result in foodborne illness. These mycotoxins, as a general rule, are extremely resistant to high temperatures; they cannot be destroyed by merely cooking food, in other words. However, measures can be taken to avoid fungal

contamination of foods. Certain foods, such as grains and plant products, are high risk for mold contamination because of frequent environmental exposure. Aflatoxin, one of the most familiar myotoxins associated with foods, is discussed in brief as an example of the risk associated with mold contaminations and preventive measures that can be taken.

Aflatoxin

Aflatoxins are secondary metabolites produced by certain strains of *Aspergillus* (*A. flavus* and *A. parasiticus*). *Aspergillus* spp are fast-growing molds that can be found everywhere. The major aflatoxins of concern to humans are aflatoxins B1, B2, G1, and G2. The B and G letters refer to the colors produced (blue or green) under ultraviolet light and the numbers 1 and 2 refer to their separation patterns on thin-layer liquid chromatography plates.[54]

Acute toxicity from aflatoxin exposure is quite rare. Of more concern are the potential long-term effects of low-level consumption: necrosis, cirrhosis, and carcinoma of the liver in animals and humans.[54] Reports have also indicated that exposure may play some role in mental retardation development.[55]

A. flavus is one of the most common mold contaminants in peanuts, oilseeds, and corn. Cereals and spices are also associated foods, but aflatoxin production in these is rare and the result of poor drying, handling, or storage.[54] Aflatoxin can also be found in milk as the result of cows eating moldy corn. Relative humidities of 88 to 94% and storage at temperatures between 25°C and 30°C provide optimal conditions for *A. flavus* growth.[56] Although the toxin is resistant to heat, reduction of oxygen through packaging can inhibit aflatoxin production. Also, caffeine has been shown to be effective in inhibiting the growth and mycotoxin production from *Aspergillus* spp.[56]

Outbreaks of aflatoxin poisoning are very rare in developed countries but do occasionally occur worldwide. A tragic incident was recently reported in Malaysia, where 13 children died from acute hepatic encephalopathy as the result of consuming noodles that contained high levels of aflatoxin.[57] In all, 17 were infected. Initial symptoms reported included vomiting, hematemesis, seizures, diarrhea, fever, and abdominal pain. All of the victims were reported to have liver dysfunction.

CHEMICAL CONTAMINANTS

Children today are exposed to nearly 15,000 synthetic chemicals, with the potential toxicity of more than half of these being untested.[58] Many of these chemicals are dispersed widely in the environment and contaminate much of our food supply. In addition to these synthetic chemicals, children can be exposed through food ingestion to the toxic effects of a vast number of natural elements, including heavy metals and toxins produced by fish.

Nearly all of the synthetic chemicals that were produced within the last 50 years pose food safety risks and include pesticides, industrial chemicals and by-products, and food additives. Synthetic and naturally occurring toxic chemicals can account for a variety of disorders and diseases. Excessive exposure to some of these agents has been linked to neurotoxicity, growth retardation, sexual and endocrine disorders, and cancer, to name a few.[58] Children are especially vulnerable to the potential threat posed by environmental contaminants because, pound for pound, they consume more food and drink more water than adults do and their metabolic pathways are immature.[59]

Pesticides

Pesticides have proven to be of value to society by increasing crop yields, improving the quality of fruits, and controlling insects and rodents in the household. Persistent organic pollutants (fat-soluble chemicals that degrade slowly) accumulate in the environment and pose a threat to health, especially children.

There are several different types of pesticides, including insecticides, herbicides, fungicides, wood preservatives, rodenticides, and insect repellents. Many different categories of chemical structures exist for each of these different types of pesticides. Organophosphates and carbamates are discussed in more detail here because they are the compounds that most commonly cause systemic illness.[60]

Organophosphates and carbamates are toxic compounds and include many insecticides used today.[61] Both of these compounds inhibit the breakdown of the enzyme neurotransmitter acetylcholinesterase. This inhibition results in overstimulation of certain parts of the nervous system that contain acetylcholine.[62] Acute symptoms may appear within 4 hours of exposure and can include headache, dizziness, nausea, and abdominal pain initially. Blurred vision, anxiety, confusion, vertigo, convulsions, and possibly coma may result from the nerve stimulatory effects of the compounds.[63] Poisoning from both compounds exhibits similar symptoms, but carbamate insecticide poisoning is more reversible; therefore, it is considered less severe than poisoning from organophosphates.[60] Symptoms from carbamate poisoning may last for only 6 to 8 hours.

Aldicarb is a specific example of a pesticide that is an important threat to children because it can be found in various vegetables and fruits, such as bananas. Some bananas have aldicarb levels that are reported to be 10 times greater than the legal limit established by the Environmental Protection Agency (EPA).[64] Aldicarb is a carbamate insecticide that is used on a variety of crops, including citrus fruits, nuts, potatoes, and ornamental plants. It is applied to the soil and is absorbed by the root system of the plant; therefore, residues can contaminate the edible portion of food crops.[64] Like other carbamate pesticides, toxicity is associated with acetylcholinesterase inhibition. When ingested, aldicarb is absorbed through the gut and is distributed throughout the body. Symptoms from aldicarb poisoning vary depending on the dosage and age of the individual and can include skeletal muscle weakness, diarrhea, excessive sweating, nausea, vomiting, nonreactive contracted pupils, blurred vision, dyspnea, and muscle convulsions.[65]

The EPA has placed aldicarb in its highest acute toxicity category.[66] Various outbreaks and incidents of aldicarb poisoning have been reported. Documented ingestion of

the pesticide has been linked to suicide attempts and from consuming cucumbers.[67,68] The largest foodborne outbreak associated with a pesticide was the result of aldicarb-contaminated watermelons.[69] In 1985, 1,373 people throughout the states of Oregon, Washington, and California reportedly became ill from consuming the contaminated watermelons.

Polychlorinated Biphenyls

Polychlorinated biphenyls (PCBs) are a family of compounds that are nonvolatile, hydrophobic oils that were extensively used by industry from the 1930s through the 1970s as hydraulic fluids, plasticizers, adhesives, fire retardants, wax extenders, lubricants, and inks, among many other things.[70] Even though PCBs are no longer used today—production was banned by the Toxic Substances Act of 1977—much of what was produced remains in the environment.[63] PCBs are a common food contaminant, especially in fish. These compounds are a special concern because they cannot be metabolized or excreted from the body (except through breast milk); therefore, even a little exposure can accumulate to significant amounts over time.

The pathology behind the toxic effects of PCBs is not understood. Symptoms from acute exposure of the compounds can include diarrhea and chloracne, a specific skin reaction associated with cyclic halogenated compounds that is characteristically similar to acne vulgaris except that cysts tend to be more severe and inflammation less prominent.[70] Prenatal exposure, through the cord blood, can occur.[63] Long-term effects from such exposure are debatable, but compelling evidence suggests that it can be quite damaging. An extensive study conducted on Michigan children whose mothers consumed fish from Lake Michigan revealed that elevated cord serum PCB levels correlated with lower birth weights and a reduction in head circumference and gestational age. These same children at the age of 4 had lower body weights and poorer short-term memory compared with other children.[71] A follow-up study on Japanese children who suffered during a massive epidemic from cooking oil contaminated with PCBs in 1968 found that the children 9 years later showed apathy, lethargy, soft neurologic signs, and growth deficiency.[72] A similar study, following a 1979 outbreak in Taiwan, reported that the children several years later showed an average reduction of 5 to 8 points on standard IQ scales, short stature, and hyperactive behavior.[72] During the 1968 epidemic in Japan, one of the children was stillborn, which suggests that high levels of prenatal exposure can prove fatal as well.

Breast milk can be a significant source of infant exposure to PCBs. However, studies suggest that the chemical levels of breast milk do not pose a significant threat to the health of infants.[73] The American Academy of Pediatrics (AAP), after considering this topic, still recommends breast-feeding.[63]

PCBs are unavoidable contaminants found in fatty foods, such as meat, fish, milk, and milk products. The US Food and Drug Administration (FDA) established tolerances for PCB levels in these foods. Milk, eggs, other dairy products, poultry, fish, shellfish, and infant foods are required to contain less than 0.2 to 3 parts of PCBs per million parts of food.[74]

Mercury

Inorganic and organic mercury are toxic to humans, but organic mercury (in the form of methylmercury) is associated with ingestion more than inorganic mercury. Inorganic mercury salts are poorly absorbed after ingestion; dermal exposure is more toxic. In contrast, nearly 100% of methylmercury is absorbed after ingestion.[63] Inorganic mercury in lakes and streams can be converted into organic mercury by bacteria and enter the food supply.[75]

Methylmercury is consumed primarily through eating fish because all fish are contaminated to some extent with the compound.[76] About 95% of methylmercury that is ingested is absorbed in the gastrointestinal tract and is rapidly distributed to all tissues.[77] It can pass easily into the nervous system, where it irreversibly damages the cells of the granular layer in the cerebellum, the cerebral cortex, and the calcarine cortex. Methylmercury crosses the placental barrier and accumulates in the fetal brain and blood.[78]

The latent period for mercury poisoning can be very long—several weeks to months to years. Clinical manifestations that result from long-term methylmercury poisoning can include paresthesia of the mouth, lips, tongue, hands, feet, fingers, and toes; constriction of visual fields; hearing difficulty; speech disorders; weakness and fatigue; memory loss; emotional instability; ataxia; coma; and, in the most extreme cases, death.[78]

To limit consumption of methylmercury, avoid eating large, long-lived fish that feed on other fish because they accumulate higher mercury levels than other fish. Examples of such fish would include shark, swordfish, king mackerel, and tilefish. Pregnant women are advised to limit consumption to 12 ounces per week of cooked fish.[79]

PHYSICAL CONTAMINANTS

Objects from the environment (pebbles, twigs, etc) and production equipment (shards of metal, plastic, glass, etc) occasionally contaminate food products. Every year, numerous recalls occur as the result of such findings in commercial food products.[80–84]Occasionally, ingestion of objects in food can cause lacerations of the mouth and digestive tract and occasionally broken teeth. Most are passed harmlessly in the feces. With children, it is probably best to closely examine foods for any evidence of foreign objects and avoid foods with damaged packaging.

FOOD SAFETY PRACTICES IN THE HOME ENVIRONMENT

So what can parents or child care providers do to prevent foodborne illness in infants and children? A wealth of information devoted to educating the general public on food safety issues can be located throughout the Internet and on bookshelves. Reliable sources of publications include government agencies (such as the Department of Agriculture Food Safety Inspection Service, the FDA, or

the CDC), international organizations devoted to health issues such as the World Health Organization (WHO), or professional and scientific societies such as the AAP and the American Society for Microbiology.

Unfortunately, the general public remains unaware of some fundamental knowledge and simple steps to be taken to prevent foodborne illnesses. For instance, a national survey in 1993 revealed that consumers falsely believe that foodborne illness is a minor sickness and that such illnesses usually result from eating a contaminated food at a restaurant.[85] Table 13-2 summarizes the recommendations of several reliable organizations.[86–90] Although some of this advice seems obvious and merely common sense, it is warranted to briefly discuss it in more detail because the general public is not fully aware of these basic concepts.

Cook Foods Properly

Probably the best defense mechanism against foodborne illness is heat. All foods should be thoroughly defrosted before cooking. It is important to cook foods until steaming hot throughout, making sure that the internal portions of meat are not left merely warm; a minimum internal temperature of 160°F should be reached for beef, 180°F for poultry, 160°F for pork, and 145°F for seafood. Thermometers should be used to determine that hamburgers have reached an internal temperature of 160°F to ensure that *E. coli* O157:H7 is killed. Microwave ovens need to be used with extreme caution because they do not uniformly heat foods. In addition, high salt concentrations in foods suppress microwave heating.[91] When heating foods in microwave ovens, make sure to use appropriate containers recommended by the manufacturer of the unit. To ensure that foods are heated uniformly in microwave ovens, avoid salting foods before they go into the microwave and occasionally mix the foods when heating.

Properly Store Cooked Foods

It is important to properly store foods before and after they are cooked. When serving infants, serve cooked foods immediately after preparation and avoid, if at all possible, storing leftovers altogether. If foods are stored, keep the foods at either cold temperatures (below 45°F) or at high temperatures (above 140°F). Remember, some organisms, most notably *L. monocytogenes,* can survive in the cold environment of the refrigerator; therefore, always reheat foods before serving to a temperature of at least 74°C (165°F). Always refrigerate leftover foods immediately and re-serve within 3 days unless the foods are frozen completely. Make a habit of checking the temperature on your refrigerator and freezer. Refrigerators should operate at a temperature range of 40°F to 42°F and freezers should be kept at a temperature of 0°F.

Be Cautious of Raw Foods

Raw foods provide very attractive vehicles for a number of microorganisms and should be handled with care. Avoid cross-contaminating raw foods with cooked foods. For instance, avoid having cooked foods or foods that will be served raw coming into any contact with utensils, dishes, or cutting boards that were previously in contact with raw meats or seafood. It is important to separate raw food items from other foods in the grocery cart and bag as well. Avoid serving raw meats, raw unpasteurized milk, or cheese made from raw milk. Also, avoid items that contain raw eggs, such as homemade ice cream or mayonnaise; *Salmonella* can be harbored in uncooked whole eggs.

Clean Hands are Essential

Proper hand washing technique is paramount to ensuring food safety in the home. Most people are under the mistaken impression that splashing the hands with running faucet water and patting them dry with a towel is the required approach to achieving sanitized hands. When washing your hands, always use warm, running water and soap. Rub the hands together until a soapy lather develops and continue for at least 20 seconds. Rinse your hands and dry with a clean towel. Always wash your hands before preparing food, after handling raw meat and poultry, and after any interruption, such as going to the restroom, coming into contact with pets, or changing diapers.

Use Clean Equipment

A clean kitchen with clean appliances is also an essential requirement for food safety. A seemingly clean kitchen may not actually be so. A study of 14 households revealed that the sites in the households that were contaminated with the most fecal bacteria were the sponge/dishcloths in the kitchen and the kitchen sink drain area; the areas that had the lowest contamination were the bathroom countertops and the toilet seats.[92] The point is that if dirty dishcloths are used to clean dishes and surface areas in the kitchen, the work is done in vain. Change hand and dish towels frequently and use hot soapy water or a disinfectant solution when cleaning kitchen surface areas. Also, do not soak dishes in water without detergent. Use only hard wood or nonporous cutting boards because these surfaces can be disinfected.

Other important advice includes always washing fruits and vegetables before serving. With infants, peel the fruit or vegetable if possible. Avoid serving honey to children under the age of 1 year owing to the risk of infant botulism. In group settings with children, such as daycare centers or schools, make sure that children do not share foods and that diaper-changing areas are located away from food preparation areas. Avoid serving apple cider or unpasteurized fruit juices to children; *E. coli* O157:H7 can grow at a pH less than 4.0, meaning that it can survive in apple cider and unpasteurized juices.[93] If you cannot determine if a juice product has been pasteurized, avoid it. Make sure that you store all food items away from garbage, pesticides, disinfecting agents, or other chemicals. Finally, clean water is an essential prerequisite for food safety. Ice made from unsafe water is unsafe itself.

Traveling

Food safety is very important to consider when traveling with children. When traveling on the road with food for longer than 30 minutes, always place items in a cooler with ice or freezer packs. Meat and poultry should be packed

TABLE 13-2 Guidelines for Food Safety

Agency/ Organization	*Cook Foods Properly*	*Properly Store Cooked Foods*	*Be Cautious of Raw Foods*	*Clean Hands Are Essential for Food Safety*	*Food Safety Also Means Using Clean, Proper Equipment*	*Other Advice*
World Health Organization[86]	All foods must be cooked at minimum temperature of 70°C.	Keep cool (below 10°C. When served again, heat to at least 70°C.	Do not cross-contaminate cooked foods with raw foods. Hands and utensils should be washed after coming into contact with raw foods.	Wash hands thoroughly before preparing food and after every interruption (ie, changing baby, using toilet, coming into contact with animals, etc).	Avoid feeding infants with a bottle. It is usually difficult to get bottles and teats completely clean. Cups, spoons, dishes, and utensils should be washed thoroughly.	Water used in preparing food should be bottled unless the food is adequately cooked.
American Academy of Pediatrics[87]	Cook all foods thoroughly. Use a meat thermomenter for large items like roasts or turkeys and cut into pieces to see if it is done.	Do not let prepared foods stay at room temperature for more than 2 hours. Freeze immediately if stored. When reheating, cover and reheat thoroughly.	Wash hands and all surfaces that have come into contact with raw meat with hot, sudsy water. Do not serve raw meat. Do not use raw milk or cheese made from raw milk.	Always wash hands before preparing meals and after going to the bathroom or changing your baby's diaper.	Carefully examine any canned food for signs of bacterial contamination. Look for cracked jars, loose lids, and swollen cans or lids.	Do not give honey to a baby under 1 year of age. Buy all meats and seafoods from a reputable supplier.
Centers for Disease Control and Prevention[88]	Make sure that all meats, especially poultry and hamburger, are cooked completely.	Foods should be kept at 40°F or colder or at 140°F or warmer. Leftovers should be refrigerated immediately.	No foods containing raw eggs should be served, including homemade ice cream with raw eggs.	Use proper hand washing techniques. Don't handle food if you change diapers. In this case, proper hand washing is essential.	Use only approved food equipment (check local child care licensing regulations). Only use cutting boards that can be disinfected (made of nonporous materials such as glass, Formica, or plastic).	Don't prepare or serve food if you have diarrhea. Supervise meal and snack times to make sure that children do not share plates, utensils, or food.
Food Safety Inspection Service[89]	Cook ground meats to 100°F, ground poultry to 165°F, and all fresh pork to 160°F. Whole poultry should reach 180°F.	Discard any food left out at room temperature for more than 2 hours (1 hour if above 90°F). Place food into shallow container and immediately freeze. Use cooked leftovers within 4 days.	Separate raw meat from other foods in grocery cart and refrigerator. Always wash hands and utensils with hot, soapy water after they have come into contact with raw foods. Never serve food on a plate that previously held raw foods.	Wash your hands with hot, soapy water before and after handling food.	Keep sponges and dishcloths clean. These items can harbor bacteria.	When packing a lunch, keep hot foods hot and cold foods cold. A thermos or an ice pack will help. Keep lunch in coolest place possible; never leave in direct sun.
Food and Drug Administration[90]	Cook beef at 71°C (160°F), poultry at 82°C (180°F), and seafood at 63°C (145°F) for 15 seconds.	Cooked foods should not be left out more than 2 hours. Refrigerate leftovers as quickly as possible. Use within 3 days. Reheat foods to at least 74°C (165°F).	Always wash boards after exposure to raw meat. Keep raw foods from other foods.	Wash hands with warm water and soap for at least 20 seconds. Hot water that is comfortable for hands is not hot enough to kill bacteria. Always use soap.	Use only hard wood or nonporous cutting boards. Always use clean utensils. Wash the lids of canned foods before opening. Clean blade of can opener before use.	Don't serve juice or cider if you cannot determine if it has been pasteurized.

while frozen and kept separate from other items. When hiking or camping, do not drink from streams or rivers; instead, pack bottled drinks, especially water. Do not eat anything that sits at ambient temperatures for too long.

When traveling in developing nations, pack or order bottled drinks, such as water or carbonated sodas. If such items are not available, boil water and let it cool before consumption. This applies to unpasteurized milk also. In areas of poor sanitation, bottled or boiled water should be used to brush teeth.

Peel fruits and vegetables before eating them. If this is not possible, cook the foods first. Raw foods should be avoided because they pose a heavy risk of contamination. Foods that have been cooked and are still hot can be considered safe. Seafood in certain tropical areas of the world can be unsafe, even when cooked, owing to the presence of toxins. This especially applies to fish that are caught on tropical reefs.

Traveler's diarrhea can be a real problem when traveling in developing regions. The illness is not associated with any particular pathogen and usually is self-limiting after a few days. Sometimes the illness can be severe, however, if dehydration occurs. Pack oral rehydration solution (ORS) when traveling with infants or young children. These items can usually be located at most pharmacies. If diarrhea occurs, drink more fluids, such as bottled water, fruit juice, or soup; avoid dairy products. In the case of mild dehydration, the ORS should be used. The solution should be prepared as instructed on the package. Parents should be counseled to seek medical assistance about treatment of diarrhea in children and infants. It is recommended that children or persons with serious infection should not be administered antidiarrheal medications, such as Lomotil™, for instance. If bloody diarrhea, dehydration, fever in excess of 102°F, or persistent vomiting occurs, seek medical help immediately.

Food Safety Applied to Each Stage of Childhood

Until this point, food safety issues have been discussed in general terms, without any real consideration of the different stages of child development, but some concerns are different for each stage of childhood feeding. Steps for ensuring food safety for children ages 3 years and up are very similar to those of adults. Food safety for the infant is addressed in further detail owing to a few unique considerations for each stage.

Breast-feeding is widely recommended over formula feeding, despite the presence of chemical residues, such as DDT (dichlorodiphenyltrichloroethane) and PCBs.[94] This is because human milk provides hormones, enzymes, and immunoglobulins that simply cannot be replicated in infant formula.[95] The advantages of breast milk far exceed the minimum hazards that it poses. Local health departments provide advice specific to pediatricians when local food habits may put breast-fed infants at risk.

When formula is administered to a child, special care needs to be taken to follow label instructions. Most liquid formula should be fed directly and not diluted. Formula prepared from powder should be prepared using ingredient water (commercially sterilized). If distilled, deionized, or bottled waters that are not commercially sterile are used, water must be brought to a boil for at least 1 minute and cooled before use in infant formula preparation.[96] Reports of powdered milk–based infant formulas contaminated with the enteric bacterium *Enterobacter sakazakii* led the FDA to recommend that boiling water should be used to reconstruct powdered infant formula instead of letting the water cool.[97] In addition to using sterile water, sterile equipment (bottles, nipples, utensils used in the preparation procedure, etc) is extremely important. Honey, syrups, raw eggs, or unpasteurized milk should never be added to formula. Formula should be refrigerated properly and not stand at room temperature too long. Refrigerated formula should be used within 24 hours after preparation or discarded. Care should also be taken when electing to heat formula using a microwave oven owing to issues of uneven heating. Protocols for microwave heating of refrigerated infant formula have been established.[98] Finally, homemade infant formulas should be avoided.[99]

Introducing solid foods to the young child's diet requires some additional care. Prepare fresh fruits by scrubbing and peeling them. All bones, skin, gristle, and fat should be removed from meats. Make sure that all foods are cooked thoroughly and prepared using clean equipment and utensils. As mentioned before, avoid cross-contaminating raw foods with cooked foods and never serve unpasteurized juices or ciders. Store-bought baby foods can be considered to be safe because federal standards are stricter for processed foods. In such foods, residue levels of pesticides are generally lower. Some manufacturers of baby foods voluntarily make their products free of all pesticides.[63] Do not let baby foods sit out at room temperature for more than 2 hours and refrigerate as soon as possible. Always seal foods in clean containers tightly when storing them. Cooked vegetables or fruits should be served within 3 days and raw fruits and meats within 24 hours.

Other Factors That Influence Food Safety

Geography influences the safety of some foods. The Great Lake basin, for example, is contaminated with a wide array of chemical contaminants, including PCBs, DTT, and hexachlorethane, to name a few.[100] Consuming fish from these waters poses an increased risk, and advisory messages are periodically issued warning pregnant women and other vulnerable groups about these risks. Likewise, the Hudson River is known to be contaminated with PCBs owing to old industrial facilities along the river that still leak up to 3 ounces of PCBs each day.[101] The EPA has measured PCB levels as high as 41 ppm in fish caught in the Upper Hudson River.[101] Even though commercial fishing has been banned in the area, people still consume fish that is caught in the contaminated waters. Also, people residing in countries bordering the Gulf of Mexico are at a higher risk of consuming food or drinking water contaminated with *Vibrio* bacteria, one species of which, *Vibrio cholerae,* is the agent that causes cholera.[102]

Certain ethnic food practices, lifestyles, and feeding habits can result in increased risk of foodborne illness. As

part of the traditional Eskimo diet, for example, salmon heads, salmon eggs, whale muktuk, and seal flippers are placed in a shallow wood or animal skin and covered with moss underground, which ferments the food. This tradition has resulted in outbreaks of botulism.[103]

FOOD SAFETY TECHNOLOGY

The US food supply is one of the safest in the world, largely attributable to the work of the government and the food industry. Food processors have a wide array of techniques to use to help reduce the threat of microbial contamination of their products. A variety of physical methods of food preservation are currently used in the industry, including freeze drying, ohmic heating (electrical heating), pasteurization (a mild form of heating that minimizes damage to food but helps destroy 99 to 99.9% of bacterial cells), high hydrostatic pressure preservation, and electric and magnetic field effects, to name only a few examples. Chemical preservatives and antimicrobial compounds are added to foods to help retard microbial growth or kill microorganisms.

One of the most promising recent techniques in food technology is the use of irradiation to reduce the risk of foodborne illness. Food irradiation (sometimes called cold pasteurization) employs ionizing radiation at doses sufficient to damage the DNA of bacterial cells, destroying them in the process. Irradiation of foods is a safe process and does not induce additional radioactivity into foods.[104] Irradiation can be performed after foods are packaged, preventing additional handling. Currently, it is used on spices and certain imported fruits and vegetables and is approved for use in raw poultry and meats.

Finally, a mention must be made of the importance of the Hazard Analysis Critical Control Point System (HACCP), which has revolutionized food safety during the past 20 years. HACCP provides a systematic, structured approach to food safety. The principles behind the system can be adopted and followed by any sector of the food industry to help design programs to assist in the production of safer products. The basic idea behind the system is examining all steps of a production process, identifying places in which problems are likely to occur, and developing measures to address these potential hazards. HACCP systems are required for all meat, poultry, and seafood processors. Currently, the FDA is phasing in requirements for HACCP systems to be in place for fruit juice processors as well.

Even though the food industry does a great deal to improve the quality and safety of its food products, the threat of foodborne illness is still very present. It is essential that the general public become more educated about food safety.

CHAPTER 14

DRUG THERAPY AND THE ROLE OF NUTRITION

Kathleen M. Gura, PharmD, BCNSP, FASHP,
Lingtak-Neander Chan, PharmD, BCNSP

The nutritional status of patients and the components of their diet can significantly impact a drug's pharmacokinetic and pharmacodynamic properties.[1,2] These can affect the absorption, distribution, metabolism, transport, and excretion of drugs. Body weight and/or surface area are also important determinants of proper dosages, and abnormal body composition may impact proper drug dosing. Various nutritional components can impact gastrointestinal motility, blood flow rates, gastric secretions, and enzymatic activity, ultimately affecting drug metabolism and disposition. These interactions, however, are highly variable, complex, and often difficult to predict. When developing a therapeutic plan for the pediatric patient, it is important that practitioners consider the interactions that occur between nutritional status, age, disease state, and drug action. This chapter discusses the developmental changes that occur in the pharmacokinetics and pharmacodynamics of drugs and presents a discussion on the impact of nutrition on these factors. By definition, pharmacokinetics is the action of drugs in the body over a period of time, including the processes of absorption, distribution in tissues, metabolism, and elimination. This contrasts with pharmacodynamics, which is the study of the biochemical and physiologic effects of drugs and the mechanisms of their actions, including the correlation of actions and effects of drugs with their chemical structure, as well as the effects on the actions of another drug or nutrient.

DEVELOPMENTAL CHANGES IN BODY COMPOSITION

Unlike the adult, the pediatric patient is undergoing tremendous growth and development. Children should not be thought of as "little adults" because there are a number of developmental aspects that must be considered when approaching pediatric therapeutics. Drug–receptor interactions, ontogenetic changes in receptor number, receptor affinity, receptor-effector coupling, and receptor modulation and regulation change as the child grows.[3] Moreover, during infancy and childhood, the proportions of body weight contributed by fat, protein, intracellular water, and extracellular water change dramatically. In the full-term neonate, total body water comprises approximately 70 to 80% of body weight.[4] By age 5 months, this decreases to 60%. From infancy to young adulthood, extracellular water decreases, although the percentage of total body water does not change significantly. In addition, neonates have reduced muscle mass, lower concentrations of albumin, and less intracellular fluid than adults.[5,6] The change in body water content may significantly affect the volume of distribution of drugs, especially those that are highly hydrophilic. Changes in serum protein (eg, albumin) may alter the free concentration of certain drugs and thus change the patient's pharmacodynamic response. During the second year of life, fat mass is reduced with a corresponding increase in protein mass. For additional information, refer to Chapter 4, which discusses the differences in body composition in premature infants, neonates, and adults.

As the child grows, there is a corresponding change in liver and kidney size, with each organ reaching maximum relative size for weight in the 1- to 2-year-old child, when the capacity for drug metabolism and elimination is high.[3] In the infant and young child, body surface area is greatest relative to body mass in comparison with the older child or young adult. Furthermore, the absorptive surface of small intestine is proportionately greater, whereas gastrointestinal transit time is shorter.

During adolescence, there is an approximately 25% increase in height, whereas weight nearly doubles.[3] In prepubertal males and females, lean body mass, skeletal mass, and body fat per unit body weight are similar, but, by maturity, women have twice as much fat relative to total body weight in comparison with adult men.

Factors That Impact Drug Kinetics

The aforementioned differences in body composition in the pediatric population are an important consideration when

determining the pharmacokinetics of a given medication. Nutrients and drugs delivered via the gastrointestinal tract need to go through an absorption phase prior to reaching the systemic circulation and the sites of action. Absorption from the gastrointestinal lumen into the hepatic portal vein and subsequently to the systemic circulation is a series of complex processes including the dissolution of the solid dosage form, passing of the chyme along the gastrointestinal tract (ie, gastric emptying and intestinal transit), passive diffusion, active transport, and presystemic metabolism of the compounds. Each of these processes alone may affect the pharmacokinetics of the drug.

Gastric Emptying and Intestinal Transit

With the exception of a few acidic drugs (eg, aspirin), maximal absorption of most drugs and nutrients takes place in the small bowel. Therefore, gastric emptying and intestinal transit time have a significant impact on the rate and magnitude of the oral absorption of the drugs and certain nutrients. Gastric emptying time changes in early postnatal life and is likely one of the many explanations for erratic drug absorption rate and oral bioavailability in infants and young children.[6] In addition, gastric acid secretion is low in infants and does not reach the normal adult gastric pH until 3 to 7 years of age.[7] The lack of developed physiologic regulation of gastrointestinal motility and gastric acidity during infancy and early childhood implies that the oral route may not be a reliable route for optimal drug delivery. For instance, delayed absorption and/or decreased bioavailability have been observed for acetaminophen, phenytoin, and phenobarbital in young children.[8]

As the child continues to grow, gastrointestinal motility increases by both neuronal and hormonal input.[9,10] Vagal stimulation increases upper gastric contraction and decreases pyloric sphincter and duodenal contractions. As a result, gastric emptying is promoted and the time it takes for the drug or nutrient to reach the small intestine is shortened. For drugs that are absorbed in the small intestine, this action can result in shortening the time of reaching peak plasma concentration and may promote faster onset of drug action. In addition, because of the decrease in intestinal motility, more complete absorption of the drug may be achieved. Anticholinergic drugs (eg, sedative antihistamines, phenothiazines, tricyclic antidepressants) can reverse these trends by counteracting the effect of the vagus nerve.

Presystemic Clearance

Presystemic clearance, also known as first-pass metabolism, refers to the metabolism of orally ingested compounds prior to reaching the systemic circulation. Presystemic metabolism occurs primarily in the intestine and the liver, whereas the stomach has only a minor role.[11,12] Type III alcohol dehydrogenase, for example, is present in the gastric mucosa and is responsible for the activation of some biogenic amines and steroids.

A significantly higher content of drug-metabolizing enzymes is present in the intestinal epithelial tissues. For example, cytochrome P-450 (CYP)3A4 isoenzyme is present in the small bowel and plays a role in the regulation of oral bioavailability of a large number of medications. Induction or inhibition of the enzyme in the gut by nutrients may lead to a significant change in oral bioavailability of drugs or vice versa. Certain nutrients are known to affect the enzymatic activity of intestinal CYP3A4 and change the pharmacokinetics of the object drugs. Grapefruit juice is a classic example of an intestinal CYP3A4 inhibitor.[12] Its action is discussed in further detail below. Water-soluble vitamin E (α-tocopheryl polyethylene glycol succinate) has also been found to increase oral absorption of cyclosporine.[13,14] It is unclear whether it affects intestinal enzyme or transporters. Further research is currently under way to determine the mechanism of interaction that leads to increased oral drug absorption.

HEPATIC METABOLISM

The metabolism of a drug involves different steps once it has been absorbed from the gastrointestinal tract. As drugs are metabolized, they first undergo biotransformation (ie, phase I metabolism), which results in the formation of a more polar compound by oxidation, reduction, hydroxylation, etc. This results in either an activation of the drug or a deactivation. The second phase (ie, phase II reaction) is a synthetic process, involving conjugation of the polar compound with endogenous molecules such as glucuronic acid, sulfate, glutathione, glycine, and acetate, resulting in a more hydrophilic compound that is more suitable for excretion into bile or urine.[15] It is important to point out that some drugs do not have to go through phase I metabolism prior to undergoing phase II metabolism. Lorazepam, for example, undergoes phase II metabolism (glucuronidation) by UDP-glucuronosyltransfersae (UGT) 2B7 without any phase I reaction involved. The resultant conjugated metabolite is then excreted renally. An enzyme system responsible for the metabolism of most nutrients and drugs is the CYP enzyme superfamily, principally located in the endoplasmic reticulum of the hepatocytes and enterocytes, which is somewhat unique in its ability to use a wide range of substrates.

The maturation of phase I and phase II enzymes varies among individuals. Limited studies suggest that fetal and neonatal CYP, the most important phase I enzyme in metabolizing drugs and biogenic amines and steroids, has about 50 to 70% of the adults' activity and continues to mature throughout childhood. Whereas some children may have fully matured CYP enzyme activities as early as 6 months of age, it may take up to 12 months for others.[7,16] For example, the serum half-life of theophylline, a bronchodilator primarily metabolized by CYP1A2 and CYP3A4, is significantly longer in neonates and younger infants than in adults. Similarly, *N*-demethylation of diazepam, a CYP2C19-mediated pathway, is also significantly slower in infants.[17] There is no well-documented dietary factor known to promote the maturation of these enzymes during the prenatal period and infancy.

RECTAL ADMINISTRATION

Rectal route of drug administration is an alternative way of drug delivery when the enteral route is not preferable.

Unlike the rest of the gastrointestinal capillary mesenteric circulation, the rectal capillary blood supply collects blood directly into the inferior vena cava instead of the hepatic portal vein. Although certain phase II enzymes are present in the colon (eg, UGT1A9), there is no strong evidence to suggest the presence of drug-metabolizing enzyme in the rectum.[18] Hence, presystemic metabolism of the administered drug is prevented. Therefore, compared with oral administration, the relative bioavailability of the drug is usually higher with rectal administration.[19] Drugs that are more commonly delivered rectally in children include anticonvulsants (eg, diazepam), antiemetics (eg, trimethylbenzamide), and sedative agents (eg, chloral hydrate).

DRUG AND NUTRIENT TRANSPORT SYSTEM

Intestinal transport molecules facilitate the absorption of drugs or nutrients.[20,21] In addition, some transporters efflux molecules already absorbed in the cytoplasm of the enterocyte back into the intestinal lumen, thus decreasing the bioavailability of certain compounds. This is believed to be an intrinsic protective mechanism by the host to minimize xenobiotic exposure. P-glycoprotein (Pgp) is a representative of this type of efflux system.[22–24] Pgp belongs to the family of adenosine triphosphate–binding cassette transporters and is an efflux widely distributed in normal tissues, including the intestinal epithelium, renal tubule, liver, and blood-brain barrier. Although no formal studies have been published, nutrients may interact with drugs by either inhibiting or inducing Pgp.

Research in the last decade has proved that CYP3A4 and Pgp are the two most important limiting factors in regulating the oral bioavailability of drugs and their first-pass metabolism.[25,26] For instance, cyclosporine is a known substrate for both CYP3A4 and Pgp. After oral administration, absorption of cyclosporine across the epithelium in the small intestine is limited by Pgp efflux and prehepatic CYP3A4 metabolism. The Pgp-mediated efflux of cyclosporine from the intestinal cell back into the lumen enables the CYP3A4 enzymes another opportunity to metabolize the drug when it again enters the enterocyte. These mechanisms explain why the oral bioavailability remains poor despite improvement of its formulation to microemulsion.[27] When cyclosporine is coadministered with a CYP3A4 and Pgp inhibitor, such as ketoconazole, erythromycin, or diltiazem, significantly increased maximum blood cyclosporine concentration is observed, indicating an increase in absolute oral bioavailability. Oral bioavailablity can be increased by over 40% with concomitant administration of water-soluble vitamin E.[13] The mechanism is believed to be mediated through intestinal Pgp inhibition by the vitamin. It is uncertain, however, whether the inhibition is caused by the inactive component in the formulation of the vitamin or vitamin E itself. Current research is being directed toward a more complete understanding of the cooperative nature between CYP3A and Pgp and what types of nutrients and drugs are substrates of these two systems.

Binding Interactions between Feedings and Drugs Revisited

Feeding and food intake are common causes of drug–nutrient interactions. Enteral feeding is the preferred method of providing nutrition support and also allows easy access for administering drugs to patients who are unable to swallow. However, enteral feeding formulas have been implicated in a number of drug–nutrient interactions.[28] For example, the oral absorption of warfarin, tetracycline, fluoroquinolone antibiotics, and phenytoin is decreased with concomitant enteral feeding.[29–31] Possible explanations include a decrease in the anticoagulant effect of warfarin caused by increased vitamin K absorption from the enteral formulas or binding of warfarin by a protein component of the enteral formula.[30] Drug–nutrient interaction through chelation of divalent and trivalent cations has also been proposed (eg, enteral feeding formulas or dairy products interact with fluoroquinolones).[27]

Effects of Malnutrition on Drug Kinetics

It has become increasingly recognized that nutritional status is capable of modifying the pharmacologic effect of a medication. Both malnutrition and obesity can substantially alter drug pharmacokinetics and pharmacologic responses by causing functional and structural alterations in organs that directly affect drug disposition.[2,32,33] These changes can affect the absorption, distribution, metabolism, and elimination of a medication that can ultimately affect the therapeutic or toxic response of the drug. Moreover, interindividual and intraindividual variations in the pharmacokinetic responses to a medication can further complicate interpreting the actual impact of altered nutritional status on drug disposition. The variation can be 3- to over 20-fold, depending on genetic (eg, genetic polymorphism) and environmental factors, patient variables, and underlying disease.[2,34] Pediatric patients, of course, have a higher incidence of undernutrition (see Chapters 52 and 53).

The pathologic changes seen in malnutrition can impact the pharmacokinetics of drugs in all phases of disposition within the body, suggesting that the degree of malnutrition can determine the body's response to a particular drug.[35] Physiologic changes of protein-energy malnutrition (PEM) may result in alterations in the absorptive capacity of the gastrointestinal tract, body fluid status, cardiac output, glomerular filtration rate (GFR), and plasma protein concentrations, as well as hormonal and metabolic changes. Therapeutic drug levels may be altered as a result of malnutrition-associated tissue receptor alterations.[36] It is conceivable that the risk of toxicities owing to a drug or its metabolites is greater in malnourished patients, with a subsequent risk of morbidity or mortality. This suggests that close drug therapy monitoring and modification of dosage in malnourished patients are imperative. Drugs with narrow therapeutic indices or narrow dose-response curves (ie, phenytoin, theophylline) are particularly susceptible as even small changes in absorption can become significant.

Relatively little is known about the handling of drugs in malnourished children despite the fact that the combination of malnutrition and accompanying disease (typically

infection) in need of treatment is a common pediatric problem in many parts of the word. It is possible that the high morbidity of mortality so characteristic of malnutrition may be enhanced by adverse drug reactions.[37]

Absorption

Little research has been done on the effect of malnutrition on drug absorption. O'Doherty and colleagues observed that phenytoin absorption was slow and erratic in PEM, although the peak concentration and time to reach peak concentration did not differ significantly from controls.[38] Mehta and colleagues reported similar findings with acetaminophen disposition in children suffering from PEM.[39] Like O'Doherty and colleagues, they observed that the absorption rate constant was not altered in malnutrition. This contrasts with work by Raghuram and colleagues indicating that tetracycline absorption was significantly reduced in subjects with malnutrition and pellagra but not in patients with vitamin B complex deficiency or in patients with severe anemia.[40]

Distribution

Only free, unbound drug molecules are pharmacologically active. Because the amount of serum protein changes over the first few years of life, the pharmacokinetics and pharmacodynamics of a drug may change. The important serum proteins that bind to drug molecules and biogenic amines and lipids include albumin, α_1-acid glycoprotein, sex hormone–binding proteins, and lipoproteins. Serum albumin concentrations in children and adults seem to be very similar. However, the serum concentration of α_1-acid glycoprotein is lower in children.[41] On the other hand, the concentrations of certain fetal serum proteins are higher in infants and may lead to relatively unique pharmacokinetic changes in this population.

Drugs can distribute into various body compartments such as the intracellular fluids, extravascular space, lean body tissue, and adipose tissue.[42] Alterations in body composition, particularly the presence of edema, can influence the plasma clearance of drug by changing the medication's volume of distribution.[43] Many medications, once in the systemic circulation, become bound to plasma protein, such as albumin, globulins, and lipoproteins. These binding proteins play an important role in the intravascular transport of the drugs to the target organs. In the bloodstream, drugs that are not bound to plasma proteins are free and are able to exert their pharmacologic response. Malnutrition can alter the rate of tissue protein synthesis as well as the concentration of plasma proteins. The extent of drug-protein binding depends on the concentration of plasma bind proteins as well as the physicochemical properties of the medication. In malnutrition, albumin and lipoprotein synthesis are reduced, whereas globulin and α_1-acid glycoprotein synthesis are increased.[27] Drugs extensively bound to α_1-acid glycoprotein, such as propranolol, have a decreased percentage of drug unbound in malnutrition, resulting in a lesser amount of active drug available to exert a therapeutic response. Other drugs, such as metronidazole, have no significant change in volume of distribution between malnourished and well-fed children.[44]

Metabolism

In chronic starvation, the body is able to adapt and various processes are altered to protect or maintain enzyme activities.[45] In fact, in chronic starvation, enzyme activity may even increase.[46] Endocrine tissue is typically affected in semistarvation as many hormones serve as substrates for drug-metabolizing enzymes.[47] For example, elevations in free cortisol are often seen in malnutrition that may enhance the metabolism of contraceptive steroids in malnourished women, thus increasing the risk of contraceptive failure in that population.[48]

Clearance

Hepatic clearance of drugs may be affected by several major physiologic changes that occur during malnutrition. Protein deprivation or malnutrition may result in a reduction in heart size with a subsequent decreased perfusion of the liver and kidneys.[49] Typically, hepatic drug clearance is determined by three independent factors: hepatic blood flow, the amount of free fraction of the drug in blood, and hepatic clearance of the unbound drug. Diminished hepatic blood flow can reduce the clearance of drugs with high extraction ratios (ie, those in which hepatic clearance of the unbound drug depends on hepatic blood flow but not on changes in protein binding). Presystemic metabolism can become altered. Increases in the unbound fraction of a drug owing to hypoalbuminemia provide more available drug for metabolism, resulting in lower serum concentrations.[49]

The kidney is extensively involved in drug elimination.[50] Renal elimination includes the processes of glomerular filtration, active tubular secretion, and passive tubular excretion. Drugs or their metabolites that are primarily filtered and excreted renally may be affected by nutritional status. Dietary protein increases renal blood flow, GFR, and renal tubular function.[51] Severe PEM is associated with decreased GFR and renal blood flow.[52] When renal perfusion is reduced, less drug is available to be filtered by the tubules. However, because plasma protein binding is also reduced, more free drug becomes available for renal excretion, thus further reducing plasma drug concentrations.[32] Medications that have decreased renal elimination in severely malnourished patients include penicillins, tetracyclines, cefoxitin, aminoglycosides, and methotrexate.[2,49]

Refeeding an undernourished patient can often increase the systemic clearance of a medication, necessitating a dosage adjustment to maintain efficacy.[53] For example, with theophylline, the volume of distribution decreases and the rate of elimination gradually increases in malnourished patients given a dextrose-based parenteral nutrition solution for at least 2 days.[54] The protein component of enteral or parenteral nutrition, however, appears to be the major macronutrient enhancing systemic clearance of affected drugs in patients transitioned from the "unfed" to the "fed" state. Lares-Asseff and associates confirmed these findings in their study investigating the pharmacokinetics of metronidazole in severely malnourished children.[44,55] Based on the clearance data, they recommended that the

daily maintenance doses for pediatric patients with severe malnutrition should be 60% less of the usual pediatric dose to achieve and maintain a therapeutic plasma concentration of metronidazole.

Drugs in Kwashiorkor

Kwashiorkor is associated with edema resulting from increases in total body water, extracellular fluid volume, and plasma volume along with a decrease in intracellular water.[56] Although the majority of kinetics studies investigating the impact of nutritional status and drug response have occurred in India and other third world countries, there have been several studies investigating the influence of nutritional status and drug response in children of more developed societies.[57,58] Lares-Asseff and colleagues studied the effects of nutritional status of children with autoimmune disease on the disposition of acetylsalicylic acid (ASA) and its metabolites.[57] They concluded that a decrease in the hydrolysis and oxidative reaction of the metabolic pathway of ASA and its metabolites occurs in children with PEM with juvenile rheumatoid arthritis. This suggests that the hepatic elimination of salicylates may be altered by disorders of nutritional state.

Based on these and other studies, it is thought that low protein intake results in a negative nitrogen balance that decreases drug metabolism, whereas drug metabolism in patients receiving adequate total calories but with less than optimal protein intake is not significantly impacted.[55,59]

Drugs in Marasmus

Unlike kwashiorkor, marasmus can be considered as an adaptation to an insufficient energy intake. There is decreased total body water, reduced intracellular water, increased extracellular fluid, and increased plasma volume.[2,32] Gentamicin, which distributes predominantly to extracellular fluids, has an increased volume of distribution in malnourished patients compared with well-nourished patients.[60,61] Antipyrine, a drug model commonly used as an index of hepatic drug-metabolizing capacity, distributes primarily in total body water and has been shown to have no variation in the apparent volume of distribution in malnourished children.[62] Likewise, in patients treated with metronidazole, a medication that also has a large volume of distribution, no difference in volume of distribution was observed between malnourished and nutritionally rehabilitated children.[44] A pharmacokinetic study by Treluyer and colleagues focused on the impact of human global PEM on quinine metabolism.[63] In that study, they reported that the metabolism of quinine is increased in children with global malnutrition, suggesting that the dosing interval in these children be reduced to obtain the same therapeutic quinine levels as seen in well-nourished children.

In summary, normal or increased drug metabolism occurs in mild to moderate cases of malnutrition, whereas decreased metabolism is seen in severe cases of malnutrition.[64] Given the unique needs of the malnourished ill child, special guidelines have been created for the use of antimicrobial agents.[65]

Obesity

Obesity (ie, ≥ 95th percentile for age and sex) results in altered body composition in which there is both an increased proportion and absolute amount of adipose tissue as well as an increase in lean body mass, blood volume, cardiac output, and organ size.[66] Drug distribution depends on body composition and may be altered in obese patients. Absorption of drugs evaluated to date appears to be unchanged owing to obesity.[67] The lipophilicity of a drug determines the extent to which obesity influences the volume of distribution and ultimately whether dosing should be based on actual or adjusted body weight. Highly lipophilic drugs, such as lidocaine, thiopental, phenytoin, verapamil, and most benzodiazepines, have an increased volume of distribution.[66] Modest increases in volume of distribution have also been reported for aminoglycosides, heparin, ibuprofen, methylxanthines, prednisolone, and vancomycin, suggesting that an adjusted body weight rather than actual body weight be used to avoid toxicity.[67]

Although the protein binding of acidic drugs is unchanged, the free fraction of basic drugs may be decreased.[67] Similarly, changes in hepatic drug clearance are variable. Phase 1 reactions and phase I acetylation appear to be unaffected by obesity, but the phase II glucuronidation and sulfonation pathways are enhanced. Obesity may also affect systemic clearance of highly extracted drugs such as aminoglycosides and unmetabolized procainamide.[67] Both glomerular filtration and tubular secretion also appear to be increased.[40] Renal clearance of other drugs, such as digoxin and cimetidine, are relatively unchanged in obesity.[67]

Aminoglycosides are distributed within the extracellular fluid compartment. Early dosing recommendations suggested that initial dosing be based on ideal body weight as it was thought that the drug distributed only into lean body mass. Schwartz and colleagues, however, have since determined that when the volume of distribution is corrected for total body weight, it is significantly smaller when compared with normal-weight subjects.[68] The distribution of aminoglycosides into excess body weight is estimated to be about 40% of that distributed into ideal body tissue. The authors concluded that initial dosing of aminoglycosides in obese patients be determined by adding 40% of the excess weight to the patient's ideal body weight, with subsequent dosage adjustments based on serum drug levels and clinical status.

Example: For a 7-year-old, 41 kg, 135 cm, gentamicin, 2.5 mg/kg/dose intravenously every 8 hours, is ordered:

1. Determine ideal body weight (IBW)[69]:

$$IBW = \frac{ht^2 \times 1.65}{1{,}000} \quad \text{IBW is in kg, height is in cm}$$

$$IBW = \frac{135^2 \times 1.65}{1{,}000} \quad IBW = 30 \text{ kg}$$

2. Determine dosing weight (DW):

   DW = IBW + (ABW – IBW) × 0.4

   DW is in kg, ABW is actual body weight in kg

   DW = 30 kg + (41 – 30) × 0.4

   DW = 34.4 kg

3. Calculate gentamicin dose using dosing weight:

   mg/kg/dose × DW = dose in mg

   2.5 mg/kg/dose × 34.4 kg = 86 mg intravenously every 8 hours

A similar controversy exists for optimizing theophylline dosing in obese patients and whether actual or ideal body weight should be used to calculate the initial theophylline-loading dose. This is attributable to conflicting data suggesting that variations in distribution volume may be the result of differences in the degrees of obesity within study populations.[70] Visram and colleagues suggested that the differences in theophylline volume of distribution based on ideal body weight and actual body weight increases as the degree of obesity increases.[70] They recommended that theophylline dosing in patients with mild to moderate obesity be based on actual body weight but that ideal body weight be used when initiating therapy in severely or morbidly obese patients.

Hepatic drug metabolism may also be altered in patients with nonalcoholic steatohepatitis,[44] including enhanced glucuronidation and sulfonation, causing a faster drug excretion compared with normal-weight subjects.[67] Patients with fatty liver may also be more susceptible to the toxic effects of drugs owing to impaired metabolism.[71]

Effect of Dietary Manipulation on Drug Kinetics

Several dietary factors can alter the rate of drug metabolism. Model drugs, such as antipyrine, theophylline, and acetaminophen, have often been used in these studies. Both food and fluids can alter the rate and extent of drug absorption. These alternations in response may occur as a result of influences on gastric pH, gastric emptying time, intestinal motility, and mesenteric and hepatic portal blood flow or biliary flow.[72] Direct physicochemical interactions with dietary components can also alter the absorption of susceptible agents.[73,74] Interactions such as the binding of the medication with metal ions, solubilization of the drug in dietary fat, or adsorption of the drug to insoluble dietary components may occur.[75]

Dietary changes can alter the expression and activity of hepatic drug-metabolizing enzymes.[76] This can lead to alteration in the systemic elimination kinetics of medications metabolized by these enzymes, although the impact of this change is typically minimal.[76–78] The rate of drug metabolism can be accelerated by drugs themselves or by a variety of dietary factors, such as protein supplementation or inclusion of cruciferous vegetables or charcoal-broiled meats in the diet.[79] It has also been reported that charcoal-broiled beef induces the metabolism of antipyrine and theophylline, reducing the half-lives of these drugs by 20%.[80] It has been postulated that these effects were related to the fact that charcoal-broiled beef contains large quantities of polycyclic aromatic hydrocarbons (PAHs).[81] PAHs are potent inducers of CYP1A2, the primary metabolizing enzyme for theophylline and antipyrine. Conversely, low-protein, high-carbohydrate diets and various vitamin and mineral deficiencies can reduce levels of drug-metabolizing enzymes and consequently the rate of drug metabolism so that the serum drug concentrations decline much more slowly, resulting in increased drug potency.[79]

In general, when orally administered medications are taken with meals, the rate rather than the extent of gastrointestinal absorption is delayed. Food affects drug absorption by enhancing gastric blood flow in conjunction with delayed gastric emptying. Food can increase, decrease, or have no effect on the absolute systemic availability of a medication.[82] Concomitant food ingestion reduces the absorption of drugs such as ampicillin, penicillin, and isoniazid.[2] Conversely, food may actually enhance the absorption of other medications, including diazepam, lithium, carbamazepine, and griseofulvin. Table 14-1 lists medications whose absorption is altered by food.

The composition of the meal will alter splanchnic blood flow. Blood flow can be doubled by a high-protein liquid meal and slightly reduced by a liquid glucose meal.[83] The significance of this effect on splanchnic flow is important for those medications with high hepatic extraction.[75] Food will also slow the rate of gastric emptying, which results in a delay in drug absorption from the gastrointestinal tract. Changes in gastric emptying are related not only to the physicochemical properties of the drug but also to the type of meal itself. Hot meals, highly viscous solutions, or those rich in fat can delay emptying.[75]

Melander and colleagues reviewed the impact of food on the presystemic clearance of drugs.[84] They observed that meals commonly enhanced presystemic clearance of lipophilic basic drugs (eg, propranolol, amiptriptyline) but rarely altered the clearance of drugs that were lipophilic acids (eg, salicylic acid, penicillin). Alternatively, food may reduce presystemic clearance of some lipophilic basic drugs via transient, complex effects on splanchnic-hepatic blood flow. Furthermore, repeated intake of specific nutrients (eg, protein) and food contaminants (eg, benzopyrene) can enhance presystemic drug clearance by enzyme induction.

In some instances, dietary manipulation can act as a therapeutic strategy. Nutt and colleagues reported evidence that large neutral amino acids and the medication levodopa compete for transport from the plasma to the brain and may be partly responsible for the "on-off" phenomenon often seen in patients treated with levodopa for Parkinson's disease.[85] By reducing protein intake, patients who failed to respond to a dosage adjustment in their levodopa may see clinical improvement.

IMPACT OF SPECIFIC NUTRIENTS ON DRUG KINETICS

Until recently, most practitioners dismissed the possibility that dietary substances could significantly alter medication

TABLE 14-1 Medications Whose Absorption Is Affected by Food

Drug Absorption Reduced/ Delayed by Food	*Drug Absorption Enhanced by Food*
Ampicillin	Atovaquone
Aspirin	Carbamazepine
Atenolol	Chlorothiazide
Azithromycin	Cefuroxime
Captopril	Clofazimine
Cefaclor	Diazepam
Cefixime	Erythromycin estolate
Cephalexin	Erythromycin ethyl succinate
Ciprofloxacin	Ganciclovir
Didanosine	Griseofulvin
Doxycycline	Hydralazine
Dirithromycin	Hydrochlorothiazide
Erythromycin stearate	Itraconazole
Famciclovir	Ketoconazole
Indinavir	Lithium
Isoniazid	Lovastatin
Loratidine	Methylphenidate
Naficillin	Metoprolol
Penicillin G or V	Nelfinavir
Phenobarbital	Nitrofurantoin
Phenytoin	Propanolol
Rifampin	Propoxyphene
Sucralfate	Ritonavir
Tetracycline	Saquinavir
Thioridazine	Spironolactone
Zafirlukast

response by affecting intestinal transporter and metabolizing enzymes. This is based on the commonly believed misconception that the absorption of most drugs is a passive process and that the role of the intestine in drug elimination is minimal.[76] Since the report of the interaction between grapefruit juice and several medications was described, this premise has changed, and the role of the diet on drug performance is being re-evaluated.[86]

Carbohydrates

The impact of carbohydrates on drug metabolism is conflicting. Some suggest that carbohydrates have little impact on drug metabolism.[87] Others, such as Kappas and colleagues, noted that antipyrine and theophylline metabolism decreased in carbohydrate-supplemented diets but increased in the protein-enriched diet, suggesting that carbohydrates and protein have opposite effects on oxidative drug metabolism.[88] Although many medications are often given to children in a sugar syrup, little research has been done on its effect on disposition and action. Animal studies by Sonawane and colleagues suggested that dietary carbohydrates and fat may significantly influence the hepatic drug-metabolizing enzymes.[89] It has been hypothesized that these changes may occur owing to alteration in the phospholipid composition of endoplasmic reticulum or by limiting the supply of cofactor(s) necessary for optimal functioning of CYP and UGT.

Protein

Several investigators have reported that medications that undergo extensive first-pass effect, such as propranolol, metoprolol, and lidocaine, can have enhanced bioavailability after a high-protein meal owing to enhanced hepatic blood flow. High-extraction drugs can then rapidly pass through the liver, allowing higher drug concentrations in the systemic circulation.[76,84,90] A decrease in dietary protein depresses creatinine clearance and renal plasma flow.[91] Dietary protein also affects the renal tubular transport of certain compounds, although the mechanism by which this occurs is still not understood.

Dietary Fat

Lipids are an essential part of cell membrane structure and are involved in many of the normal enzymatic activities located within the cell membrane.[87] Diets that are deficient in fat or essential fatty acids decrease the activity of the enzyme systems responsible for the metabolism of nutrients.[92] Plasma free fatty acid levels become elevated after consumption of a high-fat meal, increasing the potential to become bound to plasma albumin, and subsequently displace albumin bound drugs, increasing the risk of drug toxicity.[87]

The effect of food on the absorption of cyclosporine is controversial. There are conflicting reports stating that food impairs, enhances, or does not affect cyclosporine compared with the fasting state.[93,94]

The antiviral agent zidovudine is also impacted by dietary fat. When orally administered, its absorption is reduced when the drug is taken with a high-fat meal in comparison with when taken in the fasted state.[95] It is recommended that zidovudine be taken on an empty stomach to achieve peak serum concentrations.

Vegetables

Cruciferous vegetables, including brussels sprouts, cabbage, turnips, broccoli, cauliflower, and spinach, contain indols that induce aryl-hydrocarbon hydroxylase enzyme activity as well as the conjugation of phenacetin and acetaminophen.[96,97] In one study, patients fed a diet of brussels sprouts and cabbage had a 50% lower serum phenacetin level in comparison with the same subjects fed a control diet that contained none of the enzyme-inducing vegetables.[97] A later study investigated the effects of cruciferous vegetables on acetaminophen conjugation.[96] The researchers found that the test diet of cruciferous vegetables enhanced acetaminophen glucuronide conjugation as evidenced by a 16% decrease in the area under the curve (AUC), a 17% increase in metabolic clearance, and an increased plasma acetaminophen glucuronide-to-acetaminophen ratio.

Grapefruit Juice and Drug Interactions

Bailey and his colleagues discovered that grapefruit juice, which was used as a taste-masking agent for alcohol, caused a two- to threefold increase in oral absorption of the calcium channel blocker felodipine.[98] This finding has subsequently led to the intensive investigation of grapefruit juice and drug interactions. This interaction is the classic example of drug–nutrient interaction exclusively caused by inhibition of intestinal CYP3A4. Oral absorption pharmacokinetic studies of CYP3A4 substrates, such as

cyclosporine or felodipine, consistently showed that grapefruit juice increased the oral bioavailability of these agents. Interestingly, the plasma half-lives of most of the drugs studied were not affected, suggesting that the clearance or hepatic metabolism of these drugs was unchanged by grapefruit juice. It was later determined that this interaction occurs in the enterocytes but not in the liver. Furthermore, Lown and his colleagues showed that repeated consumption of grapefruit juice inhibits not only the intestinal CYP3A4 activity but also the expression of this gene in the enterocytes.[12] As grapefruit juice inhibits intestinal CYP3A4 expression and thus decreases the presystemic metabolism of certain drugs, the bioavailability of the affected agents will remain increased until the expression of the *CYP3A4* gene returns to baseline. This suggests that mere separation of the administration time between grapefruit juice and the potential interacting drugs cannot prevent this interaction. Rather than dose-reduce the affected drugs to avoid toxicity, patients should be advised to avoid grapefruit juice. In some centers, grapefruit juice has been removed from the institutional formulary to minimize the risk of this interaction.

High-Fiber Diets

Dietary fiber and other bulk-forming compounds may interfere with the gastrointestinal absorption of a medication.[99] The bioavailability of digoxin is reduced significantly when given with a fiber-rich meal, with almost half of the dose sequestered in or bound to the fiber.[100] Similar effects have been reported with lithium salts and lovastatin.[101] Stewart reported that several patients with recurrent major depression who had been successfully treated with tricyclic antidepressants became refractory to treatment after beginning a high-fiber diet.[102] Nutrient absorption can also be negatively impacted in the presence of a high-fiber diet. Zinc absorption in the intestine is reduced by the binding of zinc to a number of materials, including phytate, which is found in high fiber diets.[103]

Vegetarianism

Drug metabolism among vegetarians will vary dramatically depending on the protein intake. Most research has focused on Asian vegetarians in which the half-lives of drugs that underwent significant hepatic metabolism (antipyrine, acetaminophen, phenacetin) were significantly longer than in nonvegetarians.[104,105] When similar studies were conducted in white vegetarians, they found no significant difference in half-life between the vegetarians and nonvegetarians.[106] Moreover, the authors found that protein intake between the white vegetarians and the nonvegetarians was similar, which might account for these findings.

Parenteral Nutrition

Lack of oral nutrient intake during parenteral nutrition leads to mucosal atrophy of the bowel along with a reduction in gastric biliary, pancreatic, and intestinal secretions.[50] Bacterial overgrowth can result in a progressive decline in intestinal function owing to impaired motility and depressed enzyme activity. This may alter the rate and extent of absorption of specific nutrients as well as various drugs. Decreases in nutrient absorption include fat, iron, peptides, and vitamins A and B_{12} as well as drugs such as chloramphenicol, chloroquine, tetracycline, and rifampin.[49]

Studies using antipyrine as a marker have shown that parenteral nutrition regimens containing amino acids have higher antipyrine clearance than regimens consisting mainly of dextrose.[107] Burgess and colleagues investigated the response of total parenteral nutrition (TPN) regimens on antipyrine clearance.[108] Patients receiving a postoperative 2,000 kcal TPN regimen providing all nonprotein calories as dextrose showed a 34% reduction of mean antipyrine clearance after 7 days of TPN compared with controls. In patients receiving a 2,000 kcal TPN regimen in which 500 kcal were provided as lipid, mean antipyrine clearance was not significantly different from that of the control group. This study suggested that hepatic CYP1A activity may be affected by different TPN regimens.

Effects of Drugs on Nutrient Status

Drugs can alter the use of many nutrients by a variety of mechanisms, both specific and nonspecific.[53] Malabsorption syndromes may occur from direct toxic effects of the medication to the intestinal mucosa, inhibition of enzymes, binding of bile and fatty acids, alteration of dietary ions, or alteration of gastrointestinal pH. Indirect, nonspecific effects of a drug may manifest themselves as a decrease in appetite, ultimately leading to a decrease in food intake.

Although the concept of drug–nutrient interactions is not a new one, only recently has it reached the forefront in the medical world. Malnutrition, as well as the composition of the diet, can affect the disposition of a medication's half-life.[109] In addition to traditional dietary components, nonnutrient ingredients, such as food additives, preservatives, antioxidants, sweeteners, flavoring, and coloring agents, can interact with a medication. Natural products, such as plant food groups, contain alkaloids, flavonoids, and other compounds; can behave in the body in the same manner that a drug would; and, consequently, can be involved in a variety of interactions and are potentially toxic if they are consumed or accumulate in the body.[110] Drug–nutrient interactions are typically defined as situations that result from chemical, physical, physiologic, or pathophysiologic relationships between nutrients and drugs.[111]

Infants and adolescents, like the elderly, are at particular risk for drug–nutrient interactions. Several factors may influence the possible interactions: first, their nutrient needs are typically higher; second, the systems for detoxification of nutrients may be incomplete; and third, adolescents (especially females) tend to restrict their diets and thus are unable to meet the actual recommended intakes for a variety of micronutrients.[112] Furthermore, the minimum dietary requirement may be insufficient when a patient is under psychological and pathologic stresses, as in the case of pregnancy or athletic training. In pathologic states, the requirement for some micronutrients may be increased.

Drugs may potentially cause vitamin deficiency ranging from subclinical deficiency to clinical manifestation. The

intensity of the interaction may in many cases depend on the nutritional status of the patient. Patients with borderline intake of vitamins or those in poor nutritional health appear to be at greater risk of developing symptomatic vitamin deficiency states. Other factors include the type of drug treatment, dose, and duration of therapy, as well as the age of the patient.[112] For example, individuals on a normal diet rarely become vitamin K deficient, although malnourished patients, regardless of cause, often have moderate or significant deficiency, often with prolonged bleeding times.[113] Cohen and colleagues reported that hospitalized patients may become vitamin K deficient within 7 to 10 days after admission, with those at greatest risk being those who were previously malnourished and had received antibiotics for 7 or more days.[114]

Absorption of Nutrients

There are also many secondary mechanisms that can interfere with nutrient absorption. Medications may alter gastric or intestinal secretion, pancreatic exocrine function, or hepatic bile secretion. For example, H_2 antagonists and proton pump inhibitors inhibit gastric acid production. Chronic use of these medications can significantly decrease the absorption of vitamin B_{12}.[115]

The direct systemic effect of a drug on one nutrient may have secondary effects on another nutrient. Isoniazid and cimetidine inhibit the hydroxylation of vitamin D in the liver and kidney, and phenytoin and phenobarbital promote the breakdown of vitamin D metabolites, each resulting in a functional deficiency of vitamin D and secondary impairment of calcium absorption.[116] Neomycin, colchicine, and para-aminosalicylic acid may damage intestinal mucosa and destroy intestinal villi and microvilli, resulting in an inhibition of brush border enzymes and intestinal transport systems.[117] Nonsteroidal anti-inflammatory agents can cause multiple small hemorrhages of the intestinal mucosa leading to iron deficiency anemia and decreased absorption of vitamin C.[118] Folic acid deficiency and macrocytic anemia can occur in patients on chronic aspirin therapy, especially if their diet is low in dietary sources of folate.[119]

Laxative abuse has also been implicated with malabsorption of vitamin D and calcium. Use of irritant laxatives, such as phenolphthalein and bisacodyl, may damage intestinal epithelial cells and impair colonic reabsorption, resulting in steatorrhea, protein-losing enteropathy, and decreased absorption of glucose, potassium, calcium, and vitamin D.[120] Other stool regimen medications, such as docusate, alter electrolyte transport and can cause hypomagnesemia owing to gastrointestinal losses and failure of colonic reabsorption.[121] Orally ingested mineral oil can coat ingested food particles along with the surface of the intestines. This forms a mechanical barrier to the digestion and absorption of nutrients. Mineral oil also increases gastric motility, which reduces the time required to adequately absorb ingested nutrients.[122] Furthermore, studies have shown that mineral oil, especially when taken at mealtime or during the postprandial absorptive period of optimal nutrient absorption, can reduce the absorption of vitamin D.[122]

Alterations in vitamin and mineral absorption can also occur owing to chelation or precipitation with a medication. Cholestyramine, a basic anion-exchange resin, binds bile salts and impairs the absorption of fat-soluble vitamins, vitamin B_{12}, folic acid, and the minerals calcium, iron, and zinc.[123] Aluminum- and magnesium hydroxide–containing antacids may form nonabsorbable phosphate in the gut lumen, resulting in hypophosphatemia along with anorexia and secondary syndromes of hypomagnesemia and osteomalacia.[116]

Alteration in gastrointestinal pH may also cause drug-induced malabsorption. Drugs that increase gastric pH (eg, H_2 antagonists) can also decrease the breakdown of fat necessary to complex with calcium, thus reducing gut absorption.[124,125] Antacids can also reduce the bioavailability of riboflavin and folic acid as well as copper and iron, all of which depend on a low pH.[126]

Metabolism of Nutrients

Drugs may affect nutrient metabolism by several methods. They may inhibit the essential intermediary metabolism of a nutrient, usually a vitamin, or promote the catabolism of the nutrient. Medications with these properties may be used therapeutically, as in the case of coumarin anticoagulants or methotrexate.[127] In other cases, this may be an unwanted side effect, as in the case of pyridoxine antagonism seen in isoniazid and hydralazine use. Isoniazid and hydralazine can result in pyridoxine deficiency by the inhibition of pyridoxal kinase. Both compounds deplete pyridoxine stores and consequently the neurotransmitter γ-aminobutyric acid, resulting in seizures. Administration of pyridoxine in cases of isoniazid overdose eliminates seizures and metabolic acidosis, which often occur.[128]

Many medications induce drug metabolism enzymes. This results in greater activity of these enzymes, increasing the demand for their vitamin cofactor, and, with chronic drug therapy and marginal nutrient intakes, can precipitate signs of deficiency of several vitamins, especially folic acid. Triamterene can inhibit dihydrofolate reductase, resulting in megaloblastosis.[129] The 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitor class of antihyperlipidemic agents (ie, statins) can lower plasma concentration of endogenous ubiquinone (coenzyme Q), a cellular antioxidant.[130]

Patients receiving chronic anticonvulsant therapy are at particular risk of developing metabolic bone disease as a result of these types of reactions.[131] Several mechanisms have been suggested. One suggests that drugs such as phenytoin, a microsomal enzyme inducer, stimulate the catabolism of vitamin D to produce an inactive metabolite.[132] Another theory suggests that phenytoin, alone or in combination with phenobarbital, interferes with vitamin K metabolism, with a corresponding elevation in serum osteocalcin levels without α-carboxyglutamate (Gla) residues, resulting in metabolic bone disease because osteocalcin-containing Gla residue is necessary for normal bone mineralization.[133]

Patients treated with cephalosporin antibiotics may develop hemorrhagic states owing to drug-induced vitamin

K deficiency.[134,135] It is thought that these antibiotics block the vitamin K reductase, which is necessary for vitamin K activation.[136] They may also block carboxylation of vitamin K–dependent peptides to yield Gla residues that are required for calcium binding in the conversion of vitamin K–dependent proenzymes to their active state, which are needed in the coagulation cascade.[136]

Some drugs have been linked with subnormal serum folate levels, probably owing to weakly bound folate to serum proteins that can be easily displaced by drugs.[137] The mechanism for this interaction has yet to be described, but it appears that there is a decrease in serum binding of methyltetrahydrofolate caused by the drug itself or one of its metabolites.[138]

Folate deficiency secondary to long-term phenytoin therapy is a common occurrence; approximately 75% of patients taking anticonvulsants have low serum folic acid levels.[139] Progression to megaloblastic anemia is relatively rare, however.[140] Supplementation of folic acid with as little as 1 mg per day may lead to a significant decrease in serum phenytoin concentrations in 15 to 50% of the patients.[122] Although the exact mechanism is unknown, pharmacokinetic analysis of phenytoin suggests that folic acid may increase the affinity of the metabolic enzyme(s) involved in the elimination of the phenytoin without causing overall enzymatic induction.[141,142] To avoid potential folate deficiency and subsequent fluctuations in serum phenytoin levels, practitioners should routinely supplement all patients with folate when phenytoin therapy is initiated.[141]

Like phenytoin, sulfasalazine, an anti-inflammatory agent used to treat Crohn's disease and juvenile rheumatoid arthritis, is one of the leading causes of drug-induced folic acid deficiency in children.[142,143] Megaloblastic anemia, caused by folate deficiency, has been reported in patients receiving high doses of sulfasalazine for prolonged periods.[144]

Aspirin has also been linked with folate deficiency. Serum folate levels are known to be low in many patients with rheumatoid arthritis.[112] It is thought that aspirin alters the transport of folate by competing for binding sites on serum proteins.

Methotrexate, a chemotherapeutic agent that is also used to treat psoriasis, rheumatoid arthritis, and Crohn's disease, limits the availability of methyl groups derived from one-carbon metabolism by inhibiting competitively a key enzyme in the intracellular folate metabolism.[112] Methotrexate functions as an antimetabolite, reversibly inhibiting dihydrofolate reductase.[145]

Valproic acid (VPA), an antiepileptic agent, has been associated with folate deficiency. Like other agents, the mechanism is not fully understood, although it is thought that VPA causes an alteration in the methionine cycle.[146] This results in an elevation of tetrahydrofolate levels and a reduction of both formulated forms of folate. This could also explain VPA's role as a teratogen.[147] In addition, it has been established that VPA may induce L-carnitine deficiency. Patients who develop VPA-induced carnitine deficiency typically experience hyperammonemia syndrome with no other abnormality in the liver function tests. If diagnosed early, the clinical presentation, which includes altered mental status or encephalopathy, can be reversed by L-carnitine supplementation.[148]

Drug Effects on Nutrient Transport

There are several mechanisms by which a drug can impact nutrient transport and then lead to nutritional deficiency. A nutrient can become displaced from plasma protein binding sites by a medication, leading to an increase in the renal excretion of the nutrient, or a drug may compete with a nutrient such that intracellular use of the nutrient is impaired.[149] This may occur when folate stores become depleted in patients receiving therapeutic doses of aspirin.[149]

Excretion

Thiamin deficiency can occur in patients treated with chronic loop diuretic therapy. Seligmann and colleagues reported that patients with congestive heart failure treated with long-term furosemide therapy had increased urinary excretion of thiamin, leading to frank deficiency over time that may have contributed to poor cardiac performance.[150] Similar findings were reported by Brady and colleagues, who observed laboratory evidence of thiamin deficiency in congestive heart failure patients being treated with loop diuretics on a chronic basis.[151]

Drug-Induced Fluid and Electrolyte Imbalance

Several widely used medications can affect electrolyte balance, as summarized in Table 14-2. Sodium balance is altered by thiazide diuretics and the neuroleptic carbamazepine.[152,153] Patients treated long term with carbamazepine have been reported to develop the syndrome of inappropriate antidiuretic hormone (SIADH), resulting in hyponatremia and water retention.[153] In those patients, hyponatremia develops owing to the enhanced renal conservation of water. Similarly, patients receiving excessive diuretic therapy with fluid loss replaced with excessive water are prone to developing SIADH.[53] Conversely, certain medications can cause hypernatremia as a result of water loss and subsequent dehydration. Hypernatremia, secondary to excessive lactulose therapy for hepatic encephalopathy or constipation, is a common drug-induced cause of this disorder.[154]

Renal wasting of potassium, resulting in hypokalemia, has been associated with thiazide and loop diuretics, corticosteroids, amphotericin B, and antipseudomonal penicillins.[53] Insulin and inhaled β_2-agonists (eg, albuterol) can cause a shift of potassium from the extracellular to the intracellular spaces.

Potassium-sparing diuretics (eg, spironolactone), angiotensin-converting enzyme inhibitors (eg, enalapril), heparin, and trimethoprim can cause hyperkalemia.[155] A variety of mechanisms are involved. Trimethoprim has weak diuretic properties with potassium-sparing activity.[156] Heparin can suppress aldosterone, leading to sodium wasting and potassium retention. Patients with renal insufficiency or diabetes mellitus appear to be more susceptible to heparin-induced hyperkalemia.[157]

The impact of medications on phosphorus balance is important in patients receiving nutritional support as the

TABLE 14-2 Examples of Drug–Nutrient Interactions

Medication/Drug Class	*Nutrient*	*Interaction*
Albuterol	Glucose	Hyperglycemia (in diabetics)
Aminocaproic acid	Potassium	May cause hyperkalemia
Amitriptyline	Sodium	May cause hyponatremia
Amphotericin	Magnesium, potassium, sodium	Electrolyte wasting
Aspirin	Folic acid	Decreased serum folate levels
Calcium carbonate	Iron	Decreased iron absorption
Captopril	Potassium, sodium	May cause hyperkalemia, hyponatremia
Carbamazepine	Sodium	May cause hyponatremia
Chloramphenicol	Protein, riboflavin, vitamin B_6, vitamin B_{12}	Decreased protein synthesis
Cholestyramine	Fat-soluble vitamins	Decreased absorption of fat soluble vitamins
Cimetidine	Vitamin B_{12}	Depletion of B_{12} stores
Cisplatin	Magnesium	Magnesium depletion
Corticosteroids	Glucose	Hyperglycemia
Cyclophosphamide	Sodium	May cause hyponatremia
Digoxin	Bran fiber, calcium, magnesium, potassium	Decreased drug absorption, arrhythmias, hypomagnesemia or hypokalemia may enhance toxic effects of digoxin; arrhythmias
Fluorouracil	Thiamin	Inhibits conversion of thiamin to thiamin pyrophosphatase; increased thiamin requirements
Furosemide	Calcium, magnesium, potassium, sodium	Electrolyte depletion
Gentamicin	Magnesium	May cause hypomagnesemia
Insulin	Dextrose	Increased insulin requirements
Isoniazid	Potassium, pyridoxine, tyrosine-rich foods, histamine-rich foods, tyramine-rich foods	Hyperkalemia; vitamin B_6 antagonism; blocks conversion of tyrosine to niacin; may cause headaches, itching, redness, chills, hypotension; isoniazid has some monoamine oxidase inhibitor activity; tyramine-rich foods may cause hypertensive crisis
Lithium	Sodium, magnesium	Increased sodium intake, decreased lithium effectiveness, decreased sodium intake may increase lithium toxicity, may cause hypermagnesemia
Methotrexate	Folic acid	Methotrexate may cause folate deficiency, folate supplementation may decrease methotrexate effects
Mineral oil	Fat-soluble vitamins	Decreased absorption of fat-soluble vitamins with chronic use
Neomycin	Fat-soluble vitamins, medium chain triglycerides, vitamin B_{12}, sodium, glucose, lactose, sucrose, xylose	Impaired absorption
Nonsteroidal anti-inflammatory agents	Potassium	Hyperkalemia in patients with renal disease or receiving potassium supplements or potassium-sparing diuretics
Orlistat	Vitamin E	Reduced vitamin E absorption
Oral contraceptives	Ascorbic acid, folic acid, pyridoxine	Ascorbic acid, folic acid, and vitamin B_6 requirements increased
Para-aminosalicylic acid	Vitamin B_{12}, folate, calcium, iron, magnesium	Decreased absorption of B_{12}, folate, calcium, iron, magnesium
Penicillamine	Acidic foods/beverages	Decreased penicillamine absorption/inactivation
Penicillin	Acidic foods/beverages	Penicillin inactivation
Phenobarbital	Ascorbic acid, vitamin D	Decreases ascorbic acid absorption; interferes with vitamin D metabolism
Phenytoin	Folic acid, pyridoxine, vitamin D	High-dose folic acid may antagonize phenytoin effects; phenytoin may cause folate deficiency, resulting in megaloblastic anemia; may antagonize phenytoin; interferes with vitamin D metabolism
Primidone	Folic acid	May cause folic acid deficiency, leading to megaloblastic anemia
Pyrimethamine	Folic acid	Decreased serum folate levels
Spironolactone	Sodium, potassium	May cause hyponatremia, may cause hyperkalemia
Succinylcholine	Potassium	May cause hyperkalemia
Sulfasalazine	Folic acid	Inhibits the absorption of folic acid
Terbutaline	Glucose	Hyperglycemia (in diabetics)
Theophylline	Caffeine, carbohydrates, charcoal-broiled meat, protein	Increases theophylline side effects; decreased carbohydrate intake may decrease plasma half-life of theophylline; charcoal-broiled meat may decrease theophylline half-life; increased protein intake may decrease plasma half-life of theophylline
Thiazide diuretics	Magnesium, potassium, sodium	Increased wasting
Triamterene	Folic acid	May cause folic acid depletion
Trimethoprim	Folic acid	May cause folic acid depletion
Valproic acid	Carnitine	May cause carnitine deficiency with hyperammonemia
Warfarin	Vitamin K, onions, garlic, vitamin E	May inhibit warfarin response; increased dose needed; excessive amounts may increase the fibrinolytic activity of warfarin; may enhance anticoagulant effect of warfarin
Zidovudine	Carnitine, folic acid	May cause carnitine deficiency; may cause megaloblastic anemia

synthesis of new cells increases the need for phosphorus. Patients already at risk for refeeding syndrome are particularly susceptible to the effects of drugs known to decrease available phosphorus stores.[158] Drugs such as antacids and sulcralfate can alter the absorption of phosphorus from the gastrointestinal tract by binding to dietary phosphate, thus preventing its absorption. Conversely, patients with renal dysfunction are at risk for development of hyperphosphatemia owing to the inherent phosphate content present in the phospholipid emulsifiers in intravenous fat emulsion or clindamycin phosphate injection.[159]

As previously discussed, medications such as isoniazid and cimetidine can inhibit the hepatic and/or renal hydroxylation of vitamin D, leading to impaired calcium absorption.[160,161] Odes and colleagues concluded that even short-term therapy with cimetidine altered vitamin D metabolism in humans.[161] The researchers came to this conclusion after studying 25-hydroxyvitamin D_3 levels for 30 days in patients treated with cimetidine.

Chronic corticosteroid use can cause a net negative calcium balance and increased bone resorption owing to suppressed intestinal absorption of calcium in conjunction with increased renal calcium and phosphate excretion and a subsequent decrease in renal tubular calcium resorption, resulting in bone osteopenia.[116,162,163] Even frequent use of inhaled steroids has been associated with this response.[164]

Hypomagnesemia as a result of renal wasting can occur in patients treated with loop diuretics, thiazide diuretics, amphotericin B, aminoglycosides, cisplatin, or cyclosporine. Cisplatin-induced hypomagnesemia is dose and duration dependent.[165,166] Cisplatin induces hypomagnesemia by reducing magnesium reabsorption in the ascending loop of Henle and the distal tubule.[167] Forastiere and colleagues reported that the total exposure of free platinum contributes to direct injury and renal toxicity.[168] Carboplatin, an antineoplastic with a chemical structure similar to cisplatin, has been reported to have a lower incidence of hypomagnesemia.[169,170]

Renal wasting of magnesium is also common in patients on prolonged courses of high doses of aminoglycosides.[116,171] Aminoglycosides can inhibit the proximal tubular transport of magnesium in the kidney, predisposing patients with already low intakes of magnesium to hypomagnesemia.[171]

If left untreated, hypomagnesemia will ultimately lead to hypocalcemia. Magnesium deficiency can induce a transient hypoparathyroidism by reducing the secretion of parathyroid hormone (PTH) and a blunted PTH response. This results in an inhibition of the hypocalcemic feedback loop.[165] Other agents, such as aluminum salts, also suppress PTH secretion, resulting in hypocalcemia. Treatment for hypocalcemia induced by hypomagnesemia involves correcting the hypomagnesemia first and then managing the magnesium losses. In some cases, calcium supplementation may be unnecessary.[165]

Trace Elements

Zinc is essential for the function of hundreds of enzymes such as dehydrogenases, aldolases, and peptidases and is involved in a variety of metabolic processes.[172] The formation and activation of zinc-dependent enzymes are regulated by zinc tissue levels.[173] Zinc metalloenzymes are responsible for structural integrity at the cellular level and for the regulation of various aspects of ribonucleic acid (RNA) and DNA metabolism.[173] Zinc deficiency limits the activity of these enzymes, resulting in decreased cell replication and tissue growth and repair.

Zinc does interact with other nutrients. At supplemental doses, zinc may impair copper absorption.[174] Zinc deficiency can also negatively impact vitamin A metabolism by impairing the mobilization of retinol from the liver and altering retinal visual pigment metabolism, which may contribute to the night blindness seen in zinc deficiency.[175] It is thought that zinc deficiency may result in abnormal dark adaptation and/or age-related macular degeneration.[176]

Patients receiving parenteral nutrition are at risk for developing zinc deficiency. Zinc balance during parenteral nutrition depends on the infusion of zinc in amounts sufficient to offset urinary and gastrointestinal losses that occur independent of zinc intake.[172] Premature infants receiving parenteral nutrition will experience a progressive decline in plasma zinc levels despite 14 days of continuous treatment, reflecting their high metabolic demands.[177]

Glucose

Patients with diabetes mellitus or others with insulin resistance (eg, severe infections, catabolic stress) are susceptible to the effects of medications known to impact glucose metabolism. Thiazide diuretics, corticosteroids, and cyclosporine have all been associated with inducing hyperglycemia in susceptible patients.[178] Hyperglycemia occurs in approximately 20% of patients treated with pentamidine.[179] Moreover, protease inhibitors have been recognized as a cause of hyperglycemia.[180]

The long-acting somatostatin analog octreotide has been shown to inhibit insulin secretion and may result in a transient deterioration in glucose tolerance on initiation of therapy.[181] In most cases, alteration of carbohydrate metabolism does not appear to be a problem.

Hypoglycemia is the most common metabolic abnormality associated with pentamidine therapy.[182] The mechanism responsible for this adverse effect may involve a direct cytolytic effect on pancreatic beta cells, resulting in insulin release and hypoglycemia and a subsequent insulin deficiency owing to loss of beta cell function.[183] Eventually, however, pentamidine-induced pancreatic beta cell damage may lead to insulin deficiency and result in hyperglycemia, although this is considerably less frequent than hypoglycemia.[183]

Drugs or foods that have the ability to induce a rapid release of insulin can increase the risk of hypoglycemia, especially if taken with alcohol.[184] β-Blockers such as propranolol can inhibit glycogenolysis and, during periods of vigorous exercise, induce hypoglycemia.[184]

Fat

With increased awareness of lipid abnormalities and coronary artery disease, drug-induced liprotein abnormalities

must be considered, especially in patients in whom no other causes of dyslipidemia exist. Some of the most common causes of secondary dyslipidemia are medications. When a drug is used for a short period only, practitioners need to be aware of the effects on the patient's lipoprotein profile versus the chance that an underlying dyslipidemia has been exacerbated. Drugs used chronically may be more problematic as they may predispose the patient to atherosclerosis.[185] Table 14-3 lists medications associated with dyslipidemia.

Protease inhibitors interfere with some proteins involved in fat metabolism (ie, cytoplasmic retinoic acid–binding protein type 1).[186] Protease-inhibitor binding to low-density lipoprotein (LDL) receptor–related proteins (LRPs) impair hepatic chylomicron uptake and triglyceride clearance by the endothelial LRP-lipoprotein lipase complex. The resulting hyperlipidemia contributes to central fat deposition and insulin resistance.[186] It is also thought that protease inhibitors may also disrupt steroid hormone production, leading to lipodystrophy.[187] See Chapter 38 for a full discussion of human immunodeficiency virus (HIV) lipodystrophy.

L-Asparaginase has been reported to cause abnormalities in lipid metabolism, ranging from hypocholesterolemia and hypotriglyceridemia to hypercholesterolemia and hypertriglyceridemia. Parsons and colleagues suggested that this alteration in lipid metabolism is caused by structural changes in the high-density lipoprotein (HDL) particles from high density to lower density that is reflected in an altered ratio of lipid to protein.[188] The authors suggested that prior to the initiation of L-asparaginase therapy, HDL-cholesterol particles are protein rich but gradually become lipid rich because of an asparaginase-associated reduction in protein synthesis. They also concluded that modifications in asparaginase therapy are not necessary, although close monitoring is recommended for patients whose triglyceride levels exceed 2,000 mg/dL when the risk of pancreatitis is increased.

In addition to asparaginase-associated lipid abnormalities, patients being treated for acute lymphoblastic leukemia often receive corticosteroids that may alter lipid and lipoprotein metabolism by increasing hepatic cholesterol synthesis.[188] Corticosteroids increase the frequency of hypercholesterolemia and hypertriglyceridemia with elevations in LDL and HDL levels, often in a dose-related manner.[185] Females appear to be more susceptible than males to these changes. Switching to alternate-day therapy may reduce lipoprotein levels in some patients.[185]

TABLE 14-3 Medications Associated with Dyslipidemia

Medication	*Total Lipids*	*Total Cholesterol*	*Triglycerides*	*Low-Density Lipoprotein*	*High-Density Lipoprotein*	*Very Low-Density Lipoprotein*
Abacavir			↑

Orally administered estrogens decrease serum LDL and increase serum HDL levels in a dose-related manner.[185] Moreover, these agents are known to increase serum triglyceride levels by 30 to 87%.[185] It has been suggested that low-dose estrogens be used to minimize elevations in triglyceride levels without compromising their favorable impact on LDL and HDL levels.[185] Interestingly, other routes of estrogen administration (topical, intradermal, intramuscular) tend not to have as pronounced an effect on lipoproteins, perhaps because these routes bypass first-pass metabolism through the liver, thus having a smaller impact on hepatic protein synthesis.[185,189] Progestins, often used in combination with estrogens in various oral contraceptive products, can also affect lipoprotein levels. Generally, progestins elevate LDL levels and decrease triglyceride, HDL, and very low-density lipoprotein levels, correlating with the androgenic activity associated with specific progestins.[185] Newer low-dose triphasic oral contraceptives (eg, ethinyl estradiol-levonorgestrel, ethinyl estradiol-norethindrone) do not have any appreciable alterations in lipid profiles or at best mild increases in serum cholesterol, LDL, and triglycerides.[190,191]

Like estrogens, anabolic steroids can also cause profound, dose-related effects on lipoprotein metabolism. Reductions in HDL levels in conjunction with an elevation in LDL levels are often seen in patients using these agents.[185] The exact mechanism has not yet been defined, but caution is advised in using these agents in patients prone to dyslipidemia or atherosclerosis.

Drugs and Appetite

Impairment of nutritional status owing to drug use often results in drug-induced nutritional deficiencies in those cases in which the medication results in appetite suppression and decreased food intake. Often these signs and symptoms of nutrient deficiencies are nonspecific and may mimic those of other diseases and conditions.

Drugs can reduce food intake through a variety of mechanisms. Drugs that affect appetite (Table 14-4) may do so by either a central or peripheral effect, including loss of appetite, inducing sedation, or evoking adverse response when food is ingested.[191] The primary effect typically centers around appetite suppression, a centrally acting mechanism that includes the catecholaminergic (eg, dextroamphetamine), dopaminergic (eg, levodopa), serotoninergic (eg, fenfluramine), and endorphin (eg, naloxone) modulators, which may all act to suppress appetite.[191] Peripherally acting mechanisms that can indirectly suppress appetite include those agents that inhibit gastric emptying (eg, levodopa) or bulking agents (eg, methylcellulose).

A secondary response may also occur when an adverse response to food caused by the drug results in a loss of appetite. The emetic center, located within the brainstem, is easily stimulated by the action of many drugs. These include drugs that cause nausea and vomiting (eg, digoxin-toxic dose), drugs causing a loss of taste (eg, penicillamine), drugs causing stomatitis (eg, fluorouracil), and hepatoxic agents (eg, alcohol).[191,192]

Another way in which medications can cause anorexia is through depletion of various nutrients. High doses of aluminum- or magnesium-containing antacids can result in phosphate depletion, leading to muscle weakness and anorexia.[193] Similarly, loop diuretics can lead to depletion of sodium, potassium, and magnesium, which can result in anorexia.[194] Drugs known to deplete folate, such as phenytoin, sulfasalazine, and trimethoprim, can result in weight loss and anorexia.[195] Penicillamine, which induces zinc depletion, can lead to diminished taste acuity and possibly decreased food intake.[196]

Ironically, even a nutrient can induce anorexia. Belle and Halpern reported that patients taking relatively large doses of niacin for hyperlipidemia experienced gastrointestinal symptoms that resulted in poor appetite and moderate weight loss.[197]

Zinc supplements have been used to treat drug-induced hypogeusia with mixed results. Although zinc supplementation has been used successfully to manage hypogeusia in patients undergoing dialysis, Dahl and colleagues did not see similar findings when patients with acetazolamide-induced taste disturbances were given zinc supplements.[198,199]

Appetite Enhancers

Appetite enhancers are useful in reversing the anorexia of disease, in particular cancer cachexia and HIV wasting. Several medications are frequently used, although none have yet become a standard of therapy.

The appetite-boosting properties of corticosteroids have been well established.[200] Their impact on weight gain seems to be short term, however. Moertel and colleagues suggested that patients treated with dexamethasone saw appetite improvement after 2 weeks of treatment, but the effect disappeared by week 4.[201] Some attribute the improved appetite to the mood-enhancing properties of steroids rather than a specific effect on appetite.[202]

TABLE 14-4 Drugs That Affect Appetite

Drugs That Suppress/ Decrease Appetite	*Drugs That Stimulate Appetite*
Alcohol	Anabolic steroids
Aluminum hydroxide	Benzodiazepines
Amphetamines	Clemastine
Cisplatin	Cyproheptadine HCl
Dactinomycin	Dronabinol
Digoxin	Glucocorticoids
Furosemide	Insulin
Griseofulvin	Megestrol acetate
Hydralazine	Oral contraceptives
Hydroxyurea	Phenothiazines
Methotrexate	Tricyclic antidepressants
Methylcellulose	
Mineral oil	
Penicillamine	
Spironolactone	
Sulfasalazine	
Thiazide diuretics	
Topiramate	

Adapted from Gura KM. Drug-nutrient interactions. In: Hendricks KM, Duggan C, Walker WA, editors. Manual of pediatric nutrition. Hamilton (ON): BC Decker; 2000.

The antihistamine cyproheptadine has become one of the most commonly used appetite stimulants in pediatric patients, particularly those with anorexia nervosa. It is a potent serotonin antagonist. By decreasing brain serotonin levels, appetite is enhanced and food intake is increased, resulting in weight gain.[203]

Megestrol acetate is a drug with antiestrogen properties whose original indication was in the treatment of breast cancer. It was one of the first drugs used to treat HIV wasting. It is a powerful appetite stimulant, and weight gain seen with its use is substantial, although it tends to be mostly fat, with minimal increases in lean body mass.[204] Megestrol also lowers testosterone levels in males, which may explain its minimal increases in lean body mass. Adrenal suppression has also been reported with long-term megestrol use; thus, abrupt discontinuation should be avoided.[205] Megestrol acetate also has been used to stimulate appetite and promote weight gain in a limited number of patients with cachexia associated with neoplastic disease. Although the exact mechanism of action has not been determined, it has been suggested that megestrol and/or its metabolites may, either directly or indirectly, stimulate appetite, resulting in weight gain, or may alter metabolic pathways by interfering with the production or response of mediators such as cachectin, a hormone that inhibits adipocyte lipogenic enzymes.[206]

Dronabinol is a derivative of marijuana that is primarily used in pediatric patients as an antiemetic but has some use in treating anorexia, primarily in HIV wasting.[207] Like megestrol, it can stimulate appetite as well as interest in food. Its effects on mental status, however, limit its usefulness.[208]

Because cytokine effects on appetite can contribute to the anorexia of disease, anticytokine monoclonal antibodies and receptor antagonists may have a role in inhibiting cytokine action.[209] Some agents, such as the corticosteroids, inhibit the transcription of interleukin (IL)-1, tumor necrosis factor (TNF), and other cytokinases. Other agents appear to act by binding a mitogen-activating protein kinase necessary for the translation of messenger RNAs.[209] Fish oil supplements that are rich in omega-3 fatty acids decrease the anorectic effect of IL-1 and TNF.[210,211] Unfortunately, the fishy taste associated with these supplements makes them a less than desirable option.

Appetite Suppressants

Although, for long-term success, weight loss takes a great deal of self-control to resist the many internal and external cues to eat, appetite suppressants can augment weight loss by reducing the hunger drive, thereby assisting the patient to adhere to a restricted caloric diet.[212] The major class of drugs currently in use for the adjunctive treatment is the centrally acting appetite suppressants. This class is further subdivided into those that act on the noradrenergic nervous system and those that act on the serotoninergic nervous system.

Given their high potential for abuse and numerous side effects, the noradrenergic agents (eg, dextroamphetamine) are no longer routinely used in weight loss management unless other therapies have been proven ineffective. These agents block the reuptake of dopamine and norepinephrine from the synapse, thus increasing the amount available in the cerebral cortex and reticular activating system.[212]

The neurotransmitter serotonin is responsible for appetite suppression and satiation. Serotonin, as part of a complex negative feedback loop, accumulates in certain areas of the brain in response to feeding.[212] Fenfluramine, dexfenfluramine, and fluoxetine inhibit serotonin reuptake at presynaptic spaces. They have few central stimulatory effects.

Other agents that have the potential to cause anorexia and may have a potential role in weight loss management are the thermogenic drugs.[213] These include endogenous hormones (ie, insulin, thyroid hormone) and sympathomimetic agents with α- or β-adrenergic properties.[213] Currently, exogenous thyroid has no role in obesity management owing to its adverse effects on protein breakdown, cardiovascular complications, and bone mineralization.[214]

Vitamin Supplementation/Hypervitaminosis

Megavitamin therapy has been advocated in the treatment of various disease states, including schizophrenia, cancer, and the common cold.[215] A megadose is generally considered to be 10 or more times the Recommended Dietary Allowance.[216] Although excess water-soluble vitamins are excreted and usually cause few problems, side effects have been reported in cases of excessively high doses.[217] Dietary supplementation can also impact response to medications. If used carelessly, vitamin and mineral supplementation alone or as part of a fad diet can potentiate or exacerbate nutrient–nutrient interactions, as summarized in Table 14-5. In some cases, this can be beneficial, as noted in Table 14-6.

Drug-metabolizing enzyme systems have been shown to be highly dependent on vitamin C status. Houston and colleagues showed that normal individuals receiving supplemental ascorbic acid had a substantial increase in antipyrine clearance, whereas Beatie and Sherlock reported that vitamin C deficiency was partly responsible for impaired drug clearance in patients with liver disease.[218,219] When ascorbic acid is taken in excessive amounts, enzyme saturation occurs, and the vitamin acts as a chemical and enters into nonenzymatic reactions.[220] Ascorbic acid is a strong reducing agent and is able to impact other dietary components as well as alter drug disposition.[220] Ironically, scurvy, the main deficiency state associated with inadequate dietary intake of ascorbic acid, a relatively rare condition today, can occur in infants born to mothers taking large doses of vitamin C.[220] Both the mother and fetus increase their metabolic destruction of ascorbic acid after maternal ingestion of large doses of ascorbic acid. At birth, any dietary ascorbic acid ingested by the infant is degraded rapidly, leading to a deficiency state. Reports of acute scurvy have been reported in infants breast-fed by mothers who had ingested more than 400 mg vitamin C daily during pregnancy.[221] A similar situation can occur in adults dependent on large doses of vitamin C. Therefore, it is recommended that patients receiving megadoses of vitamin C not be abruptly stopped but rather tapered by 10 to 20% until

TABLE 14-5 Examples of Nutrient–Nutrient Interactions

Nutrient	*Interaction*
Calcium	High calcium intake interferes with phosphorus and iron absorption
Cysteine	May chelate with copper in parenteral nutrition solutions
Magnesium	High magnesium intake may impair calcium absorption, decreases phosphorus absorption
Phosphorus	High intake decreases magnesium absorption
Zinc	High zinc intake may impair copper absorption
Vitamin A	Megadoses may interfere with iron, iodine, copper, calcium absorption; can also interfere with absorption of ascorbic acid, vitamin K, vitamin E, and vitamin D
Vitamin C	Increases iron absorption, impairs copper absorption, interferes with cyanocobalamin absorption
Vitamin D	Reduced intake impairs calcium and phosphorus absorption and utilization
Vitamin E	Inhibits the reticulocyte and hemoglobin response to iron

Adapted from Gura KM. Drug-nutrient interactions. In: Hendricks KM, Duggan C, Walker WA, editors. Manual of pediatric nutrition. Hamilton (ON): BC Decker; 2000.

discontinued or on maintenance doses. Other complications associated with megadoses of ascorbic acid include vitamin B_{12} deficiency. Herbert and Jacob reported that even ascorbic doses as little as 250 mg may destroy up to 81% of cyanocobalamin in a moderate vitamin B_{12}–containing meal and up to 25% in a vitamin B_{12}–rich meal.[222] To blunt the intensity of this interaction, the authors suggested that ascorbic acid be taken 2 or more hours after meals.

Oxalate stones may occur in susceptible patients receiving doses of greater than 4 g/day of ascorbic acid. Auer and colleagues reported that a hematuria and calcium oxalate dihydrate crystal formation in a 25-year-old male 8 days after ingesting 4 g of ascorbic acid daily resolved 5 days after discontinuing ascorbic acid supplementation.[223]

The daily consumption of vitamin B_6 (pyridoxine) in doses of 50 to 500 mg is not unusual given the currently available strengths of over-the-counter products. High doses, however, may have a toxic action on the nervous system.[224] Sensory neuropathies have been reported in adults who received daily doses of 2 g of pyridoxine over a 4-month period or as soon as 2 months when daily doses of 5 g were ingested.

Hypervitaminosis A and D has been described in children, but the occurrence is rare.[225,226] Both are life threatening on an acute basis; vitamin A may cause increased intracranial pressure, whereas vitamin D may cause fatal hypercalcemia. Infants and young children are especially susceptible to excessive doses of vitamin A. Acute toxicity has been reported in infants receiving doses of 50,000 to 100,000 μg (166,666 to 333,333 IU) retinol as palmitate. Individual variation is significant, however. Field studies have used periodic massive doses of vitamin A, with thousands of 1- to 6-year-old children receiving 200,000 IU of retinyl palmitate (60,000 μg retinol), with approximately 1% exhibiting signs of intolerance that disappeared within hours of administration.[227] Chronic toxicity seen in infants and young children usually results from daily doses of 10,000 to 50,000 μg (33,333 to 166,666 IU) for several months.[228] Symptoms gradually disappear on discontinuation. The American Academy of Pediatrics recommends that daily vitamin A supplementation of more than

TABLE 14-6 Examples of Vitamin–Drug Interactions

Nutrient	*Medication*	*Interaction*
Ascorbic acid (vitamin C)	Coumarin anticoagulants, gentamicin, iron salts, oral contraceptives, tricyclic antidepressants	Shortens prothrombin time, may antagonize warfarin response; acidifies urine, decreases efficacy of gentamicin; increased iron absorption; intermittent use may cause contraceptive failure; megadoses (> 2 g/day) may reduce therapeutic response of tricyclic antidepressants
Folic acid	Phenytoin, pyrimethamine	Reduces phenytoin bioavailability, may antagonize anticonvulsant action of phenytoin; reduces pyrimethamine efficacy
Niacin	Adrenergic blockers, aspirin, HMG-CoA reductase inhibitors ("statins"), isoniazid	Enhances vasodilation, may cause orthostatic hypotension; aspirin decreases flushing seen with niacin use; increased risk of statin-associated myopathy/rhabdomyolysis with concurrent use; increased niacin requirement seen with isoniazid use
Pyridoxine (vitamin B_6)	Barbiturates, levodopa, phenytoin	Reduced barbiturate response, reduces levodopa response; megadoses may impair phenytoin effect, cause decrease in phenytoin levels
Vitamin A	Aluminum hydroxide, coumarin anticoagulants, isotretinoin, oral contraceptives	Reduced vitamin A absorption; megadoses of vitamin A can enhance anticoagulant response, increase risk of bleeding; isotretinoin competes with vitamin A; increases serum vitamin A levels
Vitamin D	Digoxin	Vitamin D may cause hypercalcemia, leading to arrhythmias
Vitamin E	Coumarin anticoagulants, vitamin A, iron salts	Potentiates anticoagulant response; increases serum vitamin A levels; inhibits the reticulocyte and hemoglobin response to iron therapy
Vitamin K	Coumarin anticoagulants	Antagonizes anticoagulant response

Adapted from Gura KM. Drug-nutrient interactions. In: Hendricks KM, Duggan C, Walker WA, editors. Manual of pediatric nutrition. Hamilton (ON): BC Decker; 2000.
HMG-CoA = 3-hydroxy-3-methylglutaryl coenzyme A.

3,000 μg (10,000 IU) for young children be used under medical supervision.[229]

In typical doses, vitamin D is used to prevent and treat rickets.[230] Serious poisoning can occur with excessive doses. Sustained daily intake of as little as 1,800 IU in children has been reported as toxic.[231] Excessive vitamin D leads to increased absorption of calcium from the gastrointestinal tract and enhanced bone resorption, with a subsequent loss of renal concentrating ability. Children typically will present with anorexia, vomiting, polyuria, or irritability associated with the increased serum calcium concentrations.[232] It should be noted, however, that very high doses of vitamin D have been effective in some patients with hereditary vitamin D–resistant rickets (HVDRR).[233] HVDRR accompanied by alopecia reflects a more severe form of vitamin D receptor resistance and is rarely responsive to vitamin D. Initial ergocalciferol therapy for children with vitamin D–resistant rickets is 1,000 to 2,000 μg/day (40,000 to 80,000 U) with phosphate supplement. The daily dose is increased at 3- to 4-month intervals in 250 to 500 μg (10,000 to 20,000 U) increments.[234]

In 1992, an outbreak of hypercalcemia owing to vitamin D intoxication was noted. In the case series, eight patients suffered vitamin D toxicity that was traced to excessive amounts of the vitamin in milk produced by a single dairy.[235] These were the first reported cases of hypervitaminosis D from commercial food products in the United States since fortification became commonplace in the 1930s. A second study summarized the findings of an analysis of 42 containers of milk and 10 cans of infant formulas from supermarkets in five states.[236] Nearly two-thirds of the milk container samples had less than 80% of the stated amount, whereas 4 of the 42 samples had over 120% of the labeled vitamin D content. The 10 infant formulas tested had vitamin D levels ranging from 111 IU for every 100 kilocalories to 250 IU per 100 kilocalories, exceeding the maximum permitted by the US Food and Drug Administration (FDA) regulation of 100 IU per 100 kilocalories. FDA-compliant studies on both dairy products and infant formulas compiled over a 10-year period also showed some variance in vitamin D levels but not to the extent that would constitute a health risk.[237]

Vitamin K–rich foods (ie, green leafy vegetables, cabbage, broccoli), when intake is irregular, can alter response to anticoagulants such as warfarin. When ingested in high amounts, these foods can be associated with anticoagulant failure, resulting in the need for higher doses. Similarly, when patients who have been stable on warfarin suddenly decrease their intake of these vitamin K–rich foods, they can put themselves at risk for bleeding because they are suddenly receiving too large a warfarin dose. Warfarin creates a partial deficiency of the active form of vitamin K involved in the post-translational modification factors (II, VII, IX, X, and proteins C and S). [238] Other sources of vitamin K, such as intravenous fat emulsions that are prepared from soybean or safflower and soybean oils, contain phytosterols that contain vitamin K.[239] Warfarin resistance has been reported in patients taking warfarin who also received intravenous fat emulsions.[239] This interaction presumably occurs because of the vitamin K content of the intravenous fat emulsion. Frequent monitoring of the international normalized ratio (INR) and warfarin dosage adjustments are imperative in these patients.

CONCLUSION

The human diet is highly heterogeneous in its composition, method of preparation, quantity, and time of consumption. Consequently, drug kinetics as a result of diet varies widely in subjects based on age, gender, culture, and economic status. Even within the same individual, seasonal variations will occur that impact dietary habits and ultimately drug-related effects. Although each factor may play a small role by itself, a much larger synergistic effect could occur when combined with other dietary factors, as well as genetic and environmental factors.

CHAPTER 15

GENE EXPRESSION

Mona Bajaj-Elliott, BSc, PhD, Ian R. Sanderson, MD, MSc, MRCP

Altering the expression of genes has become a rapidly developing area of research in medicine. The realization that gene expression is important in a wide range of diseases, and not just in inherited disease, has resulted in recognition of the whole field of gene expression as one that may bring new therapeutic options. Although most recent attention has focused on the benefits of altering gene expression by inserting new genetic material into cells by a variety of vectors, the expression of genes can also be altered by other means, most notably by changing the molecular environment that cells inhabit. Using the natural responses of a cell to changes in its surroundings offers a new and amenable way to alter the expression of its genes. Many ways of altering these surroundings can be proposed, but no single act alters the environment of the cells of the body more than the ingestion of food. Thus, the future of nutrition as a therapeutic tool may lie in its potential for influencing gene regulation. This chapter examines this emerging field and outlines some concepts that may prove useful in establishing the scientific basis from which future treatments may develop.

The survival of a child to reproductive age and beyond requires an ability to respond to external demands. Every organ in the body is attuned to this need. Many organ systems have two levels of response to external changes. There is a rapid response, often occurring within seconds of a new stimulus; the contraction of muscle fibers following a neuronal impulse and the breakdown of glycogen by the liver during hypoglycemia are examples of how cells can quickly change. Such responses do not involve changes in gene expression. The cells maintain themselves in a state of readiness by synthesizing proteins whose activity can quickly alter in response to external stimuli. Behind this immediate response, there are other slower, but more lasting, responses that require genetic control. For example, when exercise increases on a regular basis, muscle mass increases, as does the activity of the attendant enzymes that serve the increased metabolic needs. Similarly, regular exposure of the liver to drugs induces the expression of enzymes that catalyze their breakdown.

There are few external stimuli on a child more important than his or her nutritional environment. The metabolic processes underlying the rapid response of cells to nutritional variations have long been documented in humans and other mammals.[1] However, the mechanisms whereby gene expression changes in response to nutritional stimuli is still poorly understood in humans or, indeed, in any multiorgan animal. This is, at first, surprising because in bacteria, the study of nutritional changes led to our understanding of some of the most fundamental mechanisms of gene expression. The elucidation of the induction of proteins that transport and hydrolyze lactose (the lac operon) after adding lactose to bacterial culture media was the first examination of any form of gene regulation.[2] These observations spawned an explosion of research in other regulatory genes in bacteria and in unicellular, eukaryotic organisms such as yeast. The up-regulation of the bacterial genes that handle tryptophan when this amino acid is scarce (the Trp operon) has become another well-understood example of nutrient–gene interaction.[3]

Progress in the study of nutrient–gene interaction in eukaryotic cells has been slower for two main reasons. First, the molecular mechanisms controlling gene expression are more complex than in bacteria, and, second, it is more difficult to identify the metabolites of nutrients that may be responsible for inducing such changes. This review therefore covers some of the recent advances in the study of nutrition and gene expression in the human and, where necessary, in other mammals. Nutritional changes ultimately impinge on most cells in the body; however, it is the epithelium of the gastrointestinal tract that first encounters any variation in nutrient intake. Much of this chapter

therefore concentrates on how nutritional factors can alter the expression of genes in intestinal epithelial cells. The relevance of nutrient–gene interactions to human physiology will also be stressed. Finally, because manipulating nutritional intake may be a way of treating disease in children, the review will discuss nutritional therapy in childhood in the light of its effects on gene expression.

PHYSIOLOGIC IMPORTANCE OF NUTRITIONAL REGULATION IN GENE EXPRESSION

The effect of nutrients on gene expression may have different implications in different individual situations (Table 15-1). First, genes may be up-regulated to better use the supply of a particular nutrient when it is scarce. Transporters of nutrients and the enzymes that metabolize them are examples of proteins that may be induced by nutrients. Second, the expression of genes required for the storage of a particular nutrient may be altered according to that nutrient's abundance. Third, nutrients regulate the secretion of hormones that control the homeostasis of metabolic processes. For example, insulin synthesis increases after increased carbohydrate intake to maintain glucose homeostasis. Finally, food is part of our external environment and, as such, represents a challenge to the cells that come into intimate contact with it. This challenge is met, in the main, by the epithelial cells lining the gastrointestinal tract.[4] The ability of these cells to alter the expression of their genes with changes in food intake is one of the ways by which the intestinal epithelium can dominate the intestinal environment.

Certain fundamental characteristics are found in the mechanisms that underlie each of these different aspects of nutrient–gene interactions. They include a specific interaction between the cell and a particular nutrient (sensing) and a pathway by which such an interaction may translate into alterations in gene expression (signal transduction) (Figure 15-1). We have little understanding of these mechanisms at present. However, some aspects of the molecular biology of these two functions will be examined later in this review.

TABLE 15-1 Physiologic Importance of Nutritional Regulation of Gene Expression

To satisfy the nutritional needs of an organ
Managing storage fuels required by other organs
Production of hormones essential to whole body metabolism
Direct interaction with the body's external environment along the gastrointestinal tract

GENES CONTROLLING THE NUTRITIONAL REQUIREMENTS OF INDIVIDUAL ORGAN SYSTEMS

Survival of cells depends on their ability to extract nutrients and other essential molecules from their surroundings, and they synthesize proteins specifically for this purpose. Broadly speaking, two categories of genes are involved: those genes that express proteins that transport nutrients across cell membranes and those genes that express enzymes that metabolize nutrients. In both cases, genes are regulated purely to satisfy the requirements of an organ system. This form of gene regulation is similar in concept to the regulatory genes of bacteria like the Trp operon.[3] The cells are changing their phenotype to their own advantage rather than to suit the needs of the body as a whole.

A good model of how cells may respond to their nutritional environment for their own needs is the use of glutamine by skeletal muscle.[5] Glutamine availability modulates muscle turnover, and glutamine is an important source of aminonitrogen for muscle cells.[6] Glutamine and glutamate are transported into cells by sodium-coupled transporters. For experimental purposes, rat skeletal muscle can be grown as primary cell cultures. These cells exhibit an up-regulation of the inward transport of both glutamine and glutamate when they are deprived of an exogenous glutamine supply.[7–9] In addition, the activity of glutamine synthetase (GS) simultaneously increases. This enzyme catalyzes the addition of an amino group to the carboxyl moiety of the glutamate molecule to form glutamine. Two different nutrients, glutamine and glutamate, can therefore ultimately satisfy the glutamine requirements of the muscle cell through separate pathways, each of which is under genetic control. This system exemplifies how different nutrients can cross-stimulate the expression of a related set of proteins: removal of glutamine or glutamate from the cell medium results in an enhancement of the transport of both amino acids. Not only does lack of glutamine and glutamate enhance the expression of their own transport proteins, but deprivation of either substrate will also up-regulate the transporter of the other.[8] A study of the

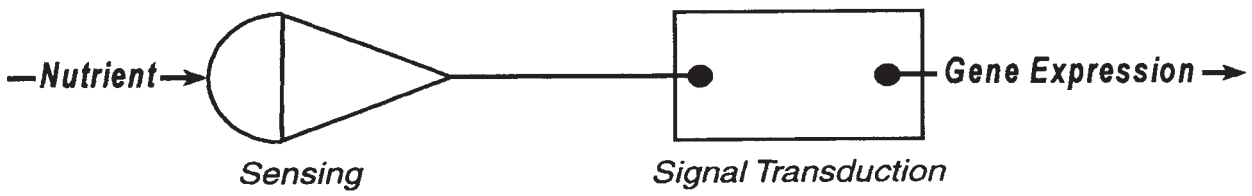

FIGURE 15-1 The regulation of gene expression by nutrients requires two generic mechanisms. First, molecules (either receptors or enzymes) within the cell must recognize the nutrient. Second, this interaction must initiate a sequence of events that ultimately alters the transcription or translation of genes. These functions of sensing and signal transduction have been depicted in this cartoon using electronic symbols.

kinetics of transport demonstrated that withdrawal of glutamine (or glutamate) enhanced the maximum rate at which the amino acid is transported into the cell (the V_{max}) and did not alter the affinity of the transporter for its amino acid.[9] This suggests that deprivation resulted in an increase in the production of the number of transporters available. The time required to double the V_{max} was 4 hours. This fact, taken together with the observation that the induction of both glutamate and glutamine transporters was lost when glutamine was withdrawn in the presence of actinomycin D (inhibitor of ribonucleic [RNA] synthesis), indicates that their regulation is mediated through the initiation of transcription.

In recent years, there has been an explosion in our understanding of the physiology of glutamine transporter systems.[10] At least four distinct families have been identified to date: the Na+-dependent glutamine transporter, system N (SN1), system A (ATA1, ATA2), system ASC/B, and system y (+)L, the latter encoding for Na+-independent glutamine transporter genes.[11,12] Molecular characterization of these systems suggests specific roles in glutamine efflux and uptake[12]; however, the exact mechanism(s) by which transport regulates gene expression remain unclear.

In vivo, glutamine homeostasis is to a large extent determined by the activities of GS and glutaminase.[13] Both enzymes exhibit regulation of gene expression at both transcriptional and post-transcriptional levels. During stress and sepsis, the production of glutamine is increased, primarily owing to greater GS activity in the skeletal muscle.[14]

Glutamate and glutamine regulation, although important, constitute only a minor part of nutrient homeostasis in vivo. Glucose, on the other hand, is central to human metabolism. Glucose, galactose, and fructose are the major dietary saccharides, and the derangement of glucose handling in diabetes mellitus constitutes the most common condition requiring nutritional advice. Intensive research in the last two decades has revealed the great complexity involved in glucose transport. Glucose is transported into enterocytes primarily by the sodium-glucose cotransporter (SGLT 1). Two Na+ ions must first bind to the transporter, and then one molecule of glucose or galactose may be actively transported into the cell. To date, six members of the SGLT 1 family have been identified on the basis of sequence homology within the human genome.[15] In addition to SGLT proteins, facilitative diffusion glucose transporter (GLUT) proteins catalyze glucose transport into cells. Until recently, five mammalian GLUT proteins had been identified, each a separate gene product with unique properties, for example, GLUT 5 being specifically activated by dietary fructose.[16] Interestingly, in the last 2 years, several novel genes with signature homology to GLUTs have been identified and characterized.[17,18] The GLUT family can be divided into three groups: class I (the previously known GLUTs 1–4), class II (GLUTs 5, 7, 9, and 11), and class III (GLUTs 6, 8, 10, and 12 and the myo-inositol transporter HM1T1). The new members exhibit both tissue and subcellular specificity, which most likely represents another level of regulation. Analysis of GLUT protein levels in patients with non–insulin-dependent diabetes mellitus revealed a four- to fivefold induction in SGLT 1, GLUT 2, and GLUT 5 protein levels, highlighting dysregulation in monosaccharide transport.[19] Identity of mechanism(s) by which these essential dietary carbohydrates directly affect their own uptake (via availability of GLUT and SGLT proteins) is most urgent if we are to understand the marked increase in the incidence of childhood obesity and diabetes facing the developed world.

Genes Regulating the Storage of Nutrients

The storage of nutrients is essential to provide energy in times of fasting, and the mechanisms that control this function must be regulated by nutrient intake to be effective. The two most important organs involved in nutrient storage are the liver and adipose tissue. Both cell types transport glucose and other nutrients and convert them into fat; in the case of the liver, glucose is also converted to glycogen. Insulin is the major hormone that promotes glucose use and induces storage. Its sensitive response to dietary intake complicates the study of the direct effects of nutrients on genes that regulate storage. The direct effects of glucose, in particular, on the expression of transporters and metabolic enzymes have to be dissected from the effects of insulin on these same genes. (The actions of hormones such as insulin on target organs are beyond the scope of this review, but it is well covered by a number of excellent articles within the field of endocrinology.[20,21]) Experiments performed in vivo make the distinction between the direct effects of nutrients and those mediated through hormonal changes difficult to achieve.

Until recently, the molecular mechanism(s) by which glucose directly modulates the transcriptional regulation of lipogenic enzymes was poorly understood. Kawaguchi and colleagues have identified a hepatic transcription factor, carbohydrate responsive element-binding protein (ChREBP), which is regulated at two different levels: nuclear entry and deoxyribonucleic acid (DNA) binding via phosphorylation events mediated by glucose and cyclic adenosine monophosphate (cAMP).[22,23] The transcription factor localizes to the cytosolic compartment of hepatocytes at low glucose levels but translocates to the nucleus in the presence of high glucose levels. Further phosphorylation of ChREBP by pyruvate kinase (PK) A led to an inhibition in its DNA-binding ability consistent with a negative feedback role for the glucagon/cAMP pathway.[24]

Earlier studies investigating the direct contribution of glucose toward increased nutrient storage in the liver have focused on the three main control points of glucose metabolism before it enters the mitochondrion as pyruvate. These are the enzymes glucokinase, 6-phosphofructokinase, and L-type PK. Fructose is also metabolized to pyruvate, bypassing the first two enzymes. PK is therefore a regulatory enzyme in the metabolism of both monosaccharides. The transcription factor ChREBP (described above) was purified by its ability to bind to the glucose-carbohydrate response elements present in the PK promoter sequence.[22]

Feeding a high-carbohydrate/low-fat diet to fasting rats resulted in the induction of genes involved in glucose uptake and lipogenesis.[25] Both insulin-mediated and

increased glucose metabolism were required for maximum induction of gene expression. Both in vitro and in vivo studies have identified a critical role for the transcription factor sterol regulatory element binding protein (SREBP) in insulin-mediated transcriptional control of genes involved in glucose, fatty acid, and triglyceride metabolism.[26,27] The involvement of at least two transcription factors (ChREBP and SREBP) for optimum lipogenesis may reflect the degree of molecular complexity required for coordinated integration of hormonal and nutritional signals in regulating energy requirements of a cell. Identification of signaling events regulating lipogenesis is crucial to further our understanding of disease states such as diabetes and obesity.[24,28]

Insulin has a major effect on the activity of the three glycolytic enzymes via transcriptional and/or post-translational modifications. Glucokinase messenger ribonucleic acid (mRNA) expression was induced by insulin via an insulin receptor substrate (IRS)-1-phosphatidylinositol-3 (PI3)-kinase–dependent pathway.[29] PI3-kinase and p44/p42 mitogen-activated protein kinase (MAPK) activities play a role in the transient activation of PK by insulin.[30] However, glucose independently alters the expression of PK by increasing the transcription of PK mRNA.[31,32] Glucose similarly enhances the expression of fatty acid synthase, a key enzyme in lipogenesis. Glucokinase regulates the flow of substrate to PK. Because glucokinase requires insulin for its activity, it has been difficult to study the independent effects of glucose and its metabolites on PK expression. Nevertheless, two separate approaches directly demonstrate the effects of glucose on PK expression. The first approach was to demonstrate that the effects of insulin on transcription of PK mRNA were glucose dependent, thus identifying glucose as a separate variable.[32] The second approach examined a particular hepatoma cell clone (mhAT3F), whose glucokinase (which is insulin dependent) had been replaced, through spontaneous mutation, by hexokinase (which is not insulin dependent). This allowed the effects of PK to be examined in the absence of insulin.[33] Several signaling pathways that may play a key role in glucose-dependent *L-PK* gene transcription have now been identified (for a review, see Hardie and colleagues[34]). The involvement of the cAMP-dependent and the adenosine monophosphate (AMP)-activated protein kinase pathways is well documented.[35] The glucose-response elements in the promoter region of the *L-PK* gene are known to interact directly or indirectly with various families of transcription factors, including the Sp1 family and the upstream stimulatory factors (USFs).[36,37] The complex interactions between the various factors (UFSs, chicken ovalbumin upstream promoter transcription factor II [COUP-TF II], ChREBP) are likely to act as a glucose-sensing mechanism, allowing the cell to respond appropriately to continuous variation in its nutritional status.

Nutrient Stimulation of Hormone Secretion

Insulin In children, hormones are secreted into the circulation in response to nutritional stimulation for two main reasons: to effectively store nutrients in appropriate storage molecules and to signal to tissues that substrate for growth is available to coordinate the cellular manifestations of growth (cell proliferation, differentiation, and controlled cell death) with the influx of nutrients. These two actions are mutually compatible, and a number of hormones and growth factors serve both functions to varying degrees. Insulin, for example, is mainly a storage hormone, but it is also able to stimulate growth; the increased weight of babies born to diabetic mothers is attributable to increased fetal insulin acting as a growth hormone. Similarly, factors primarily responsible for growth, such as insulin-like growth factor I (IGF-I), which mediates many of the actions of growth hormone (GH), are able to vary the rate of glucose uptake into cells.

The secretion of insulin by the pancreatic islets is tightly controlled by glucose concentrations in the blood. Alterations in gene expression play no part in these rapid responses to glucose. Regulatory proteins within islet cells are ready to respond to increases in glucose. Release of insulin from storage granules occurs following calcium influx, which, in turn, is probably induced by minor increases in adenosine triphosphate from the metabolism of glucose and other nutrients. Circulating hormones also affect insulin release. The quick-acting mechanisms that do not involve control lie beyond the scope of this review. Again, the reader is referred to several excellent reviews on the subject.[20,38,39]

In addition to these rapid responses, glucose also exerts a more lasting effect on insulin production through increased translation and transcription of the insulin gene. This allows a child to adapt to longer periods of starvation or carbohydrate repletion. Glucose enhances the rate of translation of proinsulin mRNA to protein by three methods.[40] It increases the transfer of initiated insulin mRNA from free to membrane-bound ribosomes. It also decreases the rate of pausing of the proinsulin mRNA as it passes along the ribosome. Lastly, glucose directly stimulates the cellular machinery involved in the elongation of proteins in pancreatic islet cells.[41,42] Long-term changes in insulin production are also mediated by transcription. Rats fasted over 4 days have low insulin mRNA concentrations, which return to normal on refeeding.[43,44] These changes control the ability of the pancreas to secrete insulin during dietary manipulations and enable the islet cell to adapt to long-term dietary changes.

In addition to whole-animal studies, pancreatic islet cell preparations have also been used to study how glucose alters insulin expression. Interesting information regarding signal transduction from nutrients to the initiation of transcription has been gleaned from this system (to be discussed). The studies on insulin expression complement those on the role of glucose in PK and fatty acid synthase expression.

IGF-I and IGF Binding Proteins Although we do not fully understand the mechanisms whereby children whose nutritional intake is reduced beyond a certain point stop growing, it is certainly true that nutrient intake has a significant effect on final adult height. This is common knowledge in developed countries with large immigrant populations from the developing world. The children in

the immigrant communities grow up to be taller on average than their parents, whose childhoods may have been spent in lands where food was less abundant. Poor linear growth also occurs in childhood diseases such as cystic fibrosis. In inflammatory diseases, such as Crohn's disease or juvenile rheumatoid arthritis, the characteristic rate of growth may, in part, be related to poor nutritional intake as well as to the direct effects of intestinal inflammation.[45,46]

IGF-I and -II are a family of polypeptide growth factors whose functions include mediation of GH action and stimulation of insulin activity and are autocrine regulators of cellular proliferation.[47,48] IGF-1 has been shown to be a key player in regulating organ and body growth during postnatal development both in rodents and humans.[49] There is now compelling evidence that IGF-1 secretion may be the point at which regulation of growth is controlled both in health and disease.[50–53] Although IGF is an important modulator of GH action, GH itself does not correlate with depressed linear growth under nutritional restriction or in children with active inflammation.[50,54,55] Alterations in tissue responses to growth hormone may therefore mediate the effects of nutrition on growth. This has resulted in two separate lines of investigation: the effect of nutritional alterations on expression of the GH receptor[56] and the study of nutritional factors on IGF-I and IGF-II secretion in association with secretion of IGF-binding proteins.

Nutritional status is a major determinant of IGF-I mRNA expression in liver and nonhepatic tissues. Fasting, caloric restriction, and animal model studies all show a decrease in circulatory IGF-I levels,[57] although circulating levels of GH remain elevated.[50] Although fasting reduces the binding of GH to its receptor,[58] down-regulation of the GH receptor does not occur with dietary restriction,[59] and it is believed that neither of the above are principal causes of reduced IGF-I. Further, administration of IGF-I, but not GH, stimulates mucosal hyperplasia in surgically stressed rats with intestinal atrophy induced by hypocaloric total parenteral nutrition.[60] Low protein intake studies in a liver-specific IGF-I-deficient mouse model led to a decrease in nonhepatic IGF-I secretion into the circulation, with an increase in GH levels. Lack of dietary protein led to induction of GH and IGF-I receptor expression in spleen. Increased IGF binding protein 3 (IGFBP) mRNA was also observed, which supports the hypothesis that the binding protein may contribute to greater sequestration of locally synthesized IGF-I.[61] These studies support the view that the splenic GH/IGF-I axis responds to nutritional stress to maintain tissue homeostasis.

Regulation of IGF mRNA expression is complex. The rat IGF-I gene contains six exons spanning 100 kb of DNA. Exons 1 and 2 encode alternative amino terminal sequences of the IGF-I protein. The gene has two distinct promoter regions upstream of exons 1 and 2, which can be separately activated. After transcription, alternative splicing results in further heterogeneity of the IGF-I mRNA. Furthermore, there are two different terminal poly A addition sequences in exon 6, adding to the general complexity. However, these myriad possibilities result in only three different-sized mRNA transcripts: a 3.8 kb, a 4.2 kb, and an 8 kb transcript. The importance of these different mRNAs to IGF-I production and to growth awaits further investigation, but they are of interest because several studies have demonstrated that different forms of malnutrition affect the transcripts differently.[47,52,62] Total energy restriction induces a coordinate decrease in all three forms of mRNA.[51] In contrast, protein restriction results in a profound decrease in the 8 kb fragment, with less effect on the two smaller fragments.[47,62] The observations open up two questions of further interest: How do different nutrients differentially affect gene expression in a particular family of genes? and How do these differences in gene expression translate into differences in a child's final phenotype? We return to similar questions when we consider the small intestinal epithelium, where nutritional variations are greater than those seen in the circulation. Corresponding changes in IGF-I have been seen in childhood illness. IGF-I concentration correlates with increased intake and subsequent growth of children with Crohn's disease, whereas growth has no correlation to GH production.[45,55,63] Children with cystic fibrosis frequently manifest hormonal abnormalities that may contribute to malnutrition. Interestingly, in a recent study, Bucuvalas and colleagues found no effect of exogenous IGF-I on linear growth in prepubertal children with cystic fibrosis, although an increase in glucose-to-insulin ratio was observed.[64]

In extracellular fluids, IGF-I is bound to IGFBPs, of which six have been cloned and characterized.[49] IGFBP-3 is the main carrier of circulating IGF-I, and in the presence of an acid-labile subunit, a bioinactive ternary complex is maintained during circulation. The complex allows greater control on IGF-I bioavailability.[65] IGFBP-3 may also modulate IGF-I-stimulated DNA synthesis.[66] The biologic function of each binding protein is under intense investigation. Protection from the hypoglycemic effects of IGF-I has also been suggested as a function. Nutritional factors alter the circulating levels of IGFBPs. There is an inverse correlation of the expression of binding proteins to that of IGF-I. Protein restriction results in an increase of IGFBP-1, which falls on refeeding. However, IGFBP-1 is sensitive to insulin, and it is not clear how nutrients in the liver alter their expression directly. Interestingly, IGFBPs are predominantly secreted by Kupffer's cells,[67] unlike IGF-I, which is synthesized by hepatocytes. The differences between these two cell types in terms of their location and their expression of surface receptors could allow for subtle regulation of IGF action in the face of nutrients and other factors in the circulation, such as cytokines.

Effect of Intestinal Contents on Genes in the Epithelium

The gastrointestinal tract is the only part of the body that normally comes into contact with nutrients before they are absorbed. The gastrointestinal tract is therefore exposed to a wider variety of nutrient molecules than any other organ of the body. The picture is further complicated because the lumen of the intestine is not a direct reflection of the food ingested. It also contains bacteria and their by-products and factors secreted into lumen in response to the inges-

tion of food (Figure 15-2). The study of nutrient effects on the enterocyte therefore should consider how changes in diet may affect the area around the apical aspect of a particular epithelial cell. The dissociation between nutrients ingested and the changes observed in the bowel lumen becomes greater the further one proceeds down the gastrointestinal tract. The contents of the distal colon are completely different from food, although even here they are affected to some extent by dietary intake. This relationship between ingested nutrients and the local environment of the lumen is a separate issue from the interaction of that local environment with genes in the enterocyte.

It has traditionally been assumed that the expression of genes in the small intestinal epithelium is preprogrammed and that their expression is not influenced by events in the lumen of the intestine. However, this view may be incomplete. An alteration in epithelial cell phenotype secondary to nutritional factors would have three possible advantages (Table 15-2). First, the intestine could adapt to absorb nutrients more effectively if specific digestive enzymes and transporters of the epithelium were up-regulated by the repeated intake of a particular nutrient. Second, as all mammals are fed from mother's milk, the opportunity exists for breast milk to influence the development of the epithelium through actions of its own constituents. Third, if the genes affected in the epithelium were immunologically important, the intestinal epithelium could influence mucosal immune responses by signaling information to the mucosal immune system and beyond through changes in the expression of epithelial cell genes. Each of these areas is likely to represent important physiologic mechanisms that have implications for child health.

Intestinal adaptation
Influence of maternal breast milk
Signaling from lumen to mucosal immune system

Polarity of Epithelia

The cell types discussed earlier in this chapter do not depend on a separation of functions to different cellular poles. For example, the pancreatic islet receives signals from the entry of glucose at any point on the plasma membrane, and, as far as we can judge, the insulin response is not affected by the site of glucose entry. Insulin can also be released in any direction, eventually diffusing into the circulation. Cells that form epithelia are different in that they exhibit polarity. This separation between the apical side (bordering the lumen in the case of the intestinal epithelium) and the basolateral side is central to epithelial activity. This property is well recognized in the field of intestinal transport. Ions, small molecules, and macromolecules are all transported differently across the apical membrane than across the basolateral membrane (Figure 15-3).[68–70] It is the polarity of the epithelium that gives direction to the movement of these substances across the epithelium into or out of the body. But this property must also be considered when one is examining all aspects of intestinal epithelial cell function. Polarity is also of fundamental relevance in the study of nutrient–gene interactions in the intestinal epithelium. The polarity of the epithelial cells distinguishes the two major mechanisms by which nutrients (and other luminal factors) affect genes: a direct effect on enterocytes and an indirect effect mediated through hormones, growth factor, and cytokines (see Figure 15-3). As with the effects of insulin on target tissues, the mechanisms of action of cytokines and growth factors on the epithelium are beyond the scope of this chapter. The reader is again referred to excellent reviews on how epithelial cell expression can be regulated by these agents.[71,72]

The apical membrane mediates the direct effects of luminal factors on the epithelium. The functions of nutrient recognition (sensing) and signal transduction (see Figure 15-1) will therefore lie between the apical membrane and the apparatus of gene expression. The exact molecular mechanisms involved require further investigation. For the purposes of investigation, they can be considered as a series of black boxes connecting the lumen and gene

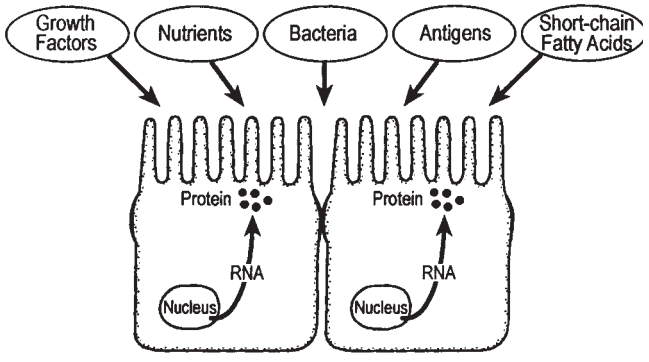

FIGURE 15-2 The luminal factors that influence gene expression in the enterocyte. Factors can affect individual genes or they may influence enterocyte differentiation and new cell lineages.

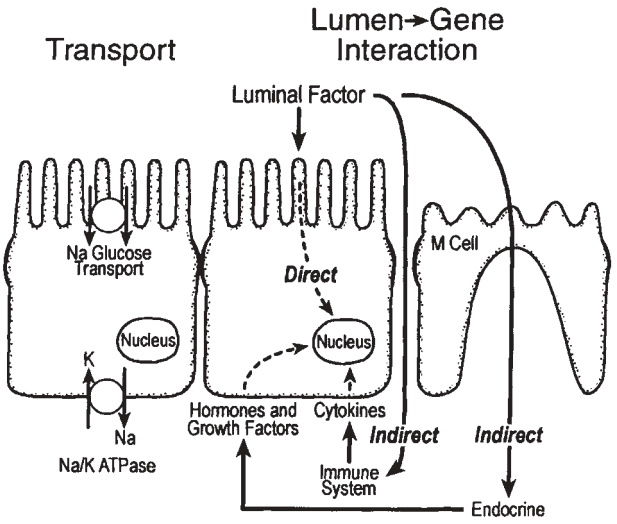

FIGURE 15-3 Dietary changes may affect gene expression directly (being mediated through the apical membrane) or indirectly (through the basolateral membrane).

expression (Figure 15-4). These black boxes contain the mechanisms that regulate gene expression and constitute the way by which molecules in the lumen "cross-talk" with the nucleus of the enterocyte. Figure 15-4 depicts the pathway linking single factors in the lumen to the expression of a single cell in a single gene. This is, of course, a gross oversimplification. As we have mentioned, an alteration in diet may alter different factors at the cell surface, and any one of these factors may have an effect on several different genes through different pathways (Figure 15-5). In addition, the methods by which a particular protein may be expressed is not necessarily always owing to the induction of a single gene in cells along the crypt-villus axis. It can also be caused by changes in the state of differentiation of the cells in the epithelium, the expression of a particular gene being just one component of that change. Lastly, alterations in luminal contents may not necessarily affect epithelial cells that are already formed along the epithelium but instead result in the generation of new lineages of cells that express the gene arising from the crypt. In this case, the mechanisms linking the lumen to gene expression would lie in the stem cell at the base of the crypt rather than in the individual enterocyte itself.

Adaptation of Enterocytes to the Nutritional Environment

The efficient use of food requires digestion, followed by absorption of digestion products and their release into the circulation. Adaptation is, by definition, the up-regulation of one or all of these functions in the presence of a relevant nutrient. Adaptive mechanisms are more likely to be associated with foods whose intake varies between different individuals. The similarity here with prokaryotic cells is clear. Bacterial gene regulation was discovered in the study of enzymes that metabolized nutrients whose abundance varied widely in the environment, like lactose or tryptophan. For children, of course, there are many foods whose abundance can vary, but to illustrate this section, we have chosen two: dietary fat and sucrose. These two examples demonstrate different aspects of adaptation. Fat digestion is primarily controlled by enzymes secreted from the pancreas and gastric glands, whereas digestion and absorption of sucrose are controlled entirely by the enterocyte itself.

Sucrose Intake The intake of sucrose can vary greatly between individual human beings. This is especially true when one compares individuals from different times in history. Until the industrial revolution, sucrose was present in the diet only when brought from the East as part of the spice trade, and its availability was limited. The introduction of plantations in the Caribbean in the eighteenth century, coupled with the industrial process of refining, resulted in an explosion of sucrose intake. In England in 1700, the estimated per capita daily consumption in adults was 4.5 g, rising to 37 g in 1800. By 1968, it had reached 140 g daily,[73] which is around 15% of the total energy derived from food. Sucrose is digested by the epithelial cell brush border, where it is hydrolyzed to fructose and glucose by sucrase isomaltase (SI). Fructose is absorbed by the carrier GLUT 5 and GLUT 16 and glucose by the specific sodium-dependent glucose transporter.[16,17] Both sugars exit the cell through the basolateral membrane by facilitated diffusion, probably via GLUT 2. The up-regulation of any of these proteins by their substrate would constitute a nutrient–gene interaction.

The four brush border disaccharidases represent the final step in the digestion of carbohydrates. Their activity can affect the glycemic response to oral carbohydrate.[74] More importantly, low levels of hydrolase activity in the face of carbohydrate in the intestine will result in osmotic diarrhea.[75] A mechanism whereby expression of these enzymes could be linked to sugar intake would therefore have clear benefits. SI is one of three β-glucosidases (together with maltase and trehalase). The remaining disaccharidase, lactase, is a β-galactosidase. Sucrase is anchored to the microvillus membrane of the enterocyte by the isomaltase subunit of the SI protein.[76,77] Both subunits are synthesized as a single protein that is later cleaved.

The regulation of the induction of sucrase is not simple. The timing of its appearance during ontogeny in rodents was elegantly shown to be independent of luminal contents.[78] When the investigators transplanted isografts into animals 5 days younger than the donors, sucrase appeared earlier in the transplanted intestine than in the host. Therefore, luminal factors in this case did not induce sucrase, nor did circulating factors in the host (whose intestine would have been susceptible to them). This evidence suggests that sucrase is controlled by an internal biologic clock within the intestine itself. However, luminal contents can have a marked effect on the activity of sucrase, which is separate from this internal mechanism: (1) early feeding with sucrose will induce precocious sucrase induction in rodents[79]; (2) reduction of carbohy-

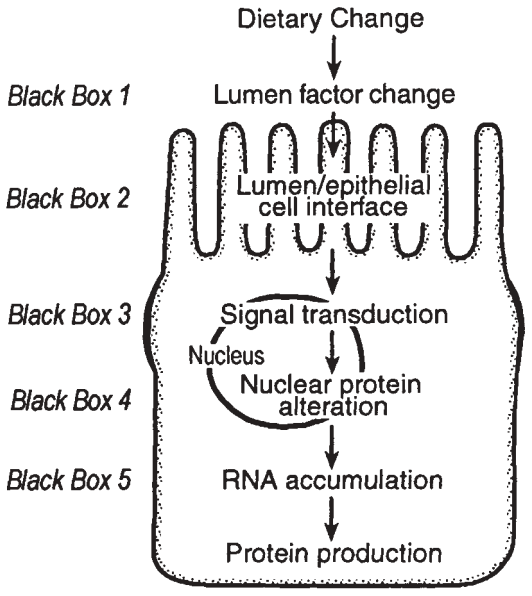

FIGURE 15-4 The pathway connecting dietary alterations to changes in gene expression is not well understood. It is likely that the pathway is mediated by a series of steps that, at present, we can regard only as black boxes. Different luminal events will influence gene expression through different series of black boxes.

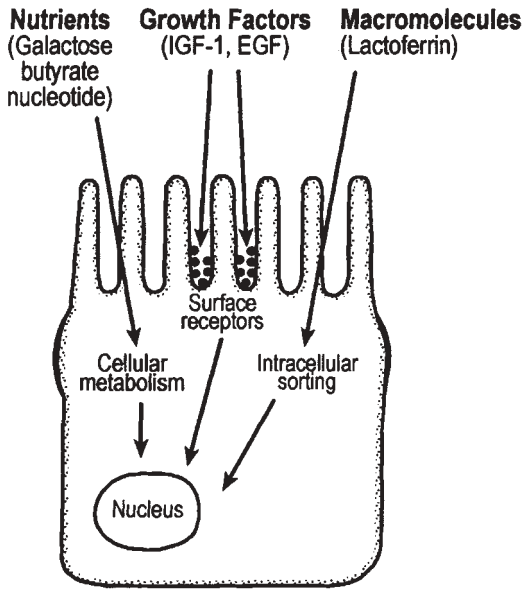

FIGURE 15-5 Cross-talk through the apical membrane will depend on the particular signal involved. EGF = epidermal growth factor; IGF = insulin-like growth factor.

drate intake results in a reduction of sucrase activity even when caloric intake is unchanged[80]; (3) feeding with glucose instead of sucrose reduces brush border hydrolase activity[81]; and (4) refeeding sucrose after a period of abstinence leads to rapid recrudescence of the hydrolase activity.[82] Increasing the intake of sucrose of mice from 2 to 55% of total energy intake had differing effects on the enterocyte, depending on the position of the cell in the small intestine.[83] Sucrase activity increased in the duodenum and upper jejunum but not in more distal segments of the intestine. The cells showing greatest alterations were those from the midvillus of the proximal intestine, with lesser increases in the villus tip and crypt-villus junction.

The control of sucrase activity is then a complex one and depends on events within the enterocyte in addition to external influences.[84] More recently, the molecular biology of sucrase expression has been examined. Sucrase activity depends mainly on events in the sucrase promoter because expression of GH mirrors that of sucrase in transgenic animals containing a sucrase promotor–GH construct.[85] The expression of sucrase may therefore reflect nuclear protein–promoter interactions.[86] In recent years, several SI promoter elements required for intestinal epithelial cell expression have been identified.[86] Evolutionarily conserved *cis*-acting elements in the promoter region have been found to interact specifically with transcription factors such as GATA-4 and caudal-related homeodomain (Cdx) proteins.[87,88] Further combinatorial interactions among hepatocyte nuclear factor (HNF)-1α protein, GATA-4, and Cdx-2 may play a critical role in the temporal and spatial regulation of the SI gene expression during postnatal development.[89] Post-transcriptional events may also be likely to influence enzymatic activity; for example, reduction in lactase activity following weaning does not necessarily correlate with lactase mRNA but may be regulated during translation.[90]

Glucose Transporter Expression Glucose enters the epithelial cell by active transport via a sodium-coupled glucose transporter, SGLT 1.[91] SGLTs represent part of a family of proteins that carry nutrients into the cell, across concentration gradients.[15] SGLT 1 is located in the brush border or apical surface of the enterocyte and, along with Na+, transports glucose and galactose into the cytosol. GLUT 2 is basolateral and transports glucose, galactose, and fructose (transported in from the lumen via GLUT 5) from the cytosol into circulation.

Direct transport studies undertaken before the identification of sodium-dependent transporters showed that glucose uptake increased with glucose feeding.[92] This increase was not attributable to changes in the affinity of glucose to the enterocyte (K_m) but to an increase in the maximum uptake (V_{max}), indicating an increase in the production of proteins that transport glucose. It is now well established that dietary sugars regulate the activity and the expression of intestinal SGLT 1. Structurally, an intact mucosa is necessary for rapid up-regulation of GLUTs by luminal glucose.[93] Modulation of SGLT 1 expression by dietary carbohydrates has also been observed in the human intestine.[94] Mechanisms involved in the regulation of glucose transport are complex and have been difficult to characterize as two distinct timescales of dietary carbohydrate exposure are now known to play a role (recently reviewed in Ferraris[95]). GLUTs can respond within an hour to glucose and also exhibit distinct changes in gene expression over a period of 1 to 3 days to a high-carbohydrate diet.[93,96,97] Intestinal glucose transport is also subject to diurnal changes, adding further complexity to the system. The increase in GLUTs in response to dietary changes is analogous to the acquisition in bacteria of enzymes and transporters that are induced by lactose (the lac operon). There are, however, notable differences between induction of enzymes and transporters in bacteria and those seen in the mammalian intestine. First, the activity of transporters in bacteria increases by 100- to 1,000-fold, whereas the nutrient transporters in mammals show smaller variation with diet. For example, feeding mice with diets containing high levels of either D-glucose or nonmetabolizable analogues of D-glucose led to only a two- to threefold increase in SGLT 1 activity.[98,99] Second, in bacteria, the cell that receives the stimulus is the same cell that exhibits alterations in gene expression. In the mammalian intestine, this appears not to be the case with the GLUT.[100,101] Sequential elution of different fractions of epithelial cells was used to distinguish different cells along the crypt-villus axis of mice.[102,103] Increase in carbohydrate intake resulted in enhanced expression of the GLUT (as measured by phlorhizin binding). Importantly, changes were observed in the crypts before they were seen in the villi. Similarly, when carbohydrate was stopped, it was in the crypts that the reduction in transporter was first observed. Thus, crypt cells respond to changes in diet before villus cells, indicating that the changes in the expression of the GLUT were effected by new cell lineages from stem cells. It is the stem cell producing the new cell lineage that therefore must contain the machinery for detection of carbohydrate. The resulting cell

population that ascends along the crypt-villus axis expresses this change. This separates carbohydrate detection temporally and spatially from GLUT expression. It is not known whether other genes in the intestine follow a similar pattern. Identification of molecular mechanisms underlying carbohydrate detection and signal transduction are currently under active investigation in several laboratories (see Figure 15-1).

Sucrose induces an increase in the enzyme that hydrolyzes it (SI) and in SGLT 1 that allows a greater influx into the enterocyte across a concentration gradient. This absorptive system is central to the efficacy of oral rehydration solution in the treatment of gastroenteritis and cholera.[104] The greater the number of transporters, the more sodium and fluid that can be transported into a child during dehydration. Up-regulation of SGLT 1 therefore has a potential therapeutic role in alleviating the loss of sodium and fluid with glucose solutions. An understanding of the mechanisms regulating this process would define to what extent and over what time period sodium and fluid transport could be maximized in children with gastroenteritis.

Intake of Dietary Fat The intake of fat as a component of total energy varies considerably between different children. Fat consumption has been increasing in children from developed countries and has accelerated over the last 100 years. Contemporary comparison of fat intake between nations now shows large variations. For example, Perissé and colleagues reviewed 105 countries for the Food and Agriculture Organization (FAO) of the United Nations and showed that between wealthy and nonwealthy countries, fat intake varies from about 12% of total energy intake to over 40%.[105] It is not only healthy children who have seen a change in fat intake; children with cystic fibrosis have been given much larger amounts of fats. This is because increased calorie intake, particularly that of fat, has resulted in improvements in respiratory function.[106–109] Much of this fat is digested in children with cystic fibrosis by the use of ingested enzyme preparations given with meals. However, lipases secreted in the gastrointestinal tract proximal to the duodenum (gastric lipase) may also play a prominent role. It is important, therefore, to document whether secretion of this enzyme varies with fat. A knowledge of mechanisms underlying this possible adaptive effect may lead to therapeutic optimization of enzyme production and better use of fat in children who are continually under threat of malnutrition.

Gastric Lipase

Gastric lipase accelerates the digestion of triglycerides in human milk by releasing free fatty acids, which enhance pancreatic lipase and colipase activities.[110] The actions of gastric lipase are magnified in children with little pancreatic lipase activity, as in cystic fibrosis. Newborn babies also have relatively low pancreatic lipase activity, and the relative importance of gastric lipase is exaggerated in the premature neonate.[111–114] There are significant biochemical differences between pancreatic and gastric lipase, most significant of which is the difference in pH required for maximal activity. In addition, gastric lipase activity requires no bile salt or colipase. In the human, the gastric mucosa secretes all of the preduodenal lipase.[115,116] In the rodent, the tongue is the most significant source, and here the equivalent enzyme is termed lingual lipase. There may also be some lingual production in the preterm human infant because lipase activity has been detected in esophageal pouches of infants with esophageal atresia with no communication to the stomach.[114] The rabbit predominantly secretes its preduodenal lipase from the gastric mucosa, making the rabbit a more appropriate model than the rodent in which to study the effect of dietary influence on this enzyme.

Gastric lipase activity is more susceptible than pancreatic lipase to dietary changes. Increasing the dietary fat intake in rabbits from 2.7 to 6% of diet for 2 weeks was sufficient to induce a 100% increase in gastric lipase activity.[117] This increase had no effect on pancreatic lipase production. Indeed, pancreatic lipase activity was enhanced only when the fat intake was increased to 12% of diet, and then the increase was only modest, a 10% increase in pancreatic lipase activity. Studies in adult human volunteers have shown similar data with a doubling (5.7 to 9.95 U/mL) of gastric lipase after changing from a low-fat to a high-fat diet.[118] The mechanisms that detect the amount of fat intake (see Figure 15-1) need further examination, but triglyceride composition had no effect on the adaptive response in the rabbit.[117] This implicates a metabolite of fatty acid breakdown, which is not specific for either saturated or unsaturated fatty acids as the cellular agent that initiates changes in gene expression. The signal may not have to come directly from the lumen of the gastrointestinal tract because there is preliminary evidence, in neonates at least, indicating that increasing lipid intake parenterally results in enhanced gastric lipase activity. This suggests that signals from the serosal side of the epithelial cell may be possible in this case.

Gastric lipase is therefore under the control of dietary signals. Although we do not at present understand the mechanisms that underlie this phenomenon, their elucidation may eventually allow us to manipulate gastric lipase expression when it is clinically important, as in the nutrition of cystic fibrosis and in the oral intake of the newborn.

Fatty Acid Uptake Fatty acid uptake in the gastrointestinal tract is facilitated by the presence of two transporter proteins, the cytosolic and plasma membrane form of the fatty acid binding protein (FABPc and FABPpm, respectively). Epidemiologic analyses of polymorphisms at codon 54(A/T) in the *FABP2* gene have revealed no clear correlation with postprandial lipemia.[118] In contrast studies in an ex vivo model of fetal jejunum explants implicated *FABP2* polymorphism may specifically influence small intestinal lipid absorption without modifying glucose uptake or metabolism.[119] Further studies are required to clarify the potential role of these transporters in health and disease. A third fatty acid transporter (CD36) associated with long-chain fatty acid as its ligand has recently been implicated to play a role in the pathogenesis of insulin resistance.[120] CD36 –/– mice exhibited enhanced insulin responsiveness

on a high-starch, low-fat diet. Based on this study, one may speculate that humans with a deficiency in this molecule are likely to exhibit enhanced/impaired insulin resistance depending on dietary influences.

Breast Milk and Gene Expression

The nutrition and protection of the infant are the primary roles of breast-feeding, and the nutritional and immunologic properties of breast milk are reviewed in Chapters 31 and 32 of this book. Nevertheless, the cells of the gastrointestinal tract are the first cells of the child to encounter breast milk, and it is not fanciful to suppose that breast milk may influence the development of these cells. A number of factors in milk can affect the expression of genes in the intestinal epithelium, particularly those genes that are associated with enterocyte differentiation. Growth factors such as epidermal growth factor (EGF) and vascular endothelial growth factor are found in breast milk and enhance brush border enzyme activity.[121–123] Although the exact effect of epidermal growth factor in breast milk on the development of the intestinal epithelium depends on the age of the subject, its effect on enterocyte growth and development is not surprising. Less expected, perhaps, is the demonstration that other breast milk components such as nucleotides also affect these same genes.[124,125] A list of how each constituent in breast milk may affect expression of genes in the intestinal epithelium would not present an illuminating picture of how breast milk affected enterocyte expression. Instead, it is more valuable to describe one factor, lactoferrin, as an example. We examine what is known about its interactions with the intestinal epithelium and how this knowledge may be increased in the future.

Lactoferrin Lactoferrin, an 80 kD iron-binding glycoprotein of the transferrin family, is a major component of mammalian colostrum and milk.[126] It is also found in mucosal secretions and neutrophil granules.[127,128] Lactoferrin has bactericidal properties and is a source of iron in breast-fed infants. The protein has been found to have diverse biologic functions, including facilitating iron absorption, host defense, regulation of cell proliferation and differentiation, modulating the immune system, and embryonic development.[129–131] Although neutrophil granules contain lactoferrin, its concentration in plasma, in contrast to transferrin, is relatively low.[127,132]

Specific binding sites for lactoferrin have been observed in activated human blood lymphocytes, liver cells, and cells lining the gastrointestinal tract.[133–135] The lactoferrin receptor has been detected in intestinal brush border membrane vesicles prepared from the human fetus, rhesus monkey, rabbit, and mouse.[136–139] Lactoferrin is relatively resistant to proteolytic degradation.[140,141] Intact protein with iron-binding capacity has been detected in the feces of mice and human infants.[142,143] The stability of the intact protein through transit in the gut suggests that it has the potential to interact directly with the intestinal epithelium. The lactoferrin protein consists of a bactericidal domain (lactoferricin), which can be generated in vitro by pepsin digestion.[144] An understanding of the actions of lactoferrin at the molecular level is particularly relevant as some artificial milk formulas now contain added bovine lactoferrin. Its major role is thought to be delivery of iron to the intestinal epithelium.[145] The number of lactoferrin binding sites increases in cultured epithelial cells when depleted of iron,[146] resulting in a specific increase of iron transport into enterocytes. The actions of lactoferrin are therefore interconnected with the actions of iron. Iron has well-characterized effects on the translation of ferritin and transferrin mRNA,[147] but its effect on gene expression in the enterocyte is less well understood.

Although lactoferrin increases the bioavailability of iron in the neonatal intestine, recent studies suggest that lactoferrin may also act as a proliferative factor in a variety of cell types, including human lymphocytes, mouse embryo fibroblasts, and rat myoblasts.[148–151] Lactoferrin also affects the proliferation of HT-29 human colon adenocarcinoma cells and adult rat crypt cells.[152,153] The effect of lactoferrin on the expression of brush border enzymes has also been examined. In tissue culture experiments, the effect of lactoferrin on sucrase- and alkaline phosphatase–specific activities depended on whether the protein was saturated with iron.[154]

There is a school of thought that proposes that the main function of lactoferrin in vivo is not to transport iron into the epithelium but to scavenge iron (and possibly other substances) in the intestinal lumen. This unbound iron might otherwise cause free radical–mediated damage to sensitive tissues.[155] Accordingly, lactoferrin would have no direct effect on the intestinal epithelium and only indirectly interact with it through the sequestration of other substances in the lumen. These luminal factors, if left free in solution, may have an impact on enterocyte gene expression. An example of this is lactoferrin's binding to lipopolysaccharide, a major component of bacterial cell walls, thereby modulating the effect of this moiety on the epithelium.[156] However, a purely luminal role for lactoferrin is difficult to reconcile with the identification of specific receptors for lactoferrin on the surface of the small intestinal brush border membrane.[138] Initially, the binding of lactoferrin to brush borders was explained on the assumption that lactoferrin was binding to transferrin receptors.[157] But the use of rhesus monkeys has made possible an examination of the specificity of lactoferrin binding to its receptor: binding was time dependent and saturable, competitive experiments with excess unlabelled lactoferrin showed that the binding was specific, and monkey and human lactoferrin effectively inhibited the binding of rhesus lactoferrin at 50-fold excess. A similar excess of bovine lactoferrin or human transferrin had no effect on binding.[137] Taken together, these results are good evidence for a specific lactoferrin receptor. The lactoferrin receptor has now been isolated from human fetal and infant small intestine.[136] Any direct effect of lactoferrin on gene expression should be transmitted through this receptor, and its analysis may therefore give clues as to how lactoferrin might do this. However, it has been difficult to isolate sufficient lactoferrin for structural analysis,[157] but the size and

number of peptide chains have been determined for both human and mouse lactoferrin receptors.[158–160] It is hoped that manipulation of lactoferrin DNA in transfected cell lines will give insights as to whether the receptor signals information to the molecular machinery of the enterocyte.

Because lactoferrin is secreted by neutrophils, its effect on the expression of genes in cells of the immune system has been closely studied. These observations have resulted in some intriguing studies on the actions of lactoferrin on gene expression, which may be relevant to the actions of lactoferrin in breast milk on epithelia. Lactoferrin interacts avidly with nucleic acids in a test tube.[161–163] Furthermore, lactoferrin is taken up by certain human myelogenous leukemia cells and appears in the nuclei bound to DNA.[164] Lactoferrin can therefore be added to culture media to study its effect on the expression of genes transfected into the leukemia cells. He and Furmanski have determined which nucleotide sequences of DNA specifically bind to lactoferrin.[165] They quantified the affinity of the binding of lactoferrin to DNA and have shown it to be greater with iron-saturated lactoferrin than with iron-unsaturated lactoferrin. Once the sequences for lactoferrin had been determined, these sequences were added to an artificial gene promoter attached to a reporter gene, which was transfected into the leukemia cells. The expression of the reporter gene was enhanced by the addition of lactoferrin to the culture medium. More importantly, gene up-regulation was much greater with iron-saturated lactoferrin than with the unsaturated form. Thus, in this system, lactoferrin specifically up-regulated an artificial gene inserted into myelogenous leukemia cells. Lactoferrin has also been found to alter the activity of promoters of natural genes in granulocytes.[166]

The exciting possibility exists, therefore, that lactoferrin from mother's milk may cross into the epithelium of the infant intestine by way of lactoferrin receptors and enter the epithelial cell nucleus, programming epithelial cells in some way. How this is achieved and what benefits this would have for the developing infant are questions that future research may well answer. Recent work in our laboratory has shown that lactoferrin affects the proliferation and differentiation of intestinal epithelial cells and that this effect depends on the degree of saturation by iron.[154] It is possible that these changes in enterocyte gene expression are mediated by mechanisms similar to those outlined by He and Furmanski in white cells. It would be particularly interesting if the entry of lactoferrin into enterocytes was a reflection of its interaction with molecules in the lumen of the intestine, in terms of the amounts of lactoferrin entering as well as of the particular ions that are attached to the lactoferrin once it has entered. It is not difficult to imagine how this molecule could then act as a modulator of enterocyte genes in the face of changes in the intestine.

Signaling from the Intestinal Lumen to the Mucosal Immune System

The function of the small intestinal epithelium is to absorb nutrients from the environment while providing a barrier to the external world.[4] The barrier is not complete as the intestine allows macromolecules to be sampled and to actively absorb nutrients. The success of the intestine in achieving the balance between these competing aims was the critical step in the evolution of multiorgan animals. The ability of the intestine to monitor the environment is a key element in this process in which the mucosal immune system plays an important part. Curiously, however, the possibility that the epithelium may respond to luminal factors (and signal their presence to the mucosal immune system) has been substantially ignored. The epithelium has mainly been regarded as a passive barrier with points of selective filtration (Figure 15-6, A), surveillance of the luminal contents occurring after this filtration has taken place.

Earlier in this chapter, we examined genes whose activity is restricted to the confines of the epithelial cell monolayer of the intestine (Figure 15-6, B). Nutrient transporters and disaccharidases all contribute to the actions of the epithelium. When genes within the enterocyte express proteins whose actions occur away from the epithelium, such as cytokines and growth factors, the relevance of luminal factors on enterocyte gene expression becomes different. In this new situation (Figure 15-6, C), the epithelium acts as a mediator between the luminal contents of the intestine and target cells beyond the epithelial barrier. Such cells include immunocytes from the mucosa, with the potential for additional cells being recruited from the circulation. The small intestinal epithelium is now recognized to be part of the mucosal immune system.[4,167] For example, it has receptors for bacterial products such as the toll-like receptor 2,[168] as well as expressing a range of molecules on its surface that contain immunoglobulin domains. The epithelial cell also expresses proteins that may interact with immunocytes within the intestine. These include surface molecules such as class II major histocompatibility complex (MHC) and secretory chemokines and cytokines that may directly alter immune responses. The epithelium also expresses families of growth factors and their binding proteins, which may affect the proliferation of immune cells. It also may itself directly present antigen to T cells. The molecular mechanisms governing the expression of these genes have features in common with other enterocyte genes that respond to nutrients and factors in the lumen. For example, the epithelial cell must recognize (or "sense") the nutrient or other luminal factor, and a mechanism must then "transduce" this recognition into molecular changes that can directly alter gene expression (see Figures 15-1 and 15-4). The main difference in molecular terms from the adaptive response described earlier (see Figure 15-6, B) is that the resultant proteins escape from the compass of the epithelium and interact with receptors on target cells (see Figure 15-6, C).

Signaling, by transducing molecular interactions with the epithelium into secretion of messenger proteins, allows luminal factors to influence immune responses while maintaining full epithelial barrier integrity (see Figure 15-6, C). Although the absorption of luminal factors (see Figure 15-6, A) is an important method by which the mucosal immune system surveys the intestinal lumen,[4] it requires the entry of molecules through the epithelial barrier. This provides a potential source for invasion by

pathogens. The poliovirus, for example, enters by this means, exploiting the normal uptake of macromolecules. The ability of the epithelium to signal information to the mucosal immune system without the need for a physical pathway from the lumen to the serosal surface offers obvious advantages in terms of epithelial protection.

The notion of epithelial signaling (see Figure 15-6, *C*) implies that the epithelium can modulate the level of immune activity in the mucosal immune system according to the environment of the intestinal lumen. Mucosal immune responses play a large part in gastrointestinal diseases, particularly Crohn's disease, ulcerative colitis, and celiac disease. The milieu of the intestinal lumen could therefore be manipulated for therapeutic purposes by alterations in diet.

Genes of Immunologic Importance in the Intestinal Epithelium. An increasing list of immunologically active proteins are now known to be synthesized by the intestinal epithelium (Table 15-3), and these were originally thought to be produced only by other cell types. Human diseases are associated with the increased production of some of these proteins in the circulation and gastrointestinal tract. Recent data from our laboratory now show that the expression of these proteins in the epithelium is influenced by dietary factors.

Cytokines. An interesting example of a cytokine secreted by the epithelium is interleukin (IL)-8. This protein is small (8,000 D) but has a long half-life in vivo relative to other cytokines, making it a feasible candidate for long-lasting control over mucosal immune responses. IL-8 is a member of a superfamily of cytokines, the chemokines, which have chemotactic properties, recruiting as well as activating a number of immunologic cell types. It is a potent chemotactic factor for neutrophils and T lymphocytes and may be important in recruiting them into the gastrointestinal tract. Invasion by neutrophils, in particular, is a hallmark of Crohn's disease, a condition in which IL-8 production is enhanced.[169] IL-8 also stimulates the release of superoxide radicals in neutrophils as well as other potential mediators of damage in intestinal inflammation. Furthermore, it increases the permeability of the vascular endothelium to albumin, resulting in tissue edema. Its production in intestinal epithelial cells has been documented in response to bacterial invasion and by other agents, including phorbol-12-myristate 13 acetate (PMA) and IL-1.[170] Recent studies from our laboratory have shown unequivocally that the surface epithelium and its products can orchestrate the mucosal immune system of the gut. Macrophage inflammatory protein 2 (MIP-2) (mouse chemokine similar to human IL-8) transgenic mice were generated where the chemokine expression was confined to the small intestinal and colonic epithelium by the use of a fatty acid binding protein promoter.[171] The epithelium from the first generation of the founder showed effects on both neutrophil and lymphocyte recruitment. In the small intestine, where the fatty acid binding protein I promoter is active, the neutrophil recruitment, expressed as myeloperoxidase activity, was significantly greater. In the distal colon, where the promoter is inactive, there was no effect. These studies show for the first time that the epithelium can, through the release of chemokines, alter the mucosal immune function in vivo.

Further analysis of the immune system demonstrated that the small intestine has increased lymphocyte infiltration in addition to neutrophils. Lymphocyte numbers in the lamina propria are significantly increased ($p < .05$), and there was also a doubling of the number of intraepithelial lymphocytes. The increase in intraepithelial lymphocytes was attributable to an increase in both $\alpha\beta$ and $\gamma\delta$ lymphocyte populations. Interestingly, these cells express CXCR2, the receptor for MIP-2. These studies highlight the potential recruitment capacity of a single chemotactic activity; the in vivo situation, however, is likely to be more complex, with simultaneous alteration of various immune regulators.

Evidence is now emerging that expression of various epithelium-derived immune regulatory molecules is altered by dietary factors.[4,172] n-Butyrate is a short-chain fatty acid produced by the metabolism of normal intestinal bacteria whose levels in the intestine vary with diet. Newborn babies have very low butyrate levels in either the small or large intestine. However, with time, butyrate levels rise, reaching adult levels by 2 years of age. It has long been known that

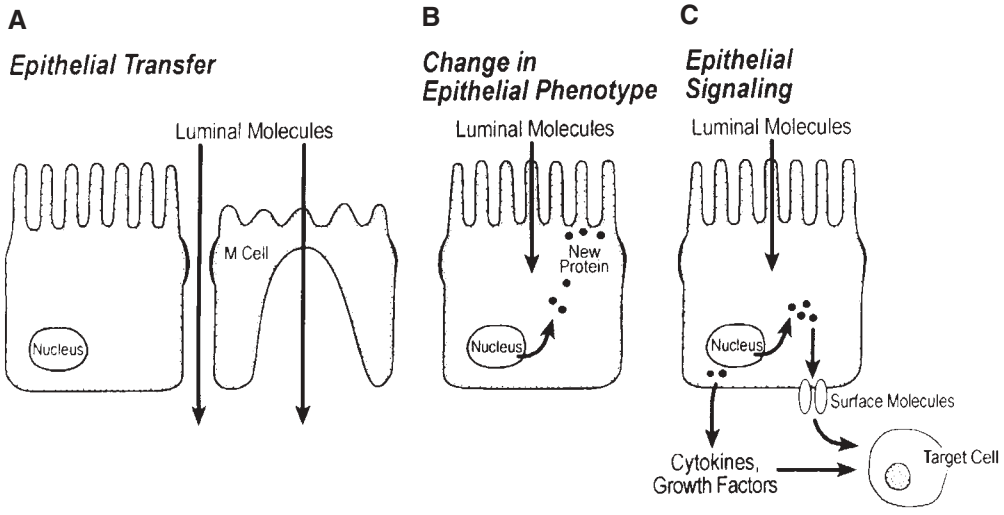

FIGURE 15-6 Possible interactions of molecules from the intestinal lumen with the epithelium. Traditionally, the epithelium has been seen as a selective barrier to molecules, admitting those required for energy intake or immunosurveillance and excluding others (*A*). However, nutrients can alter the phenotype of the epithelium to adapt to changing nutritional needs (*B*). When changes in the intestinal lumen induce new proteins that interact with mucosal immune cells, the epithelium can act as a membrane signaling information from the lumen to the immune system (*C*).

infants fed casein-based formulas produce large amounts of butyric acid and propionic acid in the stool, whereas the predominant fatty acid in breast-fed infants is acetic acid.[173] Furthermore, the bacterial flora (*Lactobacillus*) responsible for high acetate/butyrate production is inhibited by casein.[173] In addition, the amount of butyrate produced in the stool is altered by the type of fiber consumed in the diet.[174] Butyrate levels depend on the type of bacteria in the gut and how much substrate is available for butyrate production. Butyrate levels therefore reflect events in the intestinal lumen, and we hypothesized that their concentrations may alter cell signaling. We therefore examined its effects on IL-8 and *MCP-1* gene and protein expression.[175] We found that butyrate increased IL-8 secretion in enterocytes while simultaneously down-regulating another chemotactic cytokine, macrophage chemotactic protein 1 (MCP-1).[175] Further studies from our laboratory have defined a role for butyrate-induced histone acetylation in the regulation of chemokine gene expression.[175] Unlike IL-8, which attracts neutrophils, MCP-1 attracts macrophages and monocytes. It is constitutively secreted by the intestinal epithelium, whereas IL-8 is not.[176] These observations are consistent with events in the whole intestine in vivo, where, in healthy tissue, neutrophils are absent and macrophages abound. With increasing butyrate levels, IL-8 secretion is induced, but MCP-1 production is depressed. Such "chemokine switching" in response to butyrate may well alter the population of immunologic cells in the lamina propria. Thus, butyrate may affect both the number and types of cells in inflamed tissue through changes in chemokine production of epithelium during inflammation.

Antimicrobial Peptides. In recent years, a new family of endogenous epithelial cell–derived antimicrobial peptides have been identified (for a detailed review, see Diamond and Bevins[177] and Bevins and colleagues[178]). To date, mRNA expression of members of two families, the β-defensin and cathelicidin (LL-37), has been observed in enterocytes (the expression of α-defensin family is confined only to Paneth's cells). Several studies have shown dynamic changes in the expression of these peptides during infectious and inflammatory episodes, implicating them in the front line of host defense in the gastrointestinal tract.[179–181]

Class II MHC and Invariant Chain Expression. The initiation of an immune response to protein antigen normally requires the help of T lymphocytes. Activation of T cells, in turn, depends on the processing and presentation of peptides by an antigen-presenting cell (APC).[182] Class II MHC heterodimers (Ia in the rodent) are the molecules that present the processed exogenous antigen to the T cell receptor. In addition to classic APCs (dendritic cells, macrophages, B lymphocytes), a number of cell types express class II MHC (Ia antigen), including intestinal epithelial cells, and may function as APCs. In recent years, there has been increasing evidence that both the small intestinal and colonic epithelium may function as an APC.[183,184] The requirement for cell viability and an intact cytoskeleton suggests pinocytosis as a major mechanism for active antigen uptake by intestinal epithelial cells; however, passive diffusion and adsorption may also contribute to the process. Processing and presentation of exogenous antigen require an additional protein, the invariant chain (Ii).[185] Diet has a marked effect on the expression of class II MHC and its associated invariant (Ii) chain in the mouse intestinal epithelium. The expression of class II MHC and Ii mRNA is developmentally regulated in the epithelium (unlike its expression in the lamina propria, where it is expressed from before birth).[186] In addition, the timing of expression can be altered by delaying the age of weaning from mother's milk to normal chow.[187] Expression of class II MHC and Ii chain is apparent 3 to 4 days after weaning on chow. However, weaning onto an elemental diet (which contains chemically synthesized amino acids, simple sugars, and fats) did not induce the expression of class II MHC or invariant chain (Figure 15-7). Thus, the expression of these genes in the intestinal epithelium is influenced by dietary manipulation in vivo. The fact that elemental diets used in these experiments were the same as those administered therapeutically in Crohn's disease lends support to the idea that alterations in gene expression may be a significant tool in the treatment of disease (see below).

TABLE 15-3 Immunologically Relevant Genes Expressed by Intestinal Epithelial Cells

Gene	*Experimental System*	*Reference*
Cytokines		
IL-1β	Experimental colitis	184
IL-6	Isolated epithelium	185
	Rat IEC-6 cell line with IL-1	186
IL-8	Colon carcinoma cell lines	143
MIP-2	Rat IEC-6 cell line with IL-1	149
Acute-phase respondents		
	Colon carcinoma cell lines	187
Surface molecules		
Class II MHC	Sections of rat small intestine	188
Invariant chain	Freshly isolated mouse epithelial cells, IEC-6 cells	150
Growth factors		
IGF-I	Colon carcinoma cell lines	189
IGFBPs	Colon carcinoma cell lines	190

IGF = insulin-like growth factor; IGFBP = insulin-like growth factor binding protein; IL = interleukin; MHC = major histocompatibility complex; MIP = macrophage inflammatory protein.

Insulin-Like Growth Factor Binding Proteins. Immune responses depend not only on the activation of T cells but also on the ability of these T cells to proliferate. Earlier sections of this chapter described the importance of IGF-I in growth. However, IGF-I is also an agent that affects cells of the immune system. IGF-I exerts a range of effects on T-cell physiology. The growth factor induced a marked increase in the gene and protein expression of both CD25 and IL-2 and modulated T-cell proliferation via both autocrine and paracrine mechanisms.[188] Treatment of adult mice with recombinant human IGF-I induces striking modifications in lymphocyte number and function.[189] Fourteen days of treatment with IGF resulted in increases in both CD4+ T cells and splenic B cells. Mitogenic responses of T and B cells were also enhanced, demonstrating that IGF-I increases lymphocyte numbers and activity. As discussed

earlier, IGFBPs modulate the actions of IGF-I. Because cultured intestinal epithelial cells secrete IGFBPs, it is possible that the epithelium can influence the proliferation of activated B cells by this means.[190,191] Furthermore, studies have shown that nutritional factors affect the production of IGFBPs in cell lines in vitro.[192] Therefore, not only may nutritional factors influence IGF/IGFBP secretion by the liver into the circulation, resulting in changes in growth of the whole individual, but nutrients may also affect the IGF/IGFBP system in the intestinal epithelium, leading to alterations in the proliferation of the local immune system.

Nutrient Recognition and Signal Transduction

The mechanisms whereby a nutrient (or other factor in the intestinal lumen altered by dietary change) results in changes in RNA transcription are not well understood (see Figure 15-1). It is likely that increases in transcription are the consequence of alterations binding nuclear proteins to the promoter of the particular gene, but the steps by which a cell recognizes a change in that nutrient will differ for every nutrient examined; so, too, will the mechanisms that transduce this signal into alterations of nuclear protein binding. In the enterocyte, we have seen the variety of mechanisms that might occur simply by appreciating the many factors that may alter when the diet is changed (see Figure 15-2). Different theoretic mechanisms of interaction exist between the lumen and epithelial cells. These mechanisms differ, depending on the exact luminal factor involved (see Figure 15-5). Small nutrients such as butyrate or galactose are likely to enter the cell and affect gene expression through their respective metabolic pathways. Growth factors and lactoferrin involve specific receptors on the surface of the epithelium, and large proteins may enter the cell and alter gene expression as they are sorted. Some complex entities may affect more than one pathway. Bacteria, for instance, may interact through all three pathways: they could influence enterocyte metabolism; they may produce factors or components of their cell walls (eg, endotoxin), which may interact with surface receptors; and the macromolecules from which they are composed may enter enterocyte compartments and be sorted inside the cell. Each pathway may influence aspects of nuclear function. In addition, indirect actions of cytokines produced from immune cells may also play a role.

Although sensing and signal transduction mechanisms (see Figure 15-1) in the epithelium require further investigation, there are some data on the mechanisms by which glucose regulates the expression of PK (in the liver) and insulin (in pancreatic islet cells). Three key questions relate to the effect of glucose on the expression of these two proteins: (1) What are the glucose metabolites that set in train the effects on transcription? (2) How is binding of nuclear proteins to gene promoter elements induced? (3) What is the sequence of DNA in the promoter that confers glucose sensitivity on the gene in question (the so-called nutrient response element)?

In practice, this last question is the easiest to answer because DNA sequences can be easily manipulated in the laboratory. Promoters linked to reporter genes allow researchers to directly measure promoter activity. This was first examined in the PK gene in response to glucose. The actual sequence in the PK promoter was determined by mutational analysis of the promoter and its effects on reporter activity. The glucose response elements in the PK gene and in the insulin I gene were discovered by this means. To determine the glucose response element in the PK gene promoter, promoter DNA sequences were transiently transfected into hepatocytes in culture and were also examined in transgenic mice.[193–196] Mutations induced into the DNA demonstrated a glucose response element occurring twice in the PK promoter. This motif is known as an E box because of its resemblance to a similar sequence in a promoter of the adenovirus, which had been given this name. This same DNA sequence also occurs in other genes that regulate glucose metabolism, most notably the fatty acid synthase gene, whose protein product catalyzes one of the later steps in the conversion of carbohydrate to fat, one that is up-regulated when glucose is abundant in the diet.

The rat insulin gene also contains an E box, which is termed the Far element. Paradoxically, this element does not confer glucose sensitivity to the insulin gene. This attribute is conferred by a sequence 10 bases away termed the FLAT element. We now understand some of the features of the signal transduction from nutrient to nuclear function in the insulin gene. MacFarlane and colleagues identified a nuclear factor, insulin upstream factor 1 (IUF-1), which binds to the insulin promoter.[197] IUF-1 binding was examined in vitro by assessing the degree of binding of nuclear extracts from cultured islet cells to

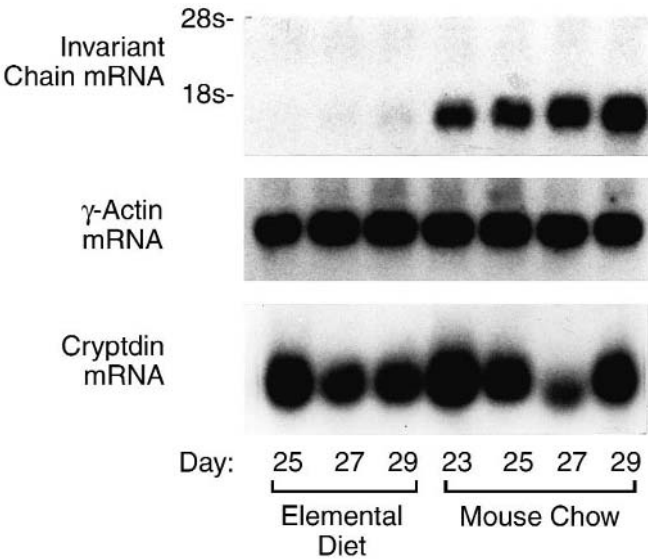

FIGURE 15-7 Dietary factors alter the expression of class II MHC and invariant chain expression in intestinal epithelial cells. Figure shows Northern blot of ribonucleic from epithelial cells taken from individual mice of a single split litter weaned at day 17 onto elemental diet or Purina mouse chow. The blot was probed with invariant chain complementary deoxyribonucleic acid (cDNA) and autoradiographed for 48 hours. Mice were examined at days 23, 25, 27, and 29. Blots were also probed with γ-actin and cryptdin cDNA to verify uniformity of enterocyte extraction. Reproduced from Sanderson et al.[187] mRNA = messenger ribonucleic acid.

radiolabeled promoter DNA. There was a high degree of IUF-1 binding in cells incubated with 20 mmol/L glucose, but this was abolished in cells incubated in 3 mmol/L glucose. In addition, this protein-DNA binding depended on the phosphorylation of IUF-1. Phosphorylation therefore alters a factor in the initiation of transcription of at least one glucose-sensitive gene. It is particularly interesting that phosphorylation is the signal that transduces glucose intake to induce insulin transcription because it is also phosphorylation that directly affects the activity of enzymes in the Embden-Meyerhof pathway. Thus, in this system, phosphorylation acts as a common transduction mechanism, responsible for both the quick and slow responses to glucose uptake.

The metabolites derived from nutrients responsible for the change in nutrient gene expression have not been elucidated in any system. Glucose-6-phosphate may possibly be the metabolite that activates the glucose response element in the fatty acid synthase and PK genes.[198] This was demonstrated by comparing the effects of the two glucose analogs, 2-deoxyglucose (2dG) and 3-O methylglucose (3OMeG). Neither analog can be metabolized. However, 2dG can be phosphorylated, but not 3OMeG; 2dG stimulated transcription, but 3OMeG did not. Therefore, only the phosphorylated sugar was able to stimulate the transduction mechanisms that resulted in transcription, which it did without further metabolism. Whether this phosphate bond provides the energy to phosphorylate a nuclear factor to bind to DNA is not known, but it is an interesting possibility.

CLINICAL AND THERAPEUTIC IMPLICATIONS OF NUTRIENT–GENE INTERACTIONS

The role of diet in diseases of many organs has become an area attracting attention from medical scientists and the general public. However, the relationship between dietary factors and the health of most organs has been difficult to examine, other than by using epidemiology.[199] Occasionally, data have emerged suggesting that particular diets benefit certain disease states. For example, renal failure was shown to be less progressive in rats whose protein intake had been restricted,[200] but even this has been difficult to substantiate in children.[201] Furthermore, it is not easy to see how the protein load has its effect. We have no knowledge of which cell types in the kidney may be affected, let alone how their phenotype may be altered by protein intake. On the other hand, in the small intestine, the relation between diet and gastrointestinal function is clearer.

In clinical practice, one of the most substantial changes in the content of the intestine occurs before and after parenteral nutrition. The effects of such changes have profound consequences for the small intestinal epithelium in human subjects (see Figure 15-6, B). Intestinal brush border hydrolase activity is diminished during parenteral feeding.[202] Moreover, the ability of the mucosa to form a barrier is compromised. Moore and colleagues studied 74 patients who had suffered abdominal trauma randomized to receive either enteral or parenteral nutrition.[203] Those fed parenterally had more episodes of infective complications (pneumonia and abdominal abscesses) than those fed enterally. Calorie and nitrogen intake was equivalent in the two groups. As it is thought that the main source of sepsis following trauma is the gastrointestinal tract, this study may be evidence that enteral feeding directly affects the ability of the injured patient to contain bacteria within the gastrointestinal lumen.

The effect of parenteral nutrition on the morphology of the intestine in animals has long been known.[204] Considerable attention has been paid to the question of which enteral components are responsible for maintaining normal bowel morphology and function. No clear answer has yet emerged. For example, Spector and colleagues observed that luminal infusion of 30% dextrose or 5% amino acids was effective in restoring intestinal weight, protein content, and DNA content after a period of intravenous alimentation.[205] Amino acids were more potent on a weight-for-weight basis or on a molar basis than dextrose. More recently, the changes in the intestine seen in animals fed via parenteral nutrition have been compared with the changes seen during weaning.[82] Intestinal length, mucosal mass, DNA, protein, and disaccharidase activities were significantly lower in animals sustained by intravenous nutrition when compared with normally weaned controls. However, restoration of luminal feeding resulted in a return to normal of the intestine in the total parenteral nutrition–fed group.

There are now many reports of the relationship of intestinal function to parenteral nutrition.[206] However, a study of the interaction between luminal content and the molecular control of intestinal cell protein synthesis is only just beginning, and this relationship is likely to provide the key to our understanding of how enteral feeds maintain a healthy epithelium.

It is also likely that epithelial signaling (see Figure 15-6, C) may have important therapeutic implications for diseased intestine. First, the contents of the intestinal lumen are directly amenable to therapeutic manipulation, whereas the environment that surrounds other, more internal organs is maintained in strict homeostasis by a plethora of mechanisms. Second, although we do not know exactly how the local environment surrounding the epithelial cell is changed by diet (see Figure 15-2), dietary manipulations are an important aspect of management of gastrointestinal disease states.

The activity of Crohn's disease is greatly influenced by altering the contents of the intestinal lumen. Inflammation subsides in patients who are fed parenterally and receive no oral nutrients and in those receiving elemental diets[207,208] (see "Enteral Products" in the Appendix). These chemically defined diets induce remission as effectively as high-dose oral corticosteroids in both adults and children.[209–211] The return of inflammatory changes to normal in the intestine has been documented indirectly by the use of markers of intestinal permeability and scanning of labeled neutrophils and directly by examining the mucosa at endoscopy with biopsies.[212–214]

It has been hypothesized that a reduction in antigen load in the intestine may underlie the efficacy of elemental

diets in Crohn's disease in a fashion similar to that in cow's milk–sensitive enteropathy and celiac disease.[210] However, the switch from a normal diet to an elemental diet alters many constituents of the intestinal milieu apart from food antigens (see Figure 15-2). In particular, bacterial populations (and therefore bacterial products) are profoundly altered by dietary alteration. Moreover, giving whole protein in the form of liquid diets (polymeric diets) is also an effective treatment for Crohn's disease.[215] Removal of protein antigen is therefore not essential for the efficacy of the formula diet. It is more likely that the diets are altering many factors in the local environment of the intestinal lumen (see Figure 15-2). The concept of genes in the epithelium signaling events to the mucosal immune system is a first step to understanding the basis of how such events may occur because it seeks to identify molecular pathways from the intestinal lumen through enterocytes to the mucosal immune system and other target cells beyond the epithelium. Certainly, this would be in keeping with data presented earlier (see Figure 15-7) showing that class II MHC and invariant chain expression in the epithelium are related to dietary factors. There was no expression in epithelial cells of the mice weaned onto an elemental diet,[187] and this diet was the same as that used in the treatment of Crohn's disease. Genes other than class II MHC, with common promoter elements, may also be altered by similar maneuvers and may be important in regulating intestinal inflammation.

CONCLUSIONS AND SPECULATION

Certain concepts have been laid down in this chapter that can be used as the basis for examining how dietary factors may affect the expression of genes in various cell types, including the intestinal epithelium. The essential components for an effective transition between nutrient and gene expression in cells have been documented. These components (see Figure 15-1) comprise a system of recognizing changes in factors as they interact with a cell (sensing) and a mechanism of converting these external molecule–cellular molecule interactions into changes in gene expression (signal transduction). It is not yet understood how these mechanisms are effected in the cell. This chapter has presented evidence that nutritional factors do indeed alter gene expression in cells, but it is likely that different molecular species are sensed by completely different mechanisms. In the case of the epithelial cell (see Figure 15-5), these sensing mechanisms can be at the cell surface or part of the internal mechanisms of the cell. It is also possible that special receptors exist on the surface of the cell and detect more complex external molecules, such as large proteins and oligosaccharides. The apical surface of mucosal epithelial cells expresses a number of molecules belonging to the immunoglobulin superfamily. Their function is at present unknown, but they have been identified because they form the attachments for invading viruses. One member of the immunoglobulin superfamily (intercellular adhesion molecule 1) allows rhinovirus attachment in nasal epithelium.[216,217] As the primary function of these molecules on the mucosal surface cannot be to serve as a conduit for viral infection, it is tempting to suggest that they and other similar molecules might play a role in the immunosurveillance of macromolecules in the gastrointestinal tract. Signaling through these molecules would require alterations in epithelial cell gene expression for this surveillance to be transmitted to the mucosal immune system. If antigens are recognized by epithelial cells of the gastrointestinal tract, it is possible that this information is correlated with information garnered from the previous penetration of similar antigens across the epithelium.[70]

Finally, this field of nutrient–gene interaction may have important therapeutic implications; the ability of the epithelium to interact with other immune cells makes it an active member of normal human defense.[218–222] This physiologic role may allow it to influence inflammatory reactions in pathologic situations. The opportunity exists through dietary means to manipulate the constituents of the lumen of the intestine by opening up a new vista for treatment of human disease. Genetic expression is now regarded as a central feature of human disease states, particularly those in which certain genes are defective. However, genetic influences also affect a much wider variety of diseases than those that are attributable to simple inherited gene mutations. The possibility that expression of genes can be modulated by means other than insertion of new DNA should be added to the armamentarium of the medical community. An understanding of how dietary factors may alter gene expression is an early step in this direction.

CHAPTER 16

HUMORAL REGULATION OF GROWTH

William E Russell, MD, J. Marc Rhoads, MD

Hormones and nutrients interact to influence growth at all levels of biologic organization. Growth is often loosely defined to include all aspects of somatic enlargement and maturation. The principal impact of malnutrition on the growing child is to diminish or reverse weight gain. When malnutrition is of sufficient duration or intensity, statural growth is retarded, although under some unusual circumstances, malnutrition may selectively impair linear growth without a preceding or concomitant loss in weight.[1] The manifestations of malnutrition effects on growth are often subtle, frequently masquerading as social, ethnic, or racial characteristics. In a study of ethnically homogeneous conscripts in the Polish army, Bielicki and colleagues found that young men from large families, from the countryside, and from lower socioeconomic classes were smaller than their counterparts from smaller, urban, and more privileged families.[2] These authors concluded that the negative impact of these variables on stature could all be attributed to suboptimal nutrition. On a large scale, the effect of malnutrition is often so striking as to produce major population differences in stature that appear to be genetic. For instance, prior to World War II, native Japanese were smaller than Americans of European ancestry and smaller than Japanese Americans raised in the United States.[3] However, with the significant nutritional improvements that took place in Japan following World War II, these differences vanished.[4]

NUTRIENTS, HORMONES, AND GROWTH

Hormones and Growth Factors

Hormones are generally defined as the secretions of glands that specialize in their production; classic hormones, acting through an endocrine mode of regulation, therefore require conveyance through the circulation to alter the function of distant tissues. Their concentrations and association with binding proteins can be readily measured in the blood and other body fluids. Regulation occurs not only through changes in the concentration of the hormone but also in the numbers and cellular distribution of their peripheral receptors and in the systems of second messengers within the target cells that convey these signals to the genome or other cellular compartment. Each of these steps can be regulated by developmental programs and by the local milieu of nutrients and other hormones.

The body-wide endocrine system, however, is also an integrating system that is superimposed on multiple local regulatory systems that employ *paracrine* modes of regulation.[5] Paracrine control refers to the release by cells of soluble messengers that act on neighboring cells of another type. A circulation is not required because only physical proximity and the presence of receptors are required for effect. In 1980, Sporn and Todaro added the concept of *autocrine* control to include the substances that cells secrete to regulate their own growth.[6] Although autocrine control was initially thought to be a mode of growth control for neoplastic cells exclusively, autocrine control also characterizes the growth and function of many normal cells. Examples of autocrine control include the release of epidermal growth factor (EGF) by ulcerated gastrointestinal mucosa and release of transforming growth factor-α by normal intestinal epithelial cells.[7] As a consequence of the narrow range of action within the extracellular space of autocrine and paracrine growth factors, their roles in cellular regulation are much more difficult to document in clinical situations. It has recently emerged that proteolytic events at the cell surface are critical regulators of the accessibility of autocrine and paracrine factors to their receptors.[8] Multiple proteases associated with extracellular matrix or cell membranes are known to solubilize and activate growth factors from their cell surface–anchored, but biologically inactive, precursors.

It has been proposed that growth factors can exert biologic actions without release into the extracellular space. *Juxtacrine* control refers to the actions of growth factors that remain anchored to the plasma membranes of the cells that produced them; cell-to-cell contact brings them into contact with receptor-bearing target cells.[9] Finally, some growth-regulatory molecules can activate receptors on intracellular membranes, including those in the cytoplasm, nucleus, nucleolus, or mitochondrion, a mode of action called *intracrine* control.[10] In some instances, intracrine factors originate within their target cell; in other instances, they are internalized from the extracellular space.

Intracrine action appears to be critical for the regulation of the chicken ovalbumin gene.[11] In conjunction with the neuroendocrine mode of regulation, which makes use of axons to direct regulatory neurotransmitters to their target cells, the multiple systems of cellular regulation provide a diversity of regulatory options, each of which has relevance to an understanding of nutritional influences on growth. The characteristics of endocrine, paracrine, autocrine, juxtacrine, intracrine, and neuroendocrine modes of regulation are summarized in Table 16-1.

In distinction to the protein and steroid molecules that comprise the classic hormones of the endocrine system, peptide growth factors are the principal agents of the paracrine, autocrine, juxtacrine, and intracrine systems.[12] The distinction between hormones and growth factors is generally a functional one. There are instances in which a substance may be released from a gland into the circulation to act as a hormone at a distant site, whereas within a highly specialized tissue, the same substance might be locally secreted as a growth factor to influence the function of adjacent cells. In many instances, nature has retained the basic structure of successful regulatory molecules and, through a divergent evolution, has created new uses for them. The structural homology of insulin and the insulin-like growth factors (IGFs), which are discussed later in this chapter, illustrates how a substance with predominantly nutrient-transporting properties, which is found in even primitive unicellular organisms, has evolved to regulate highly differentiated functions. Illustrations will be provided of how, in many instances, hormones that circulate widely can produce highly individualized local effects by differentially regulating tissue-specific production of local growth factors.

Nutrients and the Growth of Cells

Holley was among the first to propose that the intracellular availability of nutrients is the ultimate regulator of cell growth.[13,14] He postulated that when cellular nutrition is adequate, mammalian cells require no additional extrinsic growth-promoting substances, and that hormones and growth factors regulate tissue growth ultimately by altering the availability of nutrients. In the laboratory, the growth of cells and tissues clearly requires the proper combinations of hormones and growth factors in addition to an adequate supply of nutrients. There is ample evidence that growth factors and hormones influence the transport and use of nutrients by cells.[15–19]

Hormones and nutrients interact in a delicate balance: hormones alter the nutritional requirements of cells, and, conversely, nutrients alter cellular hormonal requirements. McKeehan and McKeehan found that cultured human lung fibroblasts require lower concentrations of various minerals and substrates in the culture medium as the concentration of serum growth factors is increased.[20,21] Conversely, they found that adequate concentrations of nutrients reduce the need for growth factors, an interaction that has been systematically probed by Rizzino and colleagues and Wu and Sato.[22,23]

Although adequate supplies of nutrients are necessary to allow full manifestations of the effects signaled by hormones and growth factors, hormones influence cell growth by mechanisms other than changing their cellular nutritional status. Thyroid and steroid hormones, for example, can change cell function by directly influencing the transcription of target genes in the nucleus, although adequate "nutrition" in the form of high-energy phosphates and other low-molecular-weight substrates is required for full manifestation of the signal. In contrast, most polypeptide hormones and growth factors bind to cell-surface receptors, and their ability to influence the genome requires the initiation of a cascade of reactions that involve lipids, proteins, and ions as second messengers. Specific micronutrients, such as glutamine, allow the amplification of growth factor signaling and individually activate intracellular signaling kinases (eg, mitogen-activated protein kinases) in intestinal and liver cells.[24,25] Furthermore, there are amino acid response elements in the promotor of nutritionally important genes. One gene regulated by amino acid deprivation and the endoplasmic reticulin stress response is asparagine synthetase, which is a recognized target of antileukemic chemotherapy and is essential for maintenance of cell viability.[26]

TABLE 16-1 Modes of Cellular Regulation

Mode	*Agent*	*Source*	*Vehicle*	*Target*	*Modulators*
Endocrine	Hormone	Gland	Circulation	Heterologous tissue	Neurons Hormones Growth factors
Paracrine	Growth factor	Local site	Diffusion	Heterologous cell	Hormones Growth factors
Autocrine	Growth factor	Local site	Diffusion	Autologous cell	Hormones Growth factors
Juxtacrine	Growth factor precursor	Local site	Cell contact	Adjacent cell	Proteases
Intracrine	Hormone Growth factor Nutrient	Intracellular	Cytoplasm	Intracellular receptor	?
Neuroendocrine	Neurotransmitter Growth factor	Neuron	Axon	Heterologous tissue	Hormones Growth factors Neurons

Nutrients and the Growth of Tissues

The study of cellular proliferation in the laboratory culture dish can provide information on the hormonal and nutritional needs of dividing cells, but the growth and development of the organism as a whole require that the enlargement and maturation of each tissue occur at the appropriate rate and in the proper sequence.[27] As they can influence nutrient requirements of individual cells, hormones can also affect the nutrient needs of complex tissues as well as the supply of nutrients in the fluid milieu in which they are bathed. The effects of a given hormone on its various target tissues can be quite different: catabolic in one tissue, anabolic in another (Table 16-2). These effects are generally not without coordination as catabolism in one tissue can serve to increase the supply of nutrients to another tissue that is rendered anabolic by the same hormone. For example, under normal circumstances, anabolic hormones increase the protein content of both viscera and muscles.[28] In the nutrient-deficient state, however, anabolic agents such as growth hormone (GH) and androgens continue to preferentially support carcass protein (muscle) synthesis even at the expense of visceral protein. Androgens, for instance, diminish the rate of muscle breakdown in fasted guinea pigs while accelerating the loss of protein from the liver.[29] Similarly, the weight loss of food-restricted swine can be reduced by the administration of GH, but the effect is to preferentially retain muscle mass while depleting body fat.[30] Similar effects are seen in humans (see below) and have led to abuse of GH by competitive athletes. Conversely, an important adaptive response to long-standing malnutrition is a generalized inhibition of anabolic systems, such as those involving GH and androgens, to conserve essential body compartments.

Whereas anabolic hormones preferentially preserve muscle mass when nutrients are in short supply, catabolic hormones serve to protect the viscera. Brief exposure of rats to glucocorticoids or to thyroxine (T_4) increases the protein and glycogen content of the liver, whereas the protein content of muscle is depleted.[28] These effects are direct ones on hepatic uptake and synthetic processes and not merely the result of increased substrate availability from the carcass.[31] Even a prolonged exposure to glucocorticoids, which depletes both viscera and muscle, reduces visceral mass proportionally less than muscle.

Critical Periods in Tissue Growth

The ability of tissues to recover from a nutritional insult varies greatly at different times during development. The study of normal tissue growth has provided a model of normal tissue development that has been used to analyze the variable effects of malnutrition at different developmental stages. As the organ or tissue approaches its predetermined complement of cells, the organ grows by increasing both its cell number and the size of each cell. When the adult complement of cells is attained, cell division ceases and tissue growth results totally from enlargement of existing cells.[32] In the growing rat, Enesco and Leblond found the strictly proliferative phase to last until the seventeenth postnatal day, whereas after 34 to 48 days of life, tissue growth resulted solely from increases in cell size without an increase in new cells.[32] Between these two periods, tissue growth appeared to result from both cellular hyperplasia and hypertrophy.

Widdowson and McCance performed studies on growing animals that clearly established the existence of critical periods of sensitivity to the effects of malnutrition.[33–35] They manipulated the litter size and therefore the milk supply of rat pups during suckling and observed their subsequent growth. Rats that were nutritionally deprived during this period were small, and their growth could not be restored by institution of normal food intake.[36] The mechanism for this runting appears to be an irreversible effect of undernutrition on the number of cells. Similar mechanisms are likely to operate in some forms of intrauterine growth retardation (IUGR) in children, although the irreversibility of the growth deficit has come into question with the observation that GH treatment can accelerate growth in some small for gestational age children.[37]

Winick and Noble provided further evidence that the nutritional state of the neonatal period influences cell proliferation and consequently determines the ultimate size of the animal and its organs.[38] Food restriction in the first 21 days of life produced a subnormal complement of cells in most tissues. However, the size of the cells was normal. Adequate nutrition after weaning could not restore normal growth, presumably because of an irreplaceable deficit of cells. Food restriction between 21 and 42 days resulted in a comparable stunting of growth in most tissues, but the brain and lung were able to resume normal growth with the restoration of proper nourishment. In these tissues, the total adult cell number had already been attained, and mal-

Table 16-2 Actions of Hormones on Body Compartments

Hormone	*Protein*	*Carbohydrate*	*Fat*
Glucocorticoid	Breakdown in muscle, synthesis in viscera	Permissive for gluconeogenesis, glycogen synthesis	Redistribution
Insulin	Synthesis in muscle and liver	Glycogen synthesis in liver, glycolysis	Lipogenesis, inhibits lipolysis
Growth hormone	Synthesis in muscle	Insulin-like effects (acute), insulin antagonistic (chronic)	Lipolysis, inhibits lipogenesis
Thyroid hormone	Synthesis in liver, breakdown in muscle	Glycogenolysis, gluconeogenesis	Lipolysis
Androgen	Synthesis in muscle and viscera		

Adapted from Eisenstein AP and Singh SP.[289]

nutrition produced a reversible decrease in cell size. When malnutrition was induced between 65 and 86 days, almost all organs underwent a reversible decrease in cell size only.

Growing tissues are as sensitive to an excess of nutrients as to a shortage. When rat litter sizes were reduced to provide supranormal nutrition, the offspring were larger than normal and were found to have hypercellular organs.[39]

As it has evolved from studies such as these, the critical period hypothesis proposes that abnormal nutrition, either excessive or deficient, during the phase of tissue growth by cellular proliferation can increase or decrease the ultimate size of a tissue by enhancing or impairing cell division. These effects are irreversible because they bring the tissue into the phase of growth by cellular hypertrophy with an abnormal number of cells or abnormal organization. When nutritional surfeit or deficit occurs after establishment of the adult complement of cells, the net effect is a change in cell volume, but not in cell number, and is reversible by normalization of the nutrient supply. Because tissues mature at different rates, the long-term effects of nutritional variations occur most prominently in those tissues that are at a susceptible developmental period.[40] An important example of this principle of "programming" following an insult at a critical, sensitive period of early life is that mothers who are malnourished during pregnancy often have infants with IUGR, subsequent growth retardation, and, ultimately, disproportionately high rates of coronary heart disease, high blood pressure, and high cholesterol during adult life.[41] IUGR in girls has been linked to the development of hyperandrogenism, insulin resistance, and ovulatory dysfunction in adolescent years.[42–44]

Catch-Up Growth

It has long been documented that children have the capacity to accelerate their growth when recovering from a growth-impairing influence such as malnutrition or disease. At the complex level of organization that is required for statural growth, the ability of nutritionally deprived cells and tissues to be restored to functional health is reflected in the phenomenon of "catch-up growth," a term used by Prader and colleagues.[45] Subsequently, "catch-down" was coined to refer to the complementary process that follows removal of growth-accelerating influences, such as occurs with suppression of precocious puberty, restriction of food in obesity, or cessation of GH therapy in hypopituitary children.

Even under the most favorable circumstances, the accretion of height does not occur at a fixed rate but is developmentally regulated. Gender-specific, nutritional, and—in some cultures—seasonal influences are also superimposed. The period of most rapid postnatal growth in children occurs in the first months of life, when length increases by 14 to 22 cm per year. By the second birthday, the mean growth velocity has slowed to about 8 cm per year and to about 5 cm per year just before puberty. Then, under the influence of sex steroids (but involving the coordinated actions of GH, IGFs, thyroid hormones, and others), growth velocity nearly doubles before statural growth ceases as the epiphyses close.

After the second year of life and continuing throughout childhood, growth velocity is modulated to maintain stature at a constant position relative to the general population. The height percentile attained by about 2 years of age is maintained faithfully throughout childhood and correlates well with the height percentile in adulthood.[46] Statural growth along a predetermined percentile on a growth chart is often called canalization. Growth-retarding or growth-accelerating processes disrupt canalization and growth curves cross channels. With amelioration of the abnormal condition, a compensatory acceleration or deceleration occurs to restore the original growth channel (Figure 16-1).

In the first 2 years of life, catch-up growth can be a normal adaptation in children whose birth size is at variance with their genetic potential. Whereas statural growth from age 2 years to adulthood is primarily controlled by genetic influences, the determinants of body size during fetal life are largely determined by maternal and nutritional influences. The interval between birth and roughly 2 years of age is a preprogrammed period of catch-up or catch-down growth and is characterized by a shift of growth channels as maternal influences give way to genetically determined forces. It is essential for the clinician to be aware of these forces during this period because genetically programmed changes in growth velocity can be misconstrued as manifestations of disease.[47]

From a practical standpoint, for catch-up growth to be complete, the insult must be limited in duration and must not occur during certain vulnerable periods. Williams and

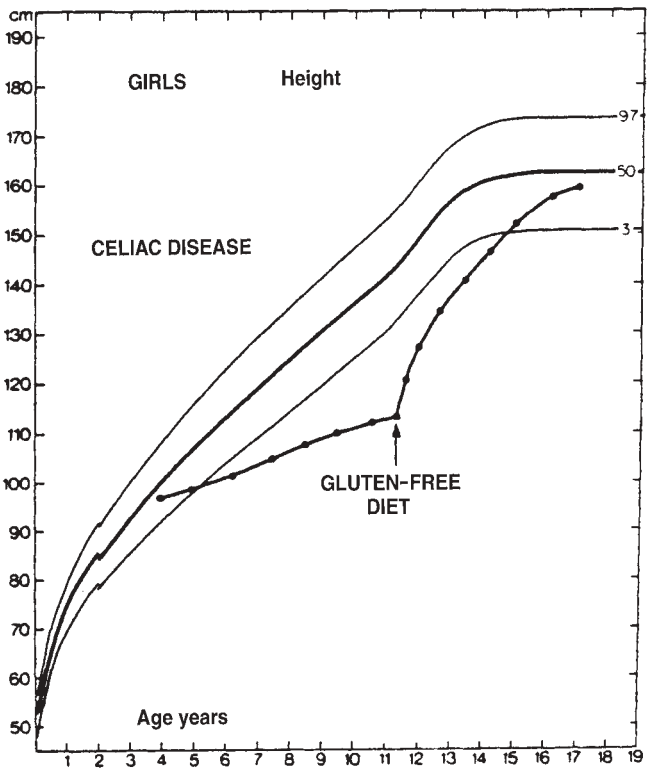

FIGURE 16-1 Catch-up growth in a girl with celiac disease. After 8 years of growth failure, she was placed on a gluten-free diet and exhibited striking catch-up growth. Note return to previous growth percentiles. Courtesy of J. M. Tanner.

coworkers noted that the degree of catch-up growth is generally muted if it begins when growth is normally decelerating.[48,49] Based on observations in birds and mammals, Wilson proposed that catch-up growth potential is modified by the nature of the insult, its severity, its duration, and the developmental state of the animal at the onset of the insult. For example, it had been assumed that GH deficiency and hypothyroidism were two conditions with the potential for essentially complete catch-up. However, the catch-up potential of hypothyroid children is diminished in proportion to the duration of the hypothyroidism before treatment.[50] Their subjects had been hypothyroid for approximately 5 years and had deficits from their predicted heights of 25 cm at the onset of therapy; however, at the conclusion of therapy, an average deficit of 7 cm remained (Figure 16-2). The magnitude of deficit between final height and predicted height was in proportion to the duration of hypothyroidism before treatment began. Similar conclusions resulted from studies of children with GH deficiency of long duration before treatment.[51] Incomplete catch-up growth has also been documented in children with acute nutritional insults, such as diarrhea, when they are superimposed on a background of chronic malnutrition.[52,53]

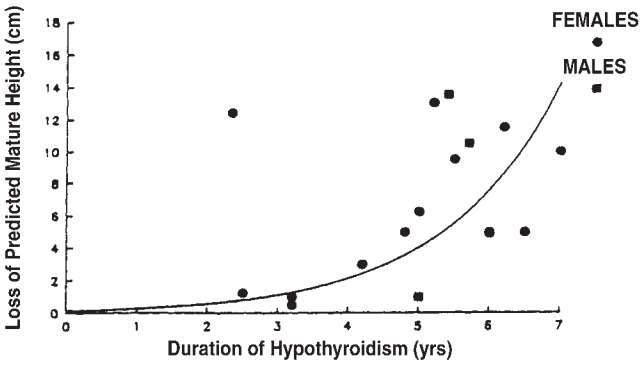

FIGURE 16-2 Loss of catch-up potential with long-standing hypothyroidism. Relationship between loss in adult height and duration of hypothyroidism before treatment in children. Loss of predicted height is predicted height at time of diagnosis minus actual mature height. Duration of hypothyroidism is chronologic age minus bone age at diagnosis. Reproduced from Rivkees S et al.[50]

In addition to its duration, the specific nature of the insult may be important in determining the extent of catch-up because some growth-arresting conditions appear to cause irreversible changes. Mosier found that cortisone-treated rats failed to regain normal body size after cessation of treatment, whereas rats that were comparably stunted by fasting resumed normal growth when refed.[54] Cartilage from the steroid-treated rats had increased numbers of dead and dying cells, altered cell morphology, and alterations in the matrix.[55]

It has been suggested that the catch-up growth of recovery from malnutrition in some experimental conditions is associated with an increase in the efficiency of energy use.[56] Fasted rats are capable of a fivefold increase in energy use efficiency for weight gain during recovery, perhaps by decreased thermogenesis.[57] The situation may be different in humans: children recovering from malnutrition often have increased appetite and caloric intake, suggesting to others that energy use is not efficient.[58] Some marasmic children do not begin to gain weight until 3 to 5 weeks of refeeding, despite an intake of more than 130 kcal/kg/day.[59]

Implied in the concept of catch-up or catch-down growth is an ability of the organism to constantly monitor its size and determine the extent of deviation from the intended size; to alter its velocity when unrestrained from the growth-perturbing influence; and, finally, to again modulate its altered velocity to prevent overshooting or undershooting the channel.[60–63] Williams stressed the theoretical importance of distinguishing between *catch-up* growth and *compensatory* growth.[63] He recognized that the former involved growth to attain a projected (and moving) statural target, whereas the latter involved the growth of a tissue or organ to restore actual lost mass. An example is the regeneration of liver following a partial hepatectomy.[64]

Two divergent, but not necessarily exclusive, models have been put forward to explain the ability of the organism to monitor body size and initiate catch-up. Tanner postulated the existence of a "sizostat" in the central nervous system (CNS) that maintained communication with the peripheral tissues.[65] Along the same lines, Leibel proposed that the concentration of a circulating hormone, such as insulin (or its ratio to other hormones or metabolites), might reflect the size of a body compartment, such as the adipose mass, by monitoring the number of insulin receptors on adipocytes.[66] With the isolation of leptin, the data to support a neuroendocrine control of weight regulation have been far stronger than those to support a neuroendocrine control of statural catch-up. The interactions between adipose mass and the CNS are discussed in the following section.

In contrast to a neuroendocrine mechanism of catch-up growth, Baron and colleagues focused on the growth plate as the key tissue in catch-up growth.[67] Their data showed that a unilateral growth-suppressing influence, accomplished by transient administration of glucocorticoids to a single growth plate, was accompanied by catch-up growth acceleration at that growth plate only, not systemically.[68] Although their model does not preclude the involvement of systemic hormones and the CNS, they proposed that growth-inhibiting conditions decrease proliferation of growth plate stem cells, thus conserving their proliferative potential. Catch-up growth results from a putative clock, or time tally to use Tanner's term, within the stem cell compartment.

Although it is likely that both systemic (neuroendocrine and endocrine) and local (paracrine, autocrine, and juxtacrine) signals will be implicated as critical regulators of the proliferation that occurs during catch-up or catch-down growth, there is little evidence to date that hormones and growth factors are significant mediators of the catch-up phenomenon. These data are extensively reviewed in reference.[69]

In this section, the interactions of nutrients and specific hormones are discussed as they pertain to normal growth, malnutrition, psychosocial growth failure, overnutrition, and growth acceleration.

GROWTH HORMONE, IGFS, AND INSULIN

Normal Growth

GH and IGFs in Normal Growth Pituitary GH (or somatotropin) is essential for normal, balanced somatic growth from childhood to normal adult stature. However, the mechanism by which this process is regulated is incompletely understood, especially in the fetus. The actions of GH are now known to involve a complex interaction among GH genes, GH receptors, somatomedins, or IGFs, IGF receptors, and IGF binding proteins (IGFBPs). In addition, the GH-somatomedin axis is entwined in a regulatory web that is strongly modulated by nutritional signals.

IGFs *and the* Somatomedin Hypothesis. With the advent of techniques for the culture of tissues and cells in the laboratory almost 50 years ago, it became evident that many of the biochemical events that had been attributed to GH in vivo could not be reproduced on isolated tissues studied in the laboratory. These included effects on chondrocyte proliferation and sulfate incorporation into glycosaminoglycans of growth plate cartilage. These observations led Salmon and Daughaday to propose the "somatomedin hypothesis": that the growth-promoting effects of GH are not direct ones on its target tissues but result indirectly from the actions of a mediator substance under GH control.[70,71] Initially called sulfation factor or thymidine factor, based on the assay system used to detect its presence, it was later determined that these two biologic activities resided in the same molecule, which was renamed somatomedin.[72] Other somatomedin species were initially distinguished, but somatomedin C was determined to be the GH mediator of serum.

IGFs were purified in parallel, but independent, studies to characterize the source of the insulin-like biologic activity of serum, only a small part of which derives from insulin itself. Two molecules were identified, IGF-I and IGF-II, the amino acid sequences of which were found to be remarkably similar to proinsulin.[73,74] Somatomedin C is identical to IGF-I, and current convention prefers the IGF terminology, although a number of IGF-I assays available from clinical reference laboratories retain the somatomedin C designation. The properties of IGF-I and IGF-II are contrasted in Table 16-3. Although the current nomenclature has the disadvantage of dissociating the IGFs from their regulatory link with GH, it does more firmly root these substances in the realm of nutritional control.

Initial iterations of the somatomedin hypothesis were inspired by endocrine models of growth control: liver was found to be a major producer of somatomedin activity, and the paradigm that evolved had the liver functioning as an endocrine gland under the control of pituitary GH to secrete somatomedins, whose ultimate target tissue was the growth plate. To further support an endocrine model, IGFs were found to feed back to the pituitary and inhibit the release of GH.

However, in the 1980s, it became clear that multiple tissues express messenger ribonucleic acid (mRNA) for IGFs and are involved in IGF production.[75,76] Most compelling was the observation that IGF-I mRNA is expressed in perichondrium and periosteum, suggesting that local production of IGFs in the epiphysis might account for the growth-stimulating effects of GH. Indeed, Isaksson and colleagues had shown that GH elicits an increase in both IGF-I mRNA and protein in rat epiphyses.[77] Based on analogy to the work of Green and colleagues on the role of GH in the differentiation of adipocytes, Isaakson and colleagues proposed that GH stimulates the differentiation of chondrocytes in the germinal zone of the growth plate; once the stem cells become chondrocytes, their proliferation would result from local (autocrine/paracrine) production of IGF-I.[77,78] However, inconsistencies remain among the data: GH- or GH receptor–deficient mice and humans have no paucity of differentiated chondrocytes, and growth plate chondrocytes can proliferate normally without IGF-I.[71] Nonetheless, the consensus is that locally generated IGFs in the epiphysis are the critical regulators of linear growth.

Table 16-3 Insulin-Like Growth Factors

Property	*IGF-I*	*IGF-II*
Synonyms	Somatomedin C, basic somatomedin	Multiplication stimulating activity (MSA), neutral somatomedin
Chromosome location	12	11
Molecular weight	7,649	7,471
Serum concentration	193 ± 58 ng/mL	647 ± 126 ng/mL
GH dependence of serum concentration	+++	+
Insulin-like actions	+	+++
Mitogenicity in cultured cells	+++	+
Developmental role	Postnatal	Fetal
Sensitivity to undernutrition	+++	+/–

GH = growth hormone.

The weakness of the original somatomedin hypothesis was most clearly illustrated by the creation of a liver-specific knockout of the IGF-I gene. Using Cre/loxP technology, Le Roith and colleagues produced mice with hepatic IGF-I mRNA levels reduced to less than 1% of normal, resulting in a 75% reduction in serum IGF-I.[79,80] Nonetheless, these mice lacking hepatic IGF-I grew normally, and "there were no phenotypic distinctions between the liver-specific IGF-1 gene-deleted animals and their wild-type littermates."[71] Although these studies do not confirm that bone-derived IGFs are the critical determinants of linear growth, they do support the contention that circulating IGFs are not critical to linear growth. As expected based on their markedly reduced serum IGF-I levels, the liver-specific IGF-I knockout animals had elevated concentrations of GH, leading LeRoith to speculate that the major role of circulating IGF-I might be to modulate GH secretion.

IGFBPs. In contrast to GH, which circulates in association with a fragment of the GH receptor called the GH binding protein, IGF concentrations in blood are maintained at relatively stable levels by serum binding proteins

that markedly delay IGF clearance. IGF binding in serum and other fluids resides in six different molecules, collectively known as the IGFBPs. The IGFBPs are summarized in Table 16-4.[81] The major IGF binding complex in serum consists of IGFBP-3 in association with the acid-labile subunit (ALS). IGFBP-5 can also interact with ALS and IGFs in the serum. Circulating IGFBP-3 concentrations, like those of IGF-I, are GH dependent. It is now clear that many, if not all, of the so-called somatomedin inhibitors identified in early bioassays of somatomedin activity, especially in conditions of malnutrition and disease, were actually IGFBPs.

All six proteins have higher affinity for both IGF-I and IGF-II than do IGF receptors. IGFBPs were initially proposed to function as IGF-sequestering agents, thus limiting the concentration of free IGFs. However, IGFBPs modify IGF actions in a variety of ways: they transport IGFs across vessel walls and capillary membranes, they regulate the concentration of IGFs in the vicinities of specific tissues and cell types, they control IGF interaction with cell-surface IGF receptors, and at least three of these molecules (IGFBP-1, -BP-3, and -BP-5) can augment IGF action. Baxter has proposed that a binary complex of a single IGFBP and IGF-I, which can leave the circulation rapidly, facilitates access of IGFs to their receptors, whereas a ternary complex consisting of IGF, IGFBP-3 (or -BP-5), and ALS cannot cross the endothelial barrier and remains in the circulation to sequester free IGF-I.[81] The implications of this on nutritional regulation of IGF action are discussed below. As noted in Table 16-4, serum concentrations of the three principal IGFBPs are profoundly influenced by nutritional signals (mediated by insulin) and by GH. IGF binding and action can also be modulated by post-translational modifications of the IGFBPs such as phosphorylation, proteolysis, and matrix association.[82] Three of the IGFBPs appear to be able to influence cell function independent of their role as an IGFBP. For example, IGFBP-3 can inhibit proliferation in cells that have no IGF receptors.[83] Specific cell-surface receptors for the IGFBPs have been proposed, and IGFBP-3 may have direct effects in the nucleus by interacting with the retinoid X receptor α, RXRα.[84]

GH, IGF, *and* IGFBP G*enes*. In humans, GH is encoded within a cluster of five structurally similar genes on the long arm of chromosome 17.[85] These genes include the so-called normal GH gene (*GH-N* or *GH-A*), a variant GH gene (*GH-V* or *GH-B*), and three genes for placental lactogen (chorionic somatomammotropin). Only GH-N is translated into GH in the pituitary gland, and the other four genes of the family are expressed in placenta. Two distinct forms of GH result from differential splicing of the mRNA that is transcribed from the *GH-N* gene. The predominant product is a single chain of 191 amino acids with a molecular weight of 22 kDA. The product of alternate splicing of the *GH-N* gene is 20 kDa GH, which results from a deletion of 15 amino acids and comprises about 10% of circulating GH. Clear evidence for a differential regulation of the secretion of these two GHs is lacking, although they may differ in some of their biologic actions.

Each of the IGFs is encoded by a separate gene, although alternative splicing of each of the genes and other post-transcriptional modifications result in multiple IGF mRNA species. The extent to which the modification of IGF gene transcripts is important in the regulation of IGF action is unclear. The IGFBPs as well arise from a gene superfamily that includes proteins whose function and relationship to IGF physiology are as yet undetermined.[86]

GH-IGF A*xis*: P*hysiologic* R*egulation*. Pituitary GH release is regulated by two principal hypothalamic peptides, one stimulatory (GH-releasing factor [GRF] or growth hormone–releasing hormone [GH-RH]) and one inhibitory somatostatin release inhibiting factor (SRIF) (Figure 16-3). Blood concentrations and patterns of GH secretion result from an interplay between these two substances on the somatotropes of the anterior pituitary. The hypothalamus receives rich innervation from higher centers in the brain, providing a mechanism by which even emotional influences can alter GH secretion (see discussion of psychosocial dwarfism later in this chapter). However, other modulating influences on GH release have been identified. Both free fatty acids and the orexigenic neuropeptide Y are known to directly inhibit GH secretion, whereas the fat-derived hormone leptin (see below) stimu-

CNS = central nervous system; CSF = cerebrospinal fluid; IGF = insulin-like growth factor.

lates GH release, perhaps by inhibiting secretion of neuropeptide Y.[87–91] Very recently, ghrelin has come to the fore as a potent regulator of GH secretion, food intake, and fat mass. Investigators studying a family of synthetic GH-releasing peptides identified a novel CNS receptor for these peptides and then identified ghrelin as its natural ligand.[92] Ghrelin is produced by hypothalamic neurons and by a highly specialized population of endocrine cells in the fundus of the stomach, where its secretion is suppressed by food intake. The model that is emerging ties stomach-produced ghrelin to the nocturnal stimulation of GH secretion, whereas hypothalamic ghrelin regulates food inake.[93]

IGFs feed back to inhibit GH secretion by the pituitary. IGF-I can stimulate the secretion of somatostatin by the hypothalamus and may directly inhibit GH synthesis.[94,95] It remains to be clarified whether IGFs of peripheral or hypothalamic origin are responsible for the inhibition of GH secretion, but the observations previously cited of enhanced GH secretion in the liver IGF-I knockout mouse suggest that circulating IGF-I is a prime regulator of GH secretion.[79]

In response to GH, but modified by other hormones and most critically by nutritional factors, multiple tissues in the body synthesize and secrete IGFs. Although the liver was the first tissue demonstrated to secrete IGFs and is the major producer of circulating IGFs, its primacy in the GH-IGF axis has been supplanted. Multiple cell types in virtually every tissue examined from both fetus and adult can synthesize IGFs. Thus, a model of IGF action has evolved that is primarily a paracrine one in which IGFs are produced practically everywhere and act on target cells in the vicinity of the producing cells. Thus, the function of the large quantities of circulating IGFs is not clear, but they may be more important for their insulin-like effects on metabolism than on their mitogenic effects.

GH *and* IGF *Concentrations in* Blood. Although it was believed that GH circulates in the blood free of binding proteins, it is now recognized that between 25 and 35% of circulating GH is loosely complexed to a 60 kDa glycoprotein referred to as the GH binding protein (GHBP).[96] This protein is identical to the extracellular domain of the GH receptor, but it is unclear whether in humans GHBP arises from alternative splicing of the GH receptor mRNA, as it does in the rat, or is shed from cell-surface receptors by peptidases. Changes in serum concentrations of GHBP reflect changes in the number of cell-surface GH receptors.[97] In contrast to the prolonged half-life of IGFs bound to the IBFBPs (more than 12 hours), the plasma half-life of GH is about 20 minutes.

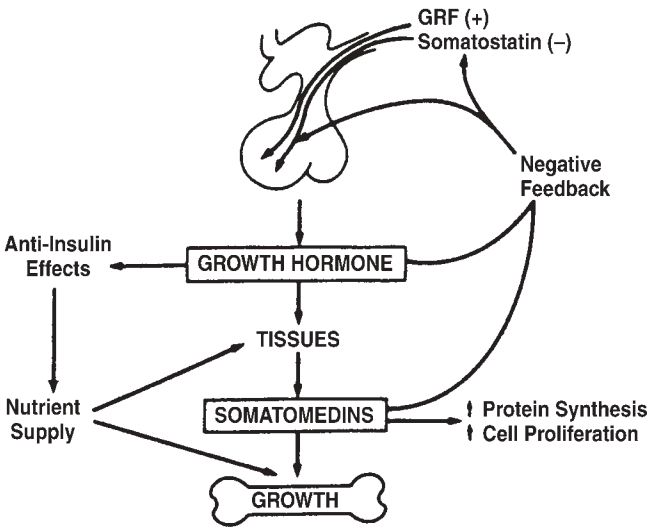

FIGURE 16-3 The growth hormone–somatomedin axis. (+) = stimulatory action; (–) = inhibitory action. GRF = growth hormone–releasing factor.

Normal GH secretion in humans is highly episodic. Blood concentrations are generally low or undetectable for much of the day and are interrupted by bursts of secretion that result in high concentrations for roughly 90 minutes before returning to the low baseline. This pattern is developmentally regulated.[98] The number and amplitude of secretory episodes are small in young children. Under the influence of gonadal steroids, both the frequency and amplitude increase dramatically and reach their highest levels during puberty, especially during sleep; they then gradually decline over the ensuing decades.

The combined concentration of IGF proteins in the blood is on the order of 750 µg/L or 100 nM. Although GH remains the predominant regulator of IGF production and IGFBPs the principal regulators of bioavailable IGFs, a number of other hormones influence IGF-I concentrations in blood. This peptide is low or nonexistent in fetal life, when IGF-II appears to be the predominant somatomedin. During fetal life, placental lactogen or the product of the *GH-V* gene is likely to be the major regulator of somatomedin production.[99] Prolactin, another GH-like hormone, can also stimulate the production of IGFs in cultured cells and probably in clinical conditions of prolactin excess. Blood levels of the IGFs remain low during infancy and early childhood but rise dramatically at puberty in response to increases in GH secretory activity. In addition, IGF-I concentrations are low in patients with hypothyroidism.[100] Clinically, IGF-I concentrations in blood have been shown to reliably mirror the total GH secretory activity. Thus, in older children and adults who are well nourished and do not have hypothyroidism, serum IGF-I measurements are more useful than random measurements of GH in diagnosing conditions of GH deficiency (hypopituitarism) and excess (gigantism or acromegaly). The marked influence of nutritional status on IGF production is discussed later in this chapter.

Direct versus Indirect Actions of* GH: A *Unifying Hypothesis? GH initiates a signal by binding to specific receptors on the surface of target cells. A single GH molecule contains two separate receptor-binding domains, which facilitate the formation of receptor homodimers on GH binding.[101] Receptor dimerization is a feature common to a number of growth factor receptors and appears to be a prerequisite for signaling. When activated by ligand, the GH receptor dimerizes and associates with a protein kinase called janus kinase 2 (JAK2). JAK2 then phosphorylates a family of proteins called signal transducers and activators of transcription (STATs). STAT proteins bind to deoxyribonucleic acid (DNA) in the nucleus and activate gene

transcription directly. The pathways of GH signal transduction are far more complex than JAK/STAT activation and also involve phosphorylation of the insulin receptor substrate proteins IRS-1 and IRS-2 and calcium fluxes, as well as the activation of the phosphatidylinositol kinase (PI-3 kinase) and protein kinase C pathways.[71]

The actions of GH in vivo have been categorized as either indirect (IGF mediated) or direct. The direct actions vary significantly depending on the duration of exposure. After short-term administration to GH-deficient individuals or to isolated GH-sensitive tissues in culture, GH has effects very much like those of insulin. They are rapid in onset, transient in duration, and not mediated through the actions of IGFs. They include the stimulation of glucose and amino acid transport and protein synthesis. GH also has inductive effects on a number of enzymes.

Chronic GH administration, in contrast, results in biochemical actions that appear antagonistic to insulin; blood sugar rises and fat mobilization and fatty acid oxidation occur. In fact, release of GH is one of the stress responses that the body uses to maintain euglycemia. In 20% of individuals with GH-secreting tumors, frank diabetes mellitus occurs.

The origins of these paradoxic "direct" actions are not clear but may reside in the structure of the GH molecule itself. The 20 kDa variant has been reported to have only one-fifth of the insulin-like activity of the 22 kDa GH molecule, while retaining normal growth-promoting and diabetogenic activity.[102,103] However, analysis of the biologic activities of both the 22 kDa and 20 kDa GH molecules in transgenic mice demonstrated largely overlapping activities with regard to linear growth and carbohydrate metabolism.[104]

The concept that IGFs can mediate the actions of GH in promoting linear growth has been validated by a number of studies that show that IGF-I injections increase tibial width and costal cartilage DNA synthesis in hypophysectomized rats to an extent that is comparable to that in GH-treated controls. In human newborn infants, umbilical cord plasma levels of IGF-I and leptin (see below) show a strong positive correlation with increasing birth weight and birth length.[105] Both IGF-I and leptin, which is secreted by both adipocytes and placenta, are important for fetal growth. The ability of IGF-I to stimulate linear growth in the absence of GH is strongly supported by studies demonstrating overgrowth in transgenic mice overexpressing IGF-I and in IGF-I-treated humans with Laron-type dwarfism, a condition that results from the hereditary absence of GH receptors.

There are major local effects of IGFs and EGF found in maternal breast milk. IGF-I, IGF-II, and a truncated form of IGF-I are also present in colostrum.[106] Importantly, intestinal IGFs are also produced by the mesenchymal cells within the lamina propria. Most of these effects are direct on the gut and do not generally affect somatic growth. Trophic effects have generally been observed in the distal bowel (ileum) more than the jejunum. In the piglet intestine, oral rhIGF-I increased small intestinal weight, protein, and DNA content and jejunal and ileal villus height.[107] Additionally, oral rhIGF-I has been shown to increase basal Na^+ absorption and the maximal rate of D-glucose and L-alanine absorption in newborn pigets.[108]

When intestinal cells are studied, IGFs are well-known stimulators of cell proliferation but also are potent stimulators of cell migration, a mechanism central to the healing of ulcers, villus damage in viral enteritis, and other lesions.[109] The mechanism by which migration/restitution is stimulated appears to be dependent on protein kinase C.[110] Other pathways are activated by IGF-1, including the PI-3 kinase pathway, c-Jun nuclear kinase, and mitogen-activated protein kinases.[111] Consequently, growth factors have been extensively investigated as therapeutic agents to enhance gut integrity and facilitate repair.

Orally administered growth factors have been found to exert trophic effects to the intestinal mucosa in experimental rotavirus enteritis and in rats with short-bowel syndrome.[112,113] In two studies, the combination of the primary metabolic fuel of the intestine, glutamine, with either GH or IGF-I resulted in a synergistic trophic response.[114,115] A synergistic trophic response of glutamine with transforming growth factor-α was seen after ischemia/reperfusion injury of the porcine intestine.[116]

In viral enteritis, exogenous growth factors have enhanced mucosal mass without reducing diarrheal output or increasing specific activities of jejunal disaccharidase enzymes.[112,117] In short-bowel syndrome and ischemic bowel disease, growth factors and the trophic amino acid L-glutamine have been shown to have synergistic effects.[115,118] These effects have not been translated into clinical therapy for diarrheal diseases to date.

Another disease for which enteral growth factor therapy has begun to be studied is short-bowel syndrome. In this condition, which is the leading cause of intestinal failure in newborns, the infant's bowel length limits absorption, leading to a prolonged dependence on parenteral nutrition and (eventually) to end-stage liver disease. In several studies, Donovan and colleagues treated newborn piglets that received 80% of required calories via parenteral nutrition with enteral IGF-I.[119] They found that enteral IGF-I augmented intestinal morphology and markedly increased disaccharidase activity in parenterally fed piglets over that observed with partial enteral nutrition alone. The mechanism by which lactase activity in the mucosa was so markedly increased appeared to be post-translational in nature.[120]

Transgenic mice overexpressing GH and IGF-I have shown increased body weight, as well as small bowel length and mass, and some notable differences between GH and IGF-I have altered the traditional concept that all effects of GH are mediated via IGF-I.[121] GH has much more profound effects on body mass compared to IGF-I (60% versus 23% increase), whereas IGF-I has much greater effects on bowel length (20% versus 44% increase), and IGF-I but not GH overexpression increases intestinal crypt cell proliferation while reducing crypt cell apoptosis. In further support, murine knockout models for IGF-I, the GH receptor, or both show that both factors have major independent effects on somatic growth (30 to 50%), whereas lack of functional expression of both growth fac-

tors profoundly affects growth. *Igf-1/ghr* double knockouts reach only 17% of the expected adult body weight.[122]

Insulin in Normal Growth The prominent influence of insulin on normal growth is best illustrated in disorders at the extremes of altered insulin secretion. Especially in the fetus, hyperinsulinemia produces somatic overgrowth. Hyperinsulinemic infants born of poorly controlled diabetic mothers exhibit visceromegaly, increased body fat, and increased length, whereas the hypoinsulinemic infant born with severe insulin resistance or pancreatic agenesis is small and depleted in body fat.[123] In postnatal life, poorly controlled diabetes mellitus can be associated with a striking growth failure, the so-called Mauriac syndrome.[124] The growth-promoting actions of insulin both in prenatal and postnatal life are complex and likely to result from both direct, largely metabolic effects mediated through the insulin receptor and indirect, predominantly mitogenic effects mediated through the structurally homologous IGF-I receptor.

Insulin Receptor–Mediated Actions of Insulin. High-affinity insulin receptors mediate the rapid biologic actions of insulin in stimulating the cellular transport of substrates and in the induction of enzymes that promote glycogen and fat synthesis and that inhibit gluconeogenesis, lipolysis, and ketogenesis.

An indirect consequence of insulin action appears to be the stimulation of IGF production. A number of clinical studies have shown that the depressed IGF concentration associated with poorly controlled diabetes mellitus can be returned to normal with insulin therapy.[125] Insulin appears to directly stimulate IGF production in whole liver, liver slices, or cultured hepatocytes.[126] Additionally, insulin may regulate IGF production by influencing the number of GH receptors on important IGF-producing tissues. In poorly controlled diabetes mellitus, there is a dramatic reduction in the number of somatogenic GH binding sites in liver. These can be restored to normal with insulin therapy.[127]

IGF Receptor–Mediated Actions of Insulin. In a few cell types, such as hepatocytes, certain teratocarcinoma cells, and mammary tumor cells, insulin appears to be directly mitogenic by binding to its own receptor at physiologic concentrations. However, some of the growth-promoting actions of insulin can be attributed to activation of IGF receptors. There are two principal IGF receptors, type I and type II. The insulin receptor and the type I IGF receptor are homologous "heterotetramers," consisting of two α and β subunits. Insulin or IGF binding to their respective α subunits activates a tyrosine kinase on the cytoplasmic portion of their respective β subunits, which, in turn, autophosphorylates the receptor and other cytoplasmic substrates that are essential for the actions of both insulin and IGF-I.[128] Both IGF-I and IGF-II can bind to and activate the insulin receptor, although with much lower affinity than insulin.

Crossover of IGF and insulin actions also occurs when type I IGF receptors are activated by insulin. Although type I receptors preferentially bind IGF-I, they can be activated by 10- to 100-fold excess concentrations of insulin, conditions that are achieved in some cases of hyperinsulinism, such as insulin-resistant states. Another level of overlap between IGF-I and insulin action is suggested by the finding that a single α, β subunit of the insulin receptor can associate with an α, β subunit of the type I IGF receptor, forming a hybrid tetramer.[129]

The type II IGF receptor is more enigmatic.[130] It preferentially binds IGF-II over IGF-I but is also the receptor that (at a different binding site) shuttles mannose-6-phosphate–containing extracellular proteins into lysosomes. The type II receptor does not contain an intracellular tyrosine kinase domain, and its role (if any) in intracellular signaling is unclear. Most of the actions of IGF-II are thought to be mediated through the type I IGF or insulin receptors. Type II IGF receptors do not bind insulin, but physiologic concentrations of insulin dramatically up-regulate the number of type II IGF receptors on adipocyte.[131]

Insulin Synergy with Other Growth Factors. One further mechanism by which insulin appears to influence cellular growth is to alter the cellular requirements for mitogenic signals from other growth factors. As discussed previously regarding the interactions of nutrients and hormones, growth factor signals frequently converge on common pathways within a cell so that low concentrations of two growth factors can amplify the actions of one another. In cultured hepatocytes, insulin can potentiate the mitogenic signal of EGF or of vasopressin,[132] and in the well-studied BALB/c 3T3 fibroblast, the presence of insulin or IGF-I strongly modulates the mitogenic actions of EGF and platelet-derived growth factor.

Malnutrition

Growth Hormone in Malnutrition ***Growth Hormone Levels in Malnutrition.*** In humans, experimental fasting and malnutrition generally result in elevated serum concentrations of GH. Studies of malnourished populations in different parts of the world have often led to conflicting conclusions, in part from differing criteria for malnutrition, from the inaccuracies inherent in characterizing complex GH secretory patterns from a single blood sample, and perhaps to some extent from confounding features such as infection.[133] The normal physiology of nutrient regulation of GH secretion is also complex; amino acids such as arginine stimulate GH release, whereas carbohydrates and fatty acids inhibit GH secretion. Clinical malnutrition results from a combination of dietary deficiencies that could be expected to have variable effects on GH release.

Recently, attention has turned to the effects of fasting on the pattern of GH release from the pituitary. As previously described, GH secretion in humans is episodic, and measurement of GH concentrations on random blood samples, as is typical of field studies, might be expected to give inconsistent results. Ho and coworkers performed frequent blood sampling (every 20 minutes) of fasted volunteers and uncovered an inherent pulsatility in GH secretion in humans that appears to be suppressed in the fed state, perhaps by the negative feedback of IGFs.[134] Over the course of a 5-day fast, those authors measured significant increases in GH pulse frequency, maximal pulse amplitude,

and 24-hour integrated concentration (Table 16-5). These changes coincided with a decline in concentrations of IGF-I and glucose and a rise in those of free fatty acids and acetoacetate. Subsequent studies led those authors to conclude that fasting-induced enhancement of GH secretion is mediated by an increase in GH-RH pulsatility and a decrease in somatostatin release.[135]

Serum GH concentrations are elevated in children with both kwashiorkor and marasmus but do not allow distinction between the two.[136–140] Becker and associates observed the magnitude of GH elevation to be inversely related to the severity of protein malnutrition, as judged by the serum albumin concentration.[136] In their subjects, GH concentrations fell after feeding a protein-rich diet for 36 to 72 hours. The critical role of protein in the refeeding diet was also demonstrated by Pimstone and colleagues, who found that refeeding with a high-carbohydrate, protein-free diet does not normalize GH concentrations.[140] When caloric deprivation predominates, the GH response appears to be variable; some groups have reported depressed GH concentrations and others have reported elevations.[141,142] In short-term malnutrition, the adaptive benefits of elevated GH concentrations are suggested by the known direct effects of GH to increase gluconeogenesis, lipolysis, and fatty acid oxidation. Elevated GH concentrations might be expected to increase glucose production initially, while shifting the organism to a lipolytic, protein-sparing state.

Whereas short-term protein-calorie malnutrition is associated with elevated GH concentrations, long-standing malnutrition results in depressed GH secretion. Beas and coworkers described a group of infants with low concentrations not only of GH but also of adrenal and thyroid hormones, suggesting generalized pituitary hypofunction.[143] An adaptive function of a hypopituitary state in reducing metabolic activity had previously been proposed by Mulinos and Pomerantz, who likened the malnourished state to a "pseudohypophysectomy."[144]

Clinical Uses of* GH *in Disease States. The adaptive changes in GH release that accompany malnutrition have prompted a number of studies on the possible uses of GH in promoting anabolism during recovery from operation or injury. Clemmons and coworkers determined the effects of GH injections on obese individuals subjected to hypocaloric diets.[145] Although dietary restriction produced comparable weight loss in subjects receiving GH and those receiving placebo, those treated with GH (0.1 mg/kg every 48 hours) had a significantly lower daily nitrogen deficit than controls. Similar findings were reported by Manson and Wilmore, who administered GH to volunteers receiving hypocaloric parenteral nutrition (Figure 16-4).[146] GH therapy decreased the rate of weight loss and increased nitrogen retention. In parenterally nourished patients recovering from gastrointestinal surgery, GH administration has resulted in sustained nitrogen retention, suggesting a possible role for this agent in promoting recovery from a variety of catabolic states.[147,148]

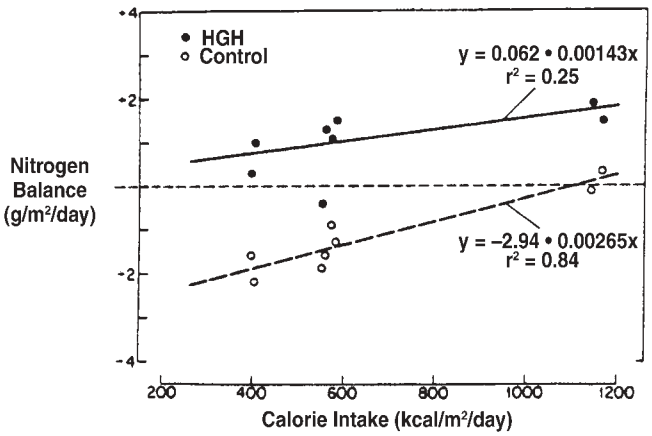

FIGURE 16-4 Positive nitrogen balance in growth hormone–treated subjects at all levels of hypocaloric calorie provision. Eight male subjects were exposed to various levels of hypocaloric intravenous feeding. Only adequate energy intake resulted in positive nitrogen balance in the controls (*open circles*), whereas growth hormone–treated subjects (*closed circles*) were in positive nitrogen balance at all levels of energy intake. Adapted from Manson J and Wilmore D.[146]

Unfortunately, a series of investigations in critically ill adults with multiorgan system failure in several placebo-controlled, masked trials found that high-dose recombinant human GH treatment produced a twofold increase in mortality, increased the length of stay in hospital, and prolonged the duration of mechanical ventilation.[149] Oddly, similar doses of GH administered to critically ill children with extensive body burns did not increase morbidity or mortality and reduced intravenous albumin and calcium requirements compared with placebo-treated children. There were increased hyperglycemic episodes and insulin requirements in the treated group, although these were not considered dangerous.[150]

In humans with several gastroenterologic conditions, exogenous GH administration has been shown to have beneficial effects. In cystic fibrosis, GH treatment improved growth rate (linear and ponderal) and—by as yet undetermined mechanisms—reduced pulmonary exacerbations.[151,152] In adults with Crohn's disease, a preliminary placebo-controlled trial of GH therapy for 4 months improved the Crohn's Disease Activity Index score significantly.[153] In these children, inflammatory bowel disease activity was not influenced, but 4-month treatment with GH improved fat-free body mass, decreased percent fat mass, and enhanced linear growth velocity.[154]

Table 16-5 Enhanced Pulsatility of Growth Hormone Release in Fasting

Measure of Pulsatility	*Day 0*	*Day 1*	*Day 5*
GH peaks (number/24 h)	5.8 ± 0.7	7.3 ± 0.6*	9.9 ± 0.7*
GH peak amplitude (ng/mL)	5.9 ± 1.1	13.1 ± 1.2*	12.3 ± 1.6*
24-hour IGHC (μg/mL/min)	2.8 ± 0.5	7.8 ± 1.1†	8.8 ± 0.8†

Frequent venous sampling of six adult male subjects was performed during a control fed day (day 0) and during the first (day 1) and fifth (day 5) days of a fast.
GH = growth hormone; IGHC = 24-hour integrated GH concentration.
*$p < .005$, compared with day 0.
†$p > .0009$.

Substantial worldwide experimental support has emerged for GH treatment of infants born small for gestational age (a condition also called IUGR). IUGR reportedly is associated with subsequently high rates of coronary heart disease, high blood pressure, glucose intolerance, and high cholesterol.[155] Treatment with daily GH shots increased linear growth velocity in many studies, while delaying the onset of puberty and exhibiting few, if any, side effects.[156–160] However, treatment for years was required, higher doses were more effective, and younger children (3 to 5 years old) were more responsive to treatment.[161] Of major concern is the global scope of this problem with IUGR, however, because IUGR affects 20% of children in Malawi and 25% of children in Pakistan.[162,163] Clearly, ethical problems will arise as to which children can be treated with this expensive and long-term therapy.

IGFs and IGFBPs in Malnutrition **IGF B*ioactivity*, IGF I*nhibitors, and* IGFBP*s*.** Despite elevated GH levels in fasting or short-term malnutrition, the production of IGF-I is dramatically reduced in malnutrition. Studies using somatomedin bioassays were the first to indicate that serum IGF bioactivity falls with malnutrition. More recent data using highly specific radioimmunoassays indicate that the depressed bioactivity of serum from fasted or malnourished individuals results from a dramatic fall in IGF-I concentrations, minimal, if any, change in IGF-II concentrations, and changes in IGFBPs (Table 16-6).[164]

Measuring serum somatomedin bioactivity in a sulfation factor assay, Grant and associates were among the first to show a nutritional influence on somatomedin activity; they found low levels in the serum of malnourished South African children despite elevated GH concentrations.[165] Those authors found both hormones to return toward normal by the ninth day of refeeding. Similar results using somatomedin bioassays were forthcoming from other malnourished populations, including malnourished Thai and Nigerian infants and children and patients with celiac disease and anorexia nervosa.[166–170]

Bioassays of IGF activity in blood, although relatively nonspecific as to which of the two IGFs is being measured, allow the detection of physiologically important IGF inhibitors in serum. Much of the older data on somatomedin inhibitors can be attributed to changes in the concentration of known IGFBPs. Increased concentrations of inhibitors have been found in the serum of malnourished children and hypopituitary adults and in serum from starved, hypophysectomized, or diabetic rats.[166,171–174] Salmon and colleagues partially purified a 27 to 40 kDa, heat-labile inhibitor from fasted rat serum.[175] Recent studies have suggested that this inhibitor may be the serum binding protein IGFBP-1 (see Table 16-4).[176] Serum concentrations of BP-1 almost double with fasting and decrease after meals.[177] In addition, they are elevated in diabetes, consonant with the proposed role of insulin in the regulation of BP-1 production.[178] Phillips and associates have shown that concurrent with the fall in IGF activity of rat serum during fasting, total IGF inhibitor activity rises.[179] The IGF inhibitory activity of serum appears to be more nutritionally sensitive than the IGF activity itself. After 6 hours of refeeding, the IGF inhibitor activity had fallen significantly, but there was little change in IGF activity; both returned to normal with continued refeeding.

Table 16-6 Effects of Undernutrition on the GH-IGF Axis

Increased GH secretion
GH resistance in peripheral tissues
Decreased GH receptor mRNA
Decreased GH binding
Diminished postreceptor signaling (P)
Decreased somatomedin bioactivity
Decreased IGF-I production
Decreased IGF-I gene transcription
Diminished IGF-I mRNA stability (P)
Diminished IGF-I mRNA translation (P)
Normal IGF-II production
Increased IGFBP-1 production
Decreased IGFBP-3 production (P)
Increased IGF-I clearance
Increased IGF inhibitor production
Decreased tissue sensitivity to IGF-I

(P) indicates features more typical of protein deprivation or chronic malnutrition than of fasting.
GH = growth hormone; IGF = insulin-like growth factor; IGFBP = insulin-like growth facor binding protein; mRNA = messenger ribonucleic acid.

IGF-I *and* IGF-II *in* Malnutrition. As measured by specific radioimmunoassays, IGF-I concentrations drop dramatically with fasting in adult volunteers, whereas those of IGF-II do not.[164,180] Clemmons and colleagues found that fasting of overweight adult volunteers for 10 days produced a drop of IGF-I concentrations to hypopituitary levels; refeeding produced a return toward normal (Figure 16-5).[180] The decline in serum IGF-I correlated with nitrogen balance. In some physiologic circumstances, however, the fall in serum IGF-I concentrations becomes dissociated from the changes in nitrogen balance. Smith and coworkers studied six conditioned athletes and concluded that strenuous exercise, which produces negative caloric balance, causes as much of a fall in serum IGF-I as does comparable caloric restriction without exercise but a much lower nitrogen loss.[181]

In contrast to the apparent insensitivity of serum IGF-II to fasting in adults, Soliman and associates have documented depressed IGF-II concentrations in children with severe marasmus and marasmic kwashiorkor.[164,182] These returned to normal with refeeding. The magnitude of IGF-II depression was not nearly as great as that of IGF-I, and the IGF-II concentrations in sera of children who were underweight or had only kwashiorkor were not depressed. Thus, severe or long-lasting malnutrition in children may eventually depress IGF-II production, although IGF-I remains the more acutely sensitive to malnutrition.

***S*erum IGF-I *as an I*ndex *of* N*utritional* S*tatus*.** The striking correlation between (as yet unidentified) aspects of nutritional status and serum IGF-I concentrations has led some investigators to suggest that the latter might provide a highly sensitive and quantitative way of following nutritional status. Clemmons and colleagues found that IGF-I increased by 170% over 10 days in six malnourished

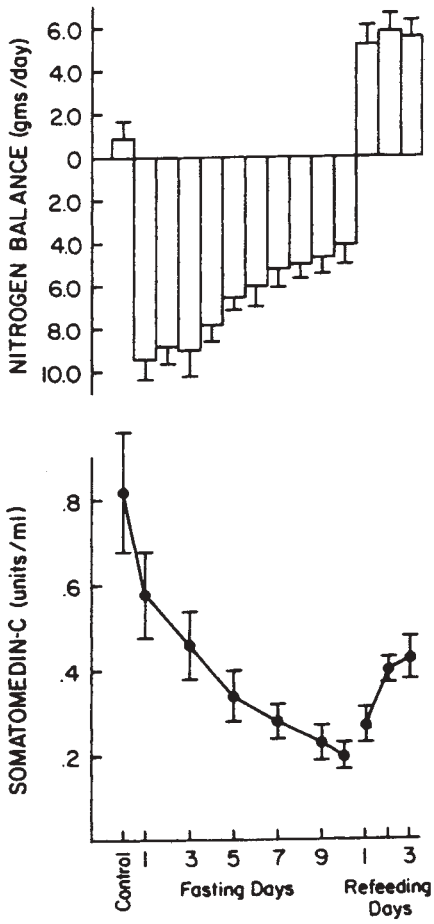

FIGURE 16-5 The effects of fasting on plasma somatomedin C (insulin-like growth factor I) and nitrogen balance. The subjects were seven males 20 to 70% above ideal body weight. During the control period, they were fed a 1,500 kcal diet for 3 days. Between days 4 and 13, they fasted, receiving only water, vitamins, and potassium chloride. Refeeding consisted of resumption of the control diet. Each point is the mean ± SEM. Adapted from Clemmons D et al. [180]

patients with gastrointestinal disorders that necessitated either total parenteral or tube feedings.[183] All patients were in positive nitrogen balance when first measured on the second day of refeeding. Other commonly used indices of nutritional status fell much less dramatically and normalized much more slowly: prealbumin by 21%, retinol binding protein by 18%, and transferrin by 10%. Unterman and coworkers came to similar conclusions when they compared IGF-I concentrations with other indices in 37 generally elderly hospitalized patients with a variety of neoplastic, gastrointestinal, and neurologic diseases.[184] The IGF-I was more depressed than albumin or transferrin in patients who had no reduction in either triceps skinfold thickness or midarm muscle circumference. In six patients given nutritional support, IGF-I concentrations rose by more than 70% in each patient, whereas the lymphocyte count and transferrin concentration rose in only four patients and albumin concentration in only one. Serum IGF-I measurements have also been suggested as a means to follow the progress of children and adolescents with chronic inflammatory bowel disease.[185] In a study of critically ill patients, serum concentrations of prealbumin, retinol binding protein, and transferrin levels were strongly correlated with levels of IGF-I, IGF-II, IGFBP-3, and ALS.[186]

***Mechanisms of* IGF *Regulation by* Nutrients.** A number of studies have attempted to determine the specific components of the refeeding diet that regulate IGF-I production in recovery from an acute fast. When normal-weight human volunteers were fasted for 5 days and then refed with a normal diet, a diet that was isocaloric but protein deficient, or a diet deficient in both protein and calories, Isley and associates concluded that intake of adequate quantities of both protein and calories is critical for the restoration of IGF-I after a fast.[187] They noted that even in the face of a protein-deficient diet, recovery of serum IGF-I concentrations was possible as long as the energy content was adequate. Animal studies have indicated that the roles played by protein and calorie intake in regulating serum IGF-I concentrations may be developmentally influenced. Prewitt and coworkers placed 3-week-old rats on diets in which the protein content was varied (5%, 10%, or 15% lactalbumin) at one of three levels of energy intake (100%, 75%, or 50% ad libitum).[188] After 2 weeks, protein intake played the major role in regulating IGF-I concentrations, whereas after 9 weeks, both protein and caloric intake were important.

The malnourished state is one of resistance to the effects of GH. As noted previously, GH secretion increases in the fasted state, whereas serum concentrations of IGF-I fall. Merimee and colleagues found that GH administered to fasted, GH-deficient subjects induced a minimal increase in serum IGF-I concentrations in comparison with the 10-fold increase in GH induced in normally fed, GH-deficient subjects.[189] Studies in fasted and diabetic rats have correlated the fall in serum IGF-I concentrations with a decline in the number of hepatic GH receptors, suggesting that a primary effect of malnutrition, perhaps mediated by decreased insulin concentrations, is to decrease GH receptors and consequently IGF-I production.[190–192] Indeed, fasting results in decreased GH receptor mRNA in the liver.[193,194] The situation may differ in protein-deprived rats, in whom a postreceptor defect in GH action has been suggested.[131] The net result of fasting is a decrease in the concentrations of IGF-I mRNA in the liver and other tissues.[193] This results from decreased transcription of the IGF-I gene, although the effects of protein deprivation may further influence IGF-I mRNA stability and also decrease the translation of IGF-I mRNA into peptide.[195]

The fasted or malnourished state is also one of resistance to the action of IGF-I. Thissen and associates showed that, in contrast to normally fed, hypophysectomized rats, an infusion of recombinant IGF-I into protein-restricted rats did not stimulate an increase in weight gain or linear growth, despite restoring normal serum concentrations.[196] Somewhat surprisingly, this nutritionally induced IGF-I resistance does not result from a decrease in IGF-I receptors at target tissues; instead, most tissues show increased IGF-I binding.[197]

IGFBPs in Malnutrition Among the IGFBPs, BP-3 is unique in its diurnal rhythm, which appears to be regu-

lated by food intake. IGFBP-1 is rapidly suppressed following a meal and acutely rises in response to hyperglycemia. In this context, IGFBP-1 may serve as a glucose counterregulatory hormone by further depressing free IGF concentrations in the hypoglycemic state. In addition to its regulation by nutrients, IGFBP-1 is stimulated by glucocorticoids and by cytokines such as tumor necrosis factor (TNF)-α and various interleukins. Nutritional status appears to also influence the phosphorylation status of IGFBP-1. Baxter postulated that increases in IGFBP-2, -BP-4, and -BP-6 during acute illness could serve to redistribute IGFs from ternary complexes in the serum to binary complexes in the extracellular space and make them more available to the tissues.[81]

Insulin in Malnutrition With fasting or protein-calorie malnutrition, plasma insulin concentrations are reduced, although, in some instances, high and normal levels have been reported.[182] Some of these discrepancies might be explained by the observations of Lunn and associates that in kwashiorkor, there is an early phase of hyperinsulinism that is followed by insulinopenia.[138] Diminished insulin release results in impaired tolerance to glucose or an amino acid load.[198] Pimstone and coworkers noted that the insulin response to oral glucose is abnormal in malnourished children but that intravenous glucose elicits a normal response, suggesting that deficiencies of glucagon or other insulinotropic factors are important in determining the response to malnutrition.[199] Those authors also demonstrated that the impaired insulin response to a glucose load in kwashiorkor could be ameliorated by the addition of potassium to the diet. The relationship of malnutrition and diabetes mellitus has been reviewed by Rao, who concluded that a malnourished condition can influence the diabetogenicity of other agents, including dietary toxins, drugs, and viruses, but does not directly cause diabetes.[200] In fact, initial presentation with dehydration and hypoglycemia (< 40 mg/dL) has been associated with a high mortality (42%) for children with diarrheal dehydration.[201]

Psychosocial Growth Failure

The interactions of nutritional and hormonal influences have been extensively studied in cases of "psychosocial growth failure" or "deprivation dwarfism," terms used to describe the growth failure that can accompany severe emotional deprivation. Early in this century, it was recognized that emotional deprivation could be associated with growth retardation in institutionalized children.[202] Subsequent studies revealed that such children need not be in an institutional setting and that an impoverished emotional environment in the home is sufficient. Affected children are observed to have a voracious appetite with bizarre eating and drinking behavior such as foraging, drinking from the toilet bowl, and gorging. In addition, delayed speech, foul-smelling stools, a protuberant abdomen, and characteristic neurologic postures have been described.[202,203]

Patton and Gardner speculated that emotional deprivation could produce growth retardation in a variety of ways, including failure of the caregiver to provide adequate nutrition, depression-induced anorexia in response to the emotional environment, altered gastrointestinal function, or changes in metabolism.[204] Considerable attention has been paid to whether the growth failure and endocrine-metabolic changes of psychosocial dwarfism are the result of emotional deprivation alone or are secondary to impaired caloric intake.

A large body of evidence suggests that a hypopituitary state can develop in some children with emotional deprivation. Talbot found significant malnutrition in a group of 51 children with growth failure of no identifiable etiology and postulated that they might have "functional hypopituitarism" as a means of adapting to limited caloric intake.[205] Twenty years later, Powell and colleagues studied emotionally deprived children and demonstrated diminished reserves of adrenocorticotropic hormone (ACTH) and GH, which were normalized when the affected children were removed from their adverse surroundings.[206,207] The authors found little evidence of caloric deprivation in their patients and suggested that psychic factors caused their hypopituitarism. Miller and colleagues demonstrated a loss of GH secretory episodes during a 6-hour period of blood sampling in four children with psychosocial deprivation.[208] In one child, GH secretion normalized after hospitalization and rehabilitation. Despite the apparent state of GH deficiency, attempts to induce growth in such children by administration of GH have been unsuccessful.[209,210]

Psychological factors were also invoked by Widdowson to explain her observations on the growth of children in two German orphanages after World War II.[211] Orphans under the care of a stern and forbidding supervisor who chose mealtimes to rebuke the children gained weight at about one-third the rate of children at another, more hospitable orphanage despite comparable food intake. When the supervisor of the first orphanage was transferred to the second, the pattern reversed, and the new children under her care gained weight poorly.

A countertheme to the hypothesis of a strictly emotional etiology of psychosocial growth failure has been the suggestion that underfeeding by caregivers is the primary cause of growth failure in these children. From their studies on emotionally deprived infants between 3 and 24 months of age, Whitten and colleagues observed dramatic weight gain in 11 of 13 children when the infants were given adequate nutrition in a hospital setting designed to reproduce the impoverished emotional ambience of their homes.[212] During a control period in which these children were fed equal amounts of food but also were given a high level of mothering care, their weight gain was no greater. Other studies have found elevated fasting levels of GH in a number of infants and children with emotional deprivation, leading to the speculation that these infants suffered from food deprivation as well as emotional deprivation.[213]

Contemporary dietary and health misconceptions have created a modern-day version of the growth-retarded child from a turn-of-the-century foundling house or war orphanage. Pugliese and colleagues described a group of 14 adolescents who presented with

short stature and malnutrition from self-imposed caloric restriction.[214] These children showed no evidence of overt psychiatric disease or anorexia nervosa but had restricted their food intake from a fear of obesity. Similar findings were reported in a group of younger children, 7 to 22 months of age, who presented with nutritional failure to thrive secondary to parental restriction of food arising from a fear of obesity, cardiovascular disease, or unhealthful eating habits.[215]

It is reasonable to propose from these somewhat disparate observations that the mechanisms involved in the growth failure associated with emotional deprivation form a spectrum (Figure 16-6). At one extreme are children in whom growth failure is nutritional in origin, whether from limited access to food, emotionally induced anorexia, or altered gastrointestinal function. In these children, endocrine alterations are adaptive and occur in response to malnutrition. At the other extreme of the spectrum are those children whose hormonal and metabolic alterations are emotionally induced. The growth failure of these children is probably mediated by hormone deficiencies rather than by inadequate nutrition. It would appear that many of the children with clinical features of psychosocial growth failure combine features of both extremes of the spectrum.

Overnutrition and Growth Acceleration

Just as a deficiency of nutrients can retard growth, so can nutritional surfeit accelerate growth. This is perhaps most pronounced in fetal life, when excessive glucose and other nutrients from conditions such as mild maternal diabetes can lead to significant overgrowth. A stimulatory influence of obesity on childhood growth appears to be the case as well. In the mid-1940s, Talbot noted that obese children tend to be tall, to have advanced skeletal maturation, and to excrete more ketosteroids than nonobese children.[216] Subsequent studies by Garn and others have confirmed a correlation between obesity and height throughout childhood.[217–220] In affluent societies, socioeconomic factors influence obesity, making correlation of the latter with adult height difficult. However, a recent study by Garn and associates in Central America indicated that the augmented stature associated with obesity in childhood persists into adulthood.[220]

In the fetus, insulin appears to play a critical role in the more commonly recognized overgrowth syndromes. Although obesity is associated with elevated circulating insulin concentrations, it is unlikely that insulin plays a direct role in the facilitation of growth because obese individuals are relatively insulin resistant and require high concentrations of insulin to maintain normal homeostasis.[221] A regulatory role for insulin in promoting growth, perhaps by stimulating appetite, has been suggested in a subgroup of children recovering from surgery for craniopharyngioma. These tumors compress the hypothalamus and often result in hypopituitarism, yet a significant number of patients are able to maintain normal growth velocities after surgery, despite a GH-deficient state. Bucher and colleagues compared a group of rapidly growing children with groups of normal- and slowly growing children after surgery for craniopharyngioma and found that those with supranormal growth rates were hyperphagic and had elevated insulin levels.[222] Comparable findings of hyperphagia, obesity, and hyperinsulinism have been made in animals with lesions in the ventromedial hypothalamus.[223]

There is a negative correlation between serum IGF-I concentrations and body fat.[224,225] It has been noted that the fall of plasma IGF-I concentrations is slower in fasted obese individuals than in normal subjects.[226] Underwood and colleagues studied the effects of overfeeding on IGF-I levels in GH-deficient subjects.[227] After 10 days of an

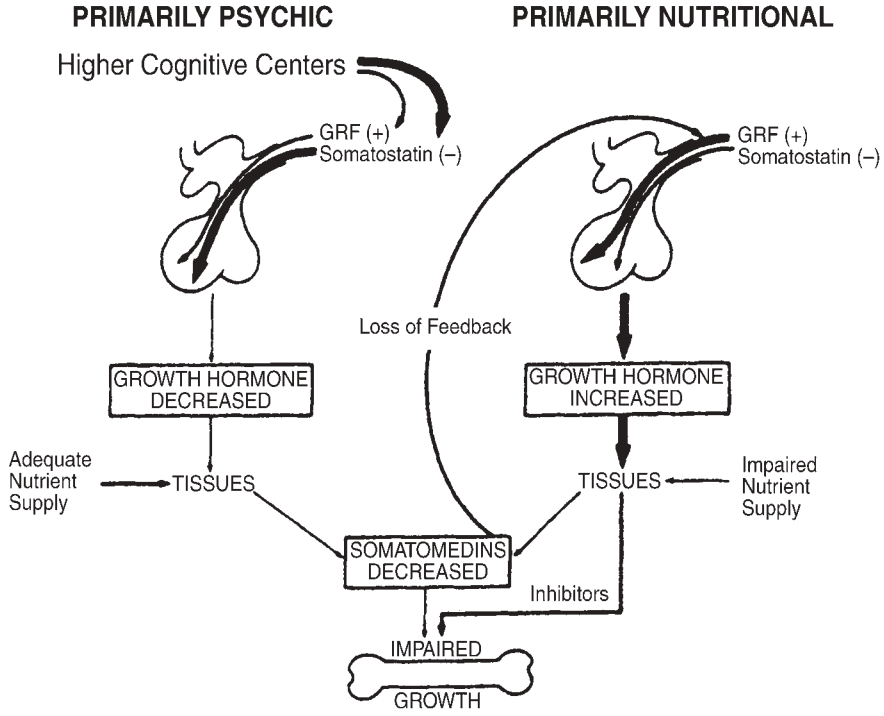

FIGURE 16-6 Psychosocial growth failure. Two possible mechanisms of psychosocial growth failure are proposed: primarily psychic (neuroendocrine) and nutritional. *Left*, Under largely psychological influences, pituitary growth hormone secretion is diminished in the face of normal nutrition. *Right*, When undernutrition predominates, the endocrine changes observed are adaptive ones. Somatomedin production is reduced, insulin-like growth factor binding proteins are increased, and growth hormone secretion is increased. GRF = growth hormone–releasing factor.

energy intake 50% above basal, those subjects experienced a significant increase in weight, nitrogen balance, fasting blood sugar, and insulin levels but no significant change in IGF-I concentrations. GH secretion may be altered in obesity, and GH release in response to pharmacologic stimuli is often blunted; however, pretreatment with beta-blocking drugs normalizes the secretory response, suggesting adequate GH reserves.[228]

Obesity as a Disorder of Humoral Signaling

Analogous to Tanner's proposed "sizostat" to monitor body size, recent studies have identified an "adipostat" factor by which the CNS monitors the peripheral adipose mass of the body and modulates appetite and thermogenesis accordingly.[65,229] The theoretic background for a central sensing mechanism of body fat stores was established by Kennedy 50 years ago.[230] A candidate adipose reporter substance is the product of the obese (*ob*) gene, mutation of which results in the genetically obese and diabetic *ob/ob* mouse; both the mouse gene and its human counterpart have been recently isolated.[231] Previous studies, in which the circulations of *ob/ob* mice had been crossed with normal mice, had suggested that *ob/ob* mice lack a bloodborne factor that might regulate adipose mass by suppressing appetite and increasing metabolic rate.[232] The *ob* gene sequence predicted a 16 kDa protein product that should be secreted from cells. Follow-up studies confirmed the expression of the *ob* gene in adipose tissue, the presence of ob protein in the circulation of normal mice, and increased ob levels in the plasma of the db strain of genetically obese diabetic mice.[233] Plasma levels of ob protein have been found to accurately reflect total body fat in mice fed high-fat diets.[234] Injections of ob protein (also called leptin) into *ob/ob* mice lower their food intake, body weight, percent body fat, and glucose concentrations while increasing their metabolic rate and body temperature.[233,235,236] However, the ob protein had no effect on obese *db/db* mice,[233] and normal mice fed high-fat diets became obese without decreasing their caloric intake despite elevated leptin levels, suggesting that genetic factors (the *db* gene product) and dietary components (lipids) may influence the actions of leptin in suppressing appetite.[234]

The model that has emerged proposes that adipocytes and placenta secrete leptin into the circulation, where it makes its way to the long form of the receptor in the CNS, in the hypothalamus (arcuate, paraventricular, lateral, ventromedial [VMN], and dorsomedial nuclei). The short form of the receptor is involved in leptin transport across the blood-brain barrier.[237] Nuclei neighboring the VMN are known to release appetite-stimulating substances such as neuropeptide Y, melanin-concentrating and -stimulating hormones, corticotropin-releasing hormone, galanin, glucagon-like peptide 1, neurotensin, and cocaine- and amphetamine-regulated transcript (CART), the suppression of which are downstream events of leptin receptor activation. Several of these, such as neuropeptide Y and CART, may mediate the effect of increased adipose mass in suppressing appetite.[237] Additionally, leptin activates the sympathetic nervous system, which impacts brown adipose tissues, kidney, hindlimb, and adrenal gland in rats, and induces uncoupling protein 1 (UCP-1) gene expression in brown adipose tissue and the homologue UCP-2 in white adipose tissue.[237,238] Activation of UCPs results in enhanced mitochondrial permeability, uncoupling of oxidative phosphorylation, and increased energy expenditure.

Acceleration of metabolism may involve the intermediacy of the β_3-adrenergic receptor, which can increase the generation of heat from the hydrolysis of fatty acids.[229] Genetic variation in the β_3-adrenergic receptor has been associated with both morbid obesity and insulin-resistant diabetes.[239–242] A third mechanism of obesity is modeled by the Zucker obese diabetic (*fa/fa*) rat, which also has a mutated leptin receptor. Transfection of normal but not *fa/fa* rats with leptin increased UCP expression and mitochondrial oxidative enzyme expression (eg, cartitine palmitoyltransferase 1 and acyl coenyzme A [CoA] oxidase). Leptin transfection reduced the expression of enzymes mediating fatty acid esterification (glycerol-3-phosphate acyltransferase and acetyl CoA carboxylase).[243] It has been shown that leptin acts in the brain to increase sympathetic stimulation of white and brown adipose tissues, which promotes their rate of fatty acid oxidation and reduces their fat content.[243] Human obesity certainly involves more genes than those of the ob protein and its receptor: to date, mutations in the *ob* gene are rarely detected in obese humans.

Just as leptin has been identified as the "satiety hormone," a recently identified hormone called ghrelin has been identified as an endogenous appetite stimulant.[244] Ghrelin, a 28–amino acid peptide named from "ghre," the proto-Indo-European root of "grow," was first identified as a GH secretagogue produced by gastric endocrine cells. Ghrelin is also produced by neurons in the hypothalamic arcuate nucleus, which is a critical region for feeding. Ghrelin levels vary diurnally, with sharp peaks before meals; its basal level and prandial peaks are sharply elevated by caloric restriction. Interestingly, extremely low ghrelin levels may explain why patients with gastric bypass surgery experience a paradoxical reduction of hunger between meals rather than a desire to eat more frequent small meals.[245] Ghrelin antagonists may be pharmacologically useful to treat obesity by mimicking the effects of gastric bypass surgery.

Mechanisms of Insulin Resistance

Obesity-related diabetes is characterized by increased hepatic glucose output and reduced glucose uptake in peripheral tissues. A key role for adipocytes in this condition has been proposed. Adipocytes secrete a number of cytokines and peptides that mediate insulin resistance, including leptin, TNF-α, adipocyte complement–related protein 30 kDa (Acrp30), interleukin (IL)-6, and resistin.[246] Acrp30 is unique in stimulating insulin sensitivity. Acrp30 is synthesized solely in adipocytes, where it is the most abundant gene transcript, and is secreted in serum. Administration to wild-type C57BL/6J and *ob/ob* mice lowers serum glucose levels while maintaining normal insulin levels. Acrp30 simultaneously accelerates fatty acid oxidation rates in muscle tissues.[246]

The cytokines TNF-α and IL-6 are produced by both immune cells and adipocytes, and levels of both are increased in obesity. TNF-α and IL-6 act to inhibit insulin-mediated tyrosine phosphorylation of the insulin receptor and the downstream mediator IRS-1. TNF-α additionally down-regulates the glucose transporter *GLUT4* expression. IL-6 increases hepatic triglyceride secretion, leading to an increase in circulating free fatty acids and increased insulin resistance.

A theory has emerged that "underleptinization" may also be responsible for the insulin resistance response of obese individuals. Leptin-deficient *ob/ob* mice and *db/db* mice lacking the leptin receptor have severe insulin resistance, reversible in the *ob/ob* mice by exogenous leptin. Hepatocytes treated with leptin exhibit decreased blood glucose and reduced insulin-stimulated tyrosine phosphorylation of the intracellular signal transducer IRS-1, which leads to decreased glucokinase activity, increased gluconeogenesis, and decreased glycogenolysis.[247]

Zhou's group has shown that diabetic rats with defective leptin receptors (Zucker diabetic fatty [ZDF] homozygous rats, also called *fa/fa* rats) have fatty infiltration of pancreatic beta cells with triglyceride. Heterozygous ZDF (fa/+) mice are lean and have only a small increase in beta cell triglyceride content; however, ZDF (fa/+) rats, when compared with control rats, have a diminished response to leptin, with partial loss of triglyceride content in pancreatic islets; the response is reduced compared with islets from normal rats. Furthermore, ZDF *fa/fa* rats have no significant proinsulin mRNA expression in response to either fatty acids or glucose, and heterozygous (fa/+) ZDF rats have a less-than-normal proinsulin mRNA response to fatty acid, providing a mechanism for reduced insulin output in obesity.[248]

Finally, resistin is an adipose tissue–derived peptide encoding a 114–amino acid polypeptide also called FIZZ1 and resistin 1α. Resistin serum levels are elevated in *ob/ob* and *db/db* mice and also in a diet-induced model of diabetes and obesity.[246] Thiazolidinedione ligands for the nuclear peroxisome proliferator activated receptors-γ receptor have been used to treat insulin resistance and function as antidiabetic drugs. These drugs induce adipocyte differentiation and facilitate increased fatty acid uptake into adipocytes as well as regulate genes related to insulin sensitivity.[249] Administration of antiresistin antibody to mice with diet-induced obesity and insulin resistance corrected blood glucose levels. A putative human homologue to resistin has been identified.

These exciting data establish new endocrine systems in the body and provide a framework for a new understanding of the relationship of adiposity to appetite and metabolism and possible mechanisms for intervention in the prevention of morbid obesity and diabetes.

THYROID HORMONES

Thyroid Hormones and Normal Growth

The actions of the thyroid hormones, like those of insulin, can be broadly separated into directly metabolic ones and those that result from thyroid induction of other genes that regulate cell growth and function. Increased oxygen consumption, heat production, and accelerated metabolism constitute the calorigenic effects of the thyroid hormones.[250] The mechanism by which thyroid hormones affect these actions is not clearly understood but probably does not involve an uncoupling of oxidative phosphorylation from respiration, as was originally postulated.[251] Unlike peptide hormones, which bind to cell membrane receptors and regulate cell function and gene transcription via second messengers, thyroid hormone receptors exist in the cytoplasm and directly regulate the transcription of other genes by binding to regulatory regions of DNA in the genome.[252] Many of the developmental effects of the thyroid hormones may result from induction of the genes for other hormones and growth factors, such as EGF and nerve growth factor.[253]

T_4 is the major hormone secreted by the thyroid, but it is deiodinated at its outer ring to produce triiodothyronine (T_3), which is the metabolically active hormone (Figure 16-7). Deiodination occurs both in the thyroid gland and at peripheral sites such as the liver, kidney, and brain. T_4 may also be deiodinated at its inner ring to form reverse T_3 (rT_3), which is metabolically inactive. Regulation of the relative activity of the inner and outer ring deiodinases to vary the concentrations of T_3, and rT_3 is a major control point in the thyroid economy. T_4 release from the thyroid is stimulated by thyroid-stimulating hormone (TSH; thyrotropin), which, in turn, is released from the anterior pituitary under the influence of the hypothalamic modulator thyrotropin-releasing hormone (TRH). Perhaps in conjunction with T_4, T_3 feeds back to inhibit TSH secretion.

The influence of thyroid hormones on growth occurs at many levels. Within the cell, they have profound effects on metabolic processes, including the induction of mitochondrial enzymes and an increase in Na,K-adenosine triphosphatase activity. Thyroid hormones influence the GH-IGF axis, as evidenced by the fact that hypothyroid rats have a diminished pituitary content of GH, low circulating GH levels, and depressed IGF levels.[253–256] T_3 has been shown to stimulate transcription of the GH gene.[257] In contrast to animal models, hypothyroid children do not consistently demonstrate subnormal GH release.[100,258,259] Furthermore, the growth-retarding effects of hypothyroidism in rats are not reversed by GH treatment. In addition to a GH-mediated influence on IGF secretion, thyroid hormones augment IGF-I actions on cartilage growth,[259] and their absence is evident at the growth plate cartilage by altered morphology.[260] In addition, some thyroid hormone actions on growth plate chondrocytes appear to be IGF mediated as the mitogenic actions of T_3 on cartilage growth can be blocked with an antibody to IGF-I. In contrast, the effects of T_3 on cartilage morphology and functional maturation do not appear to be IGF-mediated, direct ones.[261]

Thyroid Hormones and Malnutrition

Fasting and malnutrition induce a hypothyroid-like state characterized by a diminished rate of T_3 production and, consequently, a depressed heart rate and basal metabolic rate, as well as a diminished loss of nitrogen.[143,262,263] Con-

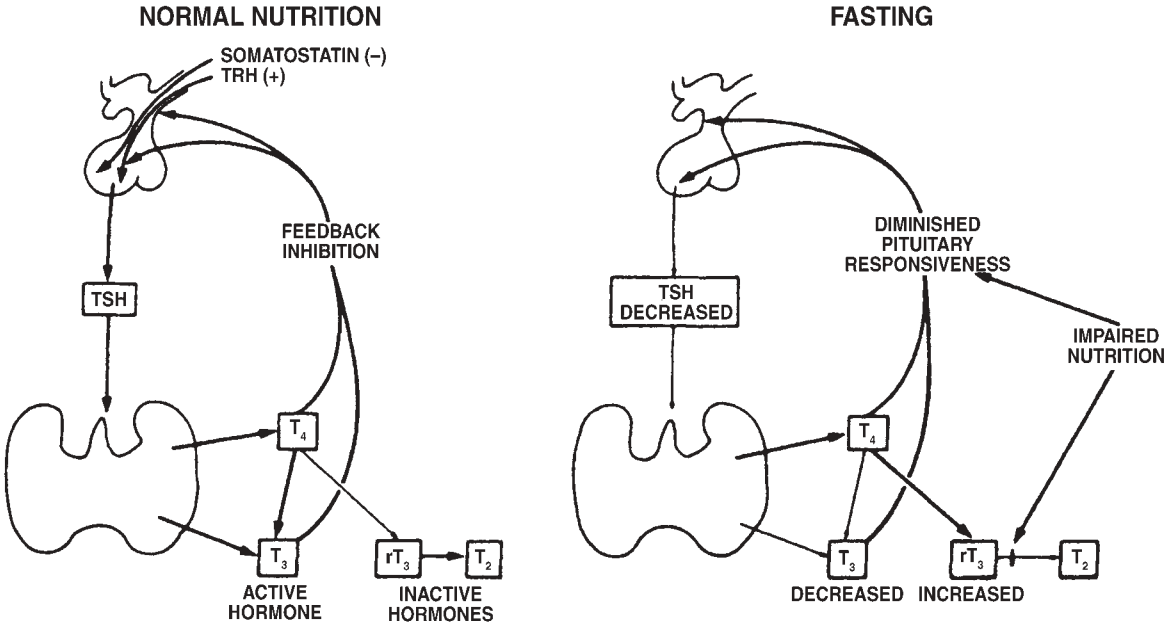

FIGURE 16-7 The pituitary-thyroid axis. *Left*, When nutrition is normal, thyroxine (T_4) is converted primarily to the calorigenic hormone triiodothyronine (T_3) in the thyroid and peripheral tissues. Levels of the inactive hormones—reverse T_3 (rT_3) and T_2—are relatively low. *Right*, After fasting, reverse T_3 concentrations rise primarily because of decreased degradation to T_2 and to some extent through preferential conversion of T_4 to rT_3. Fasting also diminishes the pituitary responsiveness to hypothalamic factors. Thyroid-stimulating hormone (TSH) levels do not rise as in other forms of hypothyroidism. (+) = stimulatory action; (–) = inhibitory action. TRH = thyrotropin-releasing hormone.

comitant with the fall in T_3 in malnutrition is a depression of sympathetic nervous system activity, as measured by norepinephrine secretion.[264] Within 48 hours of a fast, T_3 concentrations fall into the hypothyroid range, whereas concentrations of T_4 change little, and those of rT_3, the inactive metabolite of T_4, rise (see Figure 16-7). These changes result from a starvation-induced inhibition of the deiodination of T_4 to T_3, whereas the serum half-life of rT_3 is prolonged by preventing its deiodination to T_2. In addition, malnutrition also results in a diminished synthesis of the plasma thyroid-binding proteins, also leading to depressed thyroid hormone levels.

The low levels of thyroid hormones in the undernourished state are likely to be an adaptive mechanism meant to diminish the extent of catabolism. Danforth and Burger have shown that when T_3 is administered to fasting subjects sufficient to maintain T_3 levels in the normal range, nitrogen losses are accentuated.[251] Despite a low serum T_3, TSH secretion is not increased in fasting, and the TSH response to TRH is either normal or somewhat blunted.[263,265] The condition of depressed levels of metabolically active thyroid hormones without elevation in TSH in malnutrition or illness has often been called the "euthyroid sick syndrome."[266,267]

The depressed T_3 levels of the fasted state can be corrected by refeeding as little as 100 kcal of carbohydrate, whereas the protein or fat content of the diet does not significantly affect the recovery of T_3.[268] As little as 50 g of carbohydrate will prevent the effect of dietary restriction on serum T_3 levels.[86] As in those subjected to acute starvation, chronically malnourished children and adults have depressed serum T_3 and elevated rT_3 concentrations. However, the TSH concentrations are either normal or elevated in chronic malnutrition, and the TSH response to TRH is exaggerated.[139,187,269]

Thyroid Hormones and Overnutrition

Overnutrition results in changes in thyroid hormone metabolism that are predictably opposite to those seen in undernutrition. The resting metabolic rate is increased, as are T_3 levels, whereas rT_3 levels are decreased.[270] The mechanism for the changes in T_3 and rT_3 appears to be increased outer ring deiodination of T_4 in that overfeeding also results in an increased clearance of T_3. In contrast to the underfed state, it is not clear that the increased metabolic rate seen in overfeeding is associated with enhanced sympathetic nervous system activity because β-adrenergic blockade has no effect on the increased metabolic rate induced by overfeeding.[251]

The relationship between thyroid function and true obesity is minimal, despite popular opinion to the contrary. The weight gain seen in hypothyroidism is largely secondary to myxedema and fluid accumulation, and most of the metabolic effects of overfeeding on thyroid hormone levels occur independently of the degree of leanness or obesity of the subjects.

CORTISOL AND SEX STEROIDS

Cortisol in Intestinal Maturation

There is a striking maturation of absorptive function of the intestine following birth, with ample evidence to suggest that glucocorticoids regulate the process. Most of the data

on the regulation of gut maturation have been derived from studies in rats and other small mammals. Coincident with the period of weaning and, consequently, a decreasing reliance on lactose and other milk sugars for nourishment, there is a fall in the high activity of lactase in the small intestine and a rise in the activity of intestinal sucrase, maltase, and pancreatic amylase.[271] In addition, there is a loss in the abilities of the ileal and jejunal mucosa to take up macromolecules and to transport immunoglobulins. Delay of weaning has no significant effect on the timing of these changes. In contrast, deprivation of pituitary hormones by hypophysectomy in the newborn period elicits a marked delay.[272,273] These observations have led to studies of the role of pituitary-derived or pituitary-regulated hormones in the maturation of gut function.

The experimental data support roles for both glucocorticoids and thyroid hormones in intestinal maturation. Coincident with the enzymatic changes in the rat gut at the end of the second week of life, there is a prominent rise in circulating corticosterone. Breast milk might provide an additional source of glucocorticoids.[274] Glucocorticoid administration to preweanlings results in early maturation of intestinal enzymes such as sucrase[271] and of pancreatic amylase, bile acid synthesis, and transport phenomena such as bile salt absorption.[275] The dependence on glucocorticoids is not absolute, however, as adrenalectomy on day 9 of life does not prevent the appearance of sucrase or delay the maturation of sucrase to adult levels of activity.[271] A comparable role for thyroid hormones has also been suggested, although it appears that the ability of T_4 to induce maturation of the intestinal enzymes requires the presence of intact adrenal glands. Administration of T_4 to rats results in increased blood concentrations of corticosterone. Thus, the observed effects of T_4 may be through induction of glucocorticoids.[271]

Cortisol in Malnutrition

Reflecting metabolic stress, malnutrition in humans and laboratory animals results in elevated cortisol concentrations, with an abolition of the normal diurnal rhythm and a slowed clearance of exogenous cortisol.[276] Fasting also depresses production of cortisol-binding proteins, resulting in a further elevation of free glucocorticoids.[277] Despite the glucocorticoid excess, the adrenal glands remain suppressible with dexamethasone and responsive to ACTH in the malnourished state.

A prominent metabolic effect of cortisol is the diversion of substrates to the liver for protein synthesis. Rao and coworkers have demonstrated that infants with marasmus have higher cortisol levels than do infants with kwashiorkor and that the response of cortisol to ACTH is better preserved in marasmus.[278] Those authors postulated that the development of kwashiorkor is coincident with failure of the adrenal gland to secrete adequate cortisol to maintain normal protein levels. In rats, the biochemical manifestations of kwashiorkor resulting from a low-protein diet can be reversed by glucocorticoids.[279] As previously indicated, glucocorticoids have a deleterious effect on cartilage growth and act as IGF antagonists in somatomedin bioassays. In his studies on malnourished Nigerian children, Smith postulated that elevated cortisol, acting as an inhibitor of IGF action at the epiphyses, was a major contributor to the poor growth of his subjects.[168]

Reproductive Function in Malnutrition

The potent gonadal steroids testosterone and estradiol are primarily responsible for the establishment of reproductive fitness. Other, weaker androgenic hormones, however, which are produced by the gonads and adrenal glands of both sexes, are important in the maintenance of normal anabolism. These include androstenedione, dehydroepiandrosterone (DHEA), and its metabolite, DHEA sulfate. Whereas reproductive functions are expendable and potentially damaging during times of nutrient deficit, considerable attention has been paid to the importance of weaker androgenic hormones, or anabolic steroids, as possible therapeutic agents for the recovery from catabolic states.

In malnourished adults, hypogonadism often develops, and the secretion of sex steroids by the gonads decreases; in malnourished children, the onset of puberty is delayed.[280] Men suffering from chronic protein-calorie malnutrition often experience gonadal failure. In adults, nutrients appear to influence reproduction at both the hypothalamic and gonadal levels. In a group of Indian men suffering from malnutrition, Smith found low plasma testosterone and elevated gonadotropins, indicating impaired testicular function.[281] During recovery, these men continued to have elevated levels of luteinizing hormone and a subnormal release of testosterone to chorionic gonadotropin. In contrast, Klibanski found evidence for hypothalamic hypofunction when mildly obese men were fasted for 10 days.[282]

In addition to the effects of malnutrition in delaying puberty, a number of studies on young athletes have suggested a connection between body composition and reproductive fitness. In young female athletes and dancers who train extensively before puberty, menarche can be delayed by several years.[283] In some instances, the delay in menarche can be related directly to the duration of training prior to menarche: 5 months for every year of training.[284] These observations led Frisch and McArthur to propose that normal menstrual function depends on the attainment of at least 22% body fat.[285] This model, which has not been universally accepted, assumes that some aspect of body fat content signals permission for the secretion of gonadotropic hormones to trigger menstruation.[286] In light of the recent isolation of the adipocyte-derived product of the *ob* gene, leptin, this hypothesis may need to be revisited.

Anabolic Steroids as Therapeutic Agents in Catabolic Disease

Despite all attempts, it has been impossible to synthesize steroids with anabolic actions that are divorced from their androgenic (masculinizing) ones. Coupled with their anabolic effects, these hormones also have behavioral effects such as increased aggressiveness and an enhanced appetite. Like all androgens, synthetic anabolic steroids suppress gonadotropin production and result in a

lipogenic profile of cholesterol metabolism. High doses can alter liver function and result in hepatocellular carcinoma. Anabolic agents have been shown to decrease nitrogen loss after minor surgery but have had no consistent effect on weight gain in geriatric patients or in patients with chronic renal failure.[287–289]

There has been considerable popular attention in recent years to the use of anabolic steroids to increase performance in body building and other sports. Well-controlled studies in adult male athletes are few, and the results are conflicting.[290] Those whose performance stands to benefit the most from increased androgenic activity are those who produce relatively low levels of androgens endogenously: females, prepubertal children, and adolescents. These are the groups in whom additional adverse effects such as virilization, balding, sexual precocity, and premature closure of the epiphyses would be the most damaging. At this time, there appears to be no clear role for anabolic agents in the treatment of catabolic states. Their use in augmenting athletic performance entails significant medical risk.

SUMMARY AND CONCLUSIONS

The humoral controls on growth are highly sensitive to the nutritional milieu and are programmed to alter and even abort the body's developmental scheme as required during conditions of nutritional want or excess. The specific components of the diet that are monitored by the various nutritionally sensitive endocrine systems are still not known, although our understanding is growing as to how nutrients can alter the expression of specific genes that encode key regulatory hormones, growth factors, and enzymes. Nonetheless, a careful assessment of physical growth and maturation can serve as a sensitive and accurate index of nutritional status and disease, both for individuals and for whole populations.

The capacity of the growing organism to accommodate changes in the availability of nutrients by slowing or halting growth is a generally reversible process (catch-up), designed to permit adaptation to a changing nutrient supply. However, the ability to resume normal growth after the correction of metabolic insults is dependent on the nature of the insult, its duration, and the developmental phase of the organism during which it occurs. The damage incurred during certain susceptible periods of growth may be irreversible, perhaps owing to a reduction in the number or critical organization of the cells that make up key tissues. The mechanisms by which a tissue or organism can monitor its own size and correct discrepancies with its "intended" size are unknown. They probably involve coordination between mechanisms for catch-up that are extant in individual tissues and regulatory centers in the CNS; classic hormones probably do not play a key regulatory role.

Recent years have brought the discovery of new hormone systems with close ties to the nutritional status of the organism. The discoveries of leptin, an appetite suppressant produced by adipose tissue, and ghrelin, an appetite stimulant produced in the alimentary tract, shed new light on how the body monitors its nutritional status. Other adipocyte-secreted substances such as Acrp30 and resistin may mediate the insulin-resistant state of obesity. We have an abundance of candidate molecules to begin to elucidate the mechanisms involved in obesity and diabetes and to suggest therapeutic strategies against these disorders.

From our current vantage point, the metabolic changes of undernutrition are adaptive ones, designed to ensure survival until adequate reserves exist to permit growth and reproduction again. In some instances, however, morbidity may actually result from maladaptive endocrine changes. The development of kwashiorkor, for example, may result when the adrenal gland is no longer able to maintain adequate production of glucocorticoid hormones to facilitate withdrawal of proteins from structural stores, such as muscle.

A better understanding of the normal regulation of hormones and growth factors in conditions of altered nutrition has suggested new diagnostic and therapeutic approaches. Blood levels of IGF-I or some of its binding proteins may provide a more sensitive means of assessing nutritional status than many other currently employed tests. Administration of GH to individuals in catabolic states may hasten their recovery. Studies of anabolic steroid hormones in catabolic states have generally not been promising.

The future challenge is to better delineate the full spectrum of humoral and neuroendocrine changes that accompany nutritional alterations and to define those components of "nutrition" that are the actual signals that can regulate the production and actions of hormones and growth factors. The accelerated rate at which "new" hormone systems have been discovered illustrates the fact that we have not yet identified all of the relevant humoral control systems let alone understood them. The characterization of genes identified by the Human Genome Project may allow us to finally identify all of the critical components of the interface between nutrition and cellular control. At this time, the measurement of growth factors, their receptors, and their downstream signaling events within tissues is an invasive proposition and of little clinical practicality. When the physiology of these substances is better understood, however, the promise for therapeutic intervention will be great.

CHAPTER 17

ENERGY METABOLISM AND REQUIREMENTS IN HEALTH AND DISEASE

Jean Louis Bresson, MD, Jean Rey, MD, FRCP

The interpretation of the changes in metabolic rate resulting from either malnutrition or disease finds its roots in the physiologic determinants of daily energy expenditure. The technical aspects of the measurement of energy expenditure and its obligate correlate, body composition, extend beyond the scope of this chapter and have been thoroughly reviewed in the literature.[1,2] Once raw data are available, many factors may confuse cross-sectional and, even more, age-related comparisons. The influence of body components, whether fat-free mass (FFM), fat mass (FM), or organ weight, should be considered first in an attempt to account for the wide differences in metabolic rate among infants, children, and adults. This is also relevant to a better understanding of the responses to underfeeding and malnutrition. Conversely, recent advances in the field of minor contributors to energy expenditure, such as the thermic effect of feeding or the thermic response to cold, may help us to understand how physiologic mechanisms may be turned into an energy-loosing machinery.

One of the most common findings in the sick child is a reduced food intake, which is widely accepted as the main, if not the only, cause of malnutrition. However, evidence accumulates suggesting that metabolic dysregulations may also participate and, in some instances, be primarily responsible for the nutritional deficit. This may be particularly true for proteins that, unlike fat, are not stored but make up functional or structural tissues. Nitrogen balance in the adult or net protein deposition in the growing child results from protein synthesis rates equal to or higher than protein breakdown, respectively. This equilibrium may be disrupted by the overproduction of peptides, otherwise playing a pivotal role in the regulation of the immune system. It results in a protracted increase in protein breakdown over protein synthesis. This mechanism is found in acute as well as chronic inflammatory syndromes and may lead to a severe protein malnutrition, despite apparently normal nutrient intakes. Consequently, underfeeding is clearly not the only factor in malnutrition. Furthermore, these protein losses are not easily controlled by classic dietary treatment and represent a pressing case for developing a specific pharmacologic approach.

PHYSIOLOGIC DETERMINANTS OF ENERGY EXPENDITURE

Basal Metabolic Rate

Comparisons between the rates of energy expended, or heat produced, by individual subjects require that the measurements should be free of the effects of any factor known to increase it. Failure to control for the effects of activity, feeding, and physical environment on metabolic rate would obviously result in spurious interindividual differences. Benedict proposed a set of standard conditions required to perform accurate measurements of the basal metabolic rate (BMR) in adults: the subject should be awake but in complete muscular repose both before and during the measurement, ideally performed in the morning before the patient rises; the subject should be in the postabsorptive state, normally accepted as 12 or more hours after the last meal, and should have received prior to the measurement a maintenance diet ensuring the stability of body weight; the subject should be in emotional repose and familiar with the measurement devices; in women, the measurement should not be made immediately before or during the menses; and ambient temperature should be set in the range of the subject's thermal neutrality to avoid any thermoregulatory effect on heat production.[3]

Obviously, these requirements may be impractical in infants and young children or in clinical settings. Metabolic rate measurement not performed in the postabsorptive state, but complying with the remaining conditions and usually termed resting metabolic rate (RMR), is about 15% higher than true BMR.[4] It should be pointed out that, even in adults, the conventional period of 12 hours after the last meal may not be a sufficient interval to guarantee

that the continuing effects of its metabolism are negligible.[5] Hence, BMR should not be viewed as a measure of the absolute minimal metabolism. Indeed, energy expenditure is about 8 to 12% lower during sleep than under basal conditions,[6] and oxygen consumption rate is then related to the stage of sleep.[7] As it is difficult to quantify the amount of work performed during spontaneous physical activity,[4] measurement of the sleeping metabolic rate (SMR) may be a convenient way to minimize its consequences on energy expenditure in young children. Thus, rather than defining a specific physiologic event, the set of standardized conditions chosen for metabolic rate measurements is primarily aimed at reducing the variance related to uncontrolled factors to increase the power of interindividual or intergroup comparisons. When the rigorous conditions listed by Benedict are fulfilled, repeated measures display a remarkably low level of intraindividual variations. For instance, the coefficient of variation (s/m) of replicate indirect calorimetry measurements amounts to about 2 to 4%, of which 2% could be accounted for by the variability related to the technique.[4]

The reproducibility of such measurements is high, even over a prolonged investigation.[8] Thus, the range of intraindividual variations in BMR becomes much narrower than the range of interindividual variations that one may observe in cross-sectional studies of normal adult populations. A threefold difference is usually found between the lower and higher BMR individual values, expressed in kcal or kJ/d.[9] Repeated measures confirm that these are true between-subject differences. Furthermore, BMR is about 15% lower in adult females than in adult males.[6] Many of these interindividual differences may be related to body build, as suggested by the significant correlations between BMR and body weight or height, or Quételet index (weight/height^2).[10] Multiple regression analysis indicates that FFM accounts for about 65 to 75% of BMR variance between subjects[6,11] and that FM, age, and sex together account for another 5%.[11] It is noteworthy that—exclusive of pregnancy—the contribution of FM to BMR variance is limited[6,11,12] or even negligible[4] and that BMR becomes comparable in males and females after adjusting for FFM and FM.[6] Thus, FFM, FM, age, and sex account for about 80% of the interindividual variability in BMR, and nearly all of the effect of these covariates is attributable to FFM (Figure 17-1).[13] However, differences between lower and higher individual metabolic rates still amount to about 600 kcal/day even after adjustment for these factors.[11] Further studies showed that family membership is another significant determinant of BMR.[14] In the Pima Indians, metabolic rate among families may vary by nearly 500 kcal/day, whereas the mean variation within families is only about 60 kcal/day.[13] In this population, FFM, age, sex, and family membership account for 94% of the variability in metabolic rate, with family membership contributing about 11%. Actually, a metabolic rate lower than that predicted by FFM, age, and sex at the beginning of the study turned out to be a major risk factor for body weight gain during the subsequent follow-up,[11] implying that obesity may result from an economy in energy expenses. These results emphasize the necessity to express metabolic rate in relation to FFM, its major constituent, rather than in relation to any other parameter such as crude body weight or body area.

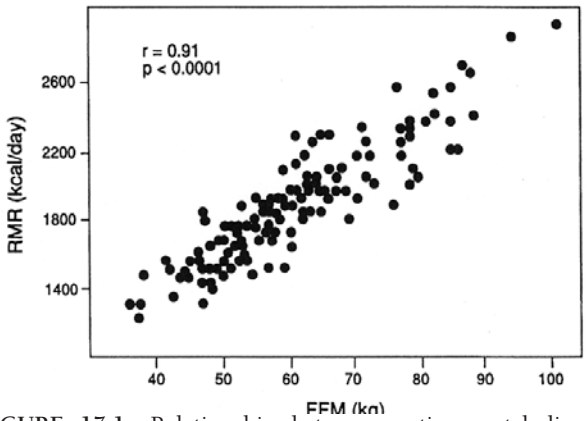

FIGURE 17-1 Relationship between resting metabolic rate (RMR) and fat-free mass (FFM) in 130 subjects. Adapted from Bogardus C et al.[13]

However, this mode of expression may still hamper interindividual comparisons in the pediatric population. During growth, RMR expressed either as kcal/kg body weight/day[15] or as kcal/kg FFM/day[16] follows a nonlinear increase, with slopes substantially higher in infants and young children than in adolescents and adults (Figure 17-2). After a steep increase in the days following birth,[17] RMR falls disproportionately to the rise in body weight or FFM, being about 67 kcal/kg FFM/day at 3 months, 46 kcal/kg FFM/day at 11 years, and 37 kcal/kg FFM/day at 13 years, compared with adult values of 28 kcal/kg FFM/day (Figure 17-3).[16] This suggests that the metabolic activity of FFM is changing as a whole,[18] or that the relative contribution of tissues with different metabolic rates to the composition of FFM is changing,[19,20] or both.

Holliday pointed out that the brain, heart, liver, and kidney together make up only 5 to 6% of the body weight but account for 60 to 70% of the BMR in the adult. Conversely, muscle mass, which makes up about 44% of the body weight, accounts for only 15 to 30% of BMR.[15] In contrast, the FFM of infants and young children comprises about 30%

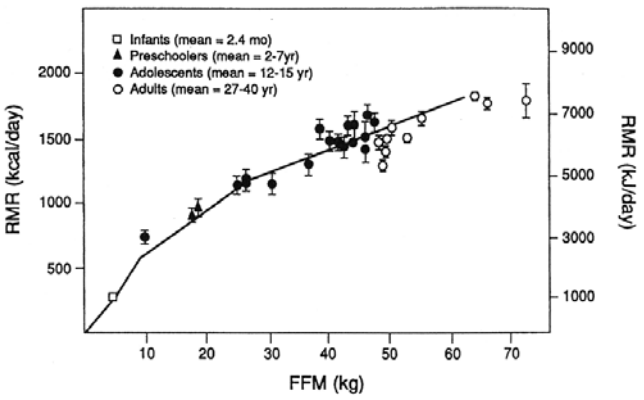

FIGURE 17-2 Relationship between resting metabolic rate (RMR) and fat-free mass (FFM) among different age groups. Adapted from Weinsier RL et al.[16]

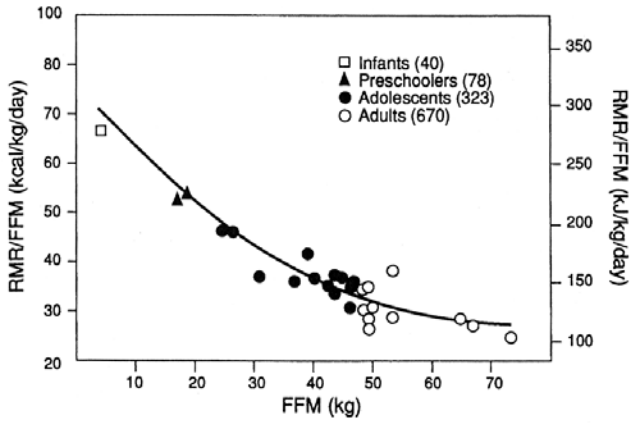

FIGURE 17-3 Relationship between resting metabolic rate (RMR) per unit fat-free mass (FFM) (RMR/FFM) to FFM among different age groups. Adapted from Weinsier RL et al.[16]

muscle and 20% other organs and that of adolescents averages 42% muscle and 8% other organs.[15] Therefore, the higher metabolic rate of infants and children in relation to FFM could be ascribed to a greater proportion of metabolically active nonmuscle organ mass and to a lesser proportion of less metabolically active muscle mass than in adults (Table 17-1).[15,16] This is exemplified by experiments carried out on pigs with different nutritional backgrounds.[21] The first group was fed to gain steadily 14 kg over 70 days. A second group was fed to gain 19 kg during the first 35 days (high-energy period) and to lose 5 kg during the second 35 days (low-energy period; group HL), and this pattern was reversed (low-energy period first) in a third group (LH). At the end of the 70-day experiment, all animals had achieved the same body weight, but the fasting metabolic rate of the LH group was 25 to 50% higher than that of the HL group and 13 to 40% higher than that of the first one. Furthermore, there was a significant correlation between fasting metabolic rate and organ weights.[21] The consequences of these observations are twofold. First, comparing the BMR to FFM ratio between two groups of subjects may be misleading when values of FFM are markedly different,[16] mainly because the ratio of the weight of organs (heart, liver, brain, spleen, and kidneys) to total FFM decreases as FFM increases.[22] Second, this raises the possibility that abnormal metabolic rates in disease states may be related to a change in the proportion of metabolically active organs to less active muscles. For instance, a reduction in muscle mass could account for the inverse relationship between RMR per kilogram of body weight and percent ideal body weight observed in patients with Crohn's disease.[23]

Differences in metabolic rate between young and mature animals have also been found in other mammalian species. These weight-related differences further extend to comparisons between mature animals of different species. For instance, mouse metabolic rate is about 5 times greater than human's and about 10 times that of the elephant.[24] Kleiber and Brody and Proctor proposed a generalization according to which RMR follows a metabolic power function corresponding to weight$^{0.75}$.[24,25] However, the mass coefficient is not the same in various species, ranging from 0.48 to 0.91, the mean value being 0.67 ± 0.03. As there is no definite value for either the intraspecific or interspecific mass exponents, any attempt to explain the Brody-Kleiber empiric relationship by a general physical principle is most likely to fail.[25] Actually, this statistical relationship may obscure rather than reveal biologically important changes. The relative proportion of metabolically active tissue may contribute to these differences as large mammals have a greater proportion of tissues with low metabolic activity, whereas smaller ones have a greater proportion of tissues with higher metabolic activity. However, Krebs showed that the rates of respiration of homologous tissues are affected by the size of the animal, although there is no strict parallelism between measured tissue oxygen consumption and the BMR of the animals.[26] A comparison between homeo- and poikilotherms might give a hint about a possible cause for this difference. The standard metabolic rate is sevenfold greater in the rat (a typical mammal) than in an ectothermic vertebrate (bearded dragon) of the same body size and at the same body temperature.[27]

This large difference in metabolism is also manifest at the cellular level. Rat hepatocytes respire fourfold faster than do hepatocytes from the lizard. The inner membrane of isolated rat liver mitochondria has a permeability that is four- to fivefold greater than the proton permeability of the lizard liver mitochondrial membrane.[27] Thus, the greater proton permeability of the mitochondrial inner membrane contributes to the greater metabolic rate of mammals. Actually, this is a major source of heat production (see below). Similarly, plasma membrane permeability to Na^+ and K^+ is higher in mammals than in ectothermic vertebrates, increasing the amount of energy devoted to active Na^+-K^+ exchange.[28] Thus, the activity of the Na^+-K^+-adenosine

TABLE 17-1 Relation between Basal Metabolic Rate (BMR) and Muscle and Organ Metabolic Rates with Age

Height (cm)	*Weight (kg)*	*BMR (kcal/d) A*	*Muscle MR (kcal/d) B*	*Organ MR (kcal/d) C*	*B/A*
60	5.5	300	21	279	7.0

180	70.0	1,800	500	1,300	27.7

Adapted from Blaxter K.[24]

triphosphatase (ATPase) accounts for about 20% of the total in vitro energy expenditure by mammalian tissues.[29] The use of ouabain to inhibit Na^+-K^+-ATPase in vivo leads to a 20 to 30% inhibition of resting oxygen consumption in guinea pigs[30] and to a 20 to 25% inhibition in mice,[31] supporting the idea that active Na^+-K^+ exchange is a significant determinant of resting energy expenditure. In humans, Na^+-K^+-ATPase activity may contribute 20 to 25% to BMR.[32] As in animals, Na^+-K^+-ATPase is subject to chronic control by thyroid hormones, and slight interindividual variations in free triiodothyronine (T_3) index among healthy adults would account for a between-subject difference in SMR of 142 kcal/day.[33] Furthermore, the magnitude of Na^+-K^+-ATPase-dependent energy expenditure in tissues appears to be related to the physiologic status and particularly to age. Muscle preparations from 7- to 21-day-old calves expend 26% more total aerobic energy in support of Na^+-K^+ transport than do the same muscles from 7-month-old calves.[29] Similarly, the Na^+-K^+-ATPase-dependent respiration of skeletal muscle preparations from 4-week-old lambs accounts for a 48% greater amount of energy than similar muscles from adult ewes. Also, energy consumption in support of active Na^+-K^+ exchange by the intercostal muscle from young lambs is 119% greater than for similar preparations taken from adults.[34] Comparable differences exist between hepatocytes obtained from 1- to 8-week-old lambs and from mature sheep.[35] In this latter case, the lower oxygen consumption of hepatocytes isolated from mature sheep is largely attributable (70 to 90%) to the decrease in the Na^+-K^+-ATPase-dependent component of respiration.

It is striking that in quiescent cultured animal cells exposed to mitogens, one of the first events to take place is a rapid, very large increase in the rate of Na^+ flow into the cells,[36] which, in turn, induces increased Na^+-K^+ pumping. Activation of Na^+-K^+-ATPase appears to be an early growth-related event, and it is tempting to speculate that increased energy expended on active Na^+-K^+ transport by young mammals is related to their higher growth rate.[34] Active ion transport is probably not the sole cause of this difference. Measurement of whole-body protein synthesis shows that the smaller mammals display the higher protein synthesis rates in relation to their body weight. Within-species comparisons also indicate that immature animals have higher protein turnover rates than adults. For instance, protein synthesis amounts to 6.7 ± 1.1 g/kg/day in term infants compared with 3.5 ± 0.6 g/kg/day in adult humans. Simultaneously, basal energy expenditure is 45.1 ± 4.6 and 23.6 ± 3.8 kcal/kg/day in newborns and adults, respectively.[37] Thus, a similar ratio of BMR to whole-body protein synthesis (6.7 to 6.9 kcal/g) applies to both healthy newborn and young adults, suggesting that the turnover of cellular constituents, including proteins, and energy expenditure change in parallel with maturation. Therefore, differences in BMR in relation to body weight or FFM during growth are not merely a matter of proportion between tissues with high or low metabolic rates but are also related to differences in the amount of work done by the cells in chemical syntheses and in maintaining membrane electrochemical gradients.[38]

Energy Cost of Growth

An estimate of the energy cost of growth can be obtained in groups of rapidly growing infants from the relationship between growth rate and metabolizable energy intake.[39] The slope of this linear relationship provides an estimate of the total amount of energy stored and expended for synthesis, and its intercept at zero growth indicates the amount of energy required for maintenance. It should be pointed out that maintenance requirement may be higher than BMR by 10% in premature infants[40] and 50% in children[41] as maintenance includes expenses for limited activity and feeding.[42] The energy cost of growth can also be estimated from the independent measurement of stored energy and energy expended for synthesis.[40] An indirect method for calculating the cost of tissue synthesis is to relate weight gain to energy expenditure, assuming that an increase in expenditure is directly related to the increase in cost of synthesis. Unfortunately, the result may be obscured by activity. A direct measurement of the cost of synthesis rests on the assumption that the thermic effect of feeding (ie, the increase in metabolic rate after the meal over the resting value in the postabsorptive state; thermic effect of feeding [TEF]) is largely accounted for by synthesis. This is supported by the positive correlation observed between weight gain and TEF in rapidly growing individuals.[42] However, the TEF may be grossly underestimated unless the interval between feeds is long enough to allow metabolic rate to return to postabsorptive levels.

Various estimates of the total cost of growth are in the range of 3 to 6 kcal/g of new tissue. A widely accepted figure in normal infants is 5 kcal/g.[40,41] Metabolic balance and body composition studies indicate that the average composition of weight gain is 28% fat and 16% protein during the first year of life.[43] Assuming crude energy contents of 9.25 kcal/g and 5.65 kcal/g for fat and protein, respectively, it is possible to estimate the amount of energy stored to about 3.5 kcal/g of body weight gain. In contrast, the cost of synthesis is about 1.5 kcal/g of body weight gain. Direct estimates of the amount of energy expended for synthesis usually provide figures in the range of 0.55 to 0.7 kcal/g.[40,44] This discrepancy may be related to an underestimation of the TEF as it is measured only 2 to 3 hours after the last meal. The so-called fasting metabolic rate used as a baseline is likely to be falsely high owing to the lasting effect of feeding. As the energy stored in weight gain represents about 70% of the total energy cost of growth, one can expect wide differences according to the composition of tissues laid down. For instance, it is possible to calculate that the total amount of energy required to deposit 1 g of protein is about 13.4 kcal/g and is 10.8 kcal/g for fat.[45] Thus, a weight gain comprising 16% protein and no fat would cost about 2.2 kcal/g. Conversely, a weight gain consisting of fat with no protein would cost about 9.7 kcal/g, assuming that adipose tissue may contain up to 90% lipids. These differences may account for the high cost of weight gain found in overfed adults. In these conditions, weight gain consists of about 70% fat and 30% fat-free tissue,[46] the theoretic cost of growth then amounting to ≈ 7 kcal/g. Similarly, the average cost of weight gain in patients with anorexia nervosa ranges from 5 to more than

7 kcal/g, suggesting either important changes in the composition of body weight gain during rehabilitation[47] or an important confounding effect of activity.[48]

The daily energy cost of growth will depend obviously on growth rate as well as on the composition of new tissue. Growth rate is highest during the first 3 months of life, reaching 30 to 35 g/day between birth and 8 weeks of age or a fractional growth rate of about 1%/day.[43] It decreases rapidly thereafter to 7 to 10 g/day at 1 year of age, or 0.07 to 0.09%/day, and to about 5 g/day (< 0.03%/day) by 5 years of age. Thus, the cost of growth represents a significant part of daily energy needs (≈ 33%) from birth to 4 months of age. Later, it decreases to about 7% between the ages of 4 and 12 months, 1.6% between 12 and 24 months, and 1% between 24 and 36 months. Thereafter, it is negligible compared to daily energy expenditure. Thus, on the basis of nutrient partition between growth and nongrowth, the 1- to 2-year-old child appears more like the adult than the small, rapidly growing infant.[49]

Thermic Effect of Feeding

It was recognized long ago that fed animals have substantially higher metabolic rates than fasted ones.[24] The effect of specific nutrients was investigated during the nineteenth century showing that the ingestion of proteins induces a greater increase in energy expenditure than carbohydrates or fat. The ingestion of a mixed meal also results in an increased metabolic rate above BMR. Energy expenditure may increase by up to 30% over BMR in response to large energy challenges,[50] a sizable change equivalent to 6 to 10% of the energy intake.[50] Unlike BMR, the TEF appears to be independent of weight, FFM, FM, and Quételet index.[50] In contrast, its duration and magnitude are linearly related to the energy intake,[50] which explains the greater effect of large meals.[51] Duration and magnitude of TEF are not significantly different when the same meal is ingested or directly delivered into the stomach.[52] However, the magnitude of the thermic effect is significantly greater if the same energy load is delivered in a short time rather than over several hours.[51,53] The route of administration of the nutrients, either intragastric or intravenous, does not seem to affect the magnitude of the response,[54] suggesting that the energy input of luminal digestion, fermentation, mechanical mixing, and nutrient absorption makes only a modest contribution to the TEF in normal subjects. Energy expenditure may still be significantly higher than postabsorptive levels by 5 to 8 hours after a large energy challenge.[50] Furthermore, the effect of the antecedent diet may significantly affect both sleeping and RMRs. For instance, RMR remains elevated by 12% 14 hours after the last meal during short-term overfeeding.[5] In these conditions, the TEF lasts not only for the whole day but also throughout the night until the following morning, when the effect is still apparent. There is also a strong indication that the TEF of one meal merges into the thermic effect of the next meal. Thus, the duration of the TEF should be carefully considered before attempting to determine either BMR or the effect of feeding, particularly in infants.

The composition of the meal bears some importance. In accordance with earlier work, the thermic response to a high-protein meal is greater than that to a high-carbohydrate one.[55] Similarly, the TEF is greater after a high-carbohydrate meal when compared with a high-fat[56] or mixed diet.[57] Thus, high-fat meals could be a risk factor for obesity in children.[58] However, the ingestion of a mixed meal elicits many simultaneous and complex events, and an experimental account of the thermic response to feeding could come only from a simplified model. The euglycemic-hyperinsulinemic insulin clamp offers several advantages in this regard.[59] It involves a single nutrient and bypasses absorption, allowing one to know precisely the rate of appearance of glucose within the body at any time. Combined with indirect calorimetry, it allows one to assess the effect of glucose infusion on glucose oxidation and storage as well as on energy expenditure. When different plasma insulin concentrations are achieved, together with glucose infusion rates appropriate for maintaining euglycemia, it is readily apparent that the increase in energy expenditure secondary to glucose administration is not related to an increase in its oxidation rate. In contrast, the increase in energy expenditure is closely related to the rate of glucose storage.[60] This is supported by studies in insulin-resistant patients showing that their blunted thermic response to glucose infusion is restored when glucose storage rate is matched to controls by further increasing insulin concentration.[61] Thus, in agreement with Flatt's proposal,[62] the TEF is primarily related to the cost of storage of the nutrients. According to the stoichiometry of these reactions, it is possible to calculate that the synthesis of glycogen costs about 4% of the energy of the glucose stored (0.15 kcal/g) and that this cost increases to 28% (1.05 kcal/g) when glucose is converted to fat. Conversely, the cost of triglyceride synthesis from absorbed fats amounts to about 2% of their energy content. Because of the many adenosine triphosphate (ATP)-consuming steps involved in the synthesis and breakdown of proteins, the cost of amino acid incorporation into proteins is estimated to be about 25% but might be as high as 55% of their energy content.[62] Indeed, comparing the thermic effect of high-protein and high-carbohydrate diets shows that the former results in a greater thermic response (+45%) than the latter. Simultaneously, the increase in protein turnover is twice as much with the high-protein diet as with the high-carbohydrate diet. The metabolic cost of protein synthesis would thus account for about 68 and 36% of the thermic effect of each diet, respectively, and the combined effect of increased protein synthesis and nitrogen excretion would account for 96% of the thermic effect of the high-protein diet.[55]

The cost of storage may not be the only component of the TEF. Indeed, the increase in energy expenditure related to glucose infusion is substantially higher than predicted from the amount of glucose stored.[60] The fact that overfeeding or the ingestion of a glucose-rich meal elicits an increase in sympathetic nervous system (SNS) outflow,[63] or in plasma noradrenaline concentration and turnover,[64,65] a known thermogenic hormone, suggests that the stimulation of the SNS is involved in the thermic

response to feeding. This is supported by the blunting of the glucose-induced increase in energy expenditure by β-adrenergic blockade during insulin clamps. As a result, the residual variation in metabolic rate becomes almost identical to the value predicted from the amount of glucose stored.[66] This implies that the TEF has two components. One is an obligatory component directly related to the intermediary storage of nutrients and accounts for about 60% of the response to feeding. The other is related to the stimulation of the SNS and represents about 30% of the increase in energy expenditure.[67] This partition is confirmed by the use of clonidine, a centrally acting α_2-adrenergic receptor agonist that inhibits SNS outflow. In association with the decreased SNS response to a carbohydrate-rich meal, TEF is blunted by 33%, a value similar to that obtained from peripheral β-adrenergic blockade during insulin clamps.[68] The effect of SNS activity on energy expenditure is not restricted to the hours following meals. Its inhibition by clonidine also decreases RMR. Although the reduction in RMR does not reach significance because of the small number of subjects, the authors aptly point out that a 6% decrease in BMR might account for a greater overall diminution in energy expenditure than the larger 33% blunting of TEF.[68] The contribution of SNS activity to energy expenditure in the postabsorptive state is further confirmed by the 8% reduction in BMR observed in response to a β-adrenergic antagonist that does not affect T_3 production, nadolol.[69] Furthermore, urinary noradrenaline excretion and muscle sympathetic nerve activity are significantly correlated to RMR adjusted for FFM, FM, and age in normal adults, implying that SNS activity is a physiologic determinant of energy expenditure.[70,71] A similar correlation between urinary noradrenaline excretion and oxygen consumption is observed in infants,[72] suggesting that the effects of SNS activity on energy expenditure extend to this age.

Therefore, the thermic effect of feeding involves a short-term meal-related component lasting for several hours and is accounted for by both nutrient storage (obligatory) and acute stimulation of the SNS (facultative). In rapidly growing infants, this short-term effect also reflects the cost of synthesis of new tissues as its magnitude is significantly correlated to growth rate.[42] However, the response to feeding also involves a longer-term component, which may affect BMR and SMR.

Thermogenesis

Heat production by living organisms is associated with respiration and concomitant oxidation of nutrients. According to the chemiosmotic hypothesis, the enthalpy of oxidation is transduced by the respiratory chain of the mitochondria into a proton gradient, which powers the ATP synthase.[73] However, the efficiency of the system characterized by the ratio of the amount of energy liberated to that recovered is far from one, even if it is higher than previously estimated from the standard-free energy of ATP, $\Delta G^{0'}$.[1] Attempts to directly evaluate this efficiency in humans indicate that about 65% of the energy liberated may be recovered under the form of ATP.[74] Thus, a minimum of 35% is lost as heat, and nutrient oxidation at the level of mitochondrial respiration appears as the primary heat-releasing process. This is consistent with the significant relationship existing between body temperature and BMR or SMR.[75] However, basal heat production may be insufficient to maintain the core temperature within a narrow range of variation, particularly when heat exchange is increased by a low ambient temperature. Extra heat production can be generated by recruiting metabolic processes that do not produce any net work. Isometric muscular contraction, as during malignant hyperthermia, is a major heat-generating process. Similarly, shivering increases oxygen consumption,[76] and because no external work is performed, the energy appears as heat.

There is some evidence in adult humans that heat production may be increased by other means. For instance, BMR or 24-hour energy expenditure increases significantly (6 to 11%) in response to an ambient temperature drop from 28°C to 20°C to 22°C, without any overt sign of shivering or any correlation with activity.[77] Similarly, the metabolic rate of full-term infants increases in response to an ambient temperature lowering from 32°C to 23°C. This increase is not correlated with activity and occurs in the absence of shivering. In these conditions, the infants' response is dramatic, amounting to a 100% increase in energy expenditure,[78,79] which suggests that a nonshivering thermogenesis is operative. In the rat, the early stage of cold adaptation is associated with shivering. However, shivering disappears with acclimatization, and a nonshivering heat source eventually takes over all of the duties of heat production.[80] It is now well established that cold exposure results in a marked increase in sympathetic activity, largely responsible for the elevated metabolic rate of the rats.[81] The dominant role in nonshivering thermogenesis has been ascribed to brown adipose tissue (BAT), even in adult animals.[82] BAT stimulation is achieved through β-adrenergic receptors, among which is a new type of receptor with pharmacologic properties differing from either β_1 or β_2, thus termed β_3.[83] BAT's prominent characteristic is the synthesis of a specific, 32,000 Da protein, known as uncoupling protein 1 (UCP-1 ; reviewed in Pecqueur and colleagues[84]), located in the inner mitochondrial membrane and acting as a proton conductance pathway. UCP-1 dissipates the proton gradient created by respiration, thus bypassing ATP synthase. In turn, the dissipation of the proton gradient causes a dramatic increase in the mitochondrial respiratory rate. On β-adrenergic stimulation, BAT substantially increases its respiration. As mitochondrial respiration and phosphorylation are uncoupled, ATP generation accounts for much less than 10% of oxygen consumption,[85] and the enthalpy of oxidation of the nutrients is essentially dissipated as heat, making BAT a tissue specialized in thermogenesis. Acute cold exposure leads to a rapid and pronounced elevation of the level of the messenger ribonucleic acid (mRNA) coding for UCP-1, and UCP-1 synthesis is evident within 15 minutes.[86] In contrast, hypothyroid rats are unable to maintain a normal body temperature when placed at 4°C, despite increased

noradrenaline turnover rates.[87] The response of UCP mRNA to adrenergic stimulation in hypothyroid brown adipocytes is readily restored by thyroxine (T_4) through mechanisms requiring its intracellular conversion to T_3.[88] For a full UCP-1 response to cold, near-saturation of the nuclear T_3 receptor is required.[88] BAT contains a type II 5′deiodinase (5′D-II), which locally generates T_3 and allows it to reach a very high level of receptor occupancy despite the low physiologic plasma T_3 levels.[89] Indeed, T_4 appears to be a much more efficient source of T_3 for BAT than plasma T_3 when the 5′D-II is activated. Conversely, iopanoic acid, an inhibitor of 5′D-II, abolishes the T_4-induced restoration of both UCP-1 response and normothermia in hypothyroid rats.[88] In turn, 5′-II activity is stimulated by SNS,[90] and nuclear T_3 receptors are nearly saturated within 4 hours of cold exposure.[89] Thus, SNS, through cyclic adenosine monophosphate (cAMP) generation, and thyroid hormones act synergistically on BAT. T_3 affects the *UCP-1* gene expression at a transcriptional[91] and post-transcriptional level.[92] However, this effect of T_3 is not sufficient to elevate UCP-1 mRNA cellular content in the absence of significant levels of transcription, explaining why T_3 cannot increase UCP-1 mRNA in vivo in the absence of adrenergic stimulation.[93] Thus, T_3 amplifies the effects of the adrenergic stimulation on UCP-1 gene expression, allowing BAT to reach its full thermogenic capacity. Conversely, pretreatment of rats with corticosterone abolishes the UCP-1 mRNA response to noradrenaline and cold by inhibiting *UCP-1* gene expression.[94] Interestingly, this effect is antagonized by the action of the corticotropin-releasing hormone (CRH; under feedback control by glucocorticoid) on the central nervous system, stimulating SNS outflow[95] and leading to an increased expression of UCP-1.[96] The simultaneous expression of several proteins (UCP, 5′D-II, and β_3-adrenoreceptors) appears to characterize functionally active BAT, although only UCP-1 is tissue specific.

The first attempts to settle the controversy about the presence or absence of BAT in humans involved the characterization of UCP-1. This protein was first reported in human fat depots from patients with pheochromocytoma.[97] It was subsequently isolated from newborn brown fat.[98] Later, UCP-1 was found in humans at all ages, but its content was highest in children.[99] Since then, the human *UCP-1* gene has been cloned. Its sequence is 80% homologous to rat UCP-1, both at the nucleotidic and amino acid levels.[100] Both UCP-1 and UCP-1 mRNA are present in infants and in an unexpected number of adult patients, UCP-1 mRNA being detected in the periadrenal adipose tissue of all of the subjects studied.[101] UCP-1 transcripts are abundant in an infant's perirenal fat but are low in quantity in subcutaneous depots.[102] Full-term newborn interscapular UCP-1 content is equal to, or even higher than, the level found in 3-week-old mice acclimatized at 20°C. In contrast, ATPase content is low in infant BAT, similar to that found in animal BAT mitochondria, compared with heart and liver mitochondria.[103] The specific content of UCP-1 in infant BAT increases twofold between 25 and 32 weeks of gestation and remains nearly constant thereafter.[103] Infant BAT also expresses 5′D-II. Strikingly, 5′D-II content follows the same pattern as UCP-1 and achieves levels comparable to 5′D-II activities found in animals stimulated during the neonatal period by exposure to cold or increased cAMP levels.[103] Moreover, β_3-adrenoreceptor mRNA content in children and adults parallels that of UCP-1 mRNA.[102] This coexpression of UCP-1, 5′D-II, and β_3-adrenoreceptor strongly suggests that functional BAT exists in humans from birth to old age. Measurements performed in vitro on isolated cell preparations as well as in vivo suggest that the heat-dissipating capacity of BAT is in the range of 300 W/kg of tissue.[104] Thus, 16 g of BAT would be sufficient to account for the 25 to 30 W/m^2 increase in energy expenditure observed in newborns exposed at 23°C.[79] This would represent about 2% of the adipose tissue mass of newborns or a figure similar to the amount of BAT found in adult rats acclimated to cold.[82] Adrenaline-mediated thermogenesis also occurs in human muscle,[105] even if its mechanism is still uncertain. Similarly, it was recently shown that T_3 administration to normal adults results in a significant increase in the activity of muscle tricarboxylic acid (TCA) cycle, without any change in the rate of ATP synthesis.[106] The disproportionate increase in TCA cycle flux compared with ATP synthesis suggests that T_3 induces an increase in muscle thermogenesis by promoting mitochondrial energy uncoupling. This might be achieved through an increase in UCP-3 protein expression, which is specific to skeletal muscle and upregulated by thyroid hormones. In this regard, it is noteworthy that the biochemical properties of muscle (ie, fast-twitch versus slow oxidative fibers) account for part of the interindividual variability in SMR and 24-hour energy expenditure in the adult.[107,108] However, the respective contributions of BAT and muscle to the overall thermogenic response are difficult to ascertain. Some studies in adults suggest that a ≈ 700 g BAT would contribute 25% to adrenaline-induced thermogenesis, whereas the ≈ 34 kg muscle mass would account for 50% of the thermic response.[109] Despite the uncertainties about its effectors, the reality of a β-sympathetically mediated thermogenesis is now recognized in humans.[71,110]

24-Hour Energy Expenditure

BMR represents a major determinant of 24-hour energy expenditure, amounting to about 60% of 24-hour energy expenditure in sedentary adults.[111] This corresponds to a 1.6 24-hour energy expenditure to BMR ratio, also named physical activity level (PAL). Actually, a PAL of 1.35 is considered the lowest value compatible with long-term maintenance in adults, other than the completely chair- or bed-bound. A PAL range of 1.55 to 1.65 represents the average of the so-called sedentary lifestyle. Data also suggest that activities do not have to be obviously strenuous for relatively high PAL values to be achieved. PAL values vary from about 1.6 to 1.7 in boys and girls between 1 year of age and adolescence (Appendix, Table A-12).[112] Indirect estimates suggest that the energy cost of spontaneous activity represents only 5 to 10% of 24-hour energy expenditure in premature infants[44]) but amounts to 20 to 26% of 24-hour energy expenditure between 1 and 4 months of

age[113] and up to 50% in 8- to 12-year-old children. A mean PAL value of 1.5 was reported in 10- to 13-year-old boys and girls. In this latter case, the variability of the 24-hour energy expenditure to BMR ratio is quite large, reflecting important individual differences in the amount of energy expended for activity (range 1.20 to 1.87).[114] Nonexercise activity may also significantly affect energy balance and may be—independent of volitional exercise—an important mediator of resistance to fat gain.[115] This suggests that components other than BMR and the energy cost of activity contribute modestly to the 24-hour energy expenditure of normal infants and children. However, an increase in the energy expended by these minor components (SNS activity and thermogenesis) may significantly contribute to the alteration of energy balance in disease states.

EFFECTS OF UNDERFEEDING AND MALNUTRITION

Effects on Energy Expenditure

Underfeeding healthy or obese adults results in a consistent 20 to 30% reduction in BMR and 24-hour energy expenditure expressed either in absolute terms or related to body weight, body surface area, body weight to the 0.73 power,[116] or FFM.[117] It should be pointed out that this effect has important implications for the clinical management of obesity as this compensatory change opposes the maintenance of a body weight that is different from the usual weight.[117] The decrease in BMR is rapid during the first weeks and then proceeds at a slower rate.[116,118] Thus, the initial, rapid decrease in BMR is not entirely accounted for by a corresponding loss of metabolically active tissue.[116] An analysis of fasting and semistarvation studies suggests that about 25 to 30% of the short-term decrease in BMR may be independent of the loss in lean body mass, indicating either a change in the composition of FFM or an alteration of cellular metabolism.[118] The dramatic effect of refeeding on BMR, which returns to normal within a few days without a parallel increase in body weight,[116] further supports the hypothesis that the decrease in metabolic rate during acute dietary restriction is of larger magnitude than that of tissue losses. A down-regulation of BMR might be related to the decrease in noradrenaline appearance rate[65,119] and in thyroid hormones[65,120,121] in response to fasting or semistarvation. This possibility is supported by the prevention or the reversal of the metabolic response to acute energy restriction by replacement with either levodopa or T_3.[120,121] The enhancement of the thermic response to adrenaline infusion by prior starvation is consistent with a reduction in SNS activity.[122] A decrease in SNS outflow might also explain the significant reduction in the energy cost of glucose storage observed after underfeeding normal adults for 7 days.[123] Similarly, it might account for the absence of any increase in the metabolic rate of undernourished patients exposed to mild cold. As their thermic response to adrenaline is conserved, the defect in cold-induced thermogenesis following weight loss cannot be ascribed to a decrease in tissue responsiveness. In these patients, the thermic response to mild cold is fully restored after weight gain.[124] Similar functional defects are apparent in children. Malnourished infants switched from 28°C to 24°C respond with a progressive fall in central temperature. When recovered, these infants increase their BMR by 20% in response to temperature lowering and are able to maintain their body temperature within the normal range without shivering.[125] A decrease in skeletal muscle respiration proportional to the change in BMR in malnourished infants further supports a decrease in cellular metabolism.[126] However, metabolic rate measurements in chronically undernourished children may provide results that apparently conflict with those observed during acute energy restriction in adults.

Surprisingly, BMR may be approximately normal relative to body weight and may even appear higher in those infants who are the most wasted.[127] Similar results are obtained in chronically undernourished adults. BMR related to body weight appears higher in the undernourished than in the controls, although, in absolute terms, it is significantly lower.[128] Body cell mass is reduced even in moderate deficiency, but muscle mass seems to decrease linearly with the increasing severity of undernutrition, whereas visceral cell mass shows limited changes. For instance, body fat and body cell mass are reduced by 29%, whereas muscle mass is decreased by 41% in severe undernutrition.[129] This is in general agreement with animal experiments, although a larger range in the weight change of some organs in response to nutritional manipulations may be observed.[130] Thus, taking into account the respective metabolic rate of tissues,[14] it is not surprising that BMR related to body cell mass or FFM may appear falsely high in some cases of severe malnutrition. This increase in metabolic rate related to FFM or body weight does not preclude an overall depression of tissue metabolism.[127,131] In infants, protein turnover, synthesis, and breakdown rates are significantly lower (≈ 40%) before than after recovery from malnutrition.[132] Diminished substrate cycling is observed in adults during short-term underfeeding, and the resulting decrease in both protein turnover and glucose cycling may account for about 35% of the reduction in 24-hour energy expenditure.[133] Conversely, the malnourished infants' increase in energy expenditure in response to dietary treatment is an early event,[127] concurrent with a dramatic increase in growth rate[42] and in protein turnover,[132] suggesting that it may not be entirely accounted for by the change in body composition. Fasting metabolic rate (related to body weight) during rapid growth is equal to, or even higher than,[127,131] the recovered values, a fact that further strengthens this possibility. Another way to look at the reality of metabolic rate down-regulation would be to measure the cost of growth, which might be decreased by a higher metabolic efficiency. Although an overall increase in food efficiency may exist during the early period of catch-up growth,[42] the cost of growth during recovery from malnutrition generally appears similar to that of the normal infant.[134] However, longitudinal studies may easily overlook any enhancement in metabolic efficiency if it is short-lived.[135]

Effects on Substrate Use

The classic studies of starvation showed that endogenous glucose production amounts to about 180 g/day after a few days fast, of which 80% is oxidized by the brain.[136] The bulk of gluconeogenic precursor is provided by body proteins.[136] After 5 or 6 weeks of starvation, ketone bodies have replaced glucose as the predominant fuel for brain metabolism,[137] and glucose production has decreased to about 86 g/day, of which about 50% comes from recycled lactate and pyruvate.[138] Thus, fasting endogenous glucose production relies on gluconeogenesis much earlier than previously expected,[139] and both decrease as peripheral glucose uptake diminishes. The reduced demand in gluconeogenic precursors is paralleled by a significant reduction in protein breakdown, which favors sparing of tissue proteins.[140] In parallel, there is a state of insulin resistance at both the hepatic and peripheral levels, which is restored after refeeding.[141] From the beginning, fat is the predominant fuel, the respiratory quotient falling to 0.70 by the fourth day of fasting.[136] Observations made in malnourished children are consistent with these results. Protein contributes little to total energy expenses.[142] The average daily amount of glucose oxidized is also lower, and glucose oxidation decreases more rapidly in response to fasting before recovery than after recovery,[142] which does not demonstrate, but is suggestive of, a reduction in glucose production.[136] It is striking that the reduction in urinary nitrogen output, which occurs in lean, starving adults, is proportionate to the simultaneous decrease in metabolic rate, suggesting that protein sparing may result from the general reduction in fuel use rather than from a specific fat-related mechanism.[143] In any case, protein sparing cannot be effective unless free fatty acids are available in sufficient amounts to cover energy expenditure; hence, fat stores are not depleted.[143]

Therefore, underfeeding results in a significant decrease in metabolic rate related to tissue loss and, to a lesser extent, to a reduction in the activity of the remaining tissues. This reduction in metabolic rate can be viewed as an attempt to save energy in the face of reduced intakes. However, such an economy goes far beyond the physiologic range of adaptation as it is obtained at the expense of growth and body composition. Furthermore, its only flexibility depends on the use of remaining functional tissues as a source of substrates. Thus, any interfering increase in energy demand may entirely jeopardize this precarious balance.

EFFECTS OF DISEASE STATES

The compromise achieved by malnourished infants may be imperiled in two obvious ways. The first one would be to increase energy expenditure, for example, through fever. The other one would be to disrupt the adaptation of protein metabolism by a selective increase in protein breakdown, leading to a rapid net loss of nitrogen.

Effects on Protein Metabolism

It has been known for a long time that urinary nitrogen output is dramatically increased during infection and trauma, in sharp contrast to what is observed during malnutrition. In vivo studies reveal that this is accounted for by a disproportionate increase in protein breakdown over synthesis.[144,145] However, infusion of counterregulatory hormones to healthy adults falls short of reproducing the massive 20 to 40 g/day nitrogen losses observed after trauma or thermal injury, although it does induce plasma hormone elevations typical of severe stress.[146] In contrast, peptides isolated from the plasma of patients with sepsis or trauma are able to specifically induce a dramatic increase in protein breakdown without affecting synthesis.[147,148] This specific effect on protein breakdown is reproduced in vitro by incubating muscle biopsies with the culture medium of activated macrophages, suggesting that cytokines are involved.[149] Cytokines are a large family of cellular regulators that include interleukins (ILs), tumor necrosis factors (TNFs), interferons (IFNs), and others. They play a pivotal role in the immune system, but their effects extend far beyond the immune cells. Each cytokine may interact with different cell types, thus exhibiting pleiotropic functions in different target cells.[150] Conversely, many different cytokines may exert the same biologic actions, a property known as redundancy. Administration of recombinant tumor necrosis factor (rTNF) or recombinant interleukin-1α (rIL-1α) to animals results in accelerated muscle proteolysis.[151,152] Chronic administration of either rTNF or rIL-1α induces muscle wasting.[151,153] Furthermore, there is a synergistic effect between TNF and IL-1 on the stimulation of proteolysis.[151] In contrast to earlier expectations, the effect of cytokines on protein breakdown is only partially abolished by inhibitors of prostaglandin E_2 synthesis.[154] Moreover, proteolysis in response to rIL-1α is not mediated by glucocorticoids.[152] In humans, administration of rTNF also results in a dose-dependent rise in the amino acid efflux from muscle,[155] confirming the central role of cytokines in disease-related protein losses. In children, rates of protein synthesis and breakdown increase markedly in response to infection. However, breakdown increases more than synthesis, leading to a net loss of nitrogen.[156] Although malnutrition blunts the response to infection, infected malnourished children have protein turnover rates twice as high as uninfected ones, the relative increase in protein breakdown resulting in a negative protein balance.[156] Increased protein breakdown was first noted in sepsis or trauma patients, but a significant change may also be observed in response to much less severe conditions, such as vaccinations,[157,158] suggesting that even mild infections are likely to offset the fragile equilibrium of undernourished children.

It should be pointed out that protein metabolism imbalance per se (ie, protein breakdown rates greater than synthesis) results in a net protein loss and thus may lead to protein deficiency.[144] Growth failure in Crohn's disease might be accounted for by such a mechanism. Growth failure is often associated with Crohn's disease[159] and may even precede symptoms. These patients have a short stature, but, in most cases, their body weight is close to the expected weight for height.[160] Obviously, their FFM is significantly lower than in age-matched controls.[161] As

growth hormone (GH) secretion is normal,[162] a search for nutritional deficiencies was undertaken. A reduction in energy intakes is noted in some reports,[163] but not all,[164,166] whereas protein intakes appear consistently within the ranges of Recommended Dietary Allowances.[163,164] Furthermore, energy losses in the feces are not different from those of normal children,[160,164] and intestinal protein losses are only slightly increased over control values.[160,164] When measured, energy expenditure related to FFM is comparable to results in matched controls.[161,165] Despite the lack of evidence in favor of nutritional deficiencies, energy supplements do result in a significant increase in growth rate,[164,166] suggesting that a nutritional deficiency is indeed responsible for growth failure in Crohn's disease. That such a deficiency could not be ascribed to an overt imbalance between intakes and needs suggests that it might result from an abnormal use of available substrates. Indeed, abnormal protein turnover rates are consistently found in these patients.[167,168] Moreover, alterations in protein metabolism are correlated with the intensity of the inflammatory syndrome[167,168] and are consistent with an increased production of TNF-α and IL-1.[169] Besides the dramatic effect of energy supplements, another line of evidence points toward a nutritional deficiency in Crohn's disease. The plasma concentration of insulin-like growth factor I (IGF-I) is significantly depressed in these patients and further correlates with growth rates.[170] Reduced plasma IGF-I concentrations, despite normal or increased circulating GH levels, are a trait of malnutrition, and measurements of IGF-I levels have been proposed as a highly efficient way of monitoring nutritional rehabilitation.[171] Of particular interest is the fact that plasma IGF-I concentration is closely correlated with protein balance in both animals and humans.[171,172] In the rat, IGF-I level is also correlated with protein intake.[173] Furthermore, low fasting IGF-I concentrations cannot be restored to normal levels by refeeding protein-free diets.[172] This is related to the direct modulation of IGF-I expression by essential amino acid availability, independently of insulin and glucocorticoid contributions.[174] Likewise, IGF-I levels in infected malnourished children are sensitive to dietary protein alterations.[175] High-protein diets result in higher IGF-I levels and improved growth rates,[175] despite the possible direct effect of some cytokines on IGF-1 expression.[176] Therefore, the decrease in IGF-I levels in Crohn's disease pinpoints the critical importance of protein metabolism in growth failure. Indeed, nutritional supplementation results in elevated IGF-I concentrations and increased growth rates.[170] Food supplements induce a significant increase in protein synthesis, which results in an increase in protein balance.[161] In contrast, nutritional support does not seem to affect the elevated breakdown rates.[167] The favorable effect of the nutritional supplements could then be accounted for by the specific induction of protein synthesis by amino acids.[177] Therefore, growth failure in Crohn's disease may be primarily related to an abnormal use of substrates, owing to an imbalance between protein synthesis and breakdown rates, the latter being specifically increased by the associated inflammatory syndrome. Reduction in food intake would exaggerate the protein debt only by further reducing the synthesis-to-breakdown ratio, whereas nutritional support compensates for the increased breakdown rates by promoting protein synthesis. Findings in rheumatoid arthritis (RA) are also consistent with a dominant effect of inflammatory syndromes on protein metabolism. RA is associated with a chronic inflammatory syndrome involving local cytokine production.[178] The immunologic response occurs in affected joints and can also be observed and monitored in peripheral blood. The circulating level of some cytokines (IL-6) is significantly correlated to the commonly used markers of inflammatory syndromes, indicating that it is related to disease activity.[179] The measurement of ^{40}K and total-body water in RA patients shows that their body cell mass (BCM) is decreased by 13% compared with controls. In addition, there is a strong dose response between RA severity and the amount of BCM adjusted for stature: the more severe the RA, the lower the BCM.[180] This difference in BCM is important in two regards: it amounts to about one-third of what is thought to be a survivable loss, and it occurs in patients with energy and protein intakes comparable to those of controls. Surprisingly, the FM measured by dual-energy x-ray absorptiometry is not very different in RA adult patients and in controls.[180,181] This last observation suggests that the covert nutritional deficiency responsible for the decrease in BCM in adults is not primarily related to energy imbalance. Alternatively, the increase in protein breakdown rates observed in these situations might account for the preferential loss in FFM,[182] particularly in muscle.[183]

A comparable increase in protein breakdown may be induced by ammonium chloride infusion to healthy volunteers,[184] an effect also found in chronic renal failure (CRF). For instance, proteolysis may be increased in children with CRF by up to threefold in relation to metabolic acidosis.[185] In contrast to cytokine-mediated protein breakdown, net proteolysis is related to changes in plasma cortisol levels, suggesting that it plays an important role in protein metabolism during metabolic acidosis.[186] It should be pointed out that the acidosis-induced increase in net proteolysis may be quite deleterious to infants and children with inherited diseases of amino acid metabolism.

Therefore, the disruption of protein metabolism regulation in the favor of breakdown, by cytokine overproduction during chronic inflammatory syndromes or by some glucocorticoid-mediated mechanisms during CRF, might well constitute an entry into severe malnutrition, independent of decreased food consumption.

Effects on Energy Expenditure and Energy Substrate Use

Obviously, fever is a common event in children. It is also an efficient way to increase energy expenditure. DuBois emphasized the striking similarity between fevers of greatly different origins by showing that metabolic rate has a much closer relationship with body temperature than with the nature of diseases. This relationship indicates that metabolic rate increases by an average 13% for each 1°C above normal temperature.[76] A comparable relationship is

found in children, resting energy expenditure increasing by about 12% for each 1°C above normal temperature.[187] For instance, during acute malaria, the mean increment in RMR is about 30%.[187,188] This would amount to a 1,200 kcal/day expenditure in a 5-year-old child, or to a 250 to 300 g/day weight loss, should the child not eat.[187] It is noteworthy that the increase in RMR for each degree of increase in temperature is positively correlated to the expected weight for height, suggesting that undernutrition blunts the RMR response to fever.[187] Although the rise in metabolic rate was first related to shivering,[76] there is some evidence that other mechanisms are operative. An endotoxin bolus delivered to healthy volunteers induces a significant pyrogenic response (+2°C in body temperature) within 90 minutes, maximal at 180 minutes, and sustained for more than 6 hours. Total-body oxygen consumption is increased by 28% at 2 hours, when body temperature is about half-maximal, and remains elevated at 6 hours. Coordinately, splanchnic oxygen consumption is increased by 64% at 2 hours and is still increased by 47% at 4 hours.[189] The increase in splanchnic oxygen extraction represents ≈ 80% of the increase in whole-body oxygen consumption at 2 hours, suggesting that shivering is not the major source of heat production at this time, although body temperature is still rising. This interpretation is consistent with the absence of increase in leg oxygen extraction at 2 hours.[189]

Both the traditional pharmacologic approach and the recent gene knockout technology stress the importance of cytokines in the development of this thermic response. However, some discrepancies persist, which may be related to cytokine redundancy and to the models used. For instance, IL-1β and IL-1 type 1 receptor knockout mice challenged with a low or high dose of lipopolysaccharide (LPS) display a thermic response similar to wild-type mice, whereas the fever, anorexia, and weight loss resulting from turpentine injection are completely abolished.[190] Similarly, the significant increase in plasma IL-6 levels observed in wild-type mice injected with turpentine is virtually absent in the IL-1β knockout mice.[191] Injection of turpentine into IL-6 knockout mice also fails to induce fever, anorexia, and weight loss.[192] All of these data support the direct implication of IL-1β and IL-6, but also TNF-α, in the induction of fever and sickness behaviors. The thermic response to LPS depends on prostaglandin synthesis as it is blocked by indomethacin, as well as by cyclooxygenase 2 or prostaglandin receptor gene disruption.[193,194] Prostaglandin receptor (subtype EP3) knockout mice fail to mount a febrile response to LPS, IL-1β, and prostaglandin E_2. The pyrogenic effect of IL-1β may also be inhibited by pretreatment with either a receptor antagonist or a monoclonal antibody to CRH.

In parallel to their effects on energy expenditure, ILs affect food intake. Chronic administration of IL-1 to rats causes persistent inhibition of feeding.[195] Strikingly, this effect is not obtained in fish oil–fed rats.[196] Anorexia induced by IL-1 is mediated by CRF,[196] melanocortin 3/4 receptors,[197] and, to a lesser extent, by prostaglandins.[198] Thus, CRF seems to modulate both aspects of energy balance regulation in the rat, that is, food intake and energy expenditure. CRF effect on energy expenditure is mediated by a stimulation of SNS outflow, as reflected by a dramatic increase in the secretion of both adrenaline and noradrenaline,[95,199] explaining that the increase in body temperature and oxygen consumption induced by experimental inflammatory syndromes may be significantly reduced by β-adrenoreceptor blockade.[200,201] Urocortin, a member of the CRF family, also increases leptin and affects mitochondrial UCPs.[202] The chronic administration of IL-1β thus induces a sustained rise in body temperature and a reduction in food intake. The simultaneous increase in energy expenditure and decrease in energy intake result in a significant reduction in body weight gain of the experimental rats compared with controls, indicating that low levels of IL-1β release, maintained over periods of several days, could be responsible for changes in energy balance during chronic infection or inflammation.[203]

Chronic cytokine overproduction also affects energy expenditure in humans. In RA, for instance, RMR adjusted for body cell mass is about 12% higher than in adult controls. Furthermore, there is a positive correlation between cytokine production and the increase in RMR, cytokine production and body cell mass accounting for about 20 and 50% of RMR variability, respectively.[180] RMR adjusted for FFM is increased by about 20% in children with systemic juvenile rheumatoid arthritis (JRA) compared with controls. As a result, they are stunted and their FFM is reduced. Oligo and polyarticular JRA children still display an 8% increase in RMR over controls.[204] Similarly, RMR is increased in stable, cystic fibrosis (CF) patients by 10 to 25% above control values,[205,206] a change that is not accounted for by the increase in the oxygen cost of breathing.[205] There is a positive relationship between RMR and TNF-α levels[207] and adrenaline levels, TNF-α accounting for about 27% of RMR variability. Contrary to RA patients, who have a significant reduction in FFM but a relatively conserved FM, in CF patients, FFM and FM are both significantly reduced.[208] Thus, besides the dramatic thermic response to infectious disease or injury, cytokines may also mediate lower-magnitude increases in metabolic rate, which might lead to a progressive depletion of energy stores if sustained for weeks or months.

Infection also induces important changes in the production or use of energy substrates. Infected patients present glucose intolerance, irrespective of the severity of the infection and of the infective agent.[209] There is a significant increase in endogenous glucose production, which is not suppressible by glucose infusion and partially accounts for the increase in plasma glucose concentration. [210] The stimulation of hepatic glucose production is principally mediated by increased levels of catecholamines and an increased glucagon-to-insulin ratio.[211] Although whole-body glucose turnover is increased, insulin ability to stimulate glucose uptake is reduced. Indeed, peripheral glucose use is impaired when compared with controls.[212,213] It is noteworthy that marked insulin resistance is present in previously healthy individuals with uncomplicated viral infections.[214] Insulin resistance is readily apparent 4 hours

after the administration of LPS to healthy volunteers.[215] The increase in glucose turnover and the peripheral insulin resistance may be partially accounted for by a sustained β_2 stimulation[216] and by the increase in free fatty acid appearance rate in infected humans and animals,[211,212] an increase related to adrenergic stimulation.[211] However, cytokines, particularly TNF-α, also contribute to insulin resistance by a direct effect on the insulin signaling cascade[217] and by increasing free fatty acid appearance rate by a stimulation of adipose tissue lipolysis[218] and a simultaneous reduction in adipocyte lipoprotein lipase activity.[219] When compared with healthy controls, fat oxidation is increased in septic patients and falls by a much lesser percentage in response to glucose and insulin.[212] Indeed, at the end of an insulin clamp, fat oxidation still contributes about 58% to the metabolic rate in the septic patients, whereas it amounts to only 23% in controls.[212] Moreover, fat oxidation rate appears to be positively related to the severity of sepsis. Despite an increase in glucose turnover, fat thus appears as a preferred calorie source during sepsis.[220] Endotoxin administration to humans induces an increase in adrenaline and cortisol levels, whereas glucagon and insulin do not change.[189] Simultaneously, there is a significant rise in free fatty acid levels. Splanchnic glucose output is also increased, and a progressive hyperglycemia ensues. The reduction in glucose use, like that observed in sepsis, is related to impaired nonoxidative glucose disposal and not abnormal glucose oxidation.[215] Increases in plasma glucose, free fatty acid turnover (126%), and fat oxidation (60%) and similar variations in hormone concentrations follow the injection of rTNF to human volunteers, further supporting the role of cytokines in the development of the metabolic response to acute infection or injury.[221] It is interesting that an increase in both free fatty acid and glycerol concentrations is also observed in CF patients despite a reduction in FM, suggesting that chronic inflammatory syndromes may result in changes in the pattern of substrate use qualitatively comparable to those observed during acute infection.

ENERGY REQUIREMENTS IN DISEASE

ENERGY

The Food and Agricultural Organization of the World Health Organization (FAO/WHO) has published detailed estimates for energy requirements in infants and children of various ages.[222] In the adult, baseline energy needs, that is, energy needed to cover the metabolic response to food and the energy cost of minor activities, are assumed to be equal to 1.35 × BMR, and the time spent sleeping is equal to BMR. This is considered a survival requirement and is of practical value only for estimating the short-term needs of inactive and dependent individuals. Otherwise, estimates should include the energy cost of various occupational activities. However, it is not possible to specify with any confidence the allowance that should be made for a desirable level of physical activity in infants and children. Thus, energy requirements from birth to 10 years have been derived from the observed intakes of healthy children growing normally.[190] Beyond 10 years, calculations are based on published BMR measurements, incremented for the cost of growth and for a cost of activity assumed to be about 1.6 × BMR.[190] Free-living measurements of 24-hour energy expenditure corrected for the energy deposited during growth show that estimated energy requirements are substantially higher than total energy expenditure.[223] Furthermore, calculated energy expenditure also exceeds the energy intakes of 10- to 17-year-old children and adolescents.[223] Clearly, the difficulties encountered in achieving an accurate prediction of the energy needs in healthy infants and children would make unrealistic any such attempt in sick children as the issue is further confused by the contradictory effects of underfeeding and disease on energy expenditure. Then the only option left is to try to identify some agreement about the range of variations in metabolic rate induced by diseases.

Studies in children with acute measles-associated underfeeding suggest that negative energy balance is related to a dramatic reduction in gross energy intake concomitant with a sustained level of energy expenditure. Metabolic rate after recovery is not significantly different from the values obtained during acute infection, although an average 20% increase would have been expected from the presence of fever.[224] The surprising stability of metabolic rate during acute infection might be accounted for by the balanced effects of underfeeding and infection. In any case, maintenance energy requirement (MER) determined at zero energy balance is 64 kcal/kg/day,[224] a figure similar to the MER of thriving immature infants.[39] In these infants, the safe level of energy intake is estimated to be between 91 and 100 kcal/kg/day, or about 1.5 × RMR,[224] compared with the 81 to 87 kcal/kg/day free-living 24-hour energy expenditure of normal infants,[223] or the average 103 kcal/kg/day estimated energy requirements for the same age group.[190] It is further possible to evaluate the consequences of sepsis and trauma on energy expenditure. Earlier measurements in adults indicated 20 to 50% increases in metabolic rate in response to severe infection or multiple trauma. Studies performed in critically ill patients without malnutrition indicate that the mean increase in fasting metabolic rate ranges between 5%[225] and 14 to 18% over predicted values.[226] This is consistent with reports comparing septic patients with matched controls and showing a 15 to 19% increase in fasting metabolic rate over normal values.[227] Comparable estimates are obtained in traumatized children. RMR peaks at 3 days after injury, representing an 8% increase over predicted values or a 14% increase over replicate measurements obtained after discharge.[228] After surgery, the mean increase in RMR over baseline reaches about 15%. In these conditions, RMR peaks at 4 hours postoperatively and returns to baseline levels by 12 hours, thus resulting in a modest overall change in metabolic rate. Furthermore, the increase in RMR is related to the nature of the surgical procedure, the maximal rise being about 5% for minor surgery and 19% for major operations.[229] A similar trend toward decreasing estimates is observed regarding the energy expenses following burn injury. RMR in burned infants is independent of burn size and of the time elapsed between burn injury and mea-

surements. Indeed, these two factors account for only 24 and 21% of the variation in RMR above predicted values, which primarily depends on body size.[230] Furthermore, β-adrenergic blockade induces a substantial decrease in RMR in severely burned children.[201] As a result, the amount of energy required to achieve energy balance may be much lower than previously estimated. Actually, caloric delivery in excess of 1.2 × RMR might only result in increased fat mass without changes in lean body mass.[231] A comparable re-evaluation of the change in metabolic rate resulting from severe head injury suggests that patients who are properly taken care of have a lower than expected increase in RMR.[232] Therefore, it is likely that an energy intake equivalent to 1.5 × BMR would meet the requirements of most septic, traumatized, or burned infants and children. That increases in RMR after trauma, sepsis, or burn injuries are somewhat comparable is consistent with the existence of common mediators. Although the increase in energy expenditure resulting from disease appears to be substantially lower than previously estimated, applying equations that were originally developed for healthy, nonhospitalized individuals to predict the energy requirements of critically ill children could result in significant errors and may lead to provision of inappropriate nutritional support.[233]

Energy Substrates and Amino Acids

Energy intake should provide glucose and fat in amounts adapted to insulin resistance and to the preferential oxidation of lipids.[234,235] Physiologic considerations also suggest that the amount of glucose infused to malnourished, uninfected patients be limited. In adults, glucose oxidation levels off at about 4 mg/kg/minute in response to increasing glucose infusion rates.[236] A similar limitation exists in 6-month-old infants, with a maximal oxidative glucose disposal rate of 12 mg/kg/minute.[237] Furthermore, this maximal oxidative disposal decreases in parallel to energy expenditure with age, amounting to about 9 mg/kg/minute at 6 years and about 6 mg/kg/minute at 10 years.[237] In the uninfected infant, glucose infusion in excess of the maximal oxidative glucose disposal rate results only in inhibiting fat oxidation, whether of endogenous or exogenous origin,[237] and may adversely affect protein metabolism and net protein deposition.[238] Thus, expecting some benefit from high glucose intakes in infected infants seems hazardous. On the contrary, glucose intakes should be lower because of the glucose intolerance. Indeed, the insulin resistance–related decrease in peripheral glucose uptake is accounted for by impaired nonoxidative glucose disposal and not by abnormal glucose oxidation.[215] Glucose intakes in the range of the physiologic endogenous glucose production of the corresponding age range are sufficient to meet the needs of glucose-requiring tissues.[239] In these conditions, the clearance of intravenous emulsions and their oxidation are enhanced in septic patients,[234] and there is no more difference in the efficiency of glucose and fat to promote nitrogen balance.[225] The other goal is to equilibrate the increased proteolysis by promoting protein synthesis. In the healthy adult, protein synthesis is primarily regulated by amino acid inflow.[177] Similarly, amino acid infusion decreases net nitrogen losses in septic patients; the higher the amino acid intake, the more rapid the effect.[240] In burned infants and toddlers, amino acid intakes in the range of 2.5 to 3 g/kg/day efficiently support recovery.[241]

The Inflammatory Syndrome: A Case for a Pharmacologic Approach

Providing nutrients may not be enough in many of these situations. Nutritional support should be aimed at avoiding unnecessary increases in metabolic rate or, better, at controlling the disease-induced increase in energy expenditure. Obviously, attention should be given to ambient temperature and humidity, particularly in infants and burn patients. Furthermore, the use of inhibitors of either cytokine expression or cyclooxygenase, as well as of blockers of SNS peripheral effects, should be considered. As glucocorticoids suppress the production and action of several cytokines as well as the production of prostaglandins, it appeared warranted to test their effects in vivo in septic patients. The results are disappointing and do not support their use in sepsis, probably because corticoids could be administered only after cytokine release.[242] The use of molecules (antibodies or receptor analogs) directed against cytokines or modulating inflammation seems to offer interesting possibilities.[243,244] Another way to curb the inflammatory response is to interfere with signal transduction in target cells through inhibitors of the cyclooxygenase. Indeed, pretreatment with ibuprofen results in the complete suppression of fever, tachycardia, and an increase in stress hormones after endotoxin injection compared with the subjects who were not pretreated, despite an identical rise in TNF in both groups.[245] Similarly, the use of β-adrenergic receptor antagonists may substantially diminish energy expenditure.[201] If these dispositions may reduce metabolic rate, in many cases, they will have little effect on the accelerated protein breakdown.

A pharmacologic intervention would be even more pressing when nutrition support fails to prevent protein losses, as is still the case in sepsis or during cancer cachexia. Animal models confirm that protein wasting is not accounted for by the effects of underfeeding in these situations,[154] thus requiring an approach other than dietary therapy. Besides their effect-boosting proteolysis, glucocorticoids have an inhibitory effect on protein synthesis,[246] which could further exaggerate cytokine-induced protein losses. Unfortunately, cyclooxygenase inhibitors seem to have only a partial and transient effect.[154] One remaining possibility is to directly inhibit cytokine production by new agents. Pretreatment with pentoxifylline inhibits TNF secretion and partially suppresses anorexia, weight loss, and muscle protein wasting in septic rats,[247] although fever, myalgia, and increased cortisol levels are unaffected in pretreated, endotoxin-injected humans.[248] However, these molecules are effective when administered prior to endotoxin or TNF injection, but little is known about their efficacy as therapeutic agents.

The other possibility is to antagonize the effects of cytokines on protein metabolism. Recombinant growth hormone (rGH) administered to postoperative patients

induces a dramatic change in nitrogen balance, despite low energy intakes.[249] Furthermore, rGH treatment is able to reverse net whole-body and skeletal muscle protein catabolism in cancer patients.[250] This positive effect has been confirmed in severe sepsis and in patients with human immunodeficiency virus–related wasting. Similarly, rIGF-I infusion to rTNF-treated animals preserves its anabolic action and induces a significant reduction in net protein losses in the face of high TNF levels.[251] It is noteworthy that decreased IGF-I levels, a common finding in acutely ill patients, may enhance protein catabolism. The protein anabolic effects of both rGH and rIGF-I may be substantially increased by using both agents simultaneously,[252] a synergy that might prevent acquired GH resistance. Although recombinant hormones are not the only agents favoring net protein synthesis, available evidence suggests that they are the best candidates to date for improving the nutritional therapy of protein-wasting inflammatory syndromes through direct pharmacologic intervention. Indeed, preliminary studies suggest that rGH treatment improves growth and clinical conditions of cystic fibrosis patients,[253] increases linear growth and lean body mass in patients with Crohn's disease,[254] may even result in a significant decrease in the Crohn's Disease Activity Index,[255] and, by and large, has substantial anabolic effects on whole-body protein and bone metabolisms in children on chronic steroid therapy.[256]

CHAPTER 18

GASTROINTESTINAL DEVELOPMENT: IMPLICATIONS FOR INFANT FEEDING

Robert K. Montgomery, PhD, Richard J. Grand, MD

The survival and prognosis of the prematurely born human infant are dependent on a successful transition from the intrauterine to the extrauterine environment. This is largely a consequence of the maturation of sufficient gastrointestinal function to provide for adequate nutrition. However, the gastrointestinal tract of the premature infant and, to some extent, of the full-term infant might be unprepared to provide the requisite absorptive function. Postnatally, the developing gastrointestinal tract is uniquely adapted to the absorption of breast milk and its nutrient components; exclusion of foreign antigens, pathogens, and some xenobiotics; adaptation to the intestinal microflora; and, with the kidney, maintenance of water balance. In the full-term infant, these processes are integrated and support normal growth and development. In the preterm infant, and under conditions of clinical disease, maturational processes can be impaired; nutritional support must then be achieved by either enteral tube or intravenous feeding.

Detailed descriptions of the morphogenesis of the human gastrointestinal tract are available in standard texts. More extensive discussion of the regulation of the development of the gastrointestinal tract is provided in several reviews.[1–3] This chapter focuses on those processes that are of relevance to successful infant feeding.

The anatomic and morphologic development of the human gastrointestinal tract and liver are summarized in Table 18-1. These data indicate that maturation of form and function occurs in a genetically regulated sequence. Many essential mechanisms are mature at birth, but some, such as bilirubin conjugation and excretion, and hepatic drug metabolism, are completed only in the early postnatal period. Others develop later in the postnatal period, including

- esophageal sphincter function and motility
- gastric acid and intrinsic factor secretion
- gastric motility
- intestinal glucose absorption
- vitamin B_{12} and bile salt absorption
- synthesis of bile acids and the expansion of the bile acid pool
- secretory response to bacterial toxins

Pancreatic exocrine function is completed after approximately 6 months of age; endocrine function, characterized by insulin release after feeding, is also delayed, but not quite as long. The process of development prepares the infant for extrauterine existence and is initially integrated with the composition of breast milk.

MOLECULAR MECHANISMS OF DEVELOPMENT

The epithelium of the gastrointestinal tract is derived from the endoderm, one of three embryonic germ layers that originate during gastrulation of the embryo. Studies in model organisms such as *C. aenorhabditis elegans*, *Drosophila*, *Xenopus*, zebrafish, and mice have identified some of the critical molecular regulators of endoderm formation.[4–6] Analysis of null mice has demonstrated that transcription factors of the HNF3β and GATA families are required for initial formation of the endoderm. Recently, the transcription factor sox-17 has also been shown to be critical for the early development of endoderm in mice.[7]

Formation and regionalization of the gut tube depend on interactions between the endoderm and mesoderm.[8] The mechanisms that mediate epithelial and mesenchymal interactions during intestinal development are beginning to be identified. The signaling protein sonic hedgehog (Shh) is expressed in the endoderm at the earliest stages of gut development. Shh has been shown to induce Bmp-4, a member of the transforming growth factor (TGF-β) superfamily, and members of the *HOX* gene family, determining the regionalization of the chick gut.[9] Expression of Bmp has also been implicated in formation of the pyloric sphincter.[10] Analysis of chick and mouse development has demonstrated that expression patterns of *HOX* genes are correlated with emerging boundaries between different parts of the gastrointestinal tract.[11,12] Generation of null alleles has produced developmental abnormalities in specific regions.[13–17] Signaling via

TABLE 18-1 Developmental Milestones in the Human Fetus

Event	*Time of First Expression*
Gastrulation	Week 3
Gut tube largely closed	Week 4
Liver and pancreas buds	Week 4
Growth of intestine into umbilical cord	Week 7
Intestinal villus formation	Week 8
Retraction of intestine into abdominal cavity	Week 10
Organ formation complete	Week 12
Parietal cells detectable, pancreatic islets appear, bile secretion, intestinal enzymes detectable	Week 12
Swallowing detectable	Week 16, 17
Mature motility	Week 36

the hedgehog and Bmp pathways not only delineates boundaries between organs but also determines the concentric tissue organization in the organs.[18,19]

Recent work has confirmed the role of Shh in mammalian gastrointestinal tract development. Shh null mice develop foregut malformations, including esophageal atresia, tracheoesophageal fistula, and other abnormalities.[20] Furthermore, the transcription factors Gli2 and Gli3, which are transducers of Shh signaling, also are required. Mice in which Gli3 expression is reduced on a Gli2 null background display esophageal atresia and tracheoesophageal fistula.[21] It has also been demonstrated that mutant mice that lack Gli2 or Gli3 exhibit imperforate anus with rectourethral fistula and anal stenosis.[22] The patterning role is apparently completed by midgestation in mice because hedgehog antibody blocking experiments initiated at embryonic day 12.5 did not affect intestinal morphology. However, crypt proliferation and lipid metabolism were disrupted, indicating additional roles for Shh at later stages of development.[23]

Although the same or related signaling molecules mediate development along the gastrointestinal tract, differences in the pattern of inducing signals and possibly receptor expression patterns lead to regionalization. Microarray analysis of gene expression profiles demonstrates that the organs of the gastrointestinal tract display distinct patterns. Furthermore, the analysis identified common regulatory elements, including those for HNF1 and GATA factors, in the 5′ flanking region of genes expressed in different regions.[24] Combination of these approaches should provide a deeper understanding of the regulation of gastrointestinal development.

ESOPHAGUS

Morphogenesis and Differentiation

The esophagus can be identified as a distinct structure early in embryogenesis (4 weeks) and elongates during subsequent development relatively more rapidly than the fetus as a whole.[25] At 10 weeks gestation, ciliated columnar epithelium appears in the esophagus. Stratified squamous epithelium replaces it at around 20 to 25 weeks, a process that begins in the midesophagus and proceeds both caudad and cephalad.[26]

Hitchcock and colleagues have studied the esophageal musculature and innervation of the esophagus in fetuses of 8 to 20 weeks gestation and in infants 22 to 161 weeks of age.[27] The circular muscle is present at 8 weeks, but the longitudinal muscle does not become apparent until approximately 13 weeks gestation. In fetuses, the thickness of the muscularis externa increases linearly from 8 weeks to term (40 weeks), and then growth slows postnatally.

Neurons can be recognized concomitantly with circular muscle at 8 weeks gestation. The density of neurons peaks at 16 to 20 weeks, falls rapidly in the second trimester of pregnancy, and is reduced further toward adult levels during infancy. Numbers of ganglion cells and nerve fibers in the myenteric plexus are also maximal at 16 to 20 weeks. Their density falls with increasing gestational age to 30 weeks, when it becomes constant, despite further esophageal growth.[27]

Functional Implications

Fetal swallowing can be detected as early as 11 weeks gestation, with sucking movements seen between 18 and 20 weeks.[28] The swallowing of amniotic fluid begins very slowly, at a few milliliters per day, and increases to 450 mL per day in the third trimester.[25] In animal models, fetal swallowing defects have been correlated with failure of growth of the gastrointestinal tract, as well as with ultrastructural abnormalities.[29,30] Careful studies are not available in human fetuses; however, human infants with esophageal atresia appear to have normal gastrointestinal function after correction of their lesions.[31] The significance of morphologic changes in animals as a consequence of the exclusion of growth factors from the fetal luminal environment during development remains to be delineated.

Postnatal Development

The development of esophageal function in premature infants has been studied by several groups. It is clear from this research that maturation of esophageal motility progresses in an orderly fashion postnatally.[28,32,33] How much of this information is of direct relevance to the fetus in utero is not known. Specifically, whether reduced lower esophageal sphincter pressure, simultaneous contractions and noncoordinated peristalsis, and frequent transient lower esophageal sphincter relaxations, characteristic of the youngest preterm infants, represent merely delayed development or confer some specific adaptive advantage to the third-trimester human fetus remains to be determined.[28] In preterm infants of approximately 28 weeks gestation, the resting pressure of the lower esophageal sphincter is only 4 mm Hg. However, it rises to adult values (15 to 45 mm Hg) by 40 weeks (Figure 18-1).[32]

STOMACH

Morphogenesis

The morphologic and histologic development of the stomach is complete at term. Prenatal ultrasound examinations

have shown that the fetal stomach grows in a linear fashion from 13 to 39 weeks gestation and that the characteristic anatomic features (greater curvature, lesser curvature, fundus, body, and pylorus) can be identified by 14 weeks. Abnormal images can identify the presence of congenital anomalies. Failure to delineate the fetal stomach ultrasonographically in the second trimester indicates esophageal atresia, and an enlarged fetal stomach can herald the presence of gastric outlet obstruction or duodenal atresia.[34]

Detailed studies of the development of the mouse stomach from Karam and Leblond have established that the epithelial cells of the gastric pits arise from stem cells located in the neck region. As these stem cells divide, they produce cell populations that move upward and populations that move downward.[35] Parietal cell lineage ablation experiments suggest that the balance between parietal, pit, and zymogen cells is maintained by interactions among the cell lineages.[36] It has been demonstrated that gastrin is an important factor in the differentiation of the parietal cells, which are reduced in numbers in transgenic mice bearing either a gastrin receptor knockout or a gastrin knockout.[37,38]

Postnatal Acid Secretion

It is known that parietal cell mass is the controlling variable in the production of gastric acid and intrinsic factor in infants and children, as well as in adults, and that parietal cell mass increases with fetal weight and age.[25,39] In the first 24 to 48 hours after birth, the acid secretory response of full-term infants is relatively resistant to pentagastrin.[40–43] The intragastric pH level remains at approximately 5.5 to 7.0. Increases in gastrin responsiveness occur over the first week of life in both premature and full-term infants. Basal and pentagastrin-stimulated acid secretion double from the first to fourth week of life in preterm infants, as found previously in full-term infants.[25,44]

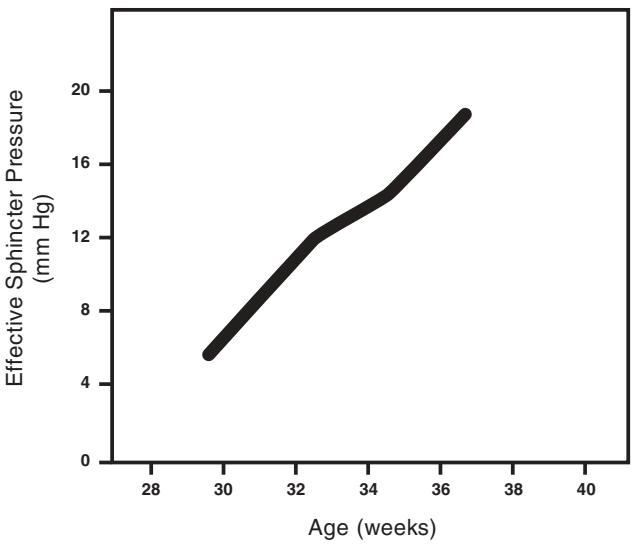

FIGURE 18-1 Lower esophageal sphincter pressure increases with gestational age in premature infants. Reproduced from the American Gastroenterological Association Undergraduate Teaching Project, Unit 35, Development of the Human Gastrointestinal System, with permission of the publisher and Milner-Fenwick; drawn from data in Newell S et al.[32]

The full-term neonatal mean serum gastrin concentration is significantly elevated to levels greater than 135 pg/mL; occasional newborns have levels greater than 200 pg/mL, and some have levels greater than 500 pg/mL.[42] In contrast to these data, Harada and colleagues have shown that the newborn stomach can respond to a glucose-containing protein hydrolysate formula by increasing proton secretion twofold over that seen with glucose alone.[45] The discrepancy between this neonatal response to formula and the previously described resistance to pentagastrin requires clarification.

During the first week of postnatal life, increases in gastrin responsiveness occur. Maximal acid output is approximately at the same level as it is in children and adults by 24 weeks of life (Figure 18-2).

Intrinsic Factor

In the parietal cell, there is an interesting dissociation between the early expression of intrinsic factor and its relatively delayed secretion.[25] In studies of 8- to 29-week-old fetuses and neonates, intrinsic factor can be identified from 11 weeks onward at the base of the gastric glands in the pylorus and corpus of the stomach.[46] Secretion of intrinsic factor, however, is delayed and is correlated in a linear fashion with the capacity for hydrogen ion secretion.[39]

Both haptocorrin (R protein) and intrinsic factor have been identified in fetal gastric extracts from 18 to 25 weeks gestation, and the ontogeny of the intrinsic factor receptor (IFr) has been described.[47] The IFr has been noted throughout the small intestine and colon in 10- to 23-week-old fetuses and becomes restricted predominantly to the distal small intestine in 25-week-old fetuses.[47] This pattern strongly suggests that the proximal-to-distal gradient of IFr expression is developmentally regulated; the mechanisms responsible require further elucidation. From a functional point of view, the early expression of all components of the vitamin B_{12} entry pathway demonstrates the potential for uptake of the receptor-IF-B_{12} complex during fetal life.

A number of genetic defects in the complex mechanism for vitamin B_{12} uptake that result in symptoms early in postnatal life have been described. A juvenile form of pernicious anemia has been reported in a number of children presenting with megaloblastic anemia and developmental delay.[48] It is attributable to the absence of functional intrinsic factor, despite normal gastric acidity and mucosal morphology. A complementary DNA for intrinsic factor of both rats and humans has been cloned, and the intrinsic factor gene has been localized to chromosome 11.[49] Nevertheless, the genetic defect, which is inherited in an autosomal recessive manner, remains unidentified. Grasbeck and colleagues[50] and Imerslünd[51] independently described a syndrome consistent with an autosomal recessive selective malabsorption of vitamin B_{12}.[51] The problem lies in the transport mechanism of the intrinsic factor-Cbl complex at the level of the ileal enterocyte. Studies indicate that the disease is the result of mutation in the gene encoding the endocytic receptor cubulin.[52]

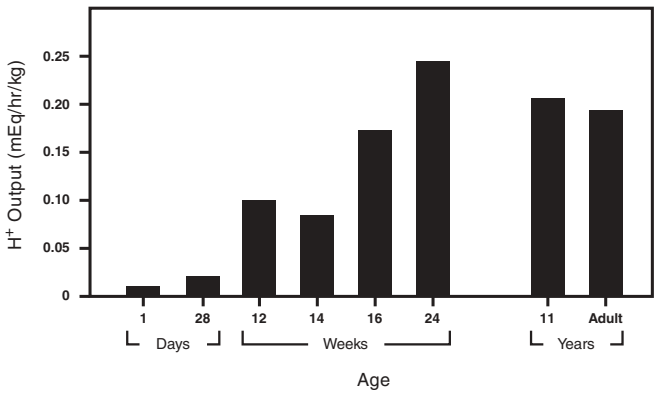

FIGURE 18-2 Maximal gastric acid secretion at birth is low and matures during the first 4 postnatal months. Reproduced from the American Gastroenterological Association Undergraduate Teaching Project, Unit 35, Development of the Human Gastrointestinal System, with permission of the publisher and Milner-Fenwick; adapted from data in Grand RJ et al.[25]

Gastric Lipase

Human gastric lipase has been shown to be expressed as early as 11 weeks gestation in a fundic location and reaches adult levels by 3 months postnatally.[53] Human gastric lipase has been cloned.[54] The enzyme consists of a 379–amino acid polypeptide with a molecular mass of approximately 43 kDa (unglycosylated) and demonstrates close amino acid homology to rat lingual lipase but is unrelated to porcine pancreatic lipase. Lingual lipase plays an important role in preduodenal fat digestion in the rat, but its involvement in lipolysis in the human is now considered to be minimal.[53,55] Lingual lipase activity represents less than 0.015% of total gastric lipase activity. Detailed topographic activity mapping of gastric lipase has been performed by DiPalma and colleagues.[56] Even in the youngest subjects studied (3 months of age), gastric lipase was found only in the body of the stomach; only 5% of the fundic value was found in the antrum. Interestingly, considerable pepsin activity was identified, which did not vary with age. The levels of pepsin and lipase activities are identical in young infants and adults, indicating early complete maturation of these enzymes.[57]

Lipid comprises 40 to 50% of the total calories of human milk, and it is well known that preterm and full-term neonates have relative pancreatic insufficiency and a diminished bile acid pool compared with children and adults.[25] Accordingly, preduodenal lipolysis assumes a critical role in lipid digestion in infants.[58–61] Bile salt-stimulated lipase (BSSL) activity in human milk is capable of initiating lipolysis and yields three fatty acid moieties and glycerol when triglyceride is the substrate and the reaction is complete. Combined with gastric lipase, milk BSSL facilitates lipid hydrolysis and either prepares intraluminal lipid for further cleavage by pancreatic lipases or bypasses the need for these enzymes.[62] Milk BSSL activity decreases with the length of the gestation period, being higher in the milk of mothers delivering preterm than in those delivering at term.[63] This pattern reflects the adaptive capacity of the fetal-maternal dyad to protect neonatal nutritional status.[64,65]

Motility

The characteristics of in utero gastric motility are unknown, but data are available from very low birth weight preterm infants from 26 to 35 weeks gestation.[66] In these infants, antral motor activity was similar in preterm and term infants, although the preterm group had fewer antral clusters coordinated with duodenal clusters than term infants did. The functional implications of these patterns can be found in studies of gastric emptying of human milk and formula. Emptying half-time doubled when newborns of 28 to 34 weeks gestation were compared with full-term neonates independent of feeding.[67] When newborns of 32 to 39 weeks gestation were compared, increasing the caloric density of feedings decreased the rate of gastric emptying, as in adults, indicating that appropriate control mechanisms were already developed.[28] There are no effects of posture, temperature, or volume of feedings on the rates of gastric emptying. Isocaloric feeds of different osmolarity produce comparable rates of gastric emptying.[68,69] Dietary fat does not delay gastric emptying in the preterm infant, whether the lipid is of long or medium chain length.[68–70]

LIVER

Morphogenesis

The liver diverticulum emerges from the most caudal portion of the foregut just distal to the stomach at about the fourth week of gestation. It is first detectable as a thickening of the ventral duodenum. Hepatogenesis is initiated through an instructive induction of ventral foregut endoderm by cardiac mesoderm. A series of elegant experiments has identified a number of signaling pathways involved in the complex process of development of the liver.[3] The immediate signal is provided by fibroblast growth factors from the cardiac mesoderm that bind to specific receptors in the endoderm.[71] After formation of the liver bud, hepatocyte growth factor is required for continued hepatocyte proliferation.[72] The hepatic diverticulum grows into the septum transversum and gives rise to the liver cords, which become the hepatocytes. During this process, a combination of signals from the cells of the septum transversum, including Bmp, is necessary for liver development.[73] Endothelial precursor cells provide another critical factor for hepatogenesis.[74] Secretion of bile into the duodenum begins during the fourth month of gestation.

Biochemical Differentiation

A vast number of hepatic enzymes undergo developmental regulation during the ontogeny of hepatic function. These are beyond the scope of this chapter. Nevertheless, they have distinctive patterns that are relevant. These are shown in Figure 18-3.

Postnatal Function

The newborn depends upon the liver, gastrointestinal tract, and kidney for the excretion of bilirubin and its metabolites. Serum levels of bilirubin peak between 60 and 120 hours after birth (Figure 18-4). By 10 days of age, most

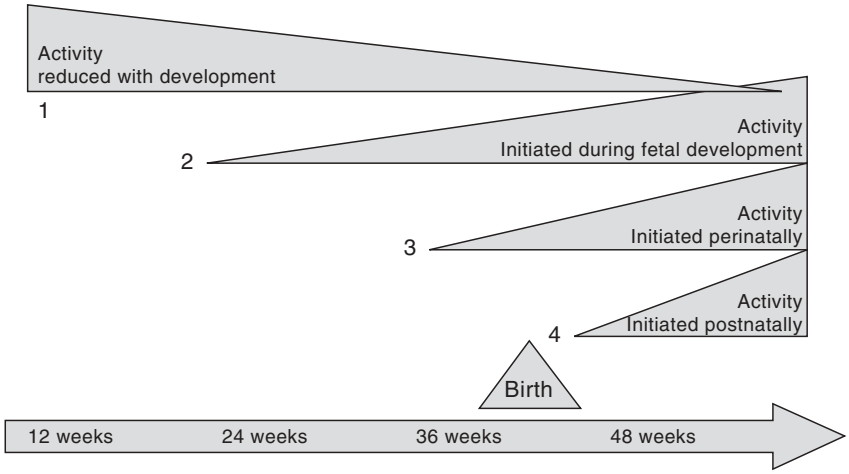

FIGURE 18-3 The quantitative pattern of enzymes in fetal human liver is significantly different from that of adult liver. Reproduced from the American Gastroenterological Association Undergraduate Teaching Project, Unit 35, Development of the Human Gastrointestinal System, with permission of the publisher and Milner-Fenwick; data adapted from Greengard O. Pediatr Res 1977;11:669–76.

babies have serum bilirubin levels comparable to those of adults. The change in bilirubin concentration results from changes in metabolic pathways. There is a dramatic increase in bilirubin production, coupled with immature levels of hepatic bilirubin-uridine diphosphate (UDP) glucuronosyltransferase activity, which conjugates bilirubin and facilitates its excretion by the kidney. In addition, the hepatic uptake of bilirubin is delayed at birth and thereafter rises slowly.

The full-term infant maintains a cholic acid pool half the size of that of the adult (Figure 18-5). After birth, the cholic acid pool size increases dramatically with maturation. In the premature infant, the pool is approximately one-sixth the level it reaches in adults.[58,61,75]

PANCREAS

Morphogenesis

Morphogenesis of the human pancreas begins at about 30 days gestation. Formation of the pancreas is initiated by the emergence of dorsal and ventral pancreatic buds on opposite sides of the foregut. As these epithelial buds enlarge, a treelike ductal system develops by growth and branching. As the gut tube grows and rotates, the two pancreatic buds come together and fuse at about the seventh week of gestation. Individual endocrine cells are identifiable initially, with islets becoming established later. The molecular basis of this process is under intense study, and a number of key regulators have been identified. The homeotic gene *PDX* is essential for initiation of pancreatic development. A single-nucleotide deletion in the human gene results in pancreatic agenesis.[76] Suppression of Shh expression in the dorsal endoderm determines the location of the dorsal pancreatic bud.[77] A more detailed description of current understanding of the molecular mechanisms is presented by Slack[78] and Kim and Hebrok.[2] At approximately 20 weeks gestation, enzyme activity is detectable in the exocrine pancreas, and secretion begins at around the fifth month, with each enzyme developing in an individual pattern.[79]

Postnatal Development

Maturation of secretory function occurs during the first few postnatal months,[79,80] and the magnitude of the increase in specific activity of each pancreatic enzyme is somewhat different. For example, amylase activity in response to cholecystokinin and secretin challenge rises several hundred-fold after the first month of life (Figure 18-6). A 10-fold rise can be achieved by 1 month of age by increasing the quantity of ingested starch. Marked increases in secretory capacity are also found for proteases, lipase, fluid, and bicarbonate.[81] Delayed maturation of pancreatic function permits contact of intact intraluminal macromolecules with enterocytes, a potentially important adaptive response.[82]

SMALL INTESTINE

Morphogenesis and Differentiation

The ontogeny of the small intestine can be thought of as proceeding through three successive phases: morphogenesis and cell proliferation, cell differentiation, and cellular and functional maturation.[83] By 13 weeks gestation,

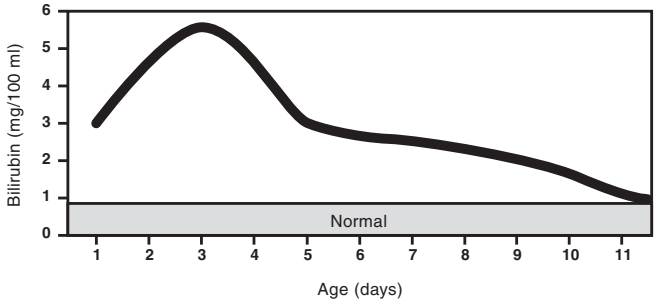

FIGURE 18-4 Physiologic jaundice in the newborn is characterized by a rise in serum unconjugated bilirubin concentration. organogenesis of the intestine is complete.[84] Organ morphogenesis is well described in standard texts and will not be considered in detail. The major milestones are indicated in Table 18-1. New data on the process and regulation of cellular differentiation are described.

It is well established that, by morphologic and biochemical criteria, the human fetal intestine is more mature at term than that of commonly examined mammalian models. In contrast to the well-studied rodents, development of the human intestine is largely completed well before birth, at approximately the end of the first trimester of pregnancy, and by week 22, the absorptive epithelial cells resemble those of the adult intestine. Human absorptive cells at midgestation resemble those of the 5- to 15-day suckling rat, whereas the proximal human absorptive cells at 22 weeks resemble those of the weaned rat.[85]

The process of morphogenesis occurs in human fetal intestine very much as it does in the rat.[85] Mucosal remodeling and villus formation proceed in a cranial–caudal direction beginning at 9 to 10 weeks. The earliest indication is the appearance of subepithelial aggregations of mesenchymal cells associated with projections into the central lumen of the overlying stratified epithelium. Studies of mouse platelet-derived growth factor (PDGF) and PDGF receptor knockouts suggest the presence of an organizing center in the mesoderm of the nascent villi that might regulate their formation.[86] Distinctive junctional complexes appear between cells in the deeper layers of the stratified epithelium during the period of villus formation. Within the mesenchymal invaginations, smooth muscle cells and blood vessels appear as development progresses. Smooth muscle–specific protein markers have been reported in the human fetal jejunum as early as 8 weeks.[87]

There are few data on human intestinal muscle development. The available information has been reviewed by McHugh.[88] Apparent abnormalities of muscle morphogenesis in children have been reported.[89] Columnar epithelium initially lines only the apices of the developing villi but appears along the sides as the villi mature. After 10 weeks, only the intervillus epithelium remains stratified. In all levels of the stratified epithelium, mitotic figures are abundant. Occasional mitoses are seen on villi until 16 weeks, but by 10 to 12 weeks, most mitotic figures are restricted to the intervillus regions and developing crypts.

Crypts first appear as solid cords of epithelial cells but by 12 weeks display a small lumen lined by undifferentiated simple columnar cells. Between 17 and 20 weeks, the first indications of muscularis mucosa develop near the base of the crypts.[84] Little information is available on mechanisms of vascularization. Analysis of mice with a targeted gene disruption has demonstrated that a chemokine receptor is necessary for normal vascularization of the gastrointestinal tract.[90] Prior to villus formation at 9 to 10 weeks, the stratified epithelium contains undifferentiated absorptive cells, goblet cells, and enteroendocrine cells. Paneth cells are observed at the base of developing crypts at 11 to 12 weeks.

All other epithelial cell types known to occur in adult human intestine appear by the beginning of the second trimester.[84] By 12 weeks, 13 morphologically distinct types of enteroendocrine cells are identifiable.[84] In addition to the four major cell lineages, M cells, unique cells restricted to domes of epithelium overlying lymphoid follicles of maturing Peyer's patches, are present by 17 weeks.[84] Available data indicate that M cells arise from the same intestinal stem cells as the other lineages.[91] Caveolated or tuft cells are identified by 16 weeks gestation.

Because they cannot be identified prospectively, little is known about development of stem cells. At an as yet unidentified time, a small number of stem cells become established just above the base of the crypts. Whether the

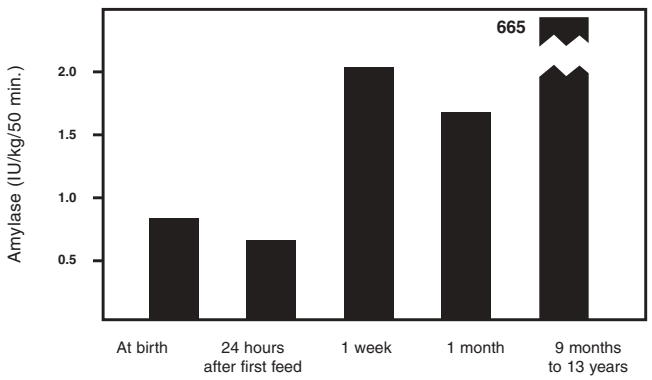

FIGURE 18-6 Pancreatic secretory function increases between infancy and childhood. establishment of stem cells is determined by crypt formation or whether the location of stem cells directs crypt formation is unknown. In mice, expression of the transcription factor Tcf-4 is essential for maintenance of the stem cell compartment in the small intestine.[92]

The stem cells produce a transit cell population, which after additional divisions, gives rise to all of the cell lineages.[93,94] Recent experiments have identified several critical transcription factors involved in the differentiation of intestinal stem cells. Yang and colleagues demonstrated that the transcription factor Math1 is required for differentiation of stem cells into the goblet, enteroendocrine, and Paneth cell lineages but not into absorptive cells. Their data suggest that members of the Notch signaling pathway are involved in cell lineage determination.[95] Hes1 is also required for enteroendocrine cell formation in the stomach and pancreas, as well as in the small intestine. Although required for goblet cell formation in the colon, KLF4 is not required for goblet cells in the small intestine.[96] In contrast to the effects of lineage ablation in the stomach, ablation of the Paneth cell lineage in small intestine did not affect the other cell lineages.[97]

Intestinal Length

Intestinal growth in utero occurs at different rates as gestation advances. It is most rapid during the third trimester and then slows during the remainder of childhood and adolescent growth. The overall increase in length of the small intestine from the fourth to the fortieth week of gestation is approximately 1,000-fold, and, in general, the small intestine is slightly more than three times the crown–heel length of the infant or the standing height of the child or adult (Figure 18-7).

Functional Differentiation

The most extensively characterized measure of human fetal intestinal function is the activity of enzymes located on the microvillus membrane of the enterocyte.[25] Available human development data are largely descriptive; with a few exceptions, little is known of regulatory mechanisms. The regulatory regions of sucrase-isomaltase (*SI*) have been compared in rodents and humans. Three identified regulatory sites are completely conserved in humans and mice.[98] There are, however, significant differences in patterns of expression. In human intestine, SI is first detectable following intestinal morphogenesis in the first trimester of pregnancy, whereas the rodent enzyme does not appear until weaning.[99] Lactase-phlorizin hydrolase (LPH) is first detectable with intestinal morphogenesis in both human and rodent intestine. In humans, LPH remains low until shortly before birth, whereas in rodents, expression increases dramatically until reaching a peak several days after birth.[100]

Most of the enzymes measured in human fetal intestine begin to be detectable shortly after the period of morphogenesis and rise with gestational age. Proximal–distal differences in level of expression are established early. Thus, there are basic similarities in patterns of expression, as well as significant differences between human enzyme expression and the patterns in other mammals. Although important distinctions do exist, this comparison is somewhat misleading because rodents are born at a more immature stage and undergo some of the enzymatic maturation postnatally that occurs in humans prior to birth.

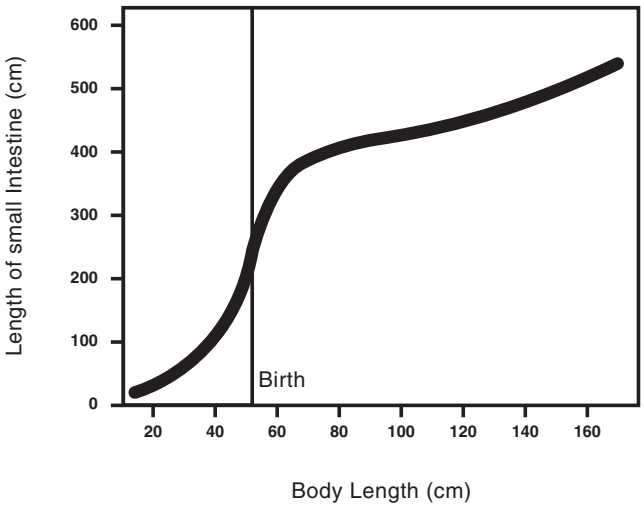

FIGURE 18-7 Intestinal elongation is rapid in utero and continues more slowly through puberty. Reproduced from the American Gastroenterological Association Undergraduate Teaching Project, Unit 35, Development of the Human Gastrointestinal System, with permission of the publisher and Milner-Fenwick; data from Underhill BML. BMJ 1955;2:1243–6; Siebert JR. Am J Dis Child 1980;134:5993–5; and Weaver LT. In Walker WA, et al, editors. Pediatric gastrointestinal disease. 2nd ed. St Louis (MO): Mosby, 1996; p. 9–30.

Disaccharidases. Lacroix and colleagues correlated enzyme activity and morphogenesis in the fetal human intestine.[101] They found that SI and LPH activities were first detectable concurrent with the appearance of duodenal villi, suggesting that enzyme expression is initiated simultaneously with enterocyte formation. Immunofluorescence studies of SI confirmed that the enzyme appeared concurrent with villus formation and enterocyte maturation.[102]

Lactase-Phlorizin Hydrolase. The human *LPH* gene, located on chromosome 2q22, comprises 17 exons and covers about 70 kb, giving rise to a messenger ribonucleic acid (mRNA) of about 6 kb that encodes 1,927 amino acids.[103] The nascent protein is heavily glycosylated so that the final translation product is about 220 kDa. This high-molecular-mass glycoprotein undergoes two cleavage events and is then inserted into the microvillus membrane of the enterocyte as a mature enzyme of approximately 160 kDa.[104]

At 8 to 9 weeks, LPH is detectable in the proximal but not the distal intestine; later, up to 14 weeks, no clear-cut gradient was seen.[101] A slight jejunal peak of LPH was reported at 22 to 24 weeks by Antonowicz and Lebenthal, with the peak becoming more pronounced toward term.[105] Skovbjerg demonstrated that LPH in the human fetal small intestine is expressed at the highest level in the jejunum, with decreased activity in the proximal and distal intestine.[106] Little difference was found in jejunal LPH mRNA levels from 9 to 18 weeks gestation, but levels were considerably lower than in adult jejunum, consistent with reported measurements of

enzyme activity.[107] Villa and colleagues found a correlation between LPH enzyme activity and mRNA levels in human fetal jejunum, both at 14 to 20 weeks, when levels were low, and in a sample from a 37-week-old fetus with elevated LPH, consistent with regulation of LPH activity at the level of transcription (Figure 18-8).[108]

In agreement with previous results, they also demonstrated that hydrocortisone treatment elevated LPH activity in explants. However, they did not find a significant elevation of LPH mRNA, suggesting that corticoids do not directly regulate transcription, consistent with the lack of a glucocorticoid binding site in the first kb of the human LPH 5′ flanking region.[103] The mechanism of corticoid-induced LPH elevation and its possible role in the late-gestation surge in LPH level thus remains unresolved. Data from adult humans indicate that LPH expression is predominantly regulated by transcriptional mechanisms, although other mechanisms also play a role.[107,109–111]

It has recently been established that the proximal promoter of LPH is regulated by the combinatorial action of Cdx-2, HNF1, and GATA factors.[112–114] In addition, *HOXC11* binds to the CE-LPH element and activates pig LPH expression.[115] Analysis of the distal 5′ flanking region in transgenic mice indicates that additional distal elements are required for correct developmental and organ-specific expression.[116]

Postnatal Development

In most of the human population, a decrease in lactase activity occurs at about 5 years of age, leading to low levels in adulthood. In contrast, a minority of the human population, especially those of Northern European extraction and a few other racial groups, retains high levels of activity throughout adult life (Figure 18-9).[117] Lactase persistence is inherited as an autosomal dominant trait.[118,119] A reduction in lactase expression coincident with weaning is the general mammalian pattern. Although the primary mechanism of this decline is decreased LPH transcription, a small number of individuals with lactase nonpersistence have an abnormality in the intracellular processing of newly synthesized lactase protein.[120]

Hydrolysis of lactose to glucose and galactose on the microvillus membrane of the intestinal absorptive cells has been considered the rate-limiting step for the overall process of lactose absorption.[121] Uptake of these monosaccharides is accomplished by the sodium-dependent glucose carrier (SGLT-1; see below). When lactose is not absorbed by the small bowel, it passes rapidly into the colon as a consequence of the osmolality of the intraluminal disaccharide. In the colon, lactose is converted to short-chain fatty acids and gas (hydrogen, methane, CO_2) by bacterial flora, producing acetate, butyrate, and propionate. The short-chain fatty acids are absorbed by the colonic mucosa, and this route salvages malabsorbed lactose for energy use. This is the mechanism by which the newborn colon also salvages lactose, and the adult with low intestinal lactase activity can adapt to persistent lactose ingestion.[117] This fermentative process not only conserves nutritionally important carbohydrate but also serves as the basis of the lactose breath hydrogen test.

The results from investigations of methods for increasing maturation of intestinal lactase remain equivocal. In premature infants, trials suggest a beneficial effect of milk compared with formula feeding in stimulating an increase in the low levels of LPH in the immature intestine.[122] On the other hand, a recent study concluded that feeding low-lactose milk to premature infants improved feeding tolerance.[123]

Congenital lactase deficiency is a very rare disorder. A study in a group of Finnish patients with congenital lactase deficiency indicated a separate gene on chromosome 2 near *LPH* but distinct from it.[124] Genetic analysis in subjects with high and low lactase levels has identified several patterns of single-nucleotide polymorphisms, but whether they have functional importance in lactase expression or are simply markers remains unclear.[125] A recent report identified a single-base polymorphism 13 kb away from the *LPH* coding region that had a 100% correlation with adult lactase nonpersistence.[126] The authors suggest that the polymorphism could be functionally important in *LPH* regulation and that it might prove useful as a diagnostic tool.

Sucrase-Isomaltase The SI gene, located on chromosome 3, encodes a polypeptide of 1,827 amino acids.[127] The final form of the protein inserted into the microvillus membrane is heavily glycosylated, such that the molecular mass is around 245 kDa. Once it is inserted into the microvillus membrane, the 245 kDa form is cleaved by pancreatic proteases into its mature form, a dimeric enzyme complex in which sucrase (approximately 130

kDa) is noncovalently linked to isomaltase (approximately 145 kDa) anchored to the microvillus membrane by a small hydrophobic anchor sequence.[128]

Similar to LPH, the proximal–distal expression of fetal SI at the earliest stages also reflects progressive proximal to distal intestinal maturation.[101] By 10 weeks, the typical pattern of a peak of activity in the midintestine is established. Over the remainder of gestation, SI levels show only a small increase.[101,105] Using polymerase chain reaction–based detection, Wang and colleagues reported SI mRNA levels to be essentially the same in fetal intestine from 9 to 18 weeks and in adult intestine.[107] Fetal SI protein from 15 to 30 weeks gestation was present in the pro-SI form, but after 30 weeks, most of the enzyme consisted of sucrase and isomaltase subunits.[129] The appearance of the subunits coincided with the beginning of enteropeptidase activity, which activates pancreatic proteases known to cleave pro-SI, at 26 weeks.[105,130]

These authors confirmed that fetal SI differs in electrophoretic mobility and lectin binding from the adult form, indicating differing carbohydrate compositions of the glycoproteins,[129] as also described by Auricchio.[131] They further showed that fetal human colon expressed the fetal form of SI until 30 weeks. A high level of SI mRNA was detected in fetal colon at 10 to 12 weeks gestation.[107] Sebastio and colleagues reported a correlation of SI mRNA and enzyme activity in human fetal intestine, indicating control at the level of transcription or mRNA stability.[132] The importance of transcriptional regulation has been well established in rodent models.[98,99,133,134]

SI deficiency is an autosomal recessive disorder characterized by undetectable levels of intestinal sucrase activity and reduced isomaltase activity. Whereas intestinal histology might show minor villous atrophy with associated malnutrition,[135] most patients with SI deficiency have normal villus architecture. The biochemical defects identified indicate that the deficiency state arises from varying allelic mutations of the *SI* gene.[136,137] At least seven different defects have been identified[136,138]:

- arrest of prosucrase-isomaltase in the rough endoplasmic reticulum (RER)
- arrest and degradation of prosucrase-isomaltase in the Golgi apparatus
- catalytically altered enzyme in the microvillus membrane and partial missorting to the basolateral membrane
- missorting to the basolateral membrane and accumulation in the RER
- intracellular loss of the sucrase subunit and expression of the isomaltase subunit at the microvillus membrane
- cleavage and secretion of the mutant sucrase
- absent immunoreactive protein

Thus, most genetic defects seem to reflect mutations in the gene, leading to changes in the primary amino acid sequence of SI.[137] The resulting mutant proteins display a broad variety of aberrant intracellular sorting or premature degradation.

SI deficiency presents at different ages.[135,139] In infancy, symptoms can occur when sucrose is introduced into the diet, with diarrhea, secondary malabsorption, and failure to thrive. In young children, chronic diarrhea can occur immediately or months after the introduction of sucrose. Because most infant formulas do not have sucrose as the primary carbohydrate, malnutrition is less commonly associated with SI deficiency.

Maltase-Glucoamylase. The third major intestinal microvillus membrane disaccharidase is maltase-glucoamylase, which hydrolyzes glucose units from the nonreducing ends of starch and dextran molecules. Less structural and functional information is available for maltase-glucoamylase than for the other disaccharidases. In the human fetal intestine, maltase activity reaches most of its normal postnatal level by week 28 of gestation, as does SI.[105] In premature infants, higher activities of glucoamylase in the colon than in the proximal intestine have been reported.[140] At the age of 1 month, glucoamylase activity is comparable to the activity in young adults.[141]

The human enzyme was recently cloned by Nichols and colleagues. A single gene located on chromosome 7 produces a 6.5 kb mRNA, which encodes a protein of approximately 210 kDa. Previous studies had demonstrated that the protein is heavily glycosylated.[142,143] The glycosylated protein forms a dimeric structure with an apparent mass of 335 kDa. Two identical catalytic sites characteristic of a family of hydrolases were identified. Although the proteins are only 59% homologous, the 6–amino acid sequence incorporating the active site aspartic acid residue in glucoamylase is identical to the active site sequences of SI, indicating that enzymatic specificity is attributable to the surrounding protein structure. In addition to the intestine,

maltase-glucoamylase transcripts were identified in granulocytes and kidney, where glucoamylase activity has been reported.[144] Little is currently known about the molecular regulation of glucoamylase expression.

Alkaline Phosphatase Brush-border alkaline phosphatase activity is detectable in fetal duodenum as early as 7 weeks gestation. It remains at low levels until 14 weeks, when it increases nearly fourfold, although it remains less than one-quarter of adult levels.[101,145] Human intestinal alkaline phosphatase is one of three isoforms, transcribed from different genes. Fetal intestinal alkaline phosphatase differs from the adult form.[146–148] Tryptic digests suggested different fetal and adult enzymes,[149] whereas sequencing of the adult and fetal forms indicates that the proteins are the same[150] but could differ in glycosylation or processing.

Peptidases Auricchio and colleagues measured the activities of five brush-border peptidases in human fetal intestine and found levels of three to be higher than those in children, whereas one was lower.[151] Cell fractionation demonstrated that all of the enzymes were predominantly microvillar rather than intracellular. There was little proximal–distal gradient, with a slight trend toward higher distal activity. The authors concluded that the full-term and preterm intestine, possibly with a few exceptions, should be able to digest peptides. As with SI, several of the peptidases were expressed as fetal forms, differing from the adult in carbohydrate composition.[152] Concurrent with villus formation, aminopeptidase was first detected at 8 weeks and increased by 14 weeks to levels comparable to those in adult intestine, when the distal segment had the highest activity.[101]

Other Enzymes Development of lysosomal enzymes was extensively analyzed by Antonowicz and colleagues, and few new human data are available.[153] There were indications of measurable enzyme activity before observable lysosomes, but Moxey and Trier reported lysosomal bodies in 9- to 10-week-old fetal intestine,[154] consistent with the initial time of appearance of lysosomal enzyme activity reported by Antonowicz and colleagues.[153]

Enterokinase Enterokinase plays a critical role in the initiation of protein digestion, activating proteolytic zymogens in the gastrointestinal tract. Antonowicz and Lebenthal were first able to detect significant levels of duodenal enterokinase activity at week 26 of gestation.[105] Activity increased gradually until term, when it was approximately one-quarter the level found in 1 year olds. Fetal duodenal activities were greater than jejunal or ileal, although much more pronounced peaks in duodenum occurred at 1 and 4 years of age. Although well-differentiated zymogen granules were detectable in the fetal pancreas by 20 weeks, tryptic activity in meconium rose markedly only after 28 weeks, suggesting that activation by enterokinase is an important determinant of tryptic activity in the fetal intestine.[105]

Transport

Hexose Transporters Hexose transport across the epithelium is one of the key functions of the small intestine. Many years ago, glucose uptake in fetal intestine was demonstrated to be present by 11 to 19 weeks gestation (reviewed by Grand and colleagues[25]). The morphologic and molecular basis of the development of human intestinal transport has been elucidated little further. The major hexose transporters in adult human intestine are the apical Na^+-coupled glucose transporter SGLT-1, the facultative glucose transporter GLUT-2 (located on the basal membrane), and GLUT-5, a high-affinity, facultative fructose transporter, located on the apical membrane of the enterocyte. Mutation of the gene encoding SGLT-1 has been shown to be responsible for glucose-galactose malabsorption, which can result in fatal diarrhea of newborn infants.[155] The disorder is inherited as an autosomal recessive trait and is attributable to the inability to absorb hexoses via SGLT-1, whereas digestion of lactose, sucrose, and maltose, as well as absorption of fructose and xylose, occurs normally.[156]

In 17- to 20-week human fetal jejunum and ileum, Malo and Berteloot demonstrated that a proximal–distal gradient of Na^+-dependent glucose transport was already established.[157] Malo presented evidence for two Na^+-dependent glucose transporters that differed in kinetic properties, as well as substrate and inhibitor specificities.[158] The relation of these fetal Na^+-dependent glucose transporters to SGLT-1 remains unclear. GLUT-5 protein has been identified immunologically on the apical membrane of human fetal small intestine, but not colon, at 16 to 25 weeks.[159] There is immunologic evidence that GLUT-2 and GLUT-5 proteins are present in fetal rat intestine prior to villus formation.[160] Rat Na^+K^+-adenosine triphosphatase has been shown to become localized to the lateral membranes in polarized cells anchored to a basal lamina as a single-layer epithelium forms, but is distributed throughout the plasma membrane of enterocytes in the stratified epithelium prior to villus morphogenesis.[161] Although likely to be similar to that in rodent models, development of transporter protein localization has not been correlated with human intestinal morphogenesis.

Glucose Absorptive Capacity in the Neonate Age-dependent increases in the rate of glucose transport continue through the first few months and up to a few years of age. Infants less than 21 months of age demonstrate a plateau in glucose absorption at approximately 0.16 g/cm/hour when studied with intraluminal perfusion techniques providing 10 g/hour. By comparison, even at sixfold higher perfusion rates, glucose absorption in adults has not reached plateau, although it has increased eightfold (Figure 18-10). These data strongly suggest that the number of glucose carriers per enterocyte increases developmentally, although the number of cells per unit area of intestine also increases. The apparent Michaelis constant (K_m) for glucose absorption in infants is 5.8 mM, compared with 20 mM or greater for adults. From a clinical point of view, these findings could explain the propensity of infants to develop loose stools or diarrhea with the ingestion of large volumes of sweetened drinks such apple juice.[162]

Amino Acid Transporters In the enterocyte microvillus membrane, at least six different amino acid transport systems have been identified.[163] Malo has characterized these

using brush-border vesicles from human fetal intestine of 17 to 20 weeks gestation.[164] Of the transport systems studied (neutral, acidic, basic, and imino classes), all were functional, and a proximal–distal gradient of transport capacity was already established by this stage of development, shortly after villus and crypt formation.

Transporter Defects

Cystic fibrosis transmembrane conductance regulator (CFTR), which functions mainly as a chloride channel, begins to be expressed in both small intestine and colon by 18 weeks gestation.[165] Mutations in CFTR represent the molecular basis of cystic fibrosis.[166]

Primary Bile Acid Malabsorption

The increasing molecular data on ileal bile acid uptake are consistent with the hypothesis of a defect in the ileal sodium-dependent transporter as a cause of chronic diarrhea, particularly if onset is early in life. The human ileal Na^+/bile acid cotransporter gene (*SLC10A2*) was cloned and used for single-stranded conformational polymorphism analysis to find possible causative mutations in a family with primary bile acid malabsorption. Mutations were identified and shown to inhibit bile acid transporter function in transfected COS cells, thus correlating mutations in a bile acid transporter with primary bile acid malabsorption.[167] Infants and children with this disorder manifest watery diarrhea, malabsorption syndrome, reduced plasma cholesterol levels, and failure to thrive.

Congenital Chloride Diarrhea

Congenital chloride diarrhea (CCD) is inherited as an autosomal recessive trait. The gene was localized to chromosome 7q31 proximal to the CFTR.[168,169] A candidate gene known as *DRA* (down-regulated in adenoma) because of its reduced expression in colonic adenoma was identified in this position. The product of this gene is expressed in the brush border of normal ileum and colonic epithelial cells.[168] *DRA* encodes a transporter with properties of Cl^-/OH^- exchange.[170] Twenty different mutations of the *DRA* gene have been identified in patients with CCD.[168]

One of the features of CCD is the fetal onset of diarrhea as evidenced by the development of maternal hydramnios.[171,172] Other clinical features can include prematurity, absence of meconium, hyperbilirubinemia, abdominal distention, and failure to thrive. Radiographic studies of newborns reveal fluid-filled intestinal loops with or without ascites, again pointing to the intrauterine onset of the disease.

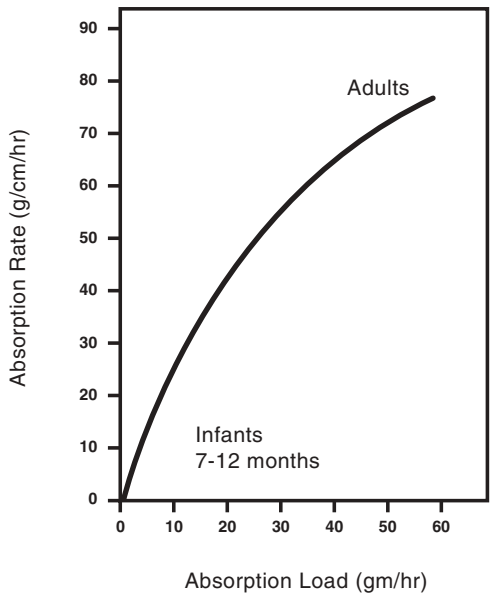

FIGURE 18-10 Glucose absorptive capacity in the neonate is lower than in children or adults. Reproduced from the American Gastroenterological Association Undergraduate Teaching Project, Unit 35, Development of the Human Gastrointestinal System, with permission of the publisher and Milner-Fenwick; data from Mobassaleh M et al.[162]

Congenital Sodium Diarrhea

Four reports have described neonatal watery diarrhea ascribed to a defect in Na^+ reabsorption in the small intestine.[173–176] Several Na^+/H^+ exchanger isoforms have been cloned to date,[177,178] in particular *NHE3*, which appears to be an epithelial brush-border exchanger, confined to the intestine and kidney. However, multifocal linkage analysis of patients excludes *NHE1*, *-2*, *-3*, and *-5* as potential genes for CSD based on their chromosomal location.[176]

Lipid Digestion. Human fetal intestine at 14 to 20 weeks-gestation studied in organ culture has an increasing capacity to elaborate lipoprotein fractions, including chylomicrons, very-low-density lipoproteins, and high-density lipoproteins.[179,180] Furthermore, release of lipoproteins is modulated by both epidermal growth factor (EGF) and insulin.[179,181]

In studies of apolipoprotein B (apo B) synthesis, Glickman and colleagues found that fetal intestine synthesized only apo B-100 at 11 weeks but both apo B-48 and apo B-100 at 16 weeks, with apo B-48 predominant in mature intestine.[182] It is known that mature intestine synthesizes only apo B-48 as a result of mRNA editing. In accordance with these data, Teng and colleagues have demonstrated that the apo B mRNA editing function is developmentally regulated in the human fetus.[183]

Abetalipoproteinemia is an autosomal recessive disease characterized by the virtual absence of apo B and apo B–containing lipoproteins in plasma of affected subjects. Triglycerides accumulate in the cytoplasm of hepatocytes and enterocytes secondary to abolished secretion. Abetalipoproteinemia is not the result of defective apo B synthesis,[184–186] as initially contended, and there is no genetic linkage between the disorder and the apo B gene.[187] The phenotype is linked to a defect in the microsomal triglyceride transfer protein (MTP), a neutral lipid transfer heterodimeric enzyme composed of protein disulfide-isomerase (PDI), a ubiquitous multifunctional resident endoplasmic reticulum protein, and a unique subunit (97 kDa) that confers lipid transfer activity to the complex.

Genetic studies have been undertaken in subjects carrying the abetalipoproteinemia phenotype.[188,189] All were carriers of a homozygous or compound heterozygous

mutation on both alleles. Most subjects demonstrated a truncated form of the MTP large subunit (97 kDa), impeding its interaction with PDI and rendering the complex nonfunctional in its role of shuttling lipids between membranes of the endoplasmic reticulum.[190] The clinical expression of this disorder depends on the age of onset. Symptoms of malabsorption and failure to thrive secondary to steatorrhea are the hallmarks of early onset in infancy and childhood.[191] Poor growth can precede overt gastrointestinal symptoms, and affected children are frequently thought to have celiac disease.

Ontogeny of Motility

The innervation of the gastrointestinal tract in utero is accompanied by functional activity of increasing complexity. The first studies to measure intestinal transit in humans used amniography; aboral transport of contrast did not occur in the intestinal tract of fetuses younger than 30 weeks gestation (reviewed by Grand and colleagues[25]). With increasing gestational age, increasing aboral transit and rate of propagation developed. Subsequent studies of gastrointestinal motility in premature infants have been performed using intraluminal catheters and have been reviewed in detail elsewhere.[28] The data reveal no regular periodicity or rhythmicity in the youngest infants studied (25 weeks). Further development occurs during the next 15 weeks, so that by term, mature motor patterns are well established. Responses to feeding vary considerably among preterm infants; in general, intestinal motility studies can predict feeding intolerance.[192] For example, the rate of feeding can determine the rate of intestinal motility. Slow infusions of preterm-infant formula led to an increase in duodenal motor activity, whereas rapid bolus feedings were associated with a reduction in duodenal motor activity (Figure 18-11).[193]

The release of gastrointestinal hormones is a characteristic response to enteral feeding in humans. Even in preterm infants of approximately 33.5 weeks gestation, some gastrointestinal hormones are responsive to feeding (enteroglucagon and gastrin) within the first 2 days of life, whereas others (motilin, gastric inhibitory polypeptide, and pancreatic polypeptide) are not responsive until after 6 days of age. The plasma enteroglucagon concentration strongly correlates with the volume of milk ingested in milliliters per kilogram of body weight. Even a small intake of 15 mL/kg is associated with a threefold rise in hormone secretion. At 125 mL/kg, a maximal response is achieved; this is a volume likely to be consumed by an average-sized, breast-fed infant. Volumes as high as 250 mL/kg do not stimulate further increases in enteroglucagon concentration (Figure 18-12).[194] Seventy-five percent of the maximal rise is obtained with approximately 50 mL/kg, giving rise to the concept of "minimal enteral feeding." This hypothesis holds that intestinal maturation can be stimulated by providing regular, small-volume feedings. The adaptive value of such a regimen and the maturation of intestinal function potentially achieved have not been rigorously studied.

COLON

Morphogenesis and Differentiation

A striking characteristic of the developing fetal colon is its initial similarity to the small intestine. The development of the colon is marked by three important cytodifferentiative stages: the appearance (from about 8 to 10 weeks) of a primitive stratified epithelium, similar to that found in the early development of the small intestine; the conversion of this epithelium to a villus architecture with developing crypts (at about 12 to 14 weeks); and the remodeling of the

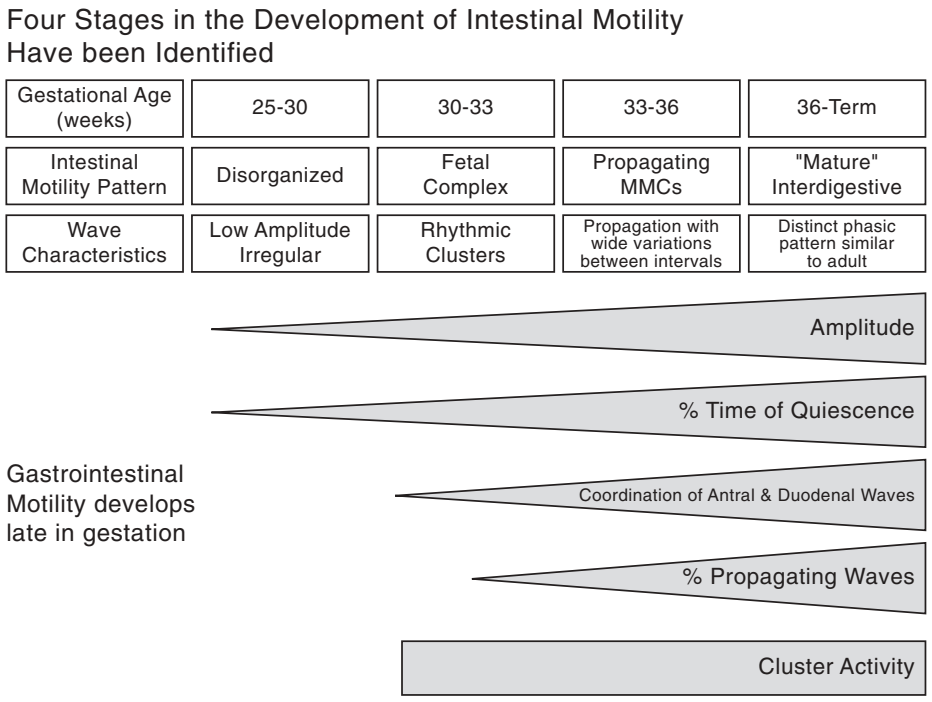

FIGURE 18-11 Four stages in the development of intestinal motility have been identified. epithelium at around 30 weeks gestation, when villi disappear and the adult-type crypt epithelium is established. Immunostaining for smooth muscle β-actin was detectable in the muscularis propria at 8 weeks gestation and in the muscularis mucosae at 15 weeks.[195] The apical surface of columnar colonocytes displays enterocyte-like microvilli,[196] and glycogen stores are abundant.[197] The quantity of intracellular glycogen, as well as the number of glycogen-positive cells identified by periodic acid–Schiff staining, decreases from 13 weeks onward. From 30 to 36 weeks, very few glycogen-positive cells are found in fetal colon.[197] During malignant transformation, glycogen expression reappears and is a prominent feature of cell lines derived from human colonic adenocarcinomas.[198]

Arsenault and Menard studied the kinetics and topography of cell proliferation in explanted fetal colon from 8 to 18 weeks gestation. Cell proliferation occurred abundantly throughout the stratified epithelium. As villi formed, labeled cells were found principally in the intervillus region. At later stages, proliferation was limited to the crypts.[199] In vitro, EGF, but not hydrocortisone, altered colonic cell proliferation.[200]

Concurrent with the presence of villus morphology, the colonic epithelial cells express differentiation markers similar to those in small intestinal enterocytes. Lacroix and colleagues showed that SI was detectable at 8 weeks in fetal colon, increased 10-fold as villus architecture emerged at 11 to 12 weeks, peaked at 20 to 28 weeks, and then decreased rapidly to barely detectable levels at term.[196] Lactase was not detected in these studies, whereas alkaline phosphatase and aminopeptidase followed a pattern generally similar to that of SI.[196] Analysis of isolated fetal colonic epithelial cells demonstrated low levels of the disaccharidases typical of small intestine.[201] In addition, the fetal human colon during the second trimester can synthesize and process lipids, phospholipids, and apolipoproteins.[202,203] Data on functional development of the human colon remain sparse. Examination of premature infants suggests that sodium transport develops in the last trimester,[204] whereas anion exchange mechanisms remain immature until the end of the first year of life.[205]

CONCLUSIONS

At term, the human gastrointestinal tract exhibits essential structural and functional maturity. However, some key functions mature postnatally, including lower esophageal sphincter pressure and esophageal motility, gastric acid secretion, pancreatic secretion, some hepatic functions (such as bilirubin conjugation, hepatic drug metabolism, and bile acid synthesis), gastrointestinal motility, and the colonic bacterial fermentative pathway for salvage of carbohydrate not absorbed in the small intestine. Genetically induced alterations in the transporters and carriers that mediate the absorptive process can lead to important pediatric diseases. Further understanding of the genetic regulation of gastrointestinal function should yield insights into the pathogenesis and treatment of many such disorders.

CHAPTER 19

IMMUNOPHYSIOLOGY AND NUTRITION OF THE GUT

Elizabeth Mannick, MD, Zili Zhang, MD, PhD, John N. Udall Jr, MD, PhD

The gastrointestinal tract is the largest lymphoid organ in the body, containing an estimated 70 to 80% of the body's immunoglobulin (Ig)-producing cells.[1] It constitutes a vast surface area—400 m^2 in the adult—which daily encounters and processes a host of nutrients and antigens.[2] This system is closely linked with the immune systems of other mucosal surfaces, and together they comprise what is known as the common mucosal immune system.

Gastrointestinal immune function of human infants is immature and remains so for the first several months of life. There are several different aspects to this immaturity, including increased intestinal permeability to macromolecules, impaired oral tolerance, decreased production of secretory IgA (S-IgA), variable production of antibody to foreign proteins, and immaturity of antigen-presenting cells (APCs) and the T-helper 1 (Th1) subset of immune cells.

Studies of the intestinal uptake of macromolecules in humans and animals suggest that increased amounts of undigested molecules are taken up by the newborn compared with the adult.[3–7] This increased intestinal permeability may be protective because it allows absorption of maternal Igs from breast milk, thereby enhancing passive immunity.[8] On the other hand, it may be one of the mechanisms underlying the increased incidence of food allergies in the young infant.[9] In addition to increased permeability, the neonatal Fc receptor FcRn, expressed on the brush border of intestinal epithelial cells (IECs), aids in the transfer of passive immunity by internalizing maternal IgG.[10]

There appears to be a defect in oral tolerance in the first months of life. Miller and colleagues fed 10 neonatal rats myelin basic protein (MBP).[11] Rather than inducing tolerance, as it does in older rats, MBP feeding actually amplified subsequent immune responses to intravenously injected MBP. In human infants, administration of cow's milk–containing formula in the first 3 days of life followed by breast-feeding results in elevated IgG to β-lactoglobulin, casein, and bovine serum albumin (BSA) for up to 2 years of age compared with exclusively breast-fed infants.[12] Defective oral tolerances in the neonatal period may be antigen dependent, however. In nonobese diabetic mice, oral administration of insulin in the neonatal period suppresses the subsequent development of diabetes.[13] One factor contributing to defective oral tolerance in the neonatal period may be the deficiency of S-IgA lining the intestinal tract early in life, a deficiency that is compensated for by the provision of S-IgA in breast milk.[14,15] The production of S-IgA may contribute to oral tolerance by suppressing IgG production and dampening systemic immune responses.

In contrast to oral tolerance, neonates have increased systemic tolerance to antigen compared with older children and adults, a phenomenon known as "neonatal tolerance."[16] In addition to a decrease in T cell receptor diversity and density owing to a delay in the induction of terminal deoxynucleotidyl transferase,[17] this phenomenon appears to be attributable to a relative defect in costimulatory signals provided by neonatal APCs. Neonatal tolerance can be reversed by coculture of T cells with adult APCs or adjuvant.[18] Neonatal T cells also produce relatively low levels of the Th1 cytokines interferon (IFN)-γ and tumor necrosis factor (TNF)-α, a phenomenon that may contribute not only to tolerance but also to increased susceptibility to allergies.[19,20] This defect can also be reversed by the addition of interleukin (IL)-12, a cytokine produced by mature APCs.[21]

In premature infants, failure to produce antibodies may also contribute to impaired immunity. Rieger and Rothberg fed BSA to human newborns at different gestational ages and followed the development of anti-BSA antibodies in serum.[22] Infants born at less than 35 weeks gestation did not produce anti-BSA antibodies, whereas four of five infants born at greater than 35 weeks did. However, factors other than gestational age may be important in the development of humoral immunity. Animals raised in a germ-free environment show a striking absence of antibody-producing cells in the intestine.[23,24] Thus, age plus antigenic exposure appears to regulate the development of a normal intestinal immune response.

As the intestinal immune system matures, two functional compartments become apparent: (1) the inductive arm of the immune system composed of Peyer's patches, IgA-secreting plasmocytes, and lamina propria lymphocytes and (2) the effector arm composed of intestinal

epithelial cells, mast cells, eosinophils, macrophages, and dendritic cells. The different cell types in these two functional compartments secrete and respond to various mediators, including cytokines, adhesion molecules, growth factors, nitric oxide, prostaglandins, neurotransmitters, and hormones. These mediators are responsible for intracellular communication and the elaboration of an effective immune response.

This chapter is divided into two parts. The first part gives an overview of gastrointestinal immunology and is organized according to the different cell types participating in an immune response. The second part of the chapter addresses the interactions of different types of dietary nutrients with immunity in general and gastrointestinal immunity in particular. Where possible, it builds on concepts presented in the first part.

INTESTINAL MUCOSA

Epithelium

Intestinal Epithelial Cells IECs are highly versatile cells that have absorptive, secretory, barrier, and immune functions. The role of IECs or enterocytes as APCs has been recognized for some time.[25,26] These cells begin to express class II major histocompatibility complex (MHC) molecules shortly after birth in response to intraluminal antigenic stimulation.[26] For this reason, a state of "physiologic inflammation" has been proposed to exist in the healthy human intestine.[27]

Although IECs express class II MHC molecules, they differ from classic APCs. First, their interactions with both intraepithelial lymphocytes (IELs) and lamina propria lymphocytes involve nonclassic MHC class I–like molecules.[28–31] The intestinal nonclassic MHC class 1b molecules, CD1d, MHC class I chain-related gene A (*MICA*), the neonatal Fc receptor (FcRn), and histocompatibility leukocyte antigens (HLAs) E, F, and G are nonpolymorphic and have most likely evolved to present lipid antigens to evolutionarily conserved ligands on CD8+ T cells and natural killer (NK) cells.[32] In addition, thymic leukemia antigen, glycoprotein 180, E-cadherin, the class II invariant chain-chondroitin sulfate, and leukocyte function–associated antigen 3 can provide costimulation to IELs.[33–37] Another difference between IECs and classic APCs is their ability to present lipid and peptide but not protein antigens in a transporter-associated antigen-processing–independent manner, suggesting an intracellular antigen processing system that may share features of class I and II antigen-processing systems but may differ from both.[38] IECs were at one time thought to lack expression of costimulatory molecules present on classic APCs. However, recent data indicate that CD86 is expressed on IECs.[39]

In common with other cells of the innate immune system, IECs express toll-like receptors (TLRs). A major task of the innate immune system is to distinguish a large number of pathogens from self by recognizing unique molecules on pathogens that are not found in higher eukaryotes. These foreign molecules are called pathogen-associated molecular patterns (PAMPs) and include lipopolysaccharide (LPS) (a glycoplipid endotoxin of gram-negative bacteria), peptidoglycan (PGN) (a component of gram-positive bacteria), and unmethylated cytosine p guarine dinucleotide (CpG) dinucleotides from bacterial deoxyribonucleic acid (DNA). TLRs are part of a wider family of pattern recognition receptors. Different TLRs respond to distinct PAMPs. For example, TLR2 recognizes PGN on gram-positive bacteria, TLR4 recognizes LPS on gram-negative bacteria, and TLR9 recognizes bacterial and, possibly, host DNA.[40–42]

Although TLR-mediated signaling pathways have not been completely elucidated, it is apparent that TLR2, TLR4, and other TLRs share a common signaling cascade. The major signaling target of TLRs is the transcription factor NF-κB. Interaction of PAMPs with TLRs stimulates the adaptor molecule MyD88, which activates the IL-1 receptor–associated kinase. As a result, TNF receptor–associated factor 6 is recruited. Stimulation of these proximal signaling molecules activates the MAP kinase pathway or I-κB kinase (IKK). Activation of IKK causes I-κB phosphorylation, ubiquitination, and degradation by the proteasome, leading to NF-κB release from I-κB and its nuclear translocation (Figure 19-1).[43]

IECs express several TLRs, including TLR2, TLR3, TLR4, and TLR5.[44,45] These TLRs play an important role in innate immune responses to gastrointestinal infection. LPSs from *Helicobacter pylori* elicit proinflammatory reactions of the gastric mucosa by stimulating the TLR4 cascade in pit cells.[46] In addition, flagellin, a flagella component of *Salmonella*, activates TLR5-mediated immune responses in the intestinal epithelium.[45]

Nod2/CARD15 is a different but related pattern recognition receptor expressed on innate immune cells that was recently detected on IEC.[47] Nod2 is a leucine-rich intracellular receptor for LPS that also activates NF-κB. Nod2 is likely to play an important role in intestinal immunity because inactivating mutations have been linked to genetic susceptibility to inflammatory bowel disease.[48]

IECs have been shown to secrete cytokines and chemokines as well as present antigens and recognize pathogens. This enables them to participate directly in host defense and to recruit neutrophils to sites of inflammation. In vitro studies of IECs have demonstrated production of IL-8 in response to gastrointestinal pathogens and to stimulation by the proinflammatory agents IL-1, TNF-β, IFN-γ, or LPS.[49,50] IL-8 is an important mediator of neutrophil recruitment and adhesion in inflammatory conditions. Fractalkine is a CX3C chemokine expressed by IECs. Interestingly, IELs express the fractalkine receptor, suggesting a role for fracktalkine in IEL homing and/or activation.[51] CCL25 (thymus-expressed chemokine) is expressed on small IECs. It regulates the localization of small intestinal lymphocytes through interactions with its lymphocyte receptor, CCR9, and plays a major role in attracting IgA antibody-secreting cells to the intestine.[52] Enterocytes have also been shown to secrete the chemokines GRO-α, GRO-β, GRO-γ, extractable nuclear antigen 78, membrane cofactor protein 1, macrophage inflammatory protein 1 (MIP-1), regulated upon activation, normally T-expressed,

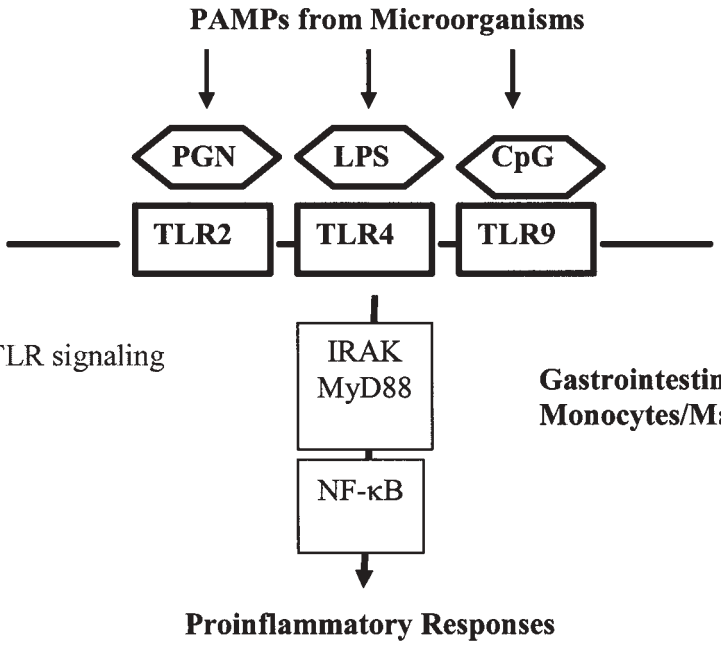

FIGURE 19-1 Pathogen-associated molecular patterns (PAMPs) such as peptidoglycan (PGN), liposaccharides (LPS), and cytosine p guarine dinucleotide (CpG) from bacteria interact with toll-like receptors (TLR) to release interleukin-1 receptor–associated kinase (IRAK), an adaptor molecule (MyD88), and transcription factor κB (NF-κB) to stimulate inflammation.

and presumably secreted (RANTES), and eotaxin and the cytokines IL-1, IL-5, IL-6, transforming growth factor (TGF)-α, transforming growth factor (TGF)-β, IL-1, and IL-10 in animal and human studies (Table 19-1).[53–56]

One of the most interesting potential roles for IECs is a thymopoietic role in the differentiation of IELs. IECs have been found to induce T cell receptor rearrangement and T-cell development from hematopoietic precursors in vitro just as thymic epithelial cells do.[57–59]

A related putative role for IEC is the regulation of CD8+ expression on IELs. Experimental data provide two interesting clues about this process. First, in bone marrow transplant models in animals, although donor cells are for the most part CD4+ cells, it is donor CD8+ cells that populate the host intestinal epithelium.[60] Second, coculture of peripheral blood lymphocytes with IECs leads to the induction of CD8+ cells.[61,62] In situations of inflammation, however, the reverse occurs with repopulation of the intestinal epithelium by CD4+ cells.[63] The molecular mechanisms governing these phenomena most likely involve the CD8 specificity of classic and nonclassic MHC class I molecules expressed on IECs.

Another important function of IECs is the creation of an effective epithelial barrier. The barrier consists of epithelial cells and the tight and adherens junctions between them as well as the mucin and S-IgA layer above the cells. Tight junctions have been shown to be fine-tuned, selectively permeable pores that are regulated both by changes in the epithelial cell cytoskeleton and by the secretion of cytokines, growth factors, and hormones in the local microenvironment.[64,65] Tight and adherens junctions are made up of a network of proteins including zona occludens 1, 2, and 3; membrane-associated guanylate kinase-related 1 (MAGI-1); occludin; junctional adhesion molecule (JAM); E-cadherin, α- and β-catenin; and members of the claudin family that are anchored to the actin cytoskeleton.[66] Tight junction permeability is regulated by members of the Par family, protein kinase C family, myosin light-chain kinase, and CDC42.[67] In addition, IFN-γ and TNF-α are known to increase intestinal epithelial permeability by increasing the leakiness of tight junctions. This leads to increased antigen uptake and increased mucosal inflammation, but it also enables the body to mount an effective secretory response and flush harmful antigens out of the gut lumen.[68] Mast cell products such as oxidants, nitric oxide, platelet-activating factor (PAF), and histamine have also been shown to increase epithelial permeability.[69,70]

Finally, enterocytes are important in the secretion of dimeric S-IgA. S-IgA plays a key role in host defense against enteric pathogens. It acts by blocking antigen bind-

TABLE 19-1 Chemokines and Cytokines Expressed by Intestinal Epithelial Cells
