ing to receptors on enterocytes.[71] IgA does not appear to neutralize antigen by activation of the complement system and/or recruitment of neutrophils; thus, compared with other immunoglobulins, it is anti-inflammatory.[72] Recently, S-IgA has been shown to be internalized by immature dendritic cells, and it may inhibit their maturation.[73] S-IgA production is sensitive to host malnutrition, which may result in impairment in the function of both B and T cells.[74] Decreased S-IgA is one of the factors that predisposes malnourished individuals to enteric infection.[75]

There are two subclasses of IgA: IgA1 and IgA2. IgA1 predominates in bone marrow, spleen, tonsils, and serum.[76,77] In mucosal tissues, the amount of IgA1 and IgA2 is approximately equal.[78] Within the mucosal immune system, IgA2 tends to predominate in the colon, whereas IgA1 predominates in oral, gastric, and proximal duodenal secretions.[76,77] Several bacterial pathogens such as *Haemophilus influenzae*, *Neisseria meningitides*, *Neisseria gonorrhoeae*, and *Bacteroides* species produce proteases specific for human IgA1, aiding in their evasion of host defenses.[79]

Intestinal Epithelial Lymphocytes Interspersed among the IECs of the intestine are specialized IELs. IELs originate in the bone marrow, migrate to Peyer's patch, and recirculate to mucosal sites (Figure 19-2). Approximately one in five cells in the jejunal epithelium is an IEL, decreasing to 1 in 20 in the colon.[80] The exact role of IELs in gastrointestinal host defense has not been completely established. However, they are unique in at least five ways. First, the majority of IELs (85 to 95%) are T cells of the suppressor/cytotoxic CD8+ phenotype.[81–84] This is in marked contrast to peripheral blood lymphocytes and lamina propria lymphocytes, which are predominantly CD4+ helper T cells. Second, the majority of IEL (as well as lamina propria lymphocytes) express T-cell activation markers not normally found on peripheral blood cells, including the αEβ7 integrin, a very late activation antigen that is the ligand for E-cadherin on IECs.[85,86] Third, despite their apparently activated state, IELs proliferate in response to mitogens but not in response to specific antigens.[87,88] In addition, they proliferate sluggishly in response to activation of CD3 T cell receptor complexes but briskly in response to CD2 ligation, suggesting an alternative activation pathway.[80,89] Fourth, a significant proportion of IELs in humans lack the CD5 molecule and express an α-α CD8 molecule, a characteristic shared by extrathymically derived cells.[87,90,91] Finally, the proportion of IELs bearing the γΔ T cell receptor (5 to 30%) is significantly higher than that observed in peripheral blood, where less than 5% have the γΔ T cell receptor.[85,92–95] Some of the implications of these unique features of IELs are discussed below.

For a long time, it was suspected that the suppressor function of CD8+ IELs could explain the lack of immune responsiveness to intraluminal antigens. Recently, the CD-α subset of IELs has been shown to mediate tolerance and to participate in dampening of inflammatory responses.[96,97] Specific molecules present on the surface of IECs or secreted from IECs enhance the production and functioning of α-α IELs, including TL (thymus leukemia) antigen, IL-2, IL-7, IL-15, and glycoprotein 180.[33,34,98]

IELs are capable of producing a variety of cytokines, including IFN-γ, TNF-α, IL-2, IL-3, IL-6, TGF-β,[80,99,100] and possibly IL-5 (Table 19-2).[101] This pattern of cytokine production may be important in the regulation of neighboring epithelial cells. For instance, IFN-γ has been shown to induce class II MHC molecule expression[102] and to stimulate polymeric Ig receptors on IECs.[103]

TGF-β is an important regulator of IEC growth and repair.[104,105] Whereas IFN-γ has been shown to increase intestinal permeability,[106] TGF-β decreases it.[107] TGF-β has immunosuppressive properties and may play a significant role in oral tolerance.[108] Weiner and colleagues examined oral tolerance to MBP as a therapeutic intervention in an experimental animal model of multiple sclerosis.[109] These investigators found that the secretion of TGF-β by T cells in both Peyer's patch and in the target organ (in this case, the brain) follows oral feeding of antigen and accompanies recovery from autoimmune disease. [101] TGF-β can induce a switch from inflammatory Th1 cells to the less inflammatory Th2 cells.[110] This may be another factor contributing to oral tolerance and overall down-regulation of immune responsiveness in the gut.

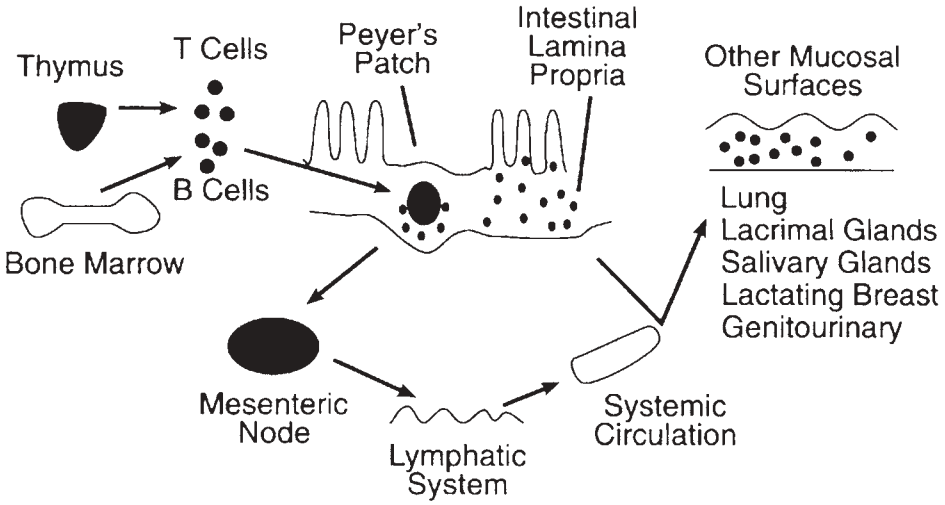

FIGURE 19-2 Intestinal lymphocytes originate in the bone marrow or thymus, migrate to Peyer's patches, and recirculate (home) to the mucosa of the intestine and other organs.

Table 19-2 Source and Effects of Cytokines in the Human Intestine

Cytokine	*Source*	*Effects*
IL-1	Macrophages Epithelial cells Endothelial cells Fibroblasts	Activates CD4+ cells, NK cells Attracts neutrophils and macrophages Increases expression of intracellular adhesion molecules (ICAM), fever
IL-2	T cells (LPL and IEL)	Induces proliferation and differentiation of antigen-stimulated T cells Induces proliferation and Ig secretion of activated B cells Activates NK cells
IL-3	CD4+ T cells Mast cells	Induces growth and differentiation of basophils
IL-4	T cells Mast cells B cells Macrophages Basophils	Induces differentiation of Ig-A-committed B cells Induces isotype switching to IgG- and IgE-producing cells in uncommitted B cells
IL-5	T cells Mast cells	Stimulates growth, differentiation, and activation of eosinophils
IL-6	T cells Macrophages Fibroblasts Endothelial cells	Induces growth and differentiation of B cells and T cells
IL-7	Unknown in gut	Activates γ-δ T cells
IL-8	T cells Fibroblasts Endothelial cells Epithelial cells Neutrophils	Induces adhesion of neutrophils to endothelial cells Activates neutrophils to secrete lysosomal enzymes
IL-10	T cells B cells Macrophages	Suppresses macrophages including production of inflammatory cytokines Enhances B cell proliferation and Ig secretion
IL-12	B cells Macrophages	Stimulates the differentiation of Th1 cells from uncommitted T cells Stimulates growth of T and NK cells
IL-13	T cells	Inhibits inflammatory cytokine production by macrophages Stimulates B cell growth and differentiation
SCF	Endothelial cells Fibroblasts	Stimulates the proliferation and maturation of mast cells
TGF-α	Macrophages Epithelial cells	Induces angiogenesis, epithelial development Induces proliferation of fibroblasts
TGF-β	T cells Fibroblasts Epithelial cells	Promotes epithelial repair Induces IgA production by uncommitted B cells Inhibits growth of mature cells Stimulates extracellular matrix production May mediate oral tolerance
TNF-α	Neutrophils Lymphocytes Endothelial cells NK cells Smooth muscle cells	Activates neutrophils and macrophages, mesenchymal and epithelial cells Causes apoptosis
IFN-γ	T cells NK cells	Modulates class II MHC expression Antiviral activity Stimulates macrophages

IEL = intraepithelial lymphocyte; IFN = interferon; Ig = immunoglobulin; IL = interleukin; MHC = major histocompatibility complex; NK = natural killer; SCF = stem cell factor; TGF = transforming growth factor; TNF = tumor necrosis factor.

In addition to cytotoxicity and cytokine secretion, IELs may play an important role in tumor surveillance. Cepek and colleagues, as well as others, have shown that IELs bind with high affinity to human colon cancer cell lines via their αEβ7 integrin receptors.[111] IELs express Fas ligand and are spontaneously cytolytic to Fas-expressing host-derived tumor cells in vitro.[112] IELs also induce apoptosis of infected and senescent IECs through the secretion of IFN-γ and TNF-α, thereby potentially reducing the risk of carcinogenesis.[113]

One of the paradoxes of gastrointestinal immunology is the observation that IELs and lamina propria lymphocytes

exist in a highly activated state as a result of continual exposure to intraluminal antigen but do not provoke either a local or a systemic immune response under normal circumstances. As mentioned earlier, the existence of a subset of suppressor or "regulatory" CD8 α-α T cells has been demonstrated. In addition, the secretion of anti-inflammatory cytokines such as IL-4 and IL-10 by Th2 cells in the lamina propria, assisted by the secretion of TGF-β by IELs and IECs, may serve to dampen the local immune response. Finally, a subset of regulatory CD4+ T cells that express the activation marker CD25 was first described in mice and has recently been shown to play a potentially significant role in the human gastrointestinal tract.[114]

Another concept central to the understanding of this paradox is the concept of T-cell anergy.[115] For T-cell activation to occur, the T cell receptor needs to bind to antigen complexed to an MHC molecule on an APC; costimulatory molecules on the surface of the T cell and the APC must interact to produce a second signal (Figure 19-3). Two of the most well characterized and important of these costimulatory molecules are CD28 and its inhibitory partner CTLA-4, expressed constitutively on 95% of CD4+ and 50% of CD8+ T cells, and B7 (CD80 and CD86), expressed on activated monocytes, dendritic cells, and activated B cells.[116–119] In the absence of B7 costimulation, T-cell anergy can result.[119] Sanderson and colleagues examined B7 (CD80) messenger ribonucleic acid (mRNA) in rat IECs and found that even when epithelial cells were stimulated with IFN-γ, B7 mRNA expression remained very low compared with that of spleen cells.[120] Paucity of B7 expression by IECs could help to explain the anergy of IELs. Deficient costimulation does not automatically translate into a quiescent immune system, however. Recent data indicate that absence of CD80 can potentiate cytotoxic CD8 T-cell responses.[121] Further, engagement of CD28 may be necessary for the subsequent expression of its inhibitor CTLA-4, an important component of regulatory T cells.[117]

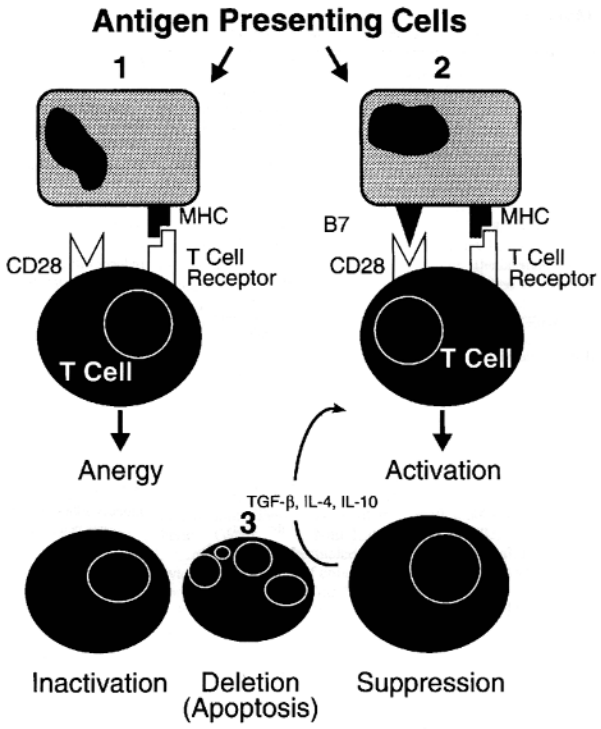

FIGURE 19-3 Immune down-regulation in the gastrointestinal tract may be mediated by (1) T-cell anergy, (2) T-cell apoptosis, or (3) the production of anti-inflammatory cytokines (transforming growth factor β [TGF-β], interleukin [IL]-4, IL-10). MHC = major histocompatibility complex.

A corollary to the concept of anergy is the concept of apoptosis or programmed cell death.[122,123] Apoptosis refers to cellular suicide characterized by internucleosomal DNA fragmentation by proteases known as caspases. Sometimes the lack of a second signal and/or exposure to noxious agents results not in anergy but in apoptosis.[124] This is one of the mechanisms by which clonal deletion of self-reactive lymphocytes occurs in the thymus.[125,126] Lamina propria T cells are known to be particularly susceptible to apoptosis, in part owing to lower levels of FLIP, an inhibitor of caspase 8.[127]

In the gastrointestinal mucosa, regulatory T cells, T-cell anergy, T-cell apoptosis, and anti-inflammatory cytokine production may all contribute to the down-regulation of the local immune system (see Figure 19-3). Conversely, release from the tight control afforded by these mechanisms may occur in conditions such as inflammatory bowel disease.

T cells bearing a T cell receptor with γ and Δ chains comprise a significant minority of all IELs and probably a majority of extrathymically derived IELs.[80] Despite a profusion of studies, the precise role of γΔ T cells in the gastrointestinal tract remains a mystery. Their predilection for epithelial surfaces throughout the body makes a role in the regulation and/or defense of epithelial cells likely.[128] Mice deficient in γΔ T cells have reduced epithelial cell turnover and decreased MHC class II expression.[129] Like other IELs, they have been shown to have a cytotoxic function[130] and to secrete IFN-γ.[99–101] Their likely role in combating infectious disease is supported by the observation that increased numbers of γΔ T cells are observed at sites of infection with certain *Listeria* and *Trypanosoma* species, mycobacteria, influenza virus, *Leishmania*, leprosy, and schistosomiasis.[100,131–138] Further, γΔ T cell–deficient mice are more susceptible to *Yersinia* infection.[139]

The relative oligoclonality of γΔ T cells in the intestinal tract suggests that they may recognize only a limited number of antigens.[140] Studies of γΔ T cells from other parts of the body have shown that these cells can recognize and bind mycobacterial and other heat shock proteins.[141] Heat shock proteins are proteins secreted by cells stressed by heat and other noxious agents, which are highly conserved across species.

In terms of activation, γΔ T cells are the least reactive IELs.[99,142,143] Further, γΔ T cells appear to be much less dependent on intraluminal antigenic stimulation than αβ T cells; they increase only modestly following birth, unlike αβ T cells, and they exist in germ-free mice.[88,144] Recent gene expression studies reveal, however, that γΔ T cells constitutively express high levels of both cytotoxicity genes and inhibitory signaling genes, suggesting that these cells are primed for rapid activation when

released from inhibition by signals, which are still as yet poorly understood.[139] In celiac disease, both αβ and γΔ T cells are significantly increased. However, the withdrawal of gluten from the diet leads to a rapid reduction in αβ IELs, whereas γΔ cells persist despite the removal of antigen.[80] This finding, coupled with the presence of γΔ cells in granulomata and granulomatous tissue,[131,138] suggests a potential role in healing.

The extrathymic origin of most γΔ T cells may have a functional significance. Most autoreactive T cell clones are deleted in the thymus. In the gut epithelium, some extrathymically derived αβ and γΔ autoreactive T cell clones exist that spontaneously secrete IL-2 in vitro.[31] As discussed earlier, these T cells are normally under stringent control by the local immune system and are anergic. Under special circumstances, however, such as the luminal presence of an exogenous superantigen like staphylococcal enterotoxin, these autoreactive T cells may be released from anergy and participate in the elimination of damaged epithelial cells.[57,145,146]

Lamina Propria

T Lymphocytes. Lamina propria (LP) T cells are Peyer's patch–derived T cells, which differentiate chiefly into CD4 Th cells under the influence of the local microenvironment.[147,148] Oral immunization with antigen appears to induce Th2 cells in the lamina propria.[149,150] Th2 cells can be distinguished from Th1 cells by their pattern of cytokine secretion, as can be noted in Table 19-3. Th1 cells secrete the proinflammatory cytokines IL-2, IFN-γ, and TNF-β, needed for microbial killing; Th2 cells secrete the less inflammatory cytokines, IL-4, IL-5, IL-6, IL-10, and IL-13, needed for B-cell help.[151] Under the influence of TGF-β, IL-4, IL-5, and IL-6 secreted by lamina propria Th2 cells, IgA-committed B cells undergo terminal differentiation into IgA-secreting plasma cells.[152–154]

LP T cells that have been primed with antigen in the Peyer's patches and mesenteric lymph nodes home back to the intestine by means of the integrin α4β7, which binds to the mucosal addressin cell adhesion molecule (MadCAM) on vascular endothelial cells.[155]

Table 19-3 Cytokine Secretion by T Helper 1 and T Helper 2 Cells

Cytokine	*T Helper 1 Cells*	*T Helper 2 Cells*
TNF-β	+	–
INF-γ	+	–
IL-2	+	–
IL-3	+	–
IL-4	–	+
IL-5	–	+
IL-6	–	+
IL-10	–	+
IL-13	–	+

IFN = interferon; IL = interleukin; TNF = tumor necrosis factor.

B Lymphocytes. It was noted earlier that S-IgA is important in intestinal host defense. The B lymphocytes of the lamina propria are important in the production of polymeric IgA as opposed to the monomeric IgA characteristic of serum IgA, which is produced in the bone marrow.[79,156,157] The IgA molecule consists of two heavy (α) and two light (K or Δ) polypeptide chains linked by disulfide chains. Polymeric IgA comprises polymers and tetramers of this molecule.[79,158] In addition, polymeric IgA contains a unique J chain, which may play a role in polymerization.[156,157] Polymeric IgA, with its J chain, is secreted from plasma cells in the intestinal lamina propria and binds to the polymeric Ig receptor on the basolateral side of IEC (Figure 19-4). The polymeric Ig receptor is composed of an Ig-like molecule known as secretory component with a transmembrane domain and a cytoplasmic tail.[158–160] Following binding, the IgA molecule with the secretory component attached is endocytosed, transported across the IEC, and secreted at the apical end into the intestinal lumen as S-IgA.[161]

Although secretory and serum IgA are normally two separate compartments of the immune system, the liver pro-

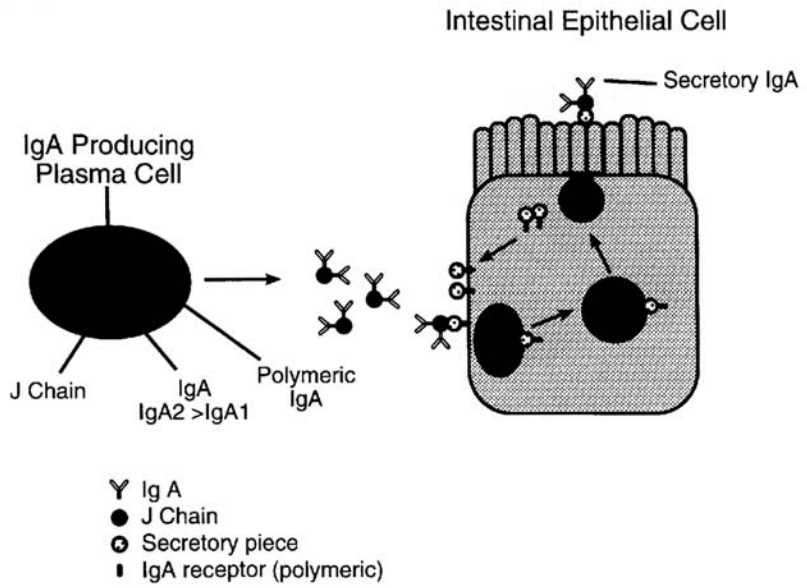

FIGURE 19-4 Secretory immunoglobulin A (IgA) is produced by IgA plasma cells in the lamina propria and is then transported to the mucosal surface by intestinal epithelial cells.

vides an interface between these two systems. Hepatocytes can bind monomeric and polymeric IgA via a sialoglycoprotein receptor (ASGP-R), which is distinct from the secretory component receptor.[162] Following binding, both serum and S-IgA may either be degraded via a lysosomal pathway or secreted into bile.[163, 164] Not only serum IgA but also bacterial antigens bound to IgA can be removed from the circulation via this mechanism.[165] Thus, hepatobiliary transport of serum IgA and immune complexes may provide a means of down-regulating systemic immune responses in a process known as "immune exclusion."[166]

Other Mucosal Cells

Mast Cells Stem cell precursors of mast cells migrate from the bone marrow preferentially to sites that border the external environment, such as the skin, respiratory mucosa, and gastrointestinal tract. Once in the skin or epithelium and under the influence of the local microenvironment, stem cells differentiate into mature mast cells. Mature mast cells are primarily involved in allergic, IgE-mediated reaction. They also play an accessory role in non–IgE-mediated immune and inflammatory responses.

There are two distinct classes of mast cells: mucosal mast cells and connective tissue mast cells, or mast cells present in the submucosa.[167] The most important growth factor for human mast cells appears to be stem cell factor, which is abundantly expressed by fibroblasts. It binds with high affinity to the c-kit receptor expressed on the mast cell membrane.[168,169] Other cytokines such as IL-3, IL-4, IL-9, IL-10, TGF-β, and nerve growth factor may play an auxiliary role in mast cell development.[168,170] The functional differences between mucosal mast cells and connective tissue mast cells are still being investigated.

Mast cells contain high-affinity receptors for the Fc portion of IgE known as Fc RI receptors. Interaction of antigen bound to IgE with these receptors results in mast cell degranulation and the release of mast cell mediators. These mediators include histamine, superoxide, leukotrienes, prostaglandins, and PAF. Many of these substances participate in type I hypersensitivity reactions with which mast cells are classically linked. Activated mast cells also release proteases such as tryptase and chymase from granules stored in the cytoplasm. These proteases cleave a wide variety of substrates, including kininogens, fibrinogen, angiotensin I, vasoactive intestinal peptide, substance P, and matrix metalloproteinases 1, 3, and 9. A wide variety of proteinase inhibitors, including secretory leukocyte proteinase inhibitor, α_1-antitrypsin, and α_1-antichymotrypsin, serve to keep this process tightly regulated. Collectively, this substrate profile supports a role for mast cells in vascular permeability, tissue and vascular remodeling, neurogenic inflammation, and allergic reactions.[168,171,172]

Mast cells also play a role in neutrophil recruitment to the intestine. In a study using murine mast cells, Ansel and colleagues showed that substance P selectively activates TNF-α mRNA expression.[173] Both substance P and mast cell–derived TNF have been shown to stimulate the expression of endothelial leukocyte adhesion molecule 1, an adhesion molecule involved in lymphocyte transmigration into tissue.[174,175]

As mentioned earlier, mast cells are important regulators of IEC permeability. Mast cell–derived histamine, nitric oxide, and TNF-α have been shown to increase epithelial permeability and induce chloride secretion. These substances have also been implicated in antibacterial innate immune responses and allergic reactions to foods.[176–178] Mast cells also mediate stress-induced increases in intestinal permeability that may play a role in irritable bowel syndrome by activating the proteinase activated receptor 2.[179]

Finally, mast cells may play a role in gastrointestinal defense against parasitic infections. An increase in both IgE and mucosal mast cells has been associated with intestinal parasitic infection in animals.[180,181] Mice with a targeted deletion of the mucosal mast cell–specific granule chymase, mouse mast cell protease 1, showed delayed expulsion of the nematode *Trichinella spiralis*.[182]

Eosinophils Eosinophils are derived from bone marrow granulocyte precursors. They are found in small numbers in the circulation but are mainly tissue-dwelling cells. Like mast cells, eosinophils are found mainly in tissues that are at the interface between the internal and external environment, including the lamina propria of the stomach, ileum, lungs, and uterus. Also like mast cells, eosinophils have been associated with allergic reactions and parasitic infection.

Eosinophils home to the gut in response to the chemokine eotaxin and mature under the influence of the cytokines IL-5 and granulocyte-macrophage colony-stimulating factor (GM-CSF).[183–185] Other chemotactic factors involved in eosinophil recruitment include the eotaxin receptor CCR3; the adhesion molecules intercellular adhesion molecule (ICAM) and vascular cell adhesion molecule (VCAM); the integrins α4β7 and CD11/CD18; IL-5, leukotriene B_4, PAF, and C5.[185–190]

Once in tissue, eosinophilic degranulation can be induced by binding of Igs and PAF to IgG, IgA, IgE, Fc, and PAF receptors on the surface of eosinophils.[191–193] Eosinophilic granules contain a number of proteins that have neurotoxic, antihelminthic, and antibacterial properties. These include major basic protein, eosinophil cationic protein, eosinophil-derived neurotoxin, and eosinophil peroxidase. In addition, eosinophils produce leukotrienes, leukotrienes C_4 and D_4, and several cytokines, including IL-3, GM-CSF, TGF-α, and TGF-β.[194–196]

Eosinophils have been implicated in host defense against intestinal parasitic infection. However, it has been shown that in mice infected with some parasites, the elimination of tissue eosinophilia with monoclonal antibody to IL-5 or genetic deletion of IL-5 had no effect on the clinical course of the infection.[197,198] In contrast, nematodes are largely susceptible to IL-5-mediated immunity.[199] Eotaxin may be necessary for containment of larval infection, whereas IL-5 may be important for expulsion of adult worms.[200]

Eosinophilia has been found in several gastrointestinal diseases, including eosinophilic gastroenteritis, cow's milk allergy, and Crohn's disease. The role of eosinophils in the

pathophysiology of these disorders has not been clearly established. For example, despite marked attenuation of eosinophilia in IL-5 mice with experimental colitis, tissue pathology and clinical course remained unchanged.[201] Eosinophilic gastroenteritis is an uncommon disorder characterized by eosinophilic infiltration of the gastric and small intestinal mucosa with subsequent inflammation, edema, and protein-losing enteropathy. Some cases have been shown to be related to specific food allergens and may respond to elimination diets, whereas others have been linked to inhaled allergens.[202,203]

Macrophages and Dendritic Cells There are at least two types of nonlymphocyte monocytes in the intestinal mucosa: macrophages and dendritic cells. Macrophages predominate in the epithelium and lamina propria, where they are involved in phagocytosis of apoptotic cells as well as antigen presentation. Their effects on the mucosal immune system depend heavily on the nature of the stimulus. They may play a proinflammatory role in response to bacterial stimuli and produce IL-12, TNF-α, and IL-6, or they may play an anti-inflammatory role after ingesting neighboring apoptotic cells and secrete anti-inflammatory cytokines such as IL-10 and TGF-β or the anti-inflammatory prostaglandin E_2.[204–206] Dendritic cells predominate in Peyer's patches, where they are involved in antigen presentation and stimulation of naive T cells. The presence of dendritic cells and macrophages appears to be necessary for optimal production of antibody by plasma cells.[207]

A profusion of research on intestinal dendritic cell biology in recent years has revealed the existence of several subclasses of dendritic cells in the intestine and the mesenteric lymph nodes. Immature dendritic cells have an activated endocytic pathway primed for uptake of antigen. They express the surface antigens CD11c, CD1a, and CCR6 and reside immediately underneath the follicle-associated epithelium in Peyer's patches in close proximity to epithelial cells expressing CCL20, the ligand for CCR6+.[208,209] Recently, dendritic cells have been shown to sample luminal antigens directly by interdigitating through epithelial tight junctions. Expression of tight junction–associated molecules on dendritic cells enables them to sample antigen without disrupting epithelial cell permeability.[210]

Dendritic cells mature in response to danger signals from bacterial antigens such as flagellin and LPS. Mature dendritic cells are CD11c+, CD83, DEC-205+, and CCR7+. They express the costimulatory molecules MHC class II, CD80, and CD86 and do not effectively phagocytose antigen. They also can secrete high levels of IL-12, which stimulates IFN-γ production in nearby Th1 cells.[208,209]

Dendritic cells can, in some instances, modulate tolerance in the intestinal mucosa. Two subsets of mature dendritic cells have been identified in Peyer's patches and mesenteric lymph nodes in rodents. Both subsets express MHC class II, OX62, CD11c, and CD80. One subset is CD4+ and OX41/SIRP alpha+ and consists of strong APCs. The other subset is CD4– and OX41/SIRP alpha– and contains remnants of phagocytosed apoptotic epithelial cells in their cytoplasm. These cells are weak APCs and may serve to down-regulate intestinal immune responses. Administration of intravenous LPS causes a rapid shift from OX41– to OX41+ dendritic cells in mesenteric lymph nodes.[211]

Peyer's Patches

Peyer's patches are collections of lymphoid follicles located in the terminal ileum, appendix, and colon. Their function is to recognize and absorb macromolecular antigens and to initiate antigen-specific mucosal immune responses; they accomplish this task largely through the induction of IgA-committed B cells. The Peyer's patches develop early in fetal life.[212] Postnatal antigenic stimulation is necessary to activate lymphoid follicles, however. The size and number of lymphoid follicles increase up to puberty, after which there is a decline.[213]

Recent studies in knockout mice have elucidated the key signaling molecules involved in the formation of Peyer's patches. Mice deficient in the IL-7 receptor, lymphotoxin-α and lymphotoxin-β, the lymphotoxin-β receptor CXCR5, and the transcription factor Id2 all fail to develop Peyer's patches.[214–219] The IL-7 receptor may up-regulate lymphotoxin signaling, which, in turn, stimulates expression of the adhesion molecules VCAM and ICAM in the organizing center of the patch.[220] Id2 appears to be necessary for the transcription of lymphotoxin. CXCR5-expressing cells are mainly B lymphocytes, which appear to be necessary for the organization of the dome epithelium and the formation of M cells, as shown by the severe reduction in follicular associated epithelium (FAE) and M cell size and number in B cell–deficient mice.[221]

Peyer's patches consist of three distinct regions: (1) an overlying dome (also known as follicle-associated) epithelium, (2) a B cell zone or germinal center, and (3) a parafollicular T cell zone.

Dome Epithelium The dome epithelium contains specialized cells known as M cells (Figure 19-5). M cells are so called because of the presence of microfolds on their luminal surface, which can be distinguished by electron microscopy from the longer, more slender, more abundant microvilli on the surface of neighboring epithelial cells.[222] The lack of microvilli and membrane-associated hydrolases is consistent with the M cell's lack of absorptive and digestive capability. The absence of a thick, protective brush border glycocalyx and goblet cells in the dome epithelium contributes to the M cell's increased accessibility to microorganisms. Because of their increased exposure to the luminal antigens, M cells have evolved to more efficiently bind and endocytose antigens and transport them to macrophages, dendritic cells, B cells, and T cells in the follicles below.[221]

How M cells recognize luminal antigen is not completely understood. These cells have been shown to adhere to and/or take up various pathogens, including the RDEC-1 strain of *Escherichia coli*, *Vibrio cholerae*, *Shigella flexneri*, poliovirus, *Salmonella typhi*, reovirus, *Campylobacter jejuni*, and mycobacteria.[223–228] In contrast, most normal gut flora are taken up little if at all. One clue to the selec-

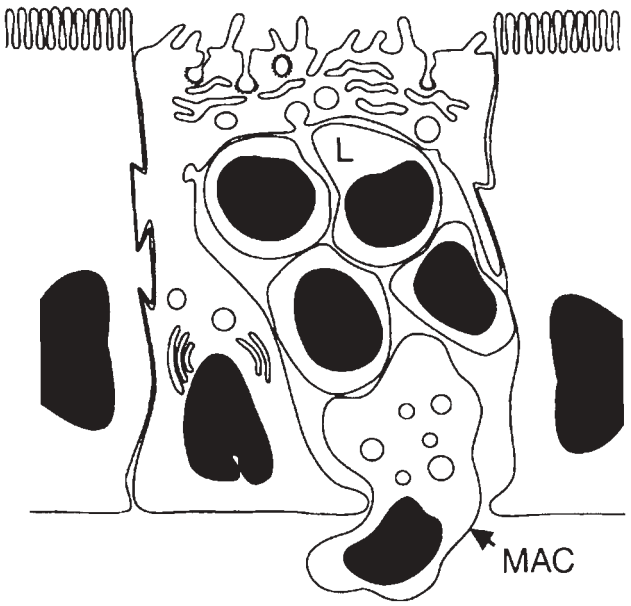

FIGURE 19-5 Diagram of an M cell. The M-cell basolateral surface is modified to form an intraepithelial packet into which lymphocytes (L) and macrophages (MAC) migrate. Antigens, microorganisms, and particles that adhere to the M-cell apical membrane are efficiently endocytosed and transported into the packet, and hence into underlying mucosal lymphoid tissue.

tive uptake of foreign antigen is the finding that there are Fc receptors for Ig on M cells and that S-IgA adheres preferentially to the apical surface of rabbit and mouse M cells.[229–231] Hence, binding of antigen-specific IgA and/or IgA-antigen complexes may prime the M cell for endocytosis of antigen.[232,233] Additionally, M cells in mice and rabbits have been shown to selectively bind sugar-specific lectins distinct from lectins bound by other enterocytes, indicating specificity of glycoconjugates on the M cell apical membrane.[234, 235] In humans, the sialyl Lewis A antigen distinguishes M cells from other IEC types.[236]

Until recently, the search for specific receptors on M cells that bind intraluminal bacteria had been fruitless. Now M cells have been shown to internalize human immunodeficiency virus (HIV) via two receptors, lactosyl cerebroside and CXCR4.[237]

B Cell Zone

Following isotype switching, IgA-committed B cells as well as primed naive T cells and dendritic cells emigrate out of Peyer's patches into mesenteric lymph nodes and travel through the abdominal and thoracic lymphatic systems into the systemic circulation (see Figure 19-2). They rapidly leave the systemic circulation and migrate to mucosal tissue (salivary, lacrimal, bronchial, mammary) until they finally return to the intestinal lamina propria near their germinal centers of origin. This process is known as homing.[238] It succeeds in educating the systemic and mucosal immune system about orally ingested antigens. Through this process, breast milk cells confer immunity to dietary and enteric bacterial antigens.[239]

The molecular mechanisms of homing are now well understood. Specialized receptor molecules on lymphocytes, known as "homing receptors," direct lymphocytes to specific tissue sites.[240] At their destination, lymphocytes recognize and bind to tissue-specific adhesion molecules on vascular endothelium, known as "vascular addressins."[241] Vascular addressins are expressed on high endothelial venules (HEVs), specialized endothelial cells in postcapillary venules. Ligation of homing receptors to vascular addressins permits the migration of lymphocytes from the circulation into tissue (Figure 19-6).

In the gastrointestinal tract, a tissue-specific lymphocyte homing receptor, known as the $\alpha 4\beta 7$ integrin or lymphocyte Peyer's patch HEV adhesion molecule (LPAM-1), has been characterized.[242] It has been shown to bind to MAdCAM 1, a vascular addressin expressed in Peyer's patches, the lamina propria of the small and large intestine, and the lactating mammary gland. Other lymphocyte adhesion molecules of the integrin and selectin family bind gut mucosal cells with less specificity but may assume an important role in inflammatory conditions. Successful experimental attempts to block gut inflammation in animals by blocking the adhesion molecules $\alpha 4$ and $\beta 7$ integrins with monoclonal antibodies have shown therapeutic promise.[243,244]

Parafollicular T Cells

The majority of Peyer's patch T cells are CD4+ Th cells located in the interfollicular zones around the germinal center.[147] One of the major functions of these cells may be to help the germinal center B cells with the process of isotope switching from immature IgM-bearing cells to IgA-committed cells.[245] Dendritic cells also participate in this process.[246]

Cytokines secreted by Peyer's patch Th cells have been shown to regulate different steps in IgA production. TGF-β is a major switch factor in isotype switching.[247] It induces IgA production in B cells by inducing the binding of downstream transcription factors, Smad, AML, and ets, to promoter elements upstream of the IgA1 and IgA2 switch regions.[248,249] The interaction of costimulatory molecules on the surface of B cells and T cells, such as CD40 and CD40 ligand, may also be required for isotype switching.[250] TGF-β secreted by B cells may be a downstream effector of CD40 ligation.[251] Recent data implicate activation-induced cytidine deminase, a member of the cytidine deaminase family that is induced by TGF-β, IL-4, and CD40 ligand stimulation of B cells in isotype switching. This gene appears to regulate DNA repair genes that carry out the final steps of class switch recombination.[252,253] Once isotype switching has occurred, IL-4, IL-5, IL-6, and IL-10 all can amplify the production of S-IgA in IgA-committed cells (Table 19-2; see also Chaper 6).[254,255]

NUTRITION

An increasingly large number of dietary components have been found to alter immune function. Dietary factors

known to influence outcome by producing a pharmacologic effect rather than correcting or preventing a simple deficiency include proteins, glutamine, arginine, lipids, nucleotides, vitamins, and the metals zinc, copper, and iron.[256] Nutritional therapy using disease-specific formulations or supplements is an old idea now assuming increasing importance (see Table 19-4; see also Chapter 6).

MALNUTRITION

Malnutrition is not a discrete, all-or-none phenomenon but rather an entity that spans an entire spectrum, ranging from subclinical malnutrition to lethal nutritional deficiency states. It is now recognized that a pure deficiency of a single nutrient rarely occurs. Vitamin and mineral deficiencies accompany those of protein and calories, and, more importantly, there are interactions among these deficiencies. Protein-calorie malnutrition (PCM) may be classified as primary or secondary. Classically, children with primary malnutrition have an inadequate nutrient intake. Secondary malnutrition is present when nutrient intake appears adequate, but nutrient needs and/or losses are excessive as a result of a primary disease state. Malnutri-

tion may also be categorized as marasmus (nonedematous PEM), kwashiorkor (edematous PEM), or marasmus-kwashiorkor. Children who have been completely starved develop marasmus. They lack dietary protein, calories, vitamins, and minerals and ultimately develop the clinical picture of starvation. Marasmus generally develops over several weeks or months, whereas kwashiorkor often develops acutely, often in the context of infection.

Malnutrition varies in severity. Gomez and coworkers developed criteria for defining first-, second-, and third-degree malnutrition by comparing the gender, weight, and age of a child against locally derived growth standards.[257] Later, Waterlow stressed the importance of determining a child's deficit in weight-for-height ratio and height for age using the 50th percentile of the Harvard Standards.[258] Children with deficits in weight for height are considered to have evidence of acute malnutrition.[259] Those with height-for-age deficits suffer from chronic malnutrition (and/or chronic inflammation) and are considered to be growth retarded. Children may be both acutely and chronically malnourished. Therefore, it is important to underscore that the severity (first, second, or third degree) and chronicity of the undernourished state, as well as the presence or absence of infection, all interact to affect gastrointestinal immunity.

The intestinal mucosa atrophies in severe PCM, especially of the kwashiorkor type, resulting in the blunting of villi and an increase in antigen uptake.[260–263] Patients with kwashiorkor tend to have the most severe intestinal morphologic changes, the greatest disruption of gastrointestinal function, and probably the greatest impairment of gastrointestinal immunity. In contrast to this, patients with marasmus in many instances have what appears to be a normal intestine with minimal dysfunction.

The pathogenesis of villous atrophy is still under investigation. Two types of villous atrophy have been described. The first type is characterized by increased loss of mature enterocytes, via either shedding or apoptosis, which stimulates crypt hyperplasia.[264] Apoptosis leading to villous atrophy may be attributable to TNF-α, Fas–Fas ligand interactions, as well as perforin and antibody-mediated cytotoxicity by lymphocytes and monocytes in the intestinal mucosa.[265,266] Conversely, villous atrophy may commence with crypt hyperplasia, which, in turn, leads to premature sloughing of mature enterocytes.[267] Whichever the causative sequence, villous atrophy has been associated with the presence of activated T cells and may be cytokine mediated.[267,268] The fact that kwashiorkor, more often than marasmus, has been associated with infection and, hence, an increased production of inflammatory cytokines[269] may help to explain its preferential association with villous atrophy. An additional factor contributing to mucosal atrophy may be the withdrawal of growth factors such as insulin-like growth factor I (IGF-I); levels of IGF-I are sensitive to changes in host nutritional status. Finally, polyamine synthesis from dietary amino acids by ornithine decarboxylase is needed for normal mucosal maturation.[270] Deficient synthesis of polyamines during periods of starvation and stress may also contribute to mucosal atrophy.

Animal studies have helped to separate the individual effects of malnutrition and diarrhea on the intestinal tract in a way that is not possible in the human situation. A series of studies by Castillo and colleagues revealed that in infant rats deprived of intraluminal nutrients, intestinal length, weight, protein, and DNA were decreased.[271] After refeeding, these same variables increased at a supranormal rate.[272] Thus, "catch-up" growth is possible for the intestine just as it is for the infant itself. Studies of malnourished children provide somewhat subjective and semiquantitative data concerning intestinal morphology. Several reports indicate that in children with malnutrition and persistent diarrhea, the clinical severity and prognosis do not necessarily correlate with the degree of small intestinal mucosal damage.[273–275] Nutritional rehabilitation via the enteral route can be shown to produce a demonstrable increase in small intestinal crypt cell proliferative activity in children with persistent diarrhea.[276] Certain dietary components, such as glutamine, appear to be particularly important in reversing atrophy.[277] It is now widely accepted that children with acute diarrhea should be fed solid food throughout the course of their illness whenever possible to minimize weight loss and promote intestinal recovery.

In addition to inducing villous atrophy, malnutrition can hamper the mucosal immune system's ability to clear microbial infection. Several pathways play a role in the immune suppression associated with nutritional deprivation. Malnourished piglets have prolonged excretion of intestinal prostaglandin E_2 during rotavirus infection associated with prolonged diarrhea.[278] In mice, caloric restriction leads to an increase in the proportion of naive, CD45RA+ T cells to memory, CD45 RO+ T cells in the mesenteric lymph nodes, which may contribute to local immune suppression.[279] A similar shift in T cell subsets has been seen in malnourished humans.[280] Protein-restricted mice have a defect in mesenteric lymph node IL-4 production that has been associated with prolonged survival of intestinal nematodes.[281] Recently, leptin, a hormone linked to obesity in mice, has been shown to reverse starvation-induced immunosuppression in malnourished mice, even in the absence of refeeding, by stimulating Th1 immune responses (see Chapter 20).[282]

Total Parenteral Nutrition

Total parenteral nutrition (TPN) is also associated with atrophy of the intestinal mucosa and increased infectious complications.[283,284] Several studies have evaluated the effects of TPN on intestinal immune function and intestinal bacterial translocation. In one study, Wistar rats underwent central vein cannulation and were randomized to isocaloric feeding of a regular diet plus saline infusion or TPN and no enteral feedings for 7 days. Bacteria-positive mesenteric lymph nodes were found in 17% (2 of 12) of the regular diet–fed rats but in 77% (10 of 13) of TPN-fed rats ($p < .05$). In addition, *Candida albicans* phagocytosis was significantly decreased in the TPN group compared with the regular diet group. Impaired macrophage function was reversed by small oral feedings.[285] More recent studies

have elucidated some of the mechanisms leading to the villous atrophy and increased susceptibility to infection observed in TPN-nourished animals. In mice, TPN resulted in decreased T and B cell numbers in the intestinal mucosa within 2 days of initiation and to a decreased lamina propria CD4+-to-CD8+ ratio within 4 days. IgA levels in both the gastrointestinal and respiratory tracts were decreased by day 3 of TPN.[286] In addition, mice maintained on TPN had decreased levels of IL-4 and IL-10 and increased levels of the adhesion molecule ICAM compared with enterally fed mice. These changes were reversible when TPN was supplemented with either glutamine or the neuropeptide bombesin.[287] Finally, at 6 hours, endotoxin-treated fasted mice had significantly higher levels of gut apoptosis related to increased intestinal caspase 3 activation compared with endotoxin-treated, enterally fed mice.[288] These data suggest that apoptosis might contribute to the villous atrophy seen in TPN-nourished children.

Although available data support use of the enteral route for nutritional supplementation whenever possible, interestingly, a meta-analysis of studies conducted with patients being fed parenterally failed to document an increased mortality rate in patients maintained on TPN.[289]

Selected Nutrients

Glutamine Glutamine is a nonessential amino acid and the most abundant amino acid in the body.[290] However, during catabolic states, plasma levels of glutamine drop dramatically, suggesting a "conditionally essential" role for this amino acid in periods of stress.[291] Glutamine has been identified as an extremely important fuel not only for enterocytes but also for lymphocytes and macrophages, lending support to its role in the immune response.[292]

Many studies have examined the effects of glutamine on intestinal structure and function, and many excellent reviews are available.[293,294] O'Dwyer and collaborators compared the effects of TPN devoid of glutamine with TPN enriched with glutamine on the intestine of male Wistar rats.[295] Intestinal samples were taken for measurements of jejunal weight, DNA, protein, mucosal thickness, and villous height. The authors also measured nitrogen retention. They found that glutamine-enriched TPN protected the animals from atrophy of the intestinal mucosa. It also improved nitrogen retention during intravenous feeding.[295] There is other evidence to support the concept of glutamine's trophic effect on the intestine. Reducing plasma glutamine concentrations to undetectable levels by glutaminase infusion in animals causes intestinal atrophy, ulceration, and necrosis.[296] Intestinal atrophy associated with malnutrition is prevented with enteral glutamine supplementation.[277]

In humans, glutamine has been shown to decrease proinflammatory cytokine production (IL-6, TNF-α, and IL-8) while increasing production of IL-2 and IFN-γ in vitro.[294,297] Some placebo-controlled, double-blind trials of glutamine supplementation in critically ill patients have reported reductions in infectious complications, whereas others have not.[294,298–300]

Arginine Arginine is a dibasic amino acid, best known as an intermediate in the urea cycle, although it also serves as a precursor for a number of biologically significant compounds such as nitric oxide and growth hormone. It is generally considered a nonessential amino acid because, under normal conditions, requirements for the amino acid are met through tissue synthesis. However, it has been stated that arginine is "essential to the traumatized host and may have tissue-specific properties which influence components of the immune system."[301]

Arginine enhances immune function by increasing lymphocyte and monocyte proliferation, cytotoxicity, and phagocytosis and promotes nitrogen retention.[302] Diets given to burned guinea pigs when supplemented with arginine at a level of 2% of energy intake have been associated with increased survival and apparent augmentation of cell-mediated immunity.[303] Daly and collaborators studied the effect of supplemental arginine or isonitrogenous glycine in 30 cancer patients undergoing major surgery.[304] Nitrogen balance was measured daily, and immune parameters were determined before and after the surgery. Mean age, degree of preoperative weight loss, disease state, and calorie and nitrogen intake were similar for the groups studied. The authors noted that mean daily nitrogen balance was similar for the arginine- and glycine-supplemented groups. However, supplemental arginine increased mean CD4+ T cells on postoperative days 1 and 7 compared with the glycine-supplemented group. The authors concluded that arginine may benefit surgical patients who are at increased risk of infection.[304]

Madden and associates reported that survival was increased by arginine supplementation given orally before sepsis or started intravenously after cecal ligation and puncture in rats.[305] Supplemental arginine was shown to improve wound healing and immune response in 36 healthy, human volunteers.[306] However, Ronnenberg and colleagues found that arginine supplementation in a purified amino acid diet (30 g/kg diet) did not enhance mitogen-stimulated proliferation or alter IL-2 production by splenocytes of healthy young and aged rats.[307]

The importance of arginine in modulating the immune system remains somewhat controversial. A recent meta-analysis of 22 randomized trials with a total of 2,419 patients compared the use of immunomodulatory formulas, most of which contained supplemental arginine, and standard enteral formulas in surgical and critically ill patients. The use of commercial formulas with high arginine content was associated with fewer infectious complications. Benefits were most marked in surgical patients. Of note, however, was a disturbing trend toward increased mortality in septic and critically ill patients supplemented with immunomodulatory formulas.[308] In some of these studies, the cause of increased mortality was from respiratory failure.[302] In summary, arginine supplementation appears to be of benefit to uninfected, postoperative patients, but its safety has yet to be established in critically ill, infected patients.

Lipids The lipid composition of monocytes, macrophages, lymphocytes, and polymorphonuclear cells reflects

the fatty acid composition of the diet.[309] These cells synthesize all of the nonessential fatty acids of cellular lipids but require the essential omega-6 fatty acid α-linoleic acid, its products arachidonic acid, the downstream 2-series prostaglandins (eg, E_2) and thromboxanes, and 4-series leukotrienes (eg, LTB_4); and the essential omega-3 fatty acid linolenic acid and its downstream 3 series and 5 series eicosanoid products (eg, LTB_3 and LTB_5).

Omega-6 fatty acids are incorporated into cell membranes and stimulate the inflammatory arachidonic acid pathway. This results in the production of prostaglandin E_2, as well as the proinflammatory leukotrienes B_4, C_4, and D_4. In addition, omega-6 fatty acids may increase the production of the proinflammatory cytokines TNF-α, IL-1, and IL-6.[310] These substances are important in host defense against infection. Indeed, in a study of burned mice challenged with *Pseudomonas aeruginosa*, survival was significantly higher in animals fed a 40% safflower oil (omega-6) diet than in animals fed a 40% fish oil (omega-3) diet.[311]

Sometimes the host inflammatory response to trauma or infection proves more devastating than the initial insult itself. In this cast, exploiting the anti-inflammatory properties of certain types of lipids may have therapeutic benefit. The role of arachidonic acid metabolites and of proinflammatory cytokines has been studied in the pathogenesis of atherosclerosis, rheumatoid arthritis, inflammatory bowel disease, and, most recently, acquired immune deficiency syndrome (AIDS). In these disorders, omega-3 fatty acids and the omega-6 fatty acids α- and γ-linolenic acid compete with arachidonic acid, dampen the inflammatory response, and may have some therapeutic benefit.[312–316] Both omega-3 fatty acids and linolenic acids have been shown to decrease the production of the proinflammatory cytokines TNF-α, IL-1, and IL-6.[310] Fish oil, comprising eicosapentaenoic and docosahexaenoic acids, has been shown to reverse mucosal atrophy.[317] Whereas in low doses, omega-3 fatty acids are anti-inflammatory, at high doses, they may be immunosuppressive. In an animal study, Chang and colleagues demonstrated increased mortality in *Salmonella*-infected mice fed a 20% fish oil diet.[318] Clearly, caution needs to be exercised in the use and dosing of these agents in patients with significant infection.

Quantity of dietary lipid may be as important as type of dietary lipid in determining immune outcomes. Laboratory animals fed high-fat diets have decreased lymphocyte proliferation and NK cell activity compared with animals fed low-fat diets.[319]

Nucleotides Recent studies have suggested a role for dietary nucleotides as semi-essential nutrients.[320] Among their diverse roles, they serve as precursors for nucleic acid synthesis, participate in energy transfer reactions, and function as coenzymes. The endogenous supply of nucleotides is maintained both through de novo synthesis in tissue and through the salvage pathway in which precursors (purine and pyrimidine bases and nucleosides) are converted to nucleotides. Dietary purines and pyrimidines in nucleic acids are absorbed mainly in the form of nucleosides and bases. Gastrointestinal and liver tissues metabolize dietary nucleotides extensively prior to their entry into the systemic circulation. Certain tissues, including lymphocytes, may have a limited capacity for the de novo and salvage synthesis of nucleotides. Thus, it has been suggested that dietary nucleotides may optimize the function of immune cells by providing an exogenous supply. In one study, 37 healthy term infants were evaluated.[321] They were either breast-fed or fed SMA™ formula supplemented with 33 mg nucleotides/L or standard SMA formula. At 2 months of age, NK cell percent cytotoxicity was significantly higher in the breast-fed and nucleotide-supplemented groups compared with the unsupplemented group. IL-2 production by stimulated mononuclear cells at 2 months of age was higher in the nucleotide groups compared with the group fed the same formula without nucleotides. Rate of growth and incidence and severity of infections did not differ significantly among the dietary groups. The authors concluded that nucleotides may be a component of human milk that contributes to the enhanced immunity of breast-fed infants.[321]

Dietary nucleotides also contribute to humoral immunity and antibody production. A controlled, randomized, blinded, multicenter trial of 311 infants was conducted. Infants were assigned to one of three groups: milk-based control formula, milk-based control formula with nucleotides, and breast-fed infants supplemented with a cow's milk–based formula with iron. At the end of 12 months, the nucleotide-supplemented groups had significantly higher *Haemophilus influenzae* type B and diphtheria antibody titers than the formula control group. Breast-fed infants had significantly higher polio antibody titers than either the nucleotide-supplemented group or the formula controls.[322]

Vitamin A The importance of vitamin A in sustaining an adequate immune response has been recognized since as early as 1925, when Wolbach and Howe showed that rats fed diets deficient in vitamin A developed thymic atrophy.[323] Since that time, deficiencies in vitamin A have been linked in vivo and in vitro with various immune abnormalities, including a decreased number of CD4 cells,[324] impaired lymphocyte proliferation,[325] decreased antibody response to immunization,[326] decreased resistance to infection,[327,328] and increased susceptibility to certain cancers.[329,330] Indirect evidence of vitamin A's critical role in immunity has come from the achievement of a 20 to 50% reduction in childhood mortality in parts of the world where large-scale supplementation programs have been implemented.[331]

In the gastrointestinal tract, vitamin A deficiency is both a cause and a consequence of diarrheal disease. Diarrheal diseases may cause vitamin A deficiency by several mechanisms. First, steatorrhea can lead to a generalized loss of fat-soluble vitamins. Second, damage to the brush border may inhibit the function of brush border retinyl esterases, which contribute to the intestinal absorption of vitamin A.[332] Finally, if diarrheal disease is accompanied by PEM, vitamin A deficiency may be further aggravated by a decrease in retinol-binding protein as well as abnormalities in conjugated bile acids, which contribute to the digestion, absorption, and transport of dietary vitamin A.[333]

Conversely, vitamin A deficiency may predispose a child to diarrhea for several reasons. Data from animal studies indicate that vitamin A deficiency can cause goblet cell depletion, abnormal villous architecture, and villous atrophy.[334–336] In addition, hypersecretion and impaired colonic responsiveness to aldosterone have been observed.[337] When a cohort of vitamin A–deficient children from Indonesia was followed, a significant decrease in mortality from diarrheal disease and respiratory tract infections was noted in children given vitamin A supplementation.[338] A later study in Indonesian children showed, however, that vitamin A supplementation of well-nourished children was actually detrimental, with a trend toward increased incidence of diarrheal and respiratory illnesses seen.[339]

The mechanisms underlying the immunologic effects of vitamin A on the gastrointestinal tract are being elucidated. A study by Carman and colleagues examined cytokine production in vitamin A–deficient mice infected with intestinal *T. spiralis*.[340] Mesenteric lymph nodes of deficient mice produced substantially more IFN-γ and substantially less IL-2, IL-4, and IL-5 than controls. The authors concluded that this alteration in cytokine production may help to explain the poor response to tetanus toxoid (as well as hypoeosinophilia) observed in vitamin A–deficient mice.[340]

In a related series of findings, vitamin A has been shown to play an important role in the induction of S-IgA responses. Cui and colleagues studied children with viral pneumonia supplemented with high doses of vitamin A (250,000 IU/kg/day) or control doses of vitamin A (4,000 IU/kg/day) given before and during infection. Although there was no difference in disease severity between the two groups, vitamin A–supplemented children had significantly higher salivary IgA concentrations and higher IL-10 levels but lower serum IgG concentrations and lower IFN-γ levels than controls.[341] Thus, although vitamin A supplementation can improve some immunologic parameters (IgA), it can suppress IFN-γ, which is an important component of antiviral immune responses.

Vitamin C The immunologic effects of vitamin C are multiple. Ascorbic acid is an important antioxidant that scavenges free radicals (harmful oxygen derivatives such as the hydroxyl radical, superoxide, and hydrogen peroxide) under conditions of inflammation or stress. However, under certain conditions, such as the presence of free iron, ascorbic acid can act as a pro-oxidant agent.[342] It is capable of lipid peroxidation of cell membranes, and it is by this mechanism that it may act, together with TGF-β, to stimulate collagen synthesis.[343] Its in vitro antiviral properties have been extensively studied.[344–346] In vivo, vitamin C supplementation has been shown to enhance T-lymphocyte proliferation in response to mitogens and to viral infection.[347] There are also reports of improved neutrophil chemotaxis and improved phagocytic function of macrophages in supplemented patients.[348,349] Attempts to alter the clinical course of virally infected children with vitamin C supplementation have been disappointing,[350] although vitamin C supplementation may prevent the onset of certain viral infections.[351] Vitamin C may affect gastrointestinal immunity indirectly by influencing the absorption of micronutrients. For instance, it enhances the absorption of dietary iron[352] but inhibits copper uptake.[353]

There has been a good deal of research interest recently regarding the role of vitamin C in *Helicobacter pylori* infection and in the prevention of gastric cancer. Several studies have shown that gastric juice ascorbic acid levels are lower in patients with *H. pylori* infection and return to normal following eradication of the bacteria.[354,355] A study by Ruiz and colleagues has shown that serum and gastric juice levels of vitamin C are lower in adult patients with chronic atrophic gastritis or intestinal metaplasia than in patients with normal mucosa or ulcer disease.[356] Recently, Zhang and colleagues showed that vitamin C inhibits gastric cancer cell growth in vitro when administered at concentrations normally present in gastric juice but not at lower concentrations seen in individuals infected with *H. pylori*.[357]

Vitamin E α-Tocopherol or vitamin E is a fat-soluble, free radical scavenger that is incorporated in cell membranes and inhibits lipid peroxidation. Clinically, vitamin E deficiency is associated with a demyelinating neuropathy and hemolytic anemia. Children with cholestatic liver disease and children with chronic fat malabsorption are at risk for deficiencies of vitamin E. Vitamin E supplementation has been shown to result in an increase in the CD4-to-CD8 ratio, an increase in lymphocyte proliferation, and a decrease in prostaglandin E_2 synthesis.[358,359] Vitamin E augments IL-2 production in both animals and humans.[360,361] Vitamin E supplementation has been shown to prevent cancer in humans; one mechanism may be through the suppression of vascular endothelial growth factor, a major mediator of tumor angiogenesis.[362]

In the gastrointestinal tract, vitamin E deficiency in animals renders absorptive mucosa secretory and thereby contributes to the pathogenesis of diarrheal disease. Its effects on secretion may be mediated by damage to enteric neurons, particularly those that transmit 5-hydroxytryptamine.[363] Empey and colleagues studied the effects of ionizing radiation on rats pretreated with vitamin E or misoprostol (a prostaglandin E_1 analogue).[364] Only the vitamin E–treated rats were protected from radiation-induced changes in absorption. Finally, in a rat model of inflammatory colitis induced by trinitrobenzene sulfonic acid, oral vitamin E supplementation was shown to reduce macroscopic mucosal damage.[365]

Vitamin B_{12} The association of vitamin B_{12} or cobalamin deficiency with pernicious anemia, atrophic gastritis, and ileal disease is well known. Recently, however, the spectrum of clinical illness associated with vitamin B_{12} deficiency has grown. Vitamin B_{12} deficiency is relatively common in the healthy elderly and in AIDS patients.[366,367] In a study of 98 adults with vitamin B_{12} deficiency, a significantly increased number were infected with *H. pylori*.[368] These findings have not been confirmed in children. Children who are strict vegetarians or neonates whose mothers are strict vegetarians are at risk for vitamin B_{12} deficiency, as are children with Crohn's disease.[369,370]

In the gastrointestinal tract, dietary cobalamin enters the stomach bound to food proteins. Gastric acid appears to be necessary to cleave the food-cobalamin complexes so that cobalamin can then bind to intrinsic factor secreted in the stomach. Intrinsic factor–cobalamin complexes traverse the small intestine, where they bind to a specific receptor known as cubilin, present in the epithelium of kidney and intestine but located principally in the ileum.[371] Transcobalamin II is a protein constitutively expressed in the small intestinal villi that binds free cobalamin after uptake of cobalamin–intrinsic factor complexes and transports it into the microcirculation and thence the portal blood.[372] Either decreased gastric acid production or mutations in cubilin or transcobalamin II may be the initiating event in cases of vitamin B_{12} deficiency syndrome.

Vitamin B_{12} may affect immune function in a variety of ways. In patients with pernicious anemia, vitamin B_{12} supplementation leads to an increase in CD8 numbers.[373] In cobalamin-deficient adults, serum TNF-α responses were significantly higher and epidermal growth factor levels lower than in iron-deficient or healthy control subjects.[374] In cobalamin-deficient mice, IgG, IgM, C3, and IFN-γ levels are lower but IgE, CD4+ T cell, and IL-10 levels are higher, suggesting the induction of a Th2 response.[375] Animal data from our laboratory suggest that supplementation with vitamin B_{12} improves survival in septic animals and that it does so largely by sequestering nitric oxide.[376]

Trace Elements Deficiencies of zinc, copper, and iron adversely affect immune function. A lethal mutation in Holstein-Fresian cattle was shown to be responsible for decreased zinc absorption and failure of the thymus to develop normally.[377] Later, Prasad and colleagues showed that human zinc deficiency was associated with dwarfism, hypogonadism, abnormal taste sensation, diarrhea, and an increased susceptibility to infection.[378] Dietary zinc deficiency induces thymic atrophy and loss of Th cell function.[379,380] Zinc deficiency leads to decreased DNA binding of the transcription factor NF-κB and decreased IL-2 and IFN-γ production as well as increased susceptibility of lymphocytes to apoptosis.[381] Children with chronic diarrheal disease as well as those on TPN are at risk for zinc deficiency and may require supplementation. Zinc supplementation leads to mucosal regeneration, increased activity of brush border enzymes, and higher levels of secretory antibodies and augments catch-up growth by increasing levels of IGF-I, which permit catch-up growth.[382]

Although copper deficiency in humans is rare, lower total-body levels of this trace mineral have been associated with an increased incidence of infection and impaired cell-mediated immunity.[383,384] The Menkes' kinky-hair syndrome is an X chromosome–linked inborn error of metabolism owing to a mutation in the copper adenosine triphosphatase, alpha polypeptide gene that leads to copper deficiency. This condition results in increased infections, and death is often caused by bronchopneumonia.[385] Copper deficiency has been linked to defects in the respiratory burst in macrophages and an attenuation of LPS-induced cytokine production.[386] Copper has been shown to play an important role in wound healing by stimulating the expression of matrix metalloproteinases and vascular endothelial growth factor.[387,388] The corollary is, however, that copper may play a role in tumor angiogenesis as well.[389]

Iron deficiency is associated with increased susceptibility to infection.[390,391] However, excessive iron intake appears to be linked to oxidative stress and to more infections as well.[392] Iron may help in combating infection by up-regulating IL-1 production.[393] Iron may predispose to infection by nourishing certain species of bacteria[394] or by inhibiting the induction of nitric oxide synthase.[395]

Intestinal transport of dietary iron is a tightly regulated process so as to avoid the deleterious effects of either iron excess or iron deficiency. Two iron transporters belonging to the natural resistance–associated protein (Nramp) family play an important role in intestinal iron homeostasis. Nramp2 is a protein that localizes to the cell membrane and to recycling endosomes of the intestinal brush border and governs the transferrin-independent intestinal absorption of iron.[396] Nramp1 is a phagosome-associated protein that pumps iron out of the phagosome, presumably to be able to prevent the prolonged survival of intracellular bacteria.[397] Polymorphisms in these genes have been linked to increased susceptibility to infection with intracellular pathogens and possibly to Crohn's disease susceptibility.[398–400] Taken together, these data point to an important role for iron in mucosal immunity.

FUTURE DIRECTIONS

Despite a proliferation of research in the field of gastrointestinal immunology in the last 10 years and the continuing evolution of knowledge regarding nutrition and immunity, the interactions of dietary nutrients and enteric flora with the immunologically active cells functioning in the gastrointestinal tract are only beginning to be elucidated. A recent review article by Bach and an accompanying editorial by Weiss discussed early environment and the development of immune-mediated disease.[401,402]

There has been an epidemic of both autoimmune diseases (in which the immune response is dominated by Th1 cells, such as type 1 diabetes, Crohn's disease, and multiple sclerosis) and allergic diseases (in which the immune response is dominated by Th2 cells, such as asthma, allergic rhinitis, and atopic dermatitis). One theory proposed to explain this increase in the prevalence of autoimmune and allergic diseases is that it results from a decrease in the prevalence of childhood infection. Bach detailed a number of potential mechanisms by which the decrease in the frequency of childhood infections might influence the frequency of autoimmune diseases. The first is that the decrease in antigenic stimulation related to the decrease in the frequency of childhood infections has resulted in a decrease in the levels of regulatory cytokines—specifically, IL-10 and possibly TGF-β. CD25-positive T cells and other regulatory T cells produce IL-10 and TGF-β and act to down-regulate Th1-mediated responses and Th2 responses.[402]

Environmental cofactors may also be important. Endotoxin is a hitchhiker that can attach itself to particulate air

pollutants that might potentiate the immune effects of endotoxin. The levels of heat shock protein and 1,3-β-glucan, the latter an immunostimulatory cell-wall component of fungi, yeast, and plants, correlate with levels of endotoxin in house dust. A final environmental cofactor may be the presence in bacterial DNA of greater numbers of unmethylated cytidine-phosphate-guanosine sequences than are present in mammalian DNA. These sequences are sensed by TLR9, which interacts with TLR4 and may potentiate immune stimuli when activated by LPS.[402]

Finally, genetics is an additional determinant of the response in any given person. Case-control association studies have suggested that a TT polymorphism in the promoter region of CD14, the receptor that binds LPS, is associated with higher levels of soluble CD14 in peripheral blood and, in persons with allergies, with lower serum IgE levels and decreased sensitization to allergens.[402] We need to clarify and extend this so-called hygiene hypothesis concerning asthma and other allergic and autoimmune disorders.[401]

CHAPTER 20

MALNUTRITION AND HOST DEFENSES

Susanna Cunningham-Rundles, PhD, David F. McNeeley, MD, MPHTM

This at least I clearly know: that bread has different effects in the human body according as it is fine or coarse, made of wheat winnowed or unwinnowed, mixed with much or little water, knead much or not at all, baked thoroughly or underbaked and a thousand other differences besides. . . . If one fails to consider these points or having considered does not understand them, how can he know anything about human disease?[1]
—Hippocrates (460–377 BC)

The vital importance of nutrition in host defense has been recognized from the time of Hippocrates,[1] long before the development of the germ theory of infection in the nineteenth century.[2] In contrast, immunology is modern, perhaps traceable in origin to Metchnikoff and the cell theory,[3] but dating in its present form to the 1960s.[4] The fundamental relationship between malnutrition and immunity was initially described by Smythe and colleagues as a thymolymphatic deficiency caused by protein-calorie malnutrition (PCM).[5] Current investigations also describe the thymus as the "barometer of malnutrition," [6] are identifying how specific nutrient deficiencies such as zinc correlate with clinical malnutrition and impaired thymic function,[7–9] and furthermore seek to know how critical molecular processes may be affected.[10]

The selective sensitivity of the thymus to nutritional injury is specifically important in the formative phases of the fetal and neonatal immune system. Recent studies suggest that prenatal nutrition and growth during the first year of life may predict thymic function in adolescence.[11] Related studies in the mouse have shown that perinatal zinc deficiency is associated with decreased immune function in later life.[10,12] It is generally accepted that age-related changes in immune response appear to stem from programmed involution of the thymus.[13] However, both reversal of thymic involution in the mouse and induction of thymulin secretion from human thymic epithelial cells have been obtained with zinc treatment,[14] suggesting that specific nutrients may act as regulatory elements by modulating cellular programs. The potential significance of early nutrition for adaptive immune response in general is also indicated by studies of mucosal immune response to antigens, such as the work of Harrod and colleagues, who have shown that experimental priming at birth ensured both a stronger and a more lasting immune response toward potential pathogens.[15]

Current thinking about the fundamental nature of immune response places major emphasis on the microenvironment. Innate immune cells such as natural killer (NK) cells and NK T cells, monocytes, and dendritic cells influence the pattern of cytokine produced by the adaptive immune system, in part by directly secreting their cytokine products into the microenvironment.[16] Neonates and infants must rely primarily on innate immunity, although some components of innate immunity are not as functional in young children as in adults.[17] Pathogens such as parasitic infections or viruses may easily compromise these resources, and if malnutrition is present, the overall development and expression of immune response are significantly impaired.[18,19] A critical hypothesis is that conditionally essential nutrient requirements may be associated with key stages of development. Settings in which conditional nutrient requirements have already been identified include surgical stress in which glutamine and arginine are required for immune recovery[20–22] and conditions of rapid growth in which the impact of dietary nucleotides can be observed.[23] Fundamental questions for the future are likely to focus on the role of host genes as well, for example, those regulating iron uptake[24,25] or cytokine and cytokine receptor gene polymorphisms.[26] The importance of host genetic polymorphisms has already been reported for infections such as tuberculosis in which malnutrition is an important risk factor.[27,28]

Host defense requires energy expenditure, and this rapidly becomes compromised in the malnourished or chronically infected host. Infections trigger initiation of the acute-phase response, affecting nutrient metabolism and modulating cytokine pathways.[29–31] The mechanisms through which nutrients affect immune functions frequently include modulation of the cytokine response and are reflected in changes in the overall cytokine pattern. Cytokines are produced in response to triggering events such as infection and cancer but are also induced in

response to a wide range of stress signals, including nutrient deprivation.[32,33] Cytokine response is essential for host defense but, if uncontrolled, can also lead to the extreme state of septic shock, causing loss of lean tissue and body fat.[34,35] To a lesser degree, some of the observed effects of malnutrition may also involve concurrent subclinical and generalized infectious processes, particularly from opportunistic pathogens acting through mediators common to the acute-phase response,[36] as illustrated in Figure 20-1. Examples include the effects of nutrient alteration on host immune response associated with human immunodeficiency virus (HIV) infection or parasitic infections.[37,38]

In this discussion, effort will be made to distinguish indirect nutrient effects, which are general and apply to all tissues, from direct actions in which lymphoid tissues and immune response are affected either disproportionately or specifically.[39] Similarly, the mechanism of nutrient action may differ according to setting and concentration. Pharmacologic use of nutrients may have immunomodulatory effects different from those exerted by smaller amounts given to achieve physiologic repletion to normal levels (see Chapter 59, "Specific Diets"). These differences may explain why supplementation above normal levels may sometimes be associated with a decline of immune response that could not have been predicted from studies of repletion.[40,41] The impact of any supplementation is also affected by conditions in the host. Presence of infection, underlying illness, or immune deficiency may also affect response to nutrient administration, and correlations observed in these settings between immune response and nutrient level may not hold true in the healthy host.

Primary nutrient deficiency occurring in children as a single entity is usually the result of poverty, lack of adequate supply, or other environmental factors.[42,43] Rare innate occurrences include the genetic defect of zinc metabolism, acrodermatitis enteropathica,[44,45] and defects of copper in Menkes' syndrome or Wilson's disease.[46,47] However, deficient intake of essential nutrient requirements may easily be caused by altered metabolism in association with an underlying congenital condition, disease, or acute illness and can also lead to malnutrition and impaired host defense. Although malnutrition is often considered as mainly an issue for underdeveloped countries, suboptimal nutrition is relatively common in children throughout the world and is a significant cause of susceptibility to infection.[48] In the changing social conditions of childhood in general and increasingly fragmented family life, knowledge of how nutrients may affect the development of immune response will have greater critical importance for preventive efforts to support future host defense against new pathogens.

MICROENVIRONMENT AND NEONATAL IMMUNE RESPONSE

The effect of nutrients on immune response can depend on the site of action, for example, the gut-associated lymphoid tissue (GALT), thymus, spleen, regional lymph nodes, or immune cells of the circulating blood (see Chapter 19, "Immunophysiology and Nutrition of the Gut").[49,50] The same nutrient may have a different mechanism of action at various sites. For example, zinc may potentiate T helper type 1 (Th1) response systemically and T helper type 2 (Th2) responses at the level of GALT.[30,51] Responses are also affected by other host factors, including the presence of infection or other illness, stage of life, age, and antigenic history.[52–54] With the principal exception of thymulin, the zinc-dependent hormone, hormonal changes have not been taken into account in studies of immune development. However, current evidence suggests that endocrine factors affect both innate and adaptive immune response.[55,56]

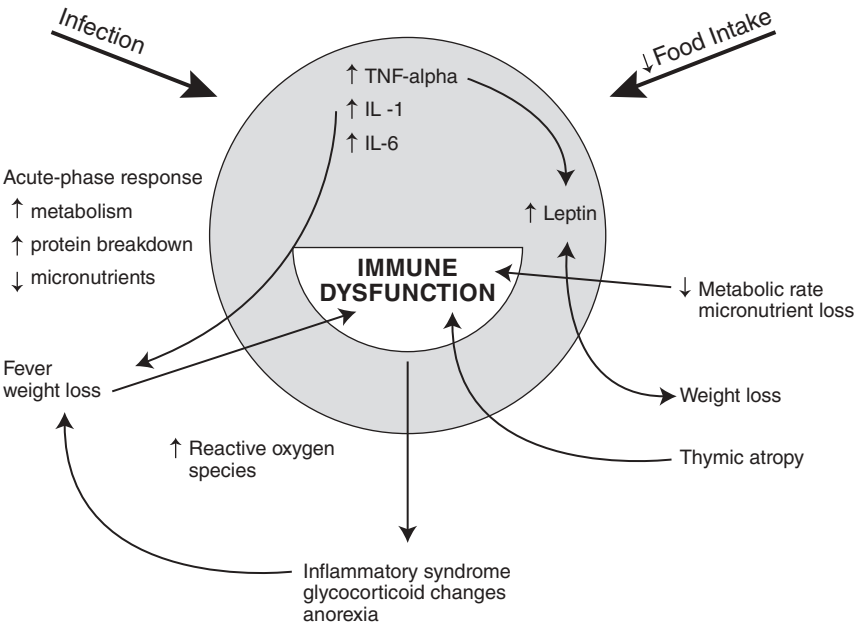

FIGURE 20-1 Illustrates some of the key interactions that lead to altered immune response in the malnourished host during infectious exposure. IL = interleukin; TNF = tumor necrosis factor.

The immune system has, until recently, been thought of as two essentially separate innate and adaptive systems responding to the evolving needs of the organism in defense against pathogens. The innate system that mediates an immediate immune reaction that is independent of specific antigens has developed to recognize microbial "nonself" through identification of conserved microbial products, pathogen-associated molecular patterns, and to know "self" by means of specific gene products. Thus, in addition to unique microbial motifs, infected or pathologically altered self can be identified as missing or altered self.[57,58] Adaptive immunity has been divided conceptually according to cell type and origin as the response of bone marrow–derived B cells belonging to the humoral immune system and thymus-derived T cells of the cellular immune system. Through antigen encounter, polyclonal T cell responses become refined to a more restricted T cell repertoire in a process that resembles the affinity maturation of B cells. Differentiation of cell function and cell–cell interactions, however, is significantly determined by the local microenvironment, for example, in the liver, immune cells such as natural T cells, which have distinct cytokine secretion patterns affecting host response to antigen.[59] Thymus-independent T-cell differentiation is also dominant in the gastrointestinal tract, as mediated by such cells as the intraepithelial lymphocyte.[60]

Micronutrients, trace elements, and vitamins present in the local environment have important regulatory effects on adaptive immune cell function. Specific nutrients such as zinc support a Th1 cytokine response in which interleukin (IL)-2 and interferon (IFN)-γ are produced, whereas other nutrients, such as vitamin A, typically support secretion of Th2 cytokines, including IL-4, IL-5, and IL-10.[30,61] Therefore, the overall effect of the microenvironment is to drive immune response toward either a Th1 or a Th2 response (Figure 20–2; see also Chapter 6, "Trace Elements").

Many nutrients interact with other immune regulatory molecules to influence immune response. Examples include the reported counterregulatory effect of vitamin E on prostaglandin E_2 (PGE_2) suppression of a cyclic adenosine monophosphate (AMP) response element binding (CREB) protein.[62] Mechanisms of nutrient action often involve several pathways and produce a range of phenotypic effects. For example, in the mouse, vitamin B_{12} (cobalamin) deficiency reduces levels of C3, immunoglobulin (Ig)M, and IgG and increases levels of IgE through causing a shift from Th1 to Th2 response.[63] Increased CD8+ T cell number and NK cell activity, as well as megaloblastic anemia, characterize human vitamin B_{12} deficiency.[64] Vitamins A and D have been intensively studied as critical regulators of gene expression for both growth and immune development. Vitamin A deficiency impedes retinol-dependent signals during embryonic development, and vitamin A supplementation enhances Th2 response to viruses such as influenza.[65,66] Vitamin D acts as a nuclear receptor for target genes and also has a regulatory influence on immune cell differentiation (see Chapter 7, "Vitamins").[67–69]

Nutrient deficiencies may have an indelible effect during critical periods of early development by exerting an imprinting effect on the fundamental program of future development. This concept, advanced by Dobbing,[70] is supported by the discovery of interactions between neonatal nutritional status and blood pressure or cognitive ability.[71,72] McDade and colleagues have now shown that prenatal undernutrition reflected in intrauterine growth retardation leads to reduced thymopoietin production.[11] The study reported that adolescents who were small for gestational age (SGA) at birth had lower thymopoietin levels when compared with control adolescents who were appropriate for gestational age (AGA) at birth. In both groups, thymopoietin level during adolescence correlated with growth in length during the first year of life.

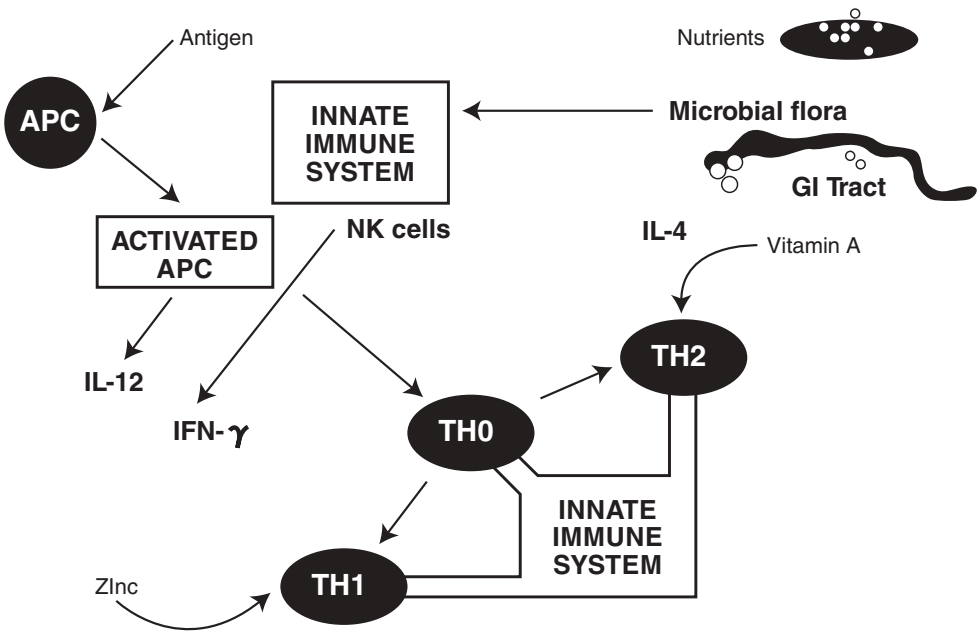

FIGURE 20-2 Indicates the role of nutrients in how the microenvironment influences the production of cytokines by the adaptive immune system. APC = antigen-presenting cell; GI = gastrointestinal; IFN = interferon; IL = interleukin; NK = natural killer; Th = T helper.

In general, impairment of cell-mediated immunity and reduction in phagocyte function are characteristic of low birth weight infants[19,73,74] Complement deficiencies are also an important cause of susceptibility to infections.[75] The development of cytokine response is crucial for the differentiation of adaptive immunity in this period.[76] Low birth weight AGA infants respond well to some immunogens such as bacille Calmette-Guérin (BCG) with respect to proliferative response to antigen, IL-2 production in vitro, and skin test response to purified protein derivative (PPD) in vivo.[77] Low birth weight infants also tolerate and respond to immunization with diphtheria-tetanus-pertussis (DTP) but do not respond effectively to *Haemophilus influenzae* type B.[78,79] Further, maternally acquired passive immunity, assessed as geometric mean antibody to viruses and to bacteria, is reduced.[80] The low birth weight infant is hypogammaglobulinemic and susceptible to nosocomial infections, but intravenous immune gammaglobulin is largely ineffective in reducing these infections.[81] Importantly, studies have also shown that the immune response of the premature infant is also affected by routine blood transfusion to replace blood drawn for clinical monitoring.[82]

A growing general concern is that nutrient intake may be suboptimal because the diseases of prematurity impose an additional metabolic burden.[83] Assessment of selenium and zinc has shown that levels are low, even when intake follows current guidelines.[84,85] Protein and lipid intake may need to be increased.[86,87] Because the development of the gut and the immune system occurs interactively, it is likely that nutrients may foster normal tolerant immune response toward food antigens. Supplementation with dietary nucleotides has been suggested as a means of beneficially affecting the growth of the gut in the premature infant through influencing intestinal permeability and absorption of macromolecules, thus affecting antibody response toward β-lactoglobulin and α-casein.[88,89] Martinez-Augustin and colleagues have found that IgG antibodies against the main antigenic proteins in cow's milk were generally higher when nucleotide supplementation was provided.[90] This difference reached significance for antibody to β-lactoglobulin at 30 days of life when gut closure had occurred. Studies by this group also suggest that IgA and IgM humoral immune response are enhanced by nucleotide supplementation.

The neonate requires micronutrients such as iron, zinc, and selenium as well as an energy-dense diet. Vitamin A is crucial for development of normal immune response and for development of epithelialization in the lung (see Chapters 6 and 7). Thus, Shenai and colleagues have shown that airway infection in the mechanically ventilated very low birth weight infant was associated with reduced plasma vitamin A.[91] Human milk normally provides bioavailable micronutrients such as zinc, as well as secretory immunoglobulin and growth factors.[92] Curiously, some maternal milk may be lacking in zinc despite normal levels in serum, and in such cases, babies may develop a condition that is phenotypically identical to acrodermatitis enteropathica.[93] Low levels of fatty acids, such as docosahexaenoic acid (DHA), in maternal milk have been found to correlate directly with low levels in malnourished children.[94] DHA is critical for visual acuity, affects postnatal brain growth,[95] and also influences immune response through inhibitory effects on the IL-2 pathway.[96] The significance of this for host defense and maturation of the immune system requires further study.

Secretory IgA antibodies in milk reactive against antigens in the maternal gut can be protective against gastrointestinal disease.[97] Recent studies show that bioactive immune mediators in milk such as transforming growth factor (TGF)-β and soluble CD14, the bacterial pattern recognition receptor, are likely to be key elements in tempering neonatal immune response.[98,99] Maternal malnutrition is associated with a decline in total milk IgA, C3, and C4 and may affect passively transferred antimicrobial defense.[100] Studies suggest that milk antibody levels are to some degree conserved, even when maternal nutrition is inadequate.[101] Maternal milk may also be important in influencing the gradual shift in immune polarity in the neonate from Th2-type pattern systemically and a Th1-type response in the GALT toward the adult pattern in which inflammatory immune response is up-regulated in the periphery and Th2 response predominates in the gut.

Changes in mucosal development occur in the neonatal period in the context of major shifts in enteral intake, microbial exposure, and immune cell maturation. Weaning is a time of enhanced risk of malnutrition and therefore of increased vulnerability to infections. Normal intestinal growth is sharply enhanced at weaning, and this is mediated through T-cell activation by food substances and microbial antigens and involves transient, localized inflammatory response. Recent studies have shown that this is accompanied by increased expression of the IL-2 receptor and expansion of α/β T-cell receptor–positive (TCR)+ cells.[102]

HOST DEFENSE IN PROTEIN-CALORIE MALNUTRITION

PCM may involve energy deficiency, protein deficiency, and vitamin and mineral deprivation (see Chapter 6). If prolonged, PCM produces wasting and stunting. PCM (or protein-energy malnutrition) encompasses a range of protein-energy deficiency states, from marasmus to marasmic kwashiorkor. Protein insufficiency alone, with or without infection, causes edema associated with hepatomegaly from fatty infiltration of the liver. The manifestations of clinical malnutrition are related to type, severity, and duration of nutritional impairment and may be subclinical, reversible, or irreversible depending on the availability of treatment, presence of other diseases or complicating disorders, and the degree of damage. A wide range of effects is observed that affect many organ systems and specific tissues, requiring integrated clinical management.[103–108] According to the severity and features at presentation, PCM is defined as marasmus, characterized by a chronic wasting condition, or kwashiorkor, which is distinguished by edema and anemia. A mixture of features of both con-

ditions and gradations of expression are frequently observed among malnourished children. Recent studies show that growth faltering actually begins very early, underscoring the need for rapid evaluation.[109]

The effect of nutrient deficiency on immune response and host defense has been primarily studied in PCM and in micronutrient deficiencies. Undernutrition, especially PCM, is clearly associated with increased susceptibility to infections and with greater morbidity from infections.[18,110] However, the proximate cause of reduced host defense and increased mortality from acute respiratory infections observed in the malnourished child is often related to a combination of factors rather than to a single factor.[111]

Both marasmus and kwashiorkor are characterized by reduced antioxidant activity, an important component of host defense. Tatli and colleagues have described reduced red cell glutathione and increased lipid peroxidation in children with marasmus,[112] whereas Reid and colleagues observed decreased erythrocyte glutathione synthesis in kwashiorkor.[113] Although the basis of edema in kwashiorkor is unclear, this is probably linked to increased levels of inflammatory cytokines, specifically IL-6 and C-reactive protein, and to the action of the soluble receptors of tumor necrosis factor (TNF).[114]

Primary malnutrition is associated with atrophy of lymphoid organs and profound immune malfunction leading to susceptibility to pathogens, reactivation of viral infections, and development of opportunistic infections.[115,116] The effect of malnutrition on T-cell maturation and thymic function is particularly important in children in whom the adaptive immune response is forming. Malnutrition leads directly to thymic involution,[8] revealing the thymus gland as the barometer of malnutrition in children.[6] As suggested by studies comparing AGA and SGA babies, prenatal undernutrition may be generally linked with thymic function in adolescence.[11] Congenital thymic absence, DiGeorge's syndrome, is associated with recurrent infections, which can be fatal. Other developmental anomalies that stem from chromosome 22q11 deletions comprising the CATCH-22 (cardiac defects, abnormal facies, thymic hypoplasia, cleft palate, and hypocalcemia) group of disorders may also have clinically significant immune deficiency in association with reduced thymic function.[117] A zinc finger gene, *ZNF74*, has been identified in the commonly deleted region.[118] Nutritionally caused thymic involution is very similar to congenital thymic aplasia in terms of effects on immune function and host defense.[8]

Lymphocyte development and differentiation are directly affected by malnutrition as a consequence of thymic deficiency. When T cells from children with severe PCM were compared with those from well-nourished children, immature differentiation was directly associated with thymic involution as measured by echoradiography.[7] Although regrowth of the thymus took longer than restoration of normal body weight when children were fed, this could be significantly hastened by the addition of zinc supplementation.[8] Thymic involution can also occur secondary to infections caused by malnutrition because the thymus is extraordinarily susceptible to stress depletion.[13]

Experimental studies show that the thymus is unusually vulnerable to programmed cell death. Studies in the genetically wasted mouse wst/wst suggest that the central abnormality may be a high or premature rate of spontaneous apoptosis in the thymocyte population.[119] Possibly related effects have been observed in rats rendered magnesium deficient by diet. In these studies, Malpuech-Brugere and colleagues found acceleration of thymic involution and apoptosis.[120] In these studies, magnesium deficiency caused enhanced inflammation and susceptibility to peroxidation in association with increased apoptosis. Recent studies by Hoffman-Goetz reported that artificial rearing without maternal factors is associated with reduced thymic cell number and weight compared with maternal rearing of rat pups.[121] These studies suggest involvement of the hypothalamic-pituitary-adrenal axis in thymic homeostasis.

Reported immunologic abnormalities in severely malnourished infants and children have been primarily related to the cellular immune system. Relatively fewer changes in overall immunoglobulin levels have been found, although IgA1 and IgA2 tend to be higher.[122] Rikimaru and colleagues undertook a systematic evaluation of lymphocyte subpopulations and immunoglobulins among normal children and children with kwashiorkor, marasmus, and marasmic kwashiorkor in Ghana.[123] IgA and C4 were higher, whereas C3 and relative B cell percentage were lower in the severely malnourished groups.

Serum levels of immunoglobulins do not predict specific de novo antibody response, and specific studies suggest that malnutrition affects some immunogens more than others. Stunting appears to be strongly associated with decreased IgG antibody response to measles.[124] Decreased C3, decreased TNF-α, and IL-6 response to lipopolysaccharide stimulation in vitro are also characteristic of malnourished children.[125,126]

Protein deprivation alone may cause reduced phagocytic activity and impaired IL-1 and IL-6 production, while sparing monocyte antigen interaction.[127] Experimental studies in the rat have suggested that low dietary protein affects the gut immune system at several levels, including mucosal IgA, secretory component, the number of IgA-containing cells, and the level of IgG. These studies were conducted in the absence of caloric restriction and could be reversed by refeeding.[128] However, the effects of a single-grain diet such as maize may also be related to metabolites of dietary constituents rather than to nutrient absence. Current thinking suggests that the high level of linoleic acid in maize in the absence of other polyunsaturated fatty acids in the diet may cause increased production of PGE_2, leading to down-regulation of Th1 cytokine production.[129]

Some of the effects of PCM might involve endocrine interaction with the immune system. Zamboni and colleagues observed high basal growth hormone (GH) levels but reduced GH receptors in malnourished children.[130] Recent studies have shown that serum leptin levels and insulin-like growth factor I (IGF-I) are reduced in both marasmus and kwashiorkor, suggesting that nutrient deprivation leads to decreased fat mass, insulin, and possibly

IGF-I, suppressing leptin, which may, in turn, stimulate the hypothalamic-pituitary-adrenal axis to increase cortisol and GH secretion.[131] Related studies have shown that GH could be used therapeutically to restore somatic and muscle growth in an experimental model of PCM.[132] In controls, an enriched diet promoted fat deposition alone. Thymic atrophy in malnutrition leads to loss of cortical CD4+ T cells. Fasting triggers this process in the genetically deleted leptin-deficient ob/ob mouse but can be counteracted by leptin administration.[133] Correlation between serum corticosterone level and thymic atrophy has been shown in a murine model of protein malnutrition.[134] Refeeding reversed this effect. These studies suggest that increases in serum corticosterone observed in PCM could also trigger apoptosis, contributing to the loss of differentiated T cells.

Although the effects of infection and malnutrition on immune response are interactive, the impact of each on immune response is also independent. A recent examination by Mishra and colleagues of graded PCM in children at risk for *Mycobacterium tuberculosis* infection included study of response to a skin test anergy panel, including PPD.[135] Impaired cellular immunity was found in all grades of malnutrition with the exception of response to PPD in grade I. Weight loss is a common presenting symptom in children with active *M. tuberculosis* infection. A recent study in adults has shown that before treatment, both leptin and TNF-α levels were elevated and intercorrelated. Although changes in body mass index (BMI) were proportional to change in leptin during treatment and weight gain was achieved early in the course of antibiotic treatment, there was no correlation between BMI and leptin before or after treatment. TNF-α levels did not change. Post-treatment leptin and TNF levels did not correlate. Thus, the underlying deregulation of leptin and TNF-α, which promoted wasting, continued to linger.[136]

PCM seriously impairs immune response to some vaccines, such as BCG. Although BCG does not prevent *M. tuberculosis* infection, immunization in endemic environments may inhibit development of invasive disease.[137] However, this protection may be largely ineffective in children with PCM, as shown in a study of immunized malnourished children who did not respond to tuberculin after immunization, became infected, and went on to develop disseminated disease. The control group of well-nourished children was skin test responsive and had a modified disease expression with greater localization and reduced hematogenous spread.[138] In contrast to the impaired reaction of malnourished children to BCG, immune response to other vaccines may be conserved. For example, seroprotection was achieved even in malnourished children with hepatitis B vaccine, although the observed frequency of protective response was reduced compared with that of healthy infants.[139]

Paradoxically, response to some pathogens may appear to be improved in some states of malnutrition. Genton and colleagues assessed incidence of malaria in children of Papua, New Guinea, and found that increased height for weight at baseline predicted incidence of malaria during the year of study, whereas lymphocyte response to malarial antigens was lower among these wasted children.[140] However, malarial incidence was not different among well-nourished compared with malnourished children when the stunted children were included in the analysis. Further, cytokine production toward malarial antigens was actually greater among the malnourished but not wasted children, suggesting that a favorable cytokine regulatory shift might be the basis of improved response. Although stunting may be considered an adaptive host response to prolonged nutrient deprivation, the stress response is negatively affected, and this would likely have a detrimental effect on immune response in acute infection.[141]

Increased incidence of infections is common in PCM. A large longitudinal study carried out over 1 year among undernourished rural Bangladeshi children has shown that wasting and skin test anergy indicating immune deficiency were linked to acute upper respiratory infections.[142] Some infections may also be pivotal in enhancing risk of malnutrition in children. Dale and colleagues have shown that *Helicobacter pylori* infection, common among Gambian children, is strongly associated with other enteric infections and chronic malnutrition in the postweaning period.[143]

MICRONUTRIENTS AND IMMUNE FUNCTION

Current studies suggest that much of the enhanced susceptibility to infections observed in PCM may be directly related to micronutrient insufficiency (see Chapters 6 and 19). This association was first recognized by Good and colleagues, who proposed that deficiency of certain key trace elements, especially zinc, might be the direct cause of immune deficiency in the malnourished host.[144] Iron, copper, and zinc deficiencies are the most common trace element nutrient deficits in North America (see Chapter 6). Selenium deficiency, like that of iodine, affects parts of the world with low levels in soil. Micronutrients are often deficient in generalized infections such as chronic viral illnesses and may directly cause impaired immune response.[145]

Low dietary intake of antioxidant nutrients can also influence response to infections and may lead to an unopposed inflammatory state. For example, *H. pylori* can lead to chronic gastritis caused by activated phagocytes. Nair and colleagues observed that patients with gastritis and peptic ulcer disease characteristically have a low level of antioxidants in both serum and mucosa whether or not *H. pylori* infection was detected.[146] Relevant studies in a mouse model have shown that treatment with antioxidants led to reduced gastric inflammation and to lowered bacterial load. Bennedsen and colleagues observed a shift from a Th1-type immune response to a mixed Th1/ Th2 response, which was dominated by IL-4 and IFN-γ production.[147]

Micronutrients have a crucial impact on immune response, both through antioxidant effects and through modulation of cytokine expression. Trace elements and vitamins perform antioxidant functions through participation in enzyme-catalyzed reactions. These reactions are essential to offset potential oxidative damage caused by free radical formation. Three antioxidant enzymes, the copper, zinc, and manganese superoxide dismutases,

require trace metals for biologic activity. In addition, micronutrients are pivotal regulators of cytokine production. Parenteral nutrient preparations may not provide adequate levels of micronutrients such as vitamin E and selenium, causing antioxidant deficiency, which may lead to lipid peroxidation, a measure of oxidative stress.[148] Table 20-1 summarizes the role of key micronutrients in regulation of immune response. The implications and significance of these functions for the development of immune response to pathogens are outlined below.

Iron

Although low iron is the most common nutrient deficiency, controversy concerning iron supplementation continues because of the possibility that iron supplementation may promote bacterial growth.[149] However, iron deficiency causes spontaneous cytokine production.[150] Iron deficiency has been implicated in chronic mucocutaneous candidiasis, and iron supplementation may support recovery from candidal infection secondary to primary immune deficiency.[151] TNF-α is a regulator of iron metabolism and has a role in the pathogenesis of the anemia of inflammation. Both iron and inflammatory cytokines regulate hepatic secretion of ferritin, which is an acute-phase protein.[152] Increased TNF-α and IL-1β production in response to lipopolysaccharide in vitro is seen in the iron deficiency anemia of infancy. Iron supplementation corrected this hyper-response.[153] Interestingly, intracellular growth of *M. tuberculosis* in the monocyte can be inhibited by iron.[154] Iron deficiency is associated with adaptive immune defects. Impaired mitogenic lymphocyte response and depressed delayed-type hypersensitivity (DTH) can be seen.[155] In a group of children with iron deficiency, almost 60% were found to have IgG subclass deficiencies. Pneumococcal polysaccharide-specific IgG1 and IgG2 were lower in these children than in healthy peers.[155]

Genetic control of iron uptake and metabolism has recently been elucidated by the discovery of the gene for hereditary hemochromatosis (HH), an autosomal recessive disorder of increased gastrointestinal iron uptake.[24] The normal gene product of *HFE*, a nonclassic gene of the major histocompatibility complex (MHC) homologous to MHC class I, regulates the metabolism and distribution of iron through affecting the binding of transferrin-bound iron to the transferrin receptor.[156] Although the incidence of HH is closely linked with homozygosity for one *HFE* mutation, the severity of disease expression is not directly associated with either gene mutation.[157,158] Recent studies indicate that a defined T cell phenotype associated with low numbers of CD8+ T lymphocytes in the peripheral circulation is linked with high iron stores.[159] Chronic, therapeutic red blood cell blood transfusion causes iron overload analogous to that of HH in β-thalassemia, a severe, congenital anemia. An analogous low CD8+ T cell phenotype has recently been observed in a large subgroup of β-thalassemia patients. The expression of this immune phenotype was independent of age and therefore did not reflect cumulative transfusion history, indicating a possible link between the immune system and response to iron.[160]

Zinc

Zinc is the most extensively studied micronutrient in relation to immune response. Secondary zinc deficiency may be a significant complication of gut disturbances such as regional enteritis, celiac disease, and diarrhea, as well as the more widely recognized settings of IgA deficiency, fetal alcohol syndrome, and the hyperzincuria of sickle cell disease. Zinc is essential for the development of normal immune function.[161] Deficiency affects the pattern of cytokine production, thymic hormone activity, and lymphopoiesis.[10,162] Nutritional replenishment with zinc-fortified formula can lead to increased DTH response, mononuclear response to PHA, and salivary IgA levels in both non–zinc-deficient and zinc-deficient marasmic infants.[163] After 1 month of zinc supplements, hemodialysis patients had increased serum zinc and B cell percentage compared with patients who received placebo, and their antibody levels to multivalent influenza vaccine were higher.[164] In a seminal investigation in which zinc deficiency was induced by diet-alone induction deficiency in healthy adult volunteers, Prasad observed decreased total CD4+ cells, ratio of naive-to-memory CD4+ cells, and Th1 cytokines,[165] and these conditions were reversed with zinc repletion.[165]

Zinc deficiency may occur as a genetically based defect of absorption in acrodermatitis enteropathica, which presents in infancy as skin lesions (acute dermatitis or hyperkeratotic plaques), diarrhea, alopecia, and increased incidence of infections caused by severe immune deficiency.[44] Although untreated disease can lead to fatal infections, all of the symptoms can be resolved with zinc therapy.[166] Zinc deficiency can also arise from malabsorption syndromes, excessive loss through hyperexcretion as in sickle cell anemia, through fluid loss, or from low intake. When zinc levels are reduced temporarily in a wide range of conditions such as prematurity, intravenous hyperalimentation, artificial feeding, and gastrointestinal disturbances, the effects on immunity range from severe thymic atrophy and profound lymphopenia to anergy in DTH skin testing to recall antigens and loss of NK cell activity.[167–169] Studies of acquired mild or marginal zinc deficiency in chronic diseases, such β-thalassemia and epidermolysis bullosa, have also shown that even modest zinc depletion is associated with significant immune impairment.[170] Zinc-fortified formulae have been used to improve both linear growth and immunocompetence, as shown by improved DTH, enhanced lymphoproliferative responses, and increased salivary IgA in severely malnourished infants.[163]

The mechanisms of zinc action include regulation of cysteine-rich intestinal protein (CRIP), a zinc finger protein for which metallothioneine serves as a source of zinc. CRIP-deficient transgenic mice show altered cytokine profiles.[171] Experimental dietary zinc deficiency leads to critical genetic changes at several levels, including the gastrointestinal tract, where differential display has shown that zinc deficiency is associated with increased expression genes coding for peptide hormones that affect fluid exchange.[51] In an experimental model of zinc deficiency using HuT-78, a human malignant T lymphoblastoid cell

TABLE 20-1 Regulatory Effects of Micronutrients on Immune Response

Nutrient	*Target Cell*	*Effect*	*Mechanism*
Zinc	T cells, NK cells, B cells	Deficiency promotes infection, impairs immune response, ↓ lymphopoiesis Required for biologic activity of thymulin Essential for antioxidant enzyme activity	Deficiency causes cytokine shifts Deficiency causes glucocorticoid mediated T-cell apoptosis Promotes Th1 response in periphery Promotes Th2 response in GALT Zinc is a T cell mitogen
Iron	T cells, monocytes	Iron deficiency causes ↓ T-cell function and cytotoxic activity Iron excess can promote bacterial growth, but iron also ↓ intracellular growth of mycobacteria	Promotes Th2 response Interacts with TNF-α Excess may suppress IFN-γ production, proliferation of T cells Excess may promote lipid peroxidation
Copper	Monocytes, T cells, neutrophils	Increases antigen presentation Deficiency leads to infections Deficiency ↓ proliferation, phagocyte activity	Modulation of MHC class II expression Affects selenoglutathione peroxidase activity Affects IL-2 receptor secretion Regulates NF-κ
Selenium	Monocytes	Deficiency suppresses antigen presentation Supplementation ↑ proliferaton, cytotoxic activity	Modulation of MHC class II expression Affects IL-2 induction Regulates NF-κB
Magnesium		Deficiency promotes neuropeptide activity SP, calcitonin gene–related peptide Thymic involution	Apoptosis leads to thymic involution SP leads to cytokine activation: IL-2, -4, -5, -10, -12, and -13 and IFN-γ and inflammatory processes
Vitamin A	T cells, NK cells, B cells promote Th2 response	Deficiency causes infections, mortality from infections, ↓ NK activity Supplementation improves gut integrity at weaning Repletion reduces morbidity, mortality from infections	Promotes Th2 cytokine and IgA production Affects keratin and mucin expression IL-2 receptor beta, IFN regulatory factor, transcription factor mRNA Affects IL-12 and IL-10 production
Betacarotene	T cells	Antioxidant/anti-inflammatory effects Low-carotenoid diet reduces T cell function	Increased production of IFN-γ and IL-4
Vitamin C	Phagocytes	Promotes phagocytic function Reduces incidence of colds associated with heavy physical stress	Increases IFN-γ response Regulates NF-κB May inhibit T-cell apoptosis
Vitamin D 1,25-dihydroxy-vitamin D_3	T cells, B cells, monocyte/macrophage/dendritic cells	Vitamin D_3 affects differentiation, maturation, and function of cells Vitamin D_3 suppresses autoimmune disease in animal models Experimental suppression of transplant rejection	Functions through a nuclear receptor, vitamin D receptor that binds to response elements in target genes (many) Modulates MHC class II Affects differentiation of monocytes Regulates cytokine secretion Transcriptional modulator of IFN-γ gene
Vitamin E	T and B cells, monocytes	Enhances response to vaccine Improves skin test response	Modulates cyclic AMP response element binding proteins Affects prostaglandin production

AMP = adenosine monophosphate; GALT = gut-associated lymphoid tissue; IFN = interferon; Ig = immunoglobulin; IL = interleukin; MHC = major histocompatibility complex; mRNA = messenger ribonucleic acid; NK = natural killer; NF = nuclear factor; SP = substance P; Th = T helper; TNF = tumor necrosis factor.

line, slower cell growth with cells remaining in S phase and not entering mitosis was detected. This was likely owing to decreased messenger ribonucleic acid production of IL-2, IL-2 receptor antagonist, and impaired NF-κB nuclear binding.[165] Zinc deficiency can promote the survival of intestinal parasites through impaired IL-4 production, leading to reduced IgE and IgG.[172] Thus, zinc deficiency may affect the Th1-type response systemically and the Th2-type response at the level of GALT in response to the regulatory influence of local conditions.

Copper

Because zinc competes with copper for gastrointestinal uptake, increased zinc intake may sometimes induce copper deficiency, causing neutropenia.[173] Copper deficiency can also impair immune response. In genetic copper deficiency, Menkes' syndrome, death is often related to intractable infections.[174] Reduced copper affects growth of lymphoid cell lines leading to reduced activity of the antioxidant enzyme superoxide dismutase and increased cellular damage associated with impaired mitochondrial

activity and calcium efflux, thereby affecting the cell membrane.[175] Copper also interacts with iron because ceruloplasmin, which contains most of the plasma copper, is a ferroxidase. Ceruloplasmin facilitates release of tissue iron into plasma by oxidizing ferrous iron into ferric iron, which is then bound to transferrin for delivery to the bone marrow for hematopoiesis. High intake of iron, zinc, and manganese can interfere with copper absorption; these interactions may also have an impact on immune response.[176] Although copper is an essential nutrient, clinical copper deficiency is rare. However, short-term dietary depletion in volunteers achieved by means of a low-copper diet was found to cause reduced immune cell proliferative response and diminished IL-2 receptor secretion in response to activation in vitro.[177]

Selenium

Selenium is a key part of the antioxidant enzyme glutathione peroxidase, which maintains the redox state of a cell and catalyzes the conversion of peroxides to nontoxic alcohol. Selenoproteins are an important component of the antioxidant host defense system.[178] Selenium affects neutrophil function and has a role in the initiation of leukocyte adherence to endothelium.[179] A nutrient intervention study has demonstrated an overall survival benefit from supplementation with betacarotene, vitamin E, and selenium among subjects in a region of China with increased stomach cancer incidence, generally low micronutrient intake, and selenium-deficient soil.[180] This benefit was primarily attributable to lowered mortality from stomach cancer. A study of selenium supplementation in healthy volunteers has reported an increase in both proliferative response and cytotoxic effector cell activity.[181,182] Reduced immune response in patients on parenteral nutrition secondary to voluntary selenium depletion has been shown to improve following selenium repletion.[183] A relationship between low selenium level and deficient immune response is observed in children with HIV infection.[184] Selenium supplements did enhance IL-2 production and improve Th cell function in this setting.[185]

Antioxidant Vitamins

The antioxidant vitamins E, C, and A and the precursor of vitamin A, betacarotene, are cofactors in immune response (see Chapter 7). Plasma vitamin E levels are observed to correlate significantly with proliferative response of both T and B lymphocytes in vitro and with resistance to infection.[186] Selenium and vitamin E interact in the development of antioxidant host defense because vitamin E is the major lipid-soluble antioxidant in serum and cellular membranes. Vitamin E appears to influence T-cell function through effects on PGE_2.[187] New studies show that the mechanism of action involves the CREB proteins. Vitamin E appears to enhance CREB2 protein expression and to down-modulate the effect of PGE_2 on CREB1 expression.[62] Murine studies show that deficiency of either vitamin E or selenium may lead to a change in the viral phenotype of coxsackievirus B from nonvirulent to virulent.[188]

Vitamin C supplementation may lead to increased levels of plasma glutathione levels.[189] Vitamin C has been successfully used to treat recurrent furunculosis and was found to restore deficient neutrophil function.[190] Vitamin C appears to lower the incidence of colds among persons under acute physical stress who were prone to upper respiratory tract infection.[191] Ascorbic acid has been shown to suppress HIV viral replication activated by cytokines.[192,193] A recent study indicates that ascorbic acid may inhibit T-cell apoptosis.[194]

Carotenoids have significant effects on immune function and appear to enhance host defense against tumor development.[195] Some studies have shown that betacarotene supplementation affects human immune cells.[196] A low-carotenoid diet may reduce T lymphocyte function.[197] One report suggests the possibility that differences in the physical location of carotenoids in lymphocyte subsets might be the basis of some functional effects.[198]

Although vitamin A is not a particularly efficient oxygen quencher, this micronutrient is emerging as a critical cofactor in host defense. Vitamin A is important for mucosal and epithelial growth. Deficiency of vitamin A can lead to impaired T-cell responses to mitogens and antigens both in vivo and in vitro and is closely associated with risk of infections.[166,199] Vitamin A deficiency may have a promoting effect on measles, *Rotavirus*-associated diarrhea, and progression of HIV infection.[200] Effects on the immune system include reduced antibody response, impaired NK cell activity, and decreased IFN production in the rat.[201,202] Supplementation appears to enhance the development of the humoral immune response.[203]

The causes of human vitamin A deficiency include altered metabolism, either through increased use or increased loss, as suggested by a study of Peruvian children in which diarrhea and low serum retinol were closely linked.[204] Another study in which vitamin A supplementation was given to children in China to prevent diarrhea and respiratory disease showed a reduction in incidence of both conditions that was greater than twofold in the treated compared with the untreated control group of children.[205]

Semba and colleagues have proposed that vitamin A works specifically through support of Th2 cytokine induction.[206] In Lewis rats, low vitamin A intake was associated with decreased ratio of CD4+-to-CD8+ cells and decreased IL-2 production.[207] Pharmacologic levels of vitamin A were able to reverse the effect of protein deprivation in mice, including decline of IgA, IL-4, and IL-5 production, and also to enhance response to immunization.[208] Vitamin A is critical for differentiation of many tissues acting through association with cellular cytoplasmic proteins and nuclear receptors.[65] The effects of vitamin A deficiency can be profound in fetal life, leading to numerous embryonic abnormalities, for example, renal malformations. The vitamin A signal is transduced by nuclear retinoic acid receptors allowing vitamin A control of epithelial mesenchymal interactions.[66]

Vitamin A supplementation studies have largely addressed the potential for support of antibody response. Given a placebo-controlled trial to study the effect of vitamin A supplements, Bangladeshi infants were randomized

to receive either vitamin A or placebo with each of the three DPT/poliovirus vaccine live oral immunizations. Compared with the placebo group, infants who received vitamin A supplementation and also achieved normal retinol levels were more likely to exhibit positive cell-mediated immunity in DTH testing.[209] Similary, children with mild vitamin A deficiency who were asymptomatic or who had mild xerophthalmia showed significantly higher IgG and IgG1 responses to tetanus immunization after vitamin A supplementation.[210,211] On the other hand, higher tetanus titers were not observed in a different group of children given vitamin A with each DPT immunization, although diphtheria titers were increased.[212]

Vitamin A has been used to enhance response to viral vaccines. Concomitant administration of vitamin A along with measles vaccine improved seroconversion rates in some studies.[213] Other investigators found no improvement except among malnourished infants.[214] Reduced secretory IgA and response to measles and polio vaccines associated with vitamin A deficiency have been successfully treated with supplementation.[215] Interestingly, the potential efficacy of vitamin A supplementation has been examined in conjunction with influenza vaccination in children with HIV infection. In these studies, there was no impact on response to influenza. However, the anticipated increment in HIV viral load after immunization was blunted.[216]

MALNUTRITION AND CHRONIC INFECTION

Impaired host defense in the malnourished often leads to a failure to respond optimally to childhood immunization and increased susceptibility to infectious pathogens. Poor response to immunization may be attributable to an inability to develop appropriate humoral and cell-mediated responses to foreign antigens and/or an inability to maintain the capacity for such responses. The extent of this parameter immune deficiency is suggested by a 70% rate of cutaneous skin test anergy in one study of children with marasmus, marasmic kwashiorkor, and kwashiorkor.[217]

Chronic undernutrition often occurs in environments with a high prevalence of enteropathogens in water, which leads to compromised mucosal immunity, which is especially dangerous for infants and children. During fetal and early neonatal life, the development of gut mucosal immune defense may be easily compromised by undernutrition and lead to susceptibility to severe infection.[110] Chronic infection commonly involves malabsorption and malnutrition that is associated with altered cytokine patterns affecting both regional and systemic or immune response and alters metabolism and growth.[36,37]

Nutrient metabolism provides an essential stimulus for the induction, differentiation, and maintenance of the mucosal immune system,[218] which is compromised by prolonged illness and reduced dietary intake. Lack of enteral dietary intake impairs mucosal IgA and secretory component production, the number of IgA-containing cells, and the level of IgG, as shown in recent studies.[49,219] The enteral route of nutritional intake promotes mucosal growth.[220] Loss of this stimulation is associated with immune suppression. Current studies show that provision of glutamine, arginine, certain combinations of n-3 polyunsaturated fatty acids, and dietary nucleotides are critical for recovery of mucosal immune function.[221]

The catabolic state imposes a strict requirement for normally nonessential amino acids, specifically arginine and glutamine. These must be supplied acutely to promote cellular proliferation in the gut and T-cell production and to protect against the development of host defense against infection, as well as to restore nitrogen balance. Glutamine use is highly increased in proliferating immune cells, and reduced availability directly limits immune response.[22] Glutamine stimulates a Th2-type cytokine response, leading to increased IL-4 production and an increase in mucosal IgA level,[222] which improves both GALT and respiratory tract immunity. Arginine has a similar function and, in experimental studies, modulated monocyte production of TNF-α.[223]

Nutrient Deficiency and HIV Infection

Weight loss is a common occurrence in chronic viral illness. Infection-induced malnutrition, as discussed above, is primarily cytokine mediated and occurs through the initiation of the acute-phase response. Fever, cellular hypermetabolism, and various endocrine and metabolic changes eventually lead to catabolism and gluconeogenesis. These are accompanied by multiple effects on metals and minerals such as fluxes of iron and zinc and cause losses of nitrogen, potassium, magnesium, phosphate, zinc, and vitamins. This process is accompanied by retention of salt and water. Malnutrition may occur early during the asymptomatic phase of HIV infection, especially in children,[224–226] in whom growth failure may be a presenting symptom.[37] Malnutrition in the late stages of acquired immune deficiency syndrome (AIDS), in the absence or failure of effective antiretroviral treatment, is closely linked to poor survival and to lower CD4+ T-cell level.[227] Response to intravenous nutrition is not impaired in the early stages of disease, and repletion of body mass through parenteral nutrition is effective in patients who have malabsorption without serious ongoing systemic disease.[228]

Trace elements and micronutrient levels are fundamentally significant for the HIV+ host response as a consequence of the need for enhanced antioxidant defense. Reactive oxygen species generated through either HIV replication or host response can damage tissues and can also up-regulate genes involved in the inflammatory response. One of these, NF-κB, is an important regulator of HIV replication.[229] Several studies have shown that micronutrient impairment is causally associated with the course of HIV infection and that there is a crucial impact on immune function.[230–233]

One key factor is iron status. The anemia of HIV infection is characterized by iron deficiency, poor erythropoietin response, reduced number of red cell progenitor colonies, and other abnormalities of reticuloendothelial iron metabolism.[234] Both iron deficiency and iron overload may affect

erythropoietin function through differential effects on Th function and cytokine patterns.[235] Whereas iron deficiency secondary to malabsorption is common in HIV infection,[236] iron overload also occurs frequently and is reflected in high serum ferritin and red cell ferritin.[237] The cytokines that mediate these effects include TNF-α, a powerful activator of NF-κB, which, in turn, is a critical activator of HIV replication. HIV replication leads to production of HIV tat protein, which further shifts the cellular milieu toward a pro-oxidative state by down-regulating the manganese-dependent superoxide dismutase.[238] Interestingly, iron chelation can be effective in blocking HIV replication.[239] The presence of oxidative stress in HIV infection has also been shown as increased lipid peroxidation.[240] This appears to be directly linked to reduction in levels of antioxidant trace elements and vitamins. Recent studies in HIV-infected persons support this connection showing that vitamin E and C supplementation led to reduced lipid peroxidation and also lowered viral load in the treated group compared with the untreated group.[241] The most commonly identified alterations in trace element and mineral levels in HIV infection involve zinc, selenium, and magnesium, with losses of selenium and zinc showing a relationship to clinical course.[185,230–233] Skurnick and colleagues found that use of supplements was associated with a better level of antioxidant micronutrients in HIV+ persons but that almost one-third of patients on supplements had reduced levels of at least one nutrient.[232] Vitamins A, C, E, and B_{12} and carotenoids are also frequently reduced.[242]

Trace elements such as zinc and selenium decline in HIV disease as lipid peroxidase levels increase, and this low status may persist at a later stage of disease, when polymorphonuclear leukocyte production of lipid peroxidases decreases. Look and colleagues found a strong correlation between the stage of clinical disease and reduced selenium such that selenium levels were positively correlated with CD4+ T-cell count and negatively correlated with TNF-α levels.[243] Furthermore, coinfection with hepatitis C virus was associated with further reduction in selenium levels. Other studies have shown that there is a correlation between very low selenium levels and morbidity.[230] The relationship between low selenium level and deficient immune response was also observed in children with HIV infection before the advent of highly active antiretroviral therapy.[184]

Vitamin A deficiency has been associated with maternal HIV transmission and as an etiologic factor in mortality from infections in general.[244–246] Assessment of vitamin A in children congenitally exposed to HIV has shown that higher proportions have levels less than 20 μg/dL, the lower limit of normal.[247,248] Semba and Tang have shown that vitamin A supplementation reduces morbidity and mortality in a wide range of bacterial and viral infections, including HIV infection.[242,249] These studies suggest that reduced levels of *trans*-retinol might compromise immune response in children congenitally exposed to HIV who are not infected. For example, these reduced levels may affect response to usual childhood immunizations or other environmental pathogens.

Host Defense against Endemic Infection

The interrelationship between parasitic infections and host nutritional status has been the object of speculation and scientific investigation for at least six decades.[250–252] The difficulty in unraveling these relationships is a consequence of the heterogeneity of human parasites, their varied life cycles, the pathology they evoke from their host, and the complexity of host immune responses to parasitic infection. The relationship among parasitic infection, malnutrition, and host immune response is also complex because parasitic infections (like all infections) not only contribute to malnutrition and reduced host immune response but are also affected by host nutrition. Intestinal parasites may irritate the intestinal tract and cause symptoms, including inflammation and loss of appetite. Intestinal protozoa that damage the intestinal tract may impair host nutrition directly as a result of inflammatory or non-inflammatory diarrhea, resulting in the loss of nutrients and micronutrients (eg, *Blastocystis hominis*, *Cryptosporidium* spp, *Entamoeba histolytica*, *Microsporidia* spp, *Giardia lamblia*). The acuteness of symptomatic infection (eg, amebiasis), diagnostic difficulties with some of these organisms (eg, *Cyclospora*, *Cryptosporidium*, *Microsporidia*), and the recognition only recently of the pathogenicity of some of these organisms (eg, *Cyclospora microsporidia*, *B. hominis*) may explain in part the emphasis of early nutrition studies on the importance of intestinal helminths as a cause of malnutrition in children.

The role of intestinal hookworms (*Necator americanus* and *Ancylostoma duodenale*) in the cause of anemia has been well documented.[38] Blood loss occurs from the worms feeding on the intestinal mucosa and is directly proportional to the intensity of infection. Even a modest infection of *N. americanus* can result in blood loss that exceeds physiologic daily requirements. Light infections of *A. duodenale* may cause severe anemia in an infant that is difficult to correct with iron supplementation alone.

The relationship of hookworms and other intestinal helminths (eg, *Trichuris trichiura*, *Ascaris lumbricoides*, *Strongyloides stercoralis*, *Enterobius vermicularis*) to other forms of nutritional impairment (eg, growth stunting, protein/caloric malnutrition, avitaminoses) has been more controversial and difficult to elucidate. Heavy infections with *Ascaris* may result in malabsorption, mild anemia, wasting, and poor growth. The worm metabolizes vitamin A, and heavy infections have been associated with vitamin A deficiency. Anemia and wasting are common in heavy infections with *Trichuris*, but light-to-moderate infections are not felt to result in significant blood loss. Strongyloidiasis causes abdominal pain and diarrhea, but hyperinfection with *S. stercoralis* has profound nutritional consequences resulting from severe diarrhea, malabsorption, and wasting.

Impairment of food absorption from sheer parasite bulk and heavy (quantitative) infection with intestinal helminths was postulated by Jelliffe.[251,252] In addition, Jelliffe and Jung also observed that heavy *Ascaris* worm burdens were frequently associated with signs of avitaminosis, including Bitot's spots, follicular keratitis, lusterless and scaly skin, and dry, light-colored hair.[253] They suggested

that the adult worm, especially the parturient female producing 200,000 eggs/day, competed directly with the host for essential nutrients. Others have proposed different adverse mechanisms, including absorption of nutrients through the worm cuticle, the elaboration of toxins, trauma to the intestinal mucosa, anorexia, and vomiting. Also of concern to early helminthologists were parasite factors that influence pathogenicity, morbidity, and mortality in the host: population density, mode and pattern of entry, virulence and adaptation to the human host, responses to intercurrent and associated infections, and responses to the "modified host."[254] Beaver emphasized the not universally accepted helminthologic principle that worms in small numbers are relatively well tolerated but that heavy and massive infections cause signs and symptoms that are characteristic of each specific infection, such as malabsorptive syndrome in ascariasis.[254] The quantitative assessment of disease-producing levels of infection and the quantitative impact of parasitic infection on protein, vitamins, and other nutrient elements have been the object of intense study during the past three decades. Large studies of schoolchildren in Kenya have demonstrated the adverse effects of ascariasis on child growth and development, as well as the beneficial effects of periodic deworming.[255–257]

More elusive is the interrelationship between parasite and host nutrition of tissue protozoa; tissue nematodes, filarial worms, and other helminths; flukes; and cestodes. An exception is schistosomiasis, which has long been known to have serious nutritional consequences. Both urinary (*Schistosoma haematobium*) and intestinal infections (*Schistosoma mansoni* and other species) cause significant blood loss. Intestinal infection results in severe pathologic lesions with accompanying malabsorption, protein loss, and anemia. Additional nutritional compromise results from the liver damage found in advanced schistosomiasis. As with hookworm, adverse nutritional consequences of schistosomiasis are related to the intensity of parasitic infection.

Malaria causes the most serious nutritional consequences of any major parasite.[38] It causes hypochromic, microcytic anemia, but this is not associated with iron deficiency, except in the case of hemoglobinuria that occurs with blackwater fever (*Plasmodium falciparum*). Anemia also results from rapid hemolysis and in cases of chronic malaria (*P. ovale*, *P. malariae, P. vivax*). Erythroid recovery from malaria requires increased amounts of folate. The malaria parasite infects the placenta of pregnant women, compromising blood flow to the fetus, and increases the risk of low birth weight among infants in developing countries. Additionally, malaria is associated with PCM in the pregnant or lactating woman and in young children, which may be caused by increased caloric requirements secondary to chronic, recurrent fever and the acute-phase cytokine response. Clinical illness also causes vomiting and anorexia, which produce adverse nutritional consequences in an already fragile child or pregnant woman.

During the past two decades, new developments in in vitro culture techniques for T lymphocytes have resulted in new understanding of cellular immune responses in parasitic infections.[258,259] A variety of immune mechanisms are elicited in helminthic infections (antibody-independent macrophages, antibody-dependent granulocyte killing), and central to this immune mechanism is a balance between Th1- and Th2-type responses, which is biased strongly toward the type 2 pathway.[260,261] The balance between the host immune response and parasitic strategies for survival is one that centers on host expulsion of the worms versus persistence of the worms and their products.[262] The results are critical for both the production of host pathology and survival of parasite progeny. The protective effect of IL-4-dependent expulsion of intestinal nematodes involves regulation of TNF and operates by mechanisms other than merely gross degradation of the parasite's environment through immune enteropathy.[263] There are essentially three major types of hypersensitivity responses to helminth infection accounting for most immunopathology: (1) DTH Type I, mediated by Th1 cytokines; (2) DTH Type II, which is mediated by the Th2 cytokines IL-4 and IL-5 and leads to eosinophilic granuloma formation; and (3) DTH Type III, which is associated with IL-4 and TGF-β and leads to fibrosis. In addition, there are down-regulatory effects associated with Th2-type cytokine expression.[264] This may be considered an evasive strategy that helminth parasites have developed against host-mediated cytokine response.[265–267]

Zinc deficiency impairs immune response to intestinal nematode infections at both the systemic and the intestinal level.[172] Conversely, infection itself can alter host nutritional status with respect to zinc. Diarrhea promotes zinc loss, and oral zinc has been used prophylactically and therapeutically to treat diarrhea. An indirect relationship also appears to occur between body zinc levels and infection with *G. lamblia*, although it is unknown whether low zinc levels predispose to giardiasis or whether the parasite depletes body zinc levels.[268] On balance, studies show that CD4+ T cells are critical for host protection and that IL-12 and IFN-γ inhibit protective immunity because Th2-type response is required for protection. In particular, IL-4 is required for host protection, can limit severity of infection, or can induce ancillary protective mechanisms. However, it is important to note that some cytokines that are stereotypically produced in response to gut nematode infections fail to enhance host protection against the eliciting parasite.[269] The nutritional status of children is affected by the symptoms of parasitic infections, for example, protein-losing enteropathy, and this also has a direct effect on the ongoing immune response toward parasitic infections, as shown by studies on the IgE response against *A. lumbricoides*.[270] Indeed, protein malnutrition may actually increase the survival of nematode parasites by decreasing gut-associated IL-4 (Th2) and increasing IFN-γ (Th1), leading to reduced intestinal and systemic Th2 effector responses.[271]

Further, proinflammatory cytokines initiated during acute-phase response to infection act to elicit cellular responses throughout the body, and nutrients are lost during any generalized febrile infections. IL-1, IL-6, TNF, and IFN-γ are particularly important in this response. Symptoms associated with the acute phase include fever, malaise, myalgia, arthralgia, anorexia, nausea, vomiting,

somnolence, weight loss, and loss of nitrogen and intracellular ions and minerals. Energy expenditure increases at the same time that the infected host experiences a decrease in intake, and diarrhea may result in decreased intestinal absorption of nutrients.[36]

Humoral immune response may play a more important role than cellular immune response for some parasites, such as *G. lamblia*. Furthermore, the evaluation of immune response to intestinal parasites is complex because polyparasitism is common, and the presence of other parasites in the stool may suppress both the type and number of other parasites present.[272] Age-related seropositivity of antibody to *G. lamblia* and other parasites may vary widely for children living in different areas and under different environmental conditions, possibly resulting from different levels of sanitation, water contamination, and person-to-person transmission.[273] A recent study of *G. lamblia* infection in infants and young children reported significant variations in the humoral immune response of children from different clinical settings. Children in a daycare setting with good hygiene habits and asymptomatic infections, children from a poor, farming community with *Giardia*-associated diarrheal episodes, and infants followed since birth in a community with universal *Giardia* infection by 2 years of age were compared.[274] Although the level of *G. lamblia*–specific IgM antibody results from exposure to the parasite, the development of sustained levels of specific IgA antibodies may require recurrent exposure to the parasite,[275] as commonly occurs in developing countries where infection is common and reinfection frequent.[276] Studies of children with chronic *Giardia* infection have suggested an impaired IgA response to *Giardia* heat shock antigen in affected children and an ineffective switch from an IgM to an IgG or IgA response.[277]

The immune response to protozoa such as *C. parvum* and *C. cayetanensis* has not been studied as extensively. The significance of these parasites in immunocompromised patients (eg, HIV-infected individuals with AIDS) supports an important role for T cell–mediated immunity. The role of specific antibodies is not yet clear. The persistence of protracted diarrhea owing to *C. parvum* infection in a group of HIV-infected individuals with lower CD4+ lymphocyte counts, despite high levels of both serum and secretory antibodies, suggests that specific secretory antibodies are not sufficient to control infection of the intestinal mucosa by this organism.[278]

In summary, susceptibility to parasitic infections is enhanced by malnutrition, and malnutrition can attenuate host response and promote parasitic survival. Most parasitic infections are subclinical and chronic in nature, and often only the most severely malnourished individuals (usually women and children) seek medical care, even though the majority of the population experiences undernutrition and growth stunting or growth retardation.

CHAPTER 21

BRAIN DEVELOPMENT

Maureen M. Black, PhD

Nutritional deprivation is a major international concern. In some low-income countries, over 20% of newborns begin life with a birth weight below 2,500 g and up to 50% of the children under 5 years of age experience moderate and severe underweight.[1] Without adequate nutrients, children's expected rate of weight gain falls off, leading to wasting, followed by a decline in their rate of linear growth, leading to stunting. Thus, millions of children experience nutritional deficiencies that are severe enough to interfere with their early growth.

This chapter examines the relationship between nutritional deficiencies and brain development in children, primarily manifested as child development. It reviews the history of research linking nutrition and children's development, methods used to study child development, and the evidence linking nutrition and child development, with an emphasis on micronutrient deficiencies. Finally, recommendations are made to reduce the burden that children experience from nutritional deficiencies. A review of the potential role of dietary fatty acids and neurodevelopmental status is included in Chapter 5.1, "Macronutrient Requirements for Growth: Fat and Fatty Acids."

HISTORICAL CONSIDERATIONS

The association between nutritional deprivation and child development has been a topic of interest for over 40 years. Initially, investigators focused on protein-energy malnutrition (PEM), caused by a lack of calories. Undernourished children adapted to the lack of calories through a decline in their rate of growth. First, they experienced a decline in their relative weight for height, followed by a decline in their height for age. Thus, wasting served as a marker of acute nutritional deprivation, and stunting was a marker of chronic nutritional deprivation. During the acute phase of nutritional deprivation, children have been described as lethargic, apathetic, and inactive, with poor performance on measures of cognitive functioning.[2,3]

Most of the research has addressed the long-term consequences associated with early nutritional deprivation. Guided by findings from animal research that nutritional deprivation leads to structural changes in the developing brain,[4] investigators used functional assessments, such as intelligence quotient (IQ) or performance tests, to determine whether previously nutritionally deprived children recovered or experienced long-term consequences. Most investigators used case-control, retrospective designs to study children with a history of nutritional deprivation and compared their performance on tasks with the performance of adequately nourished children.

Changes in height over the past century illustrate that the influence of individual factors on children's development cannot be considered in the absence of environmental factors. Although individual differences in height are determined largely by heredity, environmental influences, such as access to healthy nutrition and medical care, have contributed to the increase in the average height of adults.

Nutritional deprivation often occurs in the context of poverty. Most investigators handled socioeconomic differences in study populations by recruiting comparison children from similar socioeconomic backgrounds, matched on variables such as maternal education. Little attention has been directed to individual differences or how children's response to nutritional rehabilitation may vary by environmental characteristics. Recent advances in nutrition, animal research, behavioral neuroscience, and child development have had major impacts on the investigation of nutritional deprivation and child development.

NUTRITION

Although PEM continues to be a prevalent problem, especially in low-income countries, recent evidence suggests that micronutrient deficiencies may have greater specificity in children's development. Micronutrients represent small quantities of essential vitamins and minerals that promote healthy growth and development. Because they are not produced by the body, they must be acquired either through the diet, fortification, or supplementation. The relationship between micronutrient deficiency and early cognitive development has captured recent attention because micronutrients are related to specific physiologic and neurologic processes.[5]

Micronutrient deficiencies are a critical concern among children throughout the world. Iodine, iron, and zinc have been linked to cognitive processes in infants and young children and are addressed in this review. Approximately 30% of the world's population live in iodine-deficient areas and 25% of the world's children under age 3 years have iron deficiency anemia, with higher rates in developing countries.[6] When iron deficiency without anemia is considered, rates are even higher.[7] Less is known about rates of zinc deficiency. Estimates from dietary intakes of children from developing countries suggest high rates of zinc deficiency among infants and toddlers,[8] and low zinc intake may be common among middle-class infants and toddlers in America.[9]

Animal Research

Animal models, primarily rats, have been widely used in research linking nutrition to cognitive functioning. Much of the neurologic development of rats occurs postnatally, enabling investigators to study the timing and chronicity of nutritional deprivation.[4] In the past, animal researchers often experienced difficulty disentangling the environmental and nutritional effects on young animals. Many of the techniques used to introduce nutritional deprivation (eg, increasing the number of infants for a mother to feed, decreasing access to the mother, feeding the mother a low-nutrient diet, ligating the mother's nipples) altered mother–pup interaction and the social environment, thus confounding the research. Through innovative designs, such as the introduction of artificial feeding, investigators were able to vary both nutritional intake and environmental stimulation.[10,11] Animals who experienced both nutritional and environmental deprivation tended to have worse performance than animals deprived in only one condition, suggesting that the environmental stimulation may have "buffered the worse effects of the undernutrition."[10] Levitsky and Barnes described the process whereby nutritional deficiencies are partially mediated through caregiving behavior as functional isolation.[12] Thus, in addition to the direct effects of nutritional deprivation, undernourished animals who are unable to elicit environmental stimulation may also be denied the environmental enrichment that promotes development.

The recognition that the link between nutritional deprivation and intellectual performance depended on non-nutritional factors and could be influenced by environmental stimulation had an important impact on research involving nutritionally deprived children. It illustrated the necessity of incorporating caregiving variables, such as the quality of parent–child interaction, into models of child development rather than merely controlling for socioeconomic differences.[13]

The timing of nutritional deprivation has been a particularly relevant question in animal research because early investigations were guided by the sensitive period hypothesis that developing organs deprived of essential nutrients would experience irreversible structural damage.[4] Although some changes induced by nutritional deprivation remain following rehabilitation, particularly related to myelin (the fatty substance that surrounds nerve cells and aids with transmission), neuronal mitochondria, and neurotransmitter metabolism,[10] many structural changes can be reversed with nutritional rehabilitation.[14] The cerebellum and hippocampus were thought to be particularly vulnerable to nutritional deprivation because substantial growth occurs postnatally. However, evidence has challenged this assumption.[10]

In a review of 165 animal studies, there were no consistent findings of long-term consequences to cognitive functioning.[15] Smart concluded that following rehabilitation, nutritionally deprived animals are compromised in their ability to run complex mazes, perform tasks requiring visual discrimination, and extinguish learned responses. Their cognitive flexibility is limited, thereby inhibiting their ability to shift to new cognitive tasks and giving them a "tendency to perseverate."[10] However, rehabilitated animals are not impaired in all tasks (eg, spatial learning, active avoidance, and left/right discrimination) and, in some cases, achieve better performance than adequately nourished animals, particularly when performance is tied to a food reward.

Rehabilitated animals with a history of nutritional deprivation appear to be at risk for changes in their emotionality, motivation, anxiety, and cognitive flexibility. These behaviors are evidenced by increased spilling, hyperreactivity to unfamiliar stimuli, increased aggression, and the like and may interfere with performance on cognitive tasks. Levitsky and Strupp explained that early malnutrition may alter neurochemical receptor systems and result in "a decreased ability of adrenergic receptors to exhibit down regulation," which may result in a "diminished ability to adapt to stressful situations."[14] A recent study among stunted school-aged children with an early history of undernutrition showed an altered stress response, as indicated by elevated cortisol levels, heart rates, and urinary epinephrine.[16] Although the findings from the early animal studies linking nutritional deprivation to brain development and cognitive performance have not been as clear as originally hoped, they have made important contributions to research with children by highlighting the importance of the contextual environment and the role of emotionality, motivation, anxiety, and cognitive flexibility.

Behavioral Neuroscience

Recent advances in behavioral neuroscience have shown the important role that experiences play on brain development, particularly synaptic formation.[17] Brain development begins prenatally and continues through school years. It begins with the formation of brain cells, followed by cell migration and differentiation, and the development of synapses to enable cells to communicate with one another. Finally, the supportive tissue (myelin) is formed to protect the nerve cells and facilitate communication.[18]

The process of forming and eliminating synapses occurs throughout the developmental period and is influenced by experiences.[18] Greenough and Klintsova argued for the distinction between two types of experiences: experience expectant and experience dependent.[19,20] Experience-expectant development refers to species-specific

development, such as sensory and motor systems. The maturational influences that guide development are operationalized by experiences that are expected, such as adequate nutrients. Nutrients, like other experiences, "influence the brain by causing chemical changes within cells that influence cell function and structure."[18]

In contrast, experience-dependent development occurs by experiences that are unique to the individual. They enable individuals to adapt to specific cultures and the demands of their environment. When individuals are denied these experiences (eg, through sensory deficits or lack of nutrients), they may not develop the synapses necessary for optimal functioning. The structural changes in synaptic formation appear to be dependent on neurochemical receptor systems that, in turn, are influenced by experiences as basic as caregiving.[18]

The timing of early developmental experiences has been a central issue in studying behavioral neuroscience. The critical or sensitive period hypothesis suggests that if an event, such as nutritional deprivation, occurs during a specified period of time, often during a period of rapid development, it will have specific effects on the organism.[4] Developmental scientists often prefer the term "sensitive" period rather than "critical" period because it implies less rigidity.[21] In addition, because components of the central nervous system develop along differing schedules, it is likely that the sensitive periods of the components vary. Although there are examples of sensitive periods, particularly in the animal research, there is limited evidence to support the notion of sensitive periods related to experiences in human development.[21]

Child Development

Child development refers to the orderly progression of skills that children acquire as they mature and adapt to their specific caregiving settings. Although there are universal aspects of child development, particularly early in life as children gain motor skills and learn to roll over, sit, stand, and walk, there are also individual differences in the acquisition of skills. In addition, there are culture-specific aspects of child development that depend on specific interactions that children have with their caregivers. For example, children learn to understand and speak the languages that they hear in their household.

The transactional system provides a useful framework for understanding the link between nutrition and early child development because it emphasizes the interplay that occurs between children and their environment, mediated through relations with their caregivers.[13,22,23] Thus, children's development is influenced by characteristics from the child (eg, nutritional status), from the caregiver (eg, maternal education), and from interactions between the child and caregiver (eg, reciprocity and clarity of communication during feeding). The process becomes clear when applied to problems associated with children's growth.

For example, a woman who is undernourished during her pregnancy and does not receive prenatal care is more likely to give birth to a child with low birth weight (LBW) (< 2,500 g). In comparison with full-term infants, infants born with LBW are smaller and often have weaker cries and sucking skills.[24] These characteristics make infants with LBW more difficult to feed, particularly for mothers who are undernourished themselves. A cycle emerges whereby the small and weak infant is difficult to feed, does not grow well, may be vulnerable to illnesses, and lags behind in developmental skills. Mothers often feel frustrated and/or frightened by their infants who are small and sickly and may limit their caregiving to holding rather than talking or encouraging exploration.[25] This process results in a negative cycle whereby infants do not elicit or receive the care and attention they need to promote optimal development.

Intervention can occur at multiple points within the transactional system. For example, intervention could be directed to the infant with LBW, perhaps through nutritional and developmental intervention that might be available through community nutrition programs or through early intervention programs. If the child's growth and development improve, the child will be more likely to elicit and receive age-appropriate care and interaction from the caregiver.

Intervention could also be directed toward the caregiver and the interaction between the caregiver and the child.[26] Children's cues are analyzed to ensure that the caregiver understands how the child expresses hunger or satiety, and caregivers learn how to read and respond to children's cues. There are several examples of successful randomized controlled trials that use components of the transactional system to promote the development of undernourished children.[27,28]

Although most of the attention has been directed to the impact of inadequate nutritional and caregiving practices on children's nutritional status, children may influence caregiver behavior through their nutritional status, as predicted by the transactional system. Children with PEM have been described as negative, wary, and lethargic.[29] It is not surprising that during home observations, mothers of malnourished infants were less sensitive and responsive than mothers of healthy infants[30] and tended to hold or carry them rather than play with them.[25] Caregivers who treat their infants as though they are ill or unable to participate in age-appropriate activities may be inadvertently denying them opportunities for developmental stimulation and enrichment.

In one of the only studies to observe caregiver–child interaction prior to the child's becoming malnourished, investigators in Mexico reported that infants of mothers who lacked sensitivity and affection were more likely to become malnourished compared with infants of more sensitive mothers.[31] In turn, after infants received nutritional supplements, their mothers were more engaged, both in caregiving and in enrichment activities, compared with mothers of nonsupplemented infants, suggesting that mothers respond to their infants' increased energy and activity.

Young children depend on interactions with their primary caretaker and are more active when their caregiver is present than absent.[32] As children grow physically and demonstrate more skills, their caregivers respond with expectations for increasingly complex behavior. For exam-

ple, caregivers are likely to have higher expectations for a 3-year-old child of average height who communicates in sentences compared with a 3-year-old child who is stunted and speaks in single words or brief phrases. In addition, children who are perceived by their caregivers as having easy or pleasant temperaments are more likely to elicit positive caregiving interactions, whereas caregivers tend to become less involved with children whom they perceive to be difficult.[33]

METHODOLOGY

Most research examining associations between early nutritional deprivation and subsequent intellectual skills has been retrospective and observational. The choice of an adequate control group has been challenging, and many studies have not accounted for differences in environmental or caregiving factors that could contribute to differences in findings. This section examines the choice of outcome and predictor variables and considers environmental and caregiving variables that may confound findings.

Childhood Measure of Intelligence

The primary outcome measures used in studies of recovery from nutritional deprivation have been generalized tests of intelligence administered during the school-age years, such as the Wechsler Intelligence Scale for Children-III (WISC-III). The WISC is a standardized assessment that yields an IQ that is stable over time and predicts both academic performance and occupational status.[34] Although many other factors contribute to academic performance and occupational success (eg, motivation), the IQ is a useful indicator of successful rehabilitation.

Infant Measures of Intelligence

Infant intelligence is very difficult to measure. Not only is it challenging to ensure that infants are not hungry, tired, or irritable when testing is scheduled, but infancy is marked by rapidly changing skills with discontinuities in early development. In addition, generalized infant tests require the integration of multiple cognitive and noncognitive processes.

General Tests of Intelligence Investigators have used either generalized tests of infant intelligence, such as the Bayley Scales of Infant Development (BSID), or specific information processing tests. The BSID is a well-standardized assessment that includes three scales: a Mental Scale that yields a Mental Developmental Index (MDI), a Motor Scale that yields a Psychomotor Developmental Index (PDI), and the Behavior Rating Scale, which yields a percentile score. The BSID was designed to determine if infants were able to complete age-normed tasks, not to predict future functioning.[35] It has excellent psychometric properties, with internal consistencies measured by coefficient alphas ranging from .84 to .88 and test–retest reliabilities at 12 months ranging from .77 to .90, depending on the scale. However, correlations from infant assessments administered prior to 18 to 24 months of age to later intellectual performance are notoriously low, lower than predictions from socioeconomic variables, such as maternal IQ or education.[36] In addition, correlations between scores from the Bayley Scales and specific information processing tests, such as visual habituation and attention to a novel stimulus, are low,[37] probably because the information processing tests are tapping specific areas and the BSID examines higher-order functioning, thereby incorporating motivation, attention, and multiple cognitive processes. Beyond age 2 years, once children gain the skills of symbol formation, predictability from early childhood assessments to subsequent intellectual performance increases dramatically.[36]

Specific Tests of Information Processing There has been a great deal of enthusiasm about specific information processing tests administered during infancy (eg, visual attention, learning, and memory) because they are predictive of school-age intellectual performance.[38] The predictability from rate of habituation (number of trials to reach habituation) and response to novelty is higher than the predictability from generalized tests of infant intelligence, particularly when infants are assessed between 2 and 7 months of age. It is not clear why the associations are strongest during this period. The early infant information processing tests may measure speed of processing and/or the ability to inhibit attention to irrelevant stimuli. The drop in predictability after 7 months of age may be related to competing systems, such as sociability.

Habituation is a measurement of visual learning that has been widely used. It is measured by an infant's response to a repeating series of stimuli.[39] As the infant forms an internal representation of the stimulus, the intensity of the response decreases, resulting in a learning curve. Examiners may score the rate of the decline, the number of trials necessary to reach criterion, the duration of looking time prior to response decline, the pattern of the decline, and the infant's ability to recover and respond to a novel stimulus.[39] The psychometric properties of habituation measures, as indicated by test–retest reliability, are only modest.

The paired-comparison test has been used to assess short- and long-term visual recognition memory.[39] It includes two phases: familiarization and test. During the familiarization phase, two identical stimuli are presented, and the infant has an opportunity to view them. During the test phase, a familiar stimulus is paired with a novel stimulus. The observer notes the proportion of time the infant gazes at each stimulus. Because infants are likely to spend more time gazing at the novel stimulus, a novelty score is calculated by dividing the amount of time the infant looked at the novel stimulus by the time the infant looked at both stimuli. As with the habituation test, the psychometric properties are only modest.[39]

The Fagan test is the most widely used test of visual recognition memory. It has been standardized and published and includes guidelines for training, administration, and scoring, with reference data.[40] However, only one indicator from the test has predictive validity: percentage of infant visual fixation to the novel stimulus averaged over all items.[40]

A number of other processing tests can be administered during infancy, including focused attention (concentration

devoted to processing information about an object),[41] cross-modal transfer (transfer of learning from one sensory modality to another),[42] and the A-not-B task (a Piagetian task that examines object permanence).[43] There has been only limited use of infant information procedures with infants who experienced nutritional deprivation. For example, Rose found that nutritionally deprived infants (5 to 12 months of age) from India had difficulty with two tasks related to cognitive processing: visual recognition memory and cross-modal transfer.[44] In addition, they had difficulty demonstrating age-related improvements. Most investigators recommend that tasks should be selected to assess specific processes and that multiple measures be used, beyond IQ, to gain a comprehensive understanding of how nutritional deprivation and recovery impact processing skills.[36,39]

Direct Measures of Brain Functioning During recent years, there has been much interest in brain-behavior relationships and increased attention to behavioral neuroscience. However, there are few methods to measure brain functioning in children. Two direct measures of brain functioning are positron emission tomography (PET) and functional magnetic resonance imaging (MRI).

PET scans are done to identify the location of neural activity but require the injection of a radioactive substance. As the substance is metabolized by the brain and the radioactivity decays, positrons are emitted and can be measured by the PET scan. Thus, investigators can localize synaptogenesis or other neuronal activity.

Because the PET scan requires the injection of a small amount of radioactive substance, the procedure is not without risk and therefore is primarily used with patients who have medical reasons for the scan. In addition, the test is expensive and the spatial and temporal resolutions are low, meaning that it is not possible to identify precise locations or to identify exactly when neural activity is occurring.

Functional MRI is an alternative technique used to identify the location of neural activity. Although it does not require the injection of radioactive substances, it requires the child to be still. When a specific area of the brain is activated, blood flow to that area increases, and oxygen is created. By monitoring changes in oxygen in consecutive "slices" of the brain, the MRI scanner can determine areas of greatest activation. The functional MRI procedure has been used with adults to study the location of neural activity, and developmental scientists are beginning to use it with children.

Environmental and Caregiving Factors Related to Nutritional Deprivation

Nutritional deficiencies often occur in a context of poverty among families who have few economic resources and limited education. Not only do many low-income families have restricted access to nutritionally healthy food, but mothers who are poorly educated are less likely to choose nutritionally appropriate foods for their children compared with better educated mothers.[45] Thus, poverty and factors associated with poverty, such as low maternal education, may have a direct effect on children's development.

Caregivers contribute to their child's development through their care practices, such as providing food and basic care required by young children.[46] In the past, much attention regarding care practices was directed toward defining the quality and quantity of food that children require. However, recent evidence has demonstrated that care practices play a role in children's development that extends beyond the provision of food. Care practices include the relationships that caregivers form with their children during feeding and other daily activities.[18,46] Healthful care practices include behavior that is responsive to children's needs and is characterized by warmth and affection.[46]

Although most investigators have recognized the importance of controlling for demographic variables, little attention has been given to the role of moderating or mediating variables. Moderating variables examine how recovery works under differing conditions. For example, are there differences in cognitive performance related to the timing of the nutritional deprivation? Mediating variables examine the process whereby nutritional deprivation influences cognitive functioning.

EVIDENCE LINKING NUTRITION AND DEVELOPMENT

Long-Term Consequences of Early Nutritional Deficiencies

Information on the long-term consequences of early nutritional deficiencies is available from several natural experiments, including nutritionally deprived children being adopted into middle-class families or nutritional deficiencies occurring among children from middle-class families caused by disasters or chronic illness. In addition, information is available from follow-up studies of children from low-income countries who experienced moderate to severe nutritional deprivation or children from middle-income countries who experienced mild nutritional deprivation. However, data on the long-term consequences of early nutritional deficiencies can be difficult to interpret because children who experience nutritional deficiencies are often raised in low-income families in which they also experience environmental deficiencies.

Natural Experiments

Orphans from Korea who varied in their nutritional status were adopted by middle-class American families and tested during their school-age years. The children who had been undernourished early in life achieved scores in the normal range but lower than those of better-nourished Korean adoptees.[47] Although these findings demonstrate the impact of an enriched environment on children's intellectual skills, they also suggest that early nutritional deficiencies may limit children's ability to benefit from their environment.

In 1944, there was a famine in Holland that affected the entire population, regardless of economic standing. When the youth were tested at 19 years of age as part of an army physical, there was no long-term evidence of intellectual deficiencies compared with scores from nonfamine years.[48] These findings suggest that environmental enrichment had

overcome any deficiencies associated with the early nutritional deficiencies.

Children with chronic diseases, such as cystic fibrosis, sometimes experience malnutrition because they cannot absorb nutrients. Several investigators demonstrated that among children from middle-income families, there were no differences in intellectual scores when children who experienced nutritional deficiencies secondary to chronic diseases were compared with children who had been hospitalized but were well nourished.[49,50] In contrast, among low-income children, those who experienced nutritional deficiencies secondary to chronic disease had lower scores than those who had been hospitalized but were well nourished. These studies illustrate the buffering effects of a nurturing environment on the intellectual performance of nutritionally deprived children.

Long-Term Consequences of Moderate to Severe Nutritional Deficiencies

Mounting evidence from Peru,[51] Jamaica,[2,52] the Phillipines,[53] Guatemala,[54] and Kenya[55] suggests that children who experienced nutritional deprivation severe enough to cause stunting early in life have cognitive deficits during school-age years that can interfere with successful academic performance. In a review, Grantham-McGregor reported that previously malnourished children had academic problems, lower cognitive skills, more soft neurologic signs, more attention problems, and more problems with peer relationships compared with adequately nourished control children.[56]

Long-Term Consequences of Mild Nutritional Deficiencies

Findings on the long-term consequences of children from middle-income countries diagnosed with failure to thrive (FTT) add to our information on nutritional deprivation and cognition. Although there are no agreed-on criteria for the diagnosis of FTT, the term is generally used to describe children under age 3 years who have experienced a deceleration in growth over time, such that their weight for age or weight for height is below the 5th or 3rd percentile.[57] Children with FTT are usually experiencing milder forms of deficiency than children identified with nutritional deficiencies in low-income countries. During infancy and toddlerhood, the cognitive scores of children with FTT are lower than scores of comparison children with adequate growth and often remain low through the preschool period.[58–60]

The pattern of cognitive development is less clear during school-age years and adolescence. Two follow-up studies of infants referred for FTT reported that the children continued to score lower on cognitive assessments than comparison groups at age 11 years and during adolescence.[61,62]

In contrast, evidence from other studies suggests that by school age, children with a history of FTT do not have lower cognitive skills than children without a history of FTT, when comparison groups are matched for socioeconomic variables.[63–66] However, there is some evidence that children with a history of FTT experience more academic problems than adequately nourished peers.[64]

The differences in findings may be partially explained by differences in sampling. The studies showing no long-term cognitive deficiencies employed community samples of children who had not been hospitalized,[63–66] whereas the studies suggesting that long-term cognition is affected included children with more severe FTT, either those hospitalized or those with chronic growth failure.[61,62] Hospitalization is more likely if FTT is severe and complicated by multiple social problems,[67] which may also undermine school-age cognitive development.

The relationship between nutritional status and cognitive functioning is often mediated by family, environmental, and cultural variables,[58,68,69] making the family an ideal context for prevention of the negative consequences of FTT. Intervention studies among children with FTT highlight the importance of environmental enrichment. We conducted a randomized trial in which all infants received services through an interdisciplinary growth and nutrition clinic, but experimental infants also received weekly home intervention targeted toward enhancing caregiver–child interactions.[58] After 1 year, infants who received the home intervention had a more child-centered home environment, better cognitive scores, and better expressive language scores compared with infants who did not receive the home intervention. Two years after the intervention ended, the effects were attenuated and moderated by the affective behavior of the caregivers. Infants who received the intervention had better motor scores only if their caregivers did not report symptoms of depression, anxiety, or hostility.[59] In a similar investigation, Ramey and colleagues reported that infants with FTT who received both nutritional supplements and response-contingent stimulation had better scores on a vocal conditioning task than infants who received only the nutritional supplement.[70]

Some caution is recommended in reading the existing literature on FTT because much of the information has been derived from hospitalized children in academic referral centers. Because most children with FTT are treated on an outpatient basis, studies that rely on hospitalized patients are likely to represent extreme and complex cases of FTT.[71] In addition, many studies of FTT include small samples, a lack of appropriately matched comparison groups, unstandardized assessments, evaluators who are aware of group assignment, inattention to differences in age or nutritional status, and cross-sectional rather than longitudinal research designs.[67,72]

Intervention Studies

As illustrated by the transactional system, optimal child development depends not only on food quality and availability but also on the care the family provides to the child, especially during the first few years of life.[18] Evaluations of psychosocial stimulation delivered to malnourished children provide evidence for the importance of the caregiving environment in promoting development. In Jamaica, Grantham-McGregor and colleagues demonstrated that stunted children who received either nutritional supplementation or psychosocial stimulation showed improved mental and motor development.[27] The effects of the inter-

ventions were additive: children who received both supplementation and stimulation achieved mental and motor scores that approximated those of the nonstunted comparison group. Long-term follow-up demonstrated that although the benefits of the early interventions were still present, they were rather modest, suggesting some decay over time.[73] These findings are extremely encouraging because they demonstrate that not only can children benefit from environmental enrichment, but their benefits extend over time. They also suggest that enrichment should extend over the developmental period.

Studies from Cali and Bogota, Columbia, also illustrate the importance of including both nutritional and psychological interventions.[74,75] In the Cali study, children who received both supplementation and stimulation had better psychological performance at age 9 years compared with control group children.[76] In the Bogota study, supplemented infants were more active than nonsupplemented infants, and 3 years after the study ended, when the children were 6 years of age, those who received both supplementation and stimulation were taller.[75]

In a long-term evaluation of a community-based supplementation program in Guatemala, Pollitt and colleagues found that children who were supplemented early in life had a faster reaction time in information processing tests and higher scores on tests of knowledge, numeracy, reading, and vocabulary during adolescence compared with children who did not receive the high-protein supplement.[77] Their analysis also demonstrated the importance of looking for moderator effects because in the villages that did not receive the supplement, they found the greatest benefits on academic performance among children from the poorest homes.[78]

Micronutrients

Micronutrient deficiencies are often evaluated by conducting randomized trials among populations thought to be micronutrient deficient (see Chapter 6). Although the use of randomized trials provides a robust evaluation of the link between micronutrient deficiencies and cognitive development, the research examining the effects of micronutrient deficiencies on children's development suffers from many of the same methodologic problems that have hindered research examining PEM. Micronutrient deficiencies often occur in the context of poverty and among families who are beset by multiple stressors that may interfere with the healthy development of their children. In addition, micronutrient deficiencies often co-occur, particularly if the micronutrients are derived from the same source. Thus, if children are deficient in multiple micronutrients, it can be difficult to interpret the effects of single-micronutrient supplementation trials.

Observational studies have compared children who are thought to have a micronutrient deficiency with those who do not. Although these studies can yield useful information about micronutrients and individual differences, they lack the rigor of randomized trials because there are often other factors separating the groups that may influence children's development, such as caregiving practices. Randomized trials can often clarify differences related to micronutrients, but they are expensive and must also control for confounding factors that may influence children's development, such as the quality of the caregiving environment. In addition, as the evidence demonstrating the detrimental effects of specific micronutrients on children's development is clarified (eg, iodine), it is unethical to identify micronutrient-deficient children and not offer treatment.

Iodine Deficiency Iodine deficiency is a major problem that affects children in areas where iodine is depleted from the soil, primarily mountainous regions, such as the Himalayas and the Andes, and flood plains.[79] A 1993 World Health Organization (WHO) report estimated that 1.6 billion people or 30% of the world's population live in iodine-deficient areas and are therefore at risk for iodine deficiency.[6]

Iodine is an essential component of at least two thyroid hormones that are necessary for skeletal growth and neurologic development.[79] When iodine is deficient, hypothyroidism occurs, resulting in increased production of thyroid-stimulating hormone, which stimulates production of thyroid hormones. The most common manifestation of iodine deficiency is goiter, which is an enlarged thyroid gland.[79]

When iodine deficiency occurs in utero, it leads to fetal hypothyroidism and irreversible neurologic and cognitive deficits, manifested as cretinism. Neurologic cretinism includes mental retardation, primitive reflexes, visual problems, facial deformities, stunted growth, and diplegia.[80] When iodine deficiency occurs postnatally, the child may experience thyroid failure that can lead to hypothyroidism. Observational studies that have compared children with and without a goiter have had mixed results; some have reported cognitive deficits among children with goiters and others have not. One explanation for the lack of clarity may be that differing levels of hypothyroidism can lead to a goiter.[79] In a meta-analysis of 18 observational studies that compared children based on whether they lived in an iodine-deficient area or not, children who lived in iodine-deficient areas had deficits in cognitive functioning.[81] In a well-controlled observational study in Bangladesh, investigators found that children who were mildly hypothyroid had deficits in spelling and reading compared with healthy controls.[82] Although evidence from these studies is compelling, families who live in iodine-deficient areas are often more impoverished than families in areas where iodine is adequate.

Several randomized trials have been conducted to examine the impact of iodine supplementation on the cognitive performance of children in iodine-deficient areas. However, the results have not been consistent. In a recent longitudinal follow-up of school-aged children, all of whom received iodine, those who received iodine in utero prior to the third trimester had better scores on a measure of psychomotor performance than children who received iodine later in pregnancy or at age 2 years.[83] There was a similar trend when measures of cognitive performance were considered; however, the differences did not reach significance. Thus, the effects of postnatal iodine defi-

ciency on children's cognitive performance are less clear than the effects of prenatal iodine deficiency. In addition, many of the studies have had methodologic problems that interfere with interpretation.

Iron Deficiency Iron deficiency is the most common nutritional deficiency in the world. UNICEF and WHO committees estimate that worldwide there are 2 billion individuals with anemia and up to 5 billion who are iron deficient.[7] The highest risk of iron deficiency occurs during times of rapid growth and nutritional demand, during infancy (ages 6 to 24 months), early childhood, adolescence, and pregnancy.

Iron is necessary for hemoglobin synthesis. Iron deficiency leads to reduced oxygen-carrying capacity and can impact immunity, growth, and development. Although iron status is often assessed by anemia (low blood hemoglobin concentration), only 50% of anemia is caused by iron deficiency.[84] Iron has multiple roles in neurotransmitter systems and may affect behavior through its effects on dopamine metabolism.[85] Dopamine clearance has strong effects on attention, perception, memory, motivation, and motor control.

A number of observational studies have found that children who experienced anemia early in life had low scores on tests of mental performance and were fearful, inattentive, and solemn, with low levels of initiation and exploration.[86–88] Many children continued to demonstrate lower academic performance during their school-age years, even when the anemia had been treated. For example, Hurtado and colleagues examined the records of children who enrolled in the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) prior to age 5 years.[89] Those who were anemic were more likely to experience academic problems at 10 years of age compared with children who were not anemic on enrolment. Concurrent iron status is also related to academic performance, as demonstrated in a recent investigation using data from more than 5,000 6- to 16-year-old children from the Third National Health and Nutrition Examination Survey (NHANES III).[90] When standardized mathematics test scores were examined controlling for background variables, children with iron deficiency with and without anemia had lower scores than children with normal iron status. These findings suggest that iron deficiency, even without anemia, may place children at risk for cognitive delays.

The results of randomized trials of iron supplements have been inconsistent, regardless of the children's initial iron status.[91] Most short-term trials (< 15 days) among anemic infants have shown no differences in children's motor or mental performance.[92] Of the longer-term trials among anemic infants, only one showed positive effects of iron treatment on children's motor and mental development.[93] There have been at least seven prevention trials among infants at risk for iron deficiency. Four authors have reported that iron supplementation promotes cognitive development among children at risk for iron deficiency[94–97] and three have reported no effects.[98–100] These findings are difficult to interpret because methods varied, and some authors did not account for socioeconomic and caregiving differences among nutritionally deficient children.

Zinc Deficiency Zinc is a trace mineral that is involved with deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) synthesis and the metabolism of proteins, carbohydrates, and fat. Findings on the cognitive effects from the zinc supplementation studies also lack clarity.[101] Four published trials reported beneficial effects of zinc supplementation on children's activity, motor quality, or motor development[102–105]; one reported that zinc-supplemented infants were more cooperative[106]; three found no differences on mental development[102,105,107]; and one reported that supplemented children had slightly lower scores on mental development than comparison children.[107]

There have been at least three randomized trials of zinc supplementation measuring cognitive development among school-aged children. A trial in Canada found no differences when children were tested with subscales from the Detroit Test of Learning Abilities.[108] However, trials in China and Mexican-American children from Texas have found that zinc-supplemented children demonstrated superior neuropsychological performance, particularly reasoning, when compared with controls.[109,110] The evidence for improved neuropsychological performance among zinc-supplemented children is increasing, but more work is needed to replicate existing studies and clarify the effect on academic performance.

SUMMARY

Most of the research examining the impact of nutritional deficiencies on children's intellectual development has hypothesized a direct effect, possibly through changes in neuroanatomy or neurotransmission. However, most studies have relied on general measures of intellectual skills, and, as a result, little is known about specific processing changes related to nutritional deprivation.

It is also possible that behavior changes associated with nutritional deficiencies alter the caregiving that the child receives, thereby compromising the child's development even further. The result could be a child who experiences both the neurologic changes that have been associated with nutritional deficiency and limited environmental enrichment. Future research should consider how the caregiving system is related to child development and whether it mediates the effects of nutritional deficiencies.

The findings linking nutritional deficiencies, especially micronutrient deficiencies, and child development point to the importance of effective prevention programs that begin prenatally or early in life and extend through the periods of vulnerability, which may include adolescence. Yet there are many unanswered questions regarding nutritional deficiencies and child development that require further research, including the timing of the deficiency, the long-term consequences on academic achievement, the specific processes involved, and the impact of multiple nutrient deficiencies.

CHAPTER 22

NUTRITION AND THE BEHAVIOR OF CHILDREN

Kathleen Gorman, PhD, Elizabeth Metallinos-Katsaras, PhD, RD

The association between nutrition and behavior is widely believed to be causal. Although there is strong evidence to suggest behavioral effects of some nutrient deficiencies (ie, iron deficiency anemia [IDA]), the evidence for other nutrient deficiencies is much weaker. However, popular opinion seems to rely heavily on anecdotal data, which suggest that behavioral problems and poor academic achievement are the result of poor nutrition. Given the implications of such beliefs and the fact that many social programs have grown out of the theory that nutrition is a critical factor in children's development, it is important to thoroughly examine the available evidence.

Establishing a causal link between nutrition and behavior is complicated by the fact that malnutrition, and much less specific nutritional deficiencies, rarely occurs in isolation. Even children who are mildly malnourished are likely to come from families or homes characterized by factors (eg, low levels of education and income) well known to pose risks to the optimal development of children (Figure 22-1). Although the role of the environment has long been recognized as an explanatory factor in the association between nutrition and development, only recently has the research attempted to build environmental variation into the designs and to explore the interactions between nutrition and environmental variables.

This chapter examines the evidence for the causal effects of nutrition on behavioral outcomes in children. In general, malnutrition refers to a condition that results from an "excess, imbalance, or deficit of nutrient availability in relation to tissue needs."[1] The literature on malnutrition comes primarily from low-income countries and provides evidence for the effects of nutrient restrictions on infant and child development. In addition, a growing body of literature has emerged on the effects of hunger and related nutritional insufficiencies among well-nourished populations. A third body of literature explores how specific nutrient deficiencies or the ingestion of particular nutrients (or non-nutrient additives) may pose potential harm (or benefit) to individual development. The section on the role of specific nutrients hypothesized to affect behavior includes sugar, multivitamins, and minerals, as well as brief attention to issues of food additives. The research on overnutrition and eating disorders is not reviewed here (see Chapters 51 and 54).

Behavior, as discussed in this chapter, refers to a variety of outcomes that have been studied in association with nutrition, including cognition, achievement, activity, and attention. The behavioral outcome examined varies depending on the type of nutritional input; for example, low energy intake during gestation and infancy is often believed to affect overall cognitive function, whereas short-term hunger and intakes of specific nutrients (eg, sugar) are more often thought to affect attention and activity levels.[2]

Given the limitations of experimental research on malnutrition in human subjects, much of what is known about the causal effects of malnutrition on behavior comes from the animal literature. Early research noted that inadequate intake of nutrients results in changes in brain structure and size, and it was hypothesized that malnutrition during fetal development and periods of rapid brain growth directly impairs brain development.[3] This impaired brain growth was presumed to result in brain damage and subsequent mental retardation.

Although it is well documented that malnutrition can affect brain development and structure, there is no clear consensus that such changes are permanent or that they necessarily result in functional consequences.[3,4] At the same time, advances in neuropsychobiology have identified more subtle alterations in function associated with nutritional deficiencies such as central nervous system (CNS) changes at the level of neuroanatomy and/or neurochemistry.[4] Furthermore, it has been hypothesized that many of the behavioral effects of malnutrition observed in animals (eg, increased emotionality) may be involved in the observed deficits in learning and cognition in humans as well.[5,6] The growing body of literature on the relationship between nutrition and brain development is reviewed in Chapter 21, "Brain Development."

PROTEIN-ENERGY MALNUTRITION AND BEHAVIOR

Recent estimates (2000) suggest that 150 million children (28%) under the age of 5 years suffer from malnutrition in the developing world (see Chapter 10).[7] Nutritional deficiencies are both less common and less severe in countries such as the United States. Nonetheless, data from the Pediatric Nutrition Surveillance System 1997 on low-income

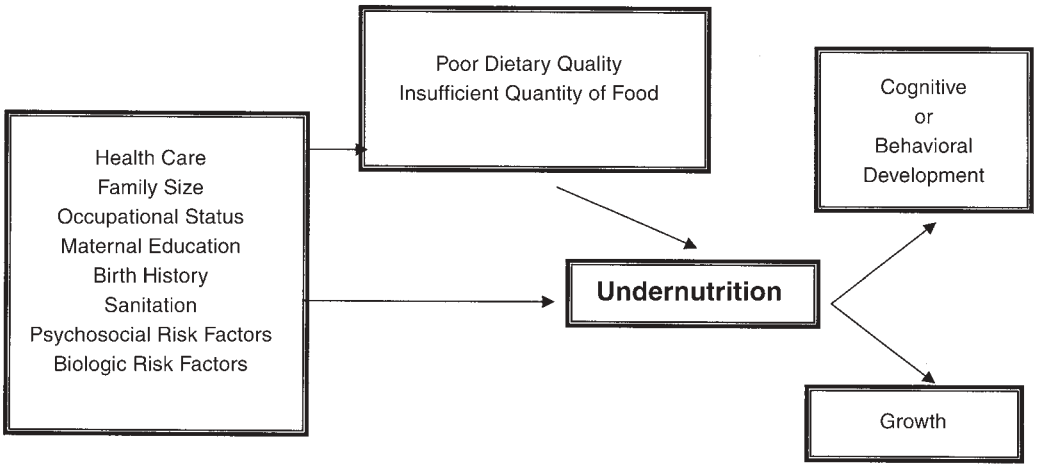

FIGURE 22-1 Model for malnutrition in environments with limited resources.

Description of Studies included in the Review: Malnutrition and Cognitive Development

children and families who participate in federally funded programs (eg, Special Supplemental Nutrition Program for Women, Infants, and Children [WIC], Head Start) show the prevalence of low height for age among children under 2 years of age to be twice as high as that expected within the general population and an overall prevalence of IDA of between 15 and 25% for this population.[8] Although the high prevalence of anemia and growth stunting within this sample may reflect, in part, the successful targeting efforts of at-risk populations (eg, WIC gives preferential enrolment to high–nutritional risk families), the evidence indicates that a large number of children in the United States are at elevated levels of health and nutritional risk. Although there remains little doubt that severe levels of malnutrition adversely affect the psychomotor and cognitive development in children as well as long-term school learning and achievement,[3,9] of relevance here is the research on mild-to-moderate malnutrition. Several large field studies were conducted in low-income countries during the 1960s and 1970s to test the hypothesis that improved nutrition at different developmental periods was associated with improved cognitive performance.[2] In each study, children at nutritional risk were supplemented and compared with children who remained unsupplemented. Overall, a summary of the results suggests small yet statistically significant findings on a variety of outcomes (eg, mental and motor development, preschool cognitive function) (Table 22-1).[2]

During the 1980s, better-designed studies and the use of improved statistical analyses strengthened the conclusions of a causal relation between nutrition and behavior.[2,5,10,11] In Jamaica, Grantham-McGregor and her colleagues randomly assigned previously malnourished children, as defined by low height for age, to one of four treatment groups: (1) food supplementation, (2) psychosocial stimulation, (3) supplementation and stimulation, and (4) control.[12] The results showed significant and independent effects of both nutrition and stimulation on the Developmental Quotient of the Griffiths Mental Development Scales compared with control subjects and an additive effect of the combined intervention. After 2 years of treatment, the combined intervention group scored significantly better than the other groups and similarly to a matched group of nonstunted children. The use of children with different nutritional histories and multiple treatment conditions in a randomized study highlights the significance of individual differences and potential interactive effects of interventions. However, follow-up of these children at 4 and 8 years post-treatment indicates few significant enduring effects of the nutritional intervention. In the first follow-up, the authors report benefits of psychosocial stimulation on cognitive performance and an interaction of the supplement with parental behavior. Children whose mothers had higher vocabulary scores showed increased effects of nutritional supplementation on cognitive performance.[13] By the time the children were about 12 years of age, only the effects of psychosocial stimulation remained.[14]

A follow-up of rural Guatemalan children who had been supplemented with either a high-calorie/high-protein supplement or a low-calorie supplement throughout the first several years of life found significantly better performance on various measures of psychoeducational tests (eg, reading, numeracy, vocabulary, and general knowledge) in adolescents who were exposed to the high-calorie/high-protein supplement.[15] More important, the effects of the supplementation varied by levels of socioeconomic status (SES) and by schooling history. That is, subjects from the poorest families seemed to benefit the most from the supplementation and performed similarly to those from higher SES homes. In addition, children with more exposure to school (beyond 3 years) showed greater benefits of the supplementation than those with fewer years of schooling. Taken together, the results of these studies provide evidence for the effects of nutritional supplementation on cognitive development. Further, the results illustrate the potential for long-term effects and the role that the environment (ie, characteristics of families, home, school) plays in mediating such a relationship.

TABLE 22-1 Description of Studies Included in This Review

			Nutrient Characteristics of Supplement					
	Age of Subjects at Initiation	*Supplementation Duration*	*Kcal*	*Protein*	*Micro-nutrient*	*Control**	*Educational Component*	*Outcomes*
Guatemala, 1969–1977	Gestation–7	Gestation and 7 yr	X	X	X	Q[†]	C, MV	Composite infant scale, preschool battery, school, psychoeducational test
Jamaica	2 mo–2 yr	2 yr	X	X		N	X	Griffiths
Cali, 1971–1974	4 yr+	3 yr	X	X	X	N	X[‡]	Preschool battery, WISC
Bogotá	Gestation–6 mo	Gestation and 3 yr	X	X	X	N	X	Griffiths, Einstein
Indonesia	6–20 mo	3 mo	X	X		Q	N	Bayley
Taiwan	Maternal only	Gestation and lactation	X	X	X	Q	C, MV	Bayley, 5-yr-old IQ
New York City	Maternal only	Gestation	X	X	X		MV	Bayley, object permanence, play, habit/deshabit
Mexico		Maternal and 3 mo+	5 yr	X	X	X	N	Mother-infant contract activity, maternal care and concern

*Supplement administered to control group: C = calorie; MV = multivitamin and mineral supplement; N = none.

[†]Consumption quantifiable.

[‡]Education not separate from nutritional intervention.

Bayley = Bayley Scales of Infant Development; Einstein = Einstein Measurement of Children's Cognitions; Griffiths = Griffiths Mental Development Scales; WISC = Wechsler Intelligence Scale for Children.

Finally, the results highlight the significance of both the timing and duration of the intervention, as well as the particular domains of cognition that may be linked to particular nutritional deficiencies.[15,16]

As a result, the focus of current research has been to attempt to elucidate the potential pathways that may account for the effects of malnutrition on behavior.[3,15–17] Most notable is the work on assessing the role of activity and motor development as a mediator in the relationship between nutrition and cognitive development.[5] In the Jamaican study of stunted children previously described, data were also collected on activity levels.[18] Baseline comparisons showed that stunted children were significantly less active than nonstunted children. However, there were no effects of supplementation on activity levels, and activity was not found to mediate the relationship between supplementation and cognition. In contrast, data from an experimental study in Pangalengan, Indonesia, provide some initial evidence on the complexity of developmental trajectories of malnourished children.[19] Building on hypotheses developed from his work in Guatemala, Pollitt and his colleagues explored the relationships among nutrition and growth, motor development, motor activity, parental behavior, affective behavior, and cognitive development.[15,16,20] In this study, two cohorts of infants (12 and 18 months) were each randomly assigned to one of three types of supplements over the course of 12 months: high energy + micronutrients, low energy + micronutrients, and low energy.[21] Data on a wide range of variables were collected periodically over the course of a year. In general, the results provide support for the benefits of a high-energy supplement on a number of outcomes. Infants receiving the high energy + micronutrient supplement showed earlier acquisition of motor milestones, higher motor development scores, and increased duration of activity compared with children receiving the low-energy supplement.[22,23] Furthermore, high energy–supplemented children showed earlier acquisition of object concept, increased vocalizations, and earlier emotional maturity (decreased fussing) than their peers.[24] The effects of the micronutrient supplement were less clear, except in the case of children with IDA.[25] This study represents the first empiric test of the complex model of relationships among malnutrition, growth, motor development, activity, and mental development (Figure 22-2).[26] Despite several of the limitations of this study (eg, small sample sizes and different patterns of results between the 12- and 18-month-old cohorts), the results provide an important addition to our increasing understanding of the mechanisms underlying the relationship between malnutrition and behavior.

BREAST MILK AND COGNITION

Although the benefits of breast-feeding on immune function, morbidity, growth, and infection are well established, the evidence for its effects on mental development, particularly among healthy, well-nourished infants, is less convincing.[27–31] The research on the effects of breast milk on cognitive function is complicated by two main factors: the fact that mothers who choose to breast-feed vary in a number of ways from those who do not and the researcher's inability to randomly assign mothers to treatment groups.[31–34] Mothers who choose to breast-feed and mothers who bottle-feed have been reported to differ in age, SES, education, and ego development, all factors also known to affect infant developmental outcomes.[32–35] Research controlling for these variables has resulted in a reduction in the magnitude of associations between breast-feeding and men-

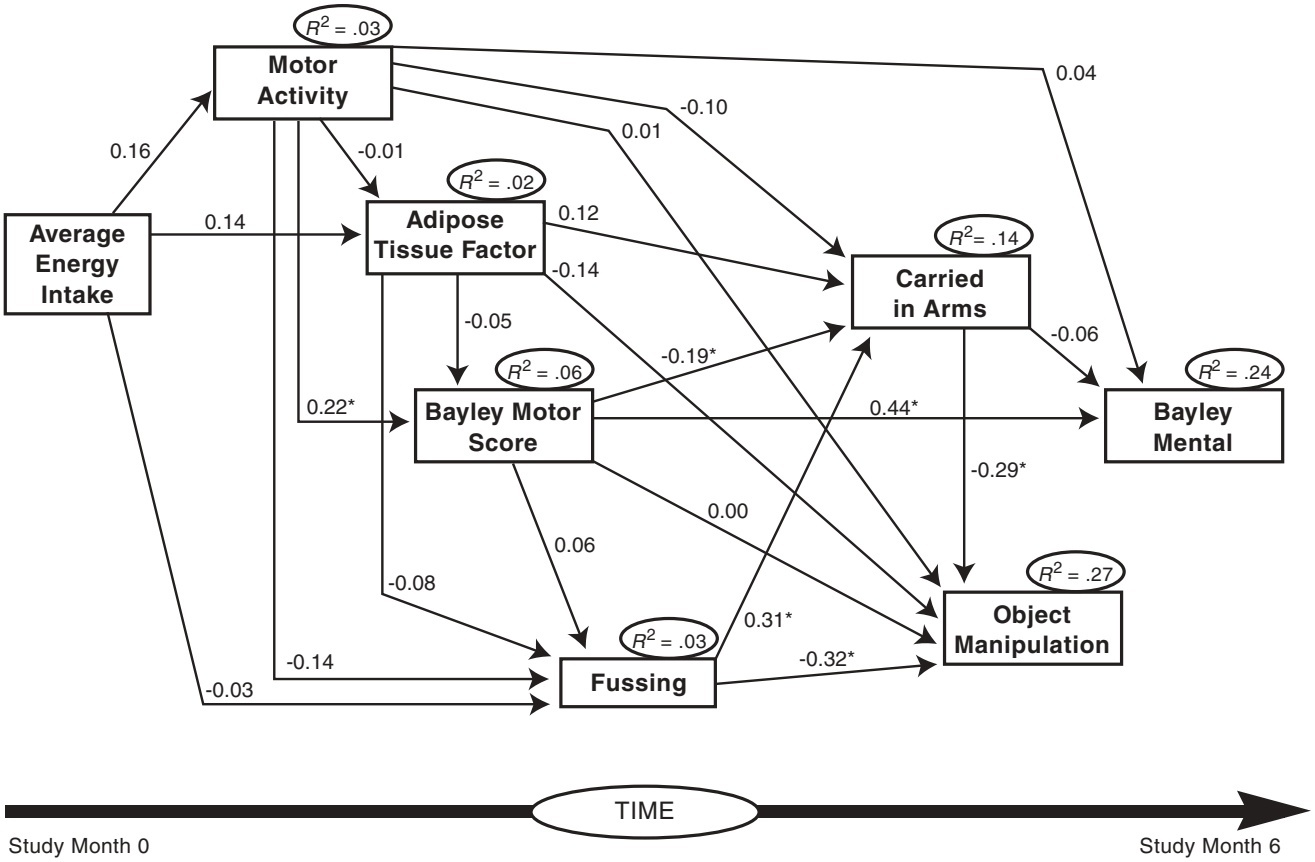

FIGURE 22-2 Path diagram of the adjusted model of the combined cohort that received the energy plus micronutrient and skimmed milk supplement (χ^2 NFI = 0.95; NNFI = 1.00; CFI = 1.00). Reproduced with permission from Pollitt E et al.[26]

tal development, suggesting that these variables account for a significant portion of variation often attributed to breast milk.[32,34–36] Furthermore, the association between breast-feeding and cognition has been reduced to zero when maternal IQ and parenting skills were also factored in.[30] Hence, studies that purport to establish a relationship between breast-feeding and cognition without controlling for these variables may not be valid.

In a series of studies in Great Britain, Lucas and colleagues attempted to control for many of these potentially confounding variables.[37–39] In their study of preterm, low birth weight infants (< 1,850 g), infants of non-breast-feeding mothers were randomly assigned to a standard full-term or a special preterm formula (designed to more closely mimic the properties of breast milk than standard formula), whereas infants whose mothers chose to provide breast milk were also randomly assigned to one of two supplemental formula groups for a period of 4 weeks. In this way, differences between breast milk and formula could be compared as well as differences in standard versus preterm formula. In an assessment of the infants at 18 months, comparisons between formula types demonstrated significant benefits of preterm compared with term formula on the Bayley Psychomotor Development Index (PDI).[37] Similarly, among infants receiving supplementary feeding in addition to breast milk, those who had received preterm formula scored higher on the social quotient from the Vineland Adaptive Behavior Scales than those receiving term formula. When subjects were combined, comparisons between term and preterm formula indicated the advantages of preterm formula on the PDI and the Vineland social maturity scale.

In a follow-up at age 7 years, comparisons were made between infants of mothers who chose to provide breast milk and those who did not on the Wechsler Intelligence Scale for Children (WISC) (revised for the United Kingdom).[38,39] According to the authors, similar percentages of infants in each group had received the different types of formulas. Initial findings show a 10-point advantage on each of the IQ scales (Verbal, Performance, and Full-Scale) for those in the breast milk group. In a subsequent analysis between formula groups,[39] the authors reported that males showed a benefit from the preterm formula compared with term formula relating to language development. There was an apparent dose-response to the preterm formula, suggesting that the more formula ingested, the greater the developmental gains.

The authors concluded that the combined results of this study, showing both the benefits of breast milk over formula and the benefits of preterm formula over standard formula, provide strong evidence that these benefits are attributable to the specific properties of breast milk.[40] These conclusions are further strengthened by the fact that all infants were fed by nasogastric tube, hence controlling for any potential behavioral differences associated with the act of breast-feeding. Additionally, the results of these studies have advanced a number of theories regarding specific properties of breast milk, most specifically, long-chain

polyunsaturated fatty acids (LC-PUFAs) and their association with brain development.[41–44]

Illustrative is a recent review on LC-PUFAs that reported that breast-fed infants have higher plasma levels of LC-PUFAs than formula-fed infants.[45] Studies that supplement formula with these LC-PUFAs, namely docosahexaenoic acid and arachidonic acid, in preterm infants, have shown some benefit of human milk or supplemented formula on visual function and visual acuity in comparison with unsupplemented formula. In contrast, studies of visual acuity in term infants have been inconsistent; some have shown the effects of supplemented formula, whereas others have not. The research on the effects of LC-PUCFAs on more general measures of cognitive and behavioral development in preterm or term infants is inconclusive.[45] Limitations owing to small sample sizes and the tests used have been noted as potentially responsible for the lack of agreement in the findings. In addition, the length of follow-up in most of these studies has been short, which makes it difficult to draw conclusions about the long-term benefits of the LC-PUFAs.

Nonetheless, it is important to note that even if subsequent analyses uphold these findings of a causal association between breast milk properties (eg, LC-PUFAs) and cognitive development among at-risk infants, the issue of generalizability must be addressed. There is little evidence to suggest that the effects observed in these studies, composed entirely of preterm, very low birth weight infants, would generalize to otherwise healthy full-term infants.

IRON DEFICIENCY ANEMIA AND OTHER MICRONUTRIENT DEFICIENCIES

Data from the Third National Health and Nutrition Examination Survey (NHANES III, 1988–1994) showed that 9% of toddlers ages 1 to 2 years and 9 to 11% of adolescent girls and women of childbearing age were iron deficient based on laboratory tests of iron status (see Chapter 49).[46] Thus, risk for IDA continues to be high in the United States. The elevated risk among toddlers during a time considered sensitive for cognitive development has provided the impetus for the infancy period being the most common target for investigations of the behavioral effects of IDA. Much less has been done on preschool- and school-aged children.

It is well established that IDA infants score lower on the Bayley Mental Development Scale and Motor Development Scale in comparison with nonanemic infants.[47] It has also been found that children's achievement, among both preschool- and school-aged subjects, is poorer for formerly anemic children than nonanemic children.[47–49] The fact that IDA rarely exists in isolation but rather coexists with a host of social, health, and environmental risk factors has constrained the interpretation of such differences as being causal.

Randomized clinical trials provide the best evidence for a causal association, although the results have not always been consistent. In some, IDA infants treated with iron show significant gains in developmental scores compared with IDA infants receiving placebo.[50] More recent investigations have focused on the reversibility of effects of IDA, which has been reported by some but not all investigators.[49–51] Several possible reasons for the lack of significant improvement with iron supplementation have been proposed, although the research has not provided support for any reason in particular. Potential explanations include the possibility that IDA is not the causal factor or that IDA causes permanent and irreversible alterations in the developmental trajectory of the infant. In addition, in some cases, the IDA may not have been successfully treated, or in other cases, the correlates of more severe and chronic IDA (eg, poorer home stimulation, lower parental IQ, socioeconomic factors) may be the cause of lower performance among those with a history of IDA.[47]

In a clinical trial of iron supplementation in Indonesian infants (12 to 18 months), iron supplementation resulted in reversal of both IDA and developmental indicators.[50] At baseline, IDA infants scored significantly lower on both the Bayley Mental Development Index (MDI) and the PDI than either iron-replete or iron-deficient nonanemic infants. After supplementation, there were no significant differences among the three groups on either the MDI or the PDI. Conversely, the IDA placebo-treated infants continued to score significantly lower than all other groups on both the MDI and the PDI.

Several preventive trials among infants have been conducted. Of the four that were randomized trials, three demonstrated some benefit of iron treatment, whereas one did not.[47,52–54] Two of these studies demonstrated effects on developmental test scores and one on fixation times at 12 months of age.[47,52,53] The one study that did not show any benefit of the trial was limited by the fact that there was only a small subset at risk for deficiency, thus limiting the statistical power of the study.[47]

Finally, a recent quasiexperimental study on infants in Indonesia examined the effects on a variety of developmental outcomes, including several indicators of motor development, mental development, and observations of children's interactions.[25] This analysis was based on a subset of children originally included in a supplementation study. This subset had biochemical evidence of IDA. At baseline, there were significant differences in scores on the Bayley Motor Development Scale, as well as in a measure of motor activity between IDA and non-IDA children. Motor development, physical activity, and emotional regulation have been postulated to be intermediate processes affected by nutritional status as well as affecting cognitive outcomes.[19] The improvement in motor activity during the first 2 months and during the first 6-month observation period was significantly larger in the IDA nontreated children than in the non-IDA children. It should be noted, however, that this design is weaker than the randomized clinical trials.

In contrast to studies showing effects with iron supplementation, some studies suggest that differences between IDA and nonanemic controls persist even after iron supplementation. Generally, these studies had one feature in common: they did not include an IDA placebo group, hence weakening the study design.

A study in Costa Rica showed that IDA infants scored significantly lower on the MDI and PDI than iron-replete

infants and that, on average, these differences persisted even after 3 months of iron therapy.[55] Further analyses revealed that the effect of iron supplementation depended on the degree to which the anemia was reversed.[56] Specifically, infants whose IDA was completely reversed (n = 9) scored similarly to the iron-sufficient infants on the MDI and PDI, whereas infants whose deficiency was not completely corrected continued to score significantly lower than the iron-sufficient infants. It should be noted that significant treatment effects were the result of an observed decline in performance in the iron-sufficient children, which was not evident in those children successfully treated with iron.[56] Such a decline in the latter part of infancy has been reported elsewhere in disadvantaged populations.[56,57] It is possible that the successful iron treatment of these nine infants prevented a further decline in this group; however, without a comparable placebo group, this hypothesis could not be tested.[56] At a follow-up of subjects (age range 11 to 14 years, with excellent current hematology), children who had had severe chronic anemia during infancy (defined as those whose hemoglobin increased in response to treatment but in whom biochemical evidence of iron deficiency persisted) had significantly lower scores in writing, arithmetic, motor tests, and tests of specific cognitive processes (Table 22-2).[49] Among older children only, those who had been previously anemic had poorer selective attention. These differences persisted even after controlling for sex, mother's IQ, and an index of the home environment. As noted by the authors, these differences may be attributable to some factor that is associated with iron deficiency and not iron deficiency per se, or it may be attributable to effects of iron deficiency on the nervous system, which affect later behavior and development. Although the authors made a compelling argument for the latter, the other important aspect of this study to consider in interpreting the findings is that for this group of formerly iron-deficient infants, the iron deficiency was not fully corrected. It is not known what the long-term development of these children would have been had their iron deficiency been fully corrected.

An iron supplementation study examining the effects of IDA on CNS development indicated that infants with IDA at 6 months had longer central conduction time (proposed as an indicator of poorer CNS development) than a

*Values are means with and without adjustment for background factors. Standard scores take age into account; age is included as a covariate for Bender raw scores. Adjusted means are derived from analysis of covariance, controlling for gender, HOME score, and mother's IQ. A cumulative HOME index summed the scores obtained in infancy, school age, and early adolescence, which were highly intercorrelated (r values > .70), and all related to test scores at 11 to 14 years. Mother's IQ was the covariate, rather than mother's education, because mother's IQ generally showed higher correlations with adolescent outcome; the regression coefficient of maternal education on mother's IQ was used to estimate IQ if the mother had not been tested (32 cases). Tests of statistical significance are based on analysis of variance or covariance.

nonanemic control group.[58] Even after iron supplementation, significant differences persisted at 12 and 18 months of age despite improvements in hematology in response to treatment. It should be noted that the IDA infants improved in their central conduction time but failed to reach the levels of the nonanemic controls. The authors postulated that these differences may be owing to the effects that IDA has on myelination and/or neurotransmitter function.[58] Again, there was no IDA placebo group included in this study.

Although fewer in number, some studies on preschool- and school-aged children show an effect of IDA on measures of intelligence and other cognitive processes (eg, discrimination learning tasks, visual recall).[40,59–64] Others have shown no effect of supplementation,[65] although this may have been owing to an improvement in iron status in the IDA placebo group attributable to deworming.[47] Generally, the studies on preschool- and school-aged children provide support for the notion that brain function is vulnerable to the effects of iron deficiency even after the brain growth spurt has been completed.

A recent comprehensive review of the literature summarized the proposed mechanisms linking IDA to cognitive changes. One of the proposed mechanisms includes changes in the structure and function of the CNS. This includes effects on brain myelination and on levels and function of neurotransmitters. Another mechanism that has been proposed is based on the observation that anemic children explore their environment less and induce less stimulating behaviors in their caretakers.[47] This functional isolation may account for observed delays in anemic children.

In summary, the evidence from numerous studies supports the contention that IDA has an adverse impact on cognitive development. The effects of iron supplementation have been observed on a wide range of outcomes from performance on global tests of intelligence to specific cognitive processes and CNS development. Still, the research has not consistently found that developmental outcomes improve with iron supplementation, and, frequently, children with a history of IDA continue to perform more poorly than their nonanemic peers. Further research is needed to disentangle the effects of long-term social and economic deprivation that occur alongside IDA to more definitively label this relationship as causal and to establish the independent contribution of IDA to cognitive development.

Iodine

In addition to the fairly conclusive evidence on IDA, it is well established that maternal iodine deficiency results in cretinism, deafness, and poor motor and cognitive outcomes for the fetus.[66–70] Iodine supplementation prior to pregnancy or during the first trimester results in improved developmental outcomes.[67] The effects of mild maternal iodine deficiency are less clear; however, recent research among well-nourished populations indicates that maternal hypothyroidism during pregnancy may affect later cognitive development of offspring.[71] The effects of iodine deficiency on later cognitive development for children who display signs of iodine deficiency are inconclusive.

Zinc

More recently, considerable attention has focused on the effects of zinc deficiency on behavior. The known effects of zinc deficiency on growth have led researchers to hypothesize that there are effects on cognitive and behavioral development as well. Zinc deficiency is characterized by lethargy, apathy, and slow movement, all behaviors that closely parallel those described in other malnourished groups. In laboratory animals (eg, rhesus monkeys), zinc-deprived animals had lower activity levels, longer response times, and impaired success at learning tasks compared with controls.[72,73] In one study in which the monkeys were moderately zinc deprived, significant effects on a test of attention (Continuous Performance Task [CPT]) were observed prior to effects on growth.[73] In recent zinc intervention studies conducted on infants or toddlers at nutritional risk (low birth weight or from low-income countries), effects have been noted on motor development scores, time spent in high movement activities, and infant responsiveness.[74–76] Unfortunately, in this latter study, assignment to zinc was not random, thereby limiting the internal validity of the design. Among school-aged nutritionally at-risk children, one intervention study reported a significant improvement in scores on several neuropsychological tests (ie, CPT, oddity learning, tapping, tracking),[77] whereas another found a significant effect of zinc on reasoning (ie, fewer trials were needed to learn simple concepts).[78] In the former study, it was unclear whether assignment to different intervention groups was random. Finally, another study of stunted school-aged boys found no effect of zinc supplementation either on attention or academic performance.[79]

In summary, there is limited evidence that zinc deficiency may affect development, but, at this point, no definitive statements can be made regarding the effect of zinc deficiency on child development. Many more randomized, controlled trials are needed in human populations. In addition to general indices of development and academic performance, it has been suggested that researchers examine how neuropsychological functioning (eg, activity in infancy or abstract reasoning or concept formation in school-aged children) may contribute to overall performance within a developmental context. These mediating factors are likely to vary by age group.

Despite our brief attention to other micronutrients, it is important to note that the number of nutrients with the potential to affect behavior is vast; our knowledge of the roles of specific nutrients is constantly being revised. For example, evidence from a correlational study has suggested that maternal vitamin B_6 status is associated with performance on neonatal assessments, maternal responsiveness, and infant development between 3 and 6 months.[80]

MULTIVITAMIN AND MINERAL SUPPLEMENTATION

Over the past 20 years, a number of researchers have proposed a causal association between multivitamin supplementation and performance on intelligence tests. The hypothesis driving much of this research is that a subset of

the population, despite the absence of any anthropometric, biochemical, or clinical signs of micronutrient deficiencies, may have compromised cognitive function owing to marginal micronutrient status, even though there is no physiologic basis for such an effect in a normally nourished population (see Chapters 6 and 58). A recent review argued that the first signs of a micronutrient deficiency may be psychological[81]; however, a causal association would need to have been demonstrated vis-à-vis repeated positive findings using internally valid study designs to support such a conclusion. Whereas some studies have shown support for a causal association between multivitamin/mineral supplementation and cognitive performance,[82–86] others have not.[84,87,88] Given the implications that such an association would have for public health policy, it is important to closely scrutinize the evidence.

To test whether specific nutrients are causally related to behavioral outcomes, a rigorous model requires: selecting samples that are deficient or replete in the nutrient in question (based on quantitative assessment of nutritional status), establishing an initial relationship between cognition and a deficiency in this nutrient, conducting a randomized, placebo-controlled trial of supplementation of the nutrient that is deficient in both the replete and deficient groups, examining the differential effect of the supplement based on initial nutritional status, and accounting for any effect of study participation.[89] Although this model has been used with relative success in the iron deficiency and cognition literature, it has not been used in other areas of nutrition and behavior research, most notably in the assessment of the relationship between multivitamin/mineral supplementation and cognitive performance.[84] It should be noted that one challenge to use of this rigorous model is that unlike iron status, which is accurately assessed using a combination of biochemical indicators, some micronutrients do not have such biochemical (blood or urine) indicators that reflect status accurately.[90] On the other hand, the first step in designing such a well-controlled experiment is to determine which nutrient is of interest and is most likely to be related to the outcome in question, in this case, cognitive performance of school-aged children.

The evidence for the positive effects of multivitamins/minerals comes from several studies in which healthy children have been mass supplemented. The length of supplementation has varied between 6 weeks and 12 months, and the levels of nutrients provided differed considerably within multivitamin/mineral supplement (as low as 10% of the Recommended Dietary Allowance [RDA] for iron in some supplements) and between studies (average levels ranged from 50 to 200% RDA). Although several early studies concluded that multivitamin/mineral supplementation significantly improved the nonverbal intelligence of preschoolers and school-aged children,[84,85,91] a critical examination of the research reveals methodologic shortcomings that call the validity of these conclusions into question. For example, studies failed to document convincing evidence of a nutritional deficiency,[82–85,91] to control for confounding factors or bias that may have influenced the results,[82,85,91] and to provide a rationale for the nutrient composition of the supplementation.[82–85] Further, in some cases, the "effects" are the result of a negative effect of the placebo rather than improved performance resulting from supplementation.[84,85]

In addition to nonverbal IQ, other studies have examined multivitamin effects on more specific cognitive processes. Two studies on university students reported statistically significant treatment effects on reaction time.[82,83] However, in one study, the effects were noted among females only and were limited by a potential selection bias (only 61.4% of the original sample included in the final analysis).[82] In the second study, the treatment effect of a multivitamin supplement on reaction time was attributed to thiamin despite the fact that blood transketolase activation values did not indicate a thiamin deficiency.[83]

The results of the largest and most controversial of the mass supplementation studies of children showed a net gain of 3.5 IQ points among 401 children provided with 100% RDA of most micronutrients (compared with placebo); there were no effects in the groups supplemented with either 50% or 200% RDA.[85,91] Current knowledge of nutritional biochemistry makes a theoretical explanation of such effects difficult. Furthermore, incomplete and incorrect presentation of data, errors in statistical analyses, the exclusion of 35% of the original sample owing to their refusal to give blood, and evidence for less than ideal testing conditions for some of the tests raise serious questions about the validity of the findings.[91–93]

Three studies were conducted that attempted to address some of the limitations of previous studies by matching on baseline cognitive measures and/or on anthropometric indicators of nutritional status and/or assessing blindness to treatment.[84,86,87] Two showed no effect of multivitamin/mineral supplementation on nonverbal intelligence,[84,87] whereas one demonstrated a significant effect.[86] In the latter study, school-aged children, 6 to 12 years of age ($n = 388$), completed a randomized, double-blind, placebo-controlled trial of a multivitamin/mineral tablet; only 245 subjects were included in the final analyses owing to an a priori decision to exclude data from 6 testers who did not meet specific criteria.[85] The duration of the intervention was 3 months, and randomization was stratified by preintervention nonverbal IQ and by classroom. The multivitamin/mineral tablet included between 50 and 67% of the RDA depending on the vitamin/mineral. Teachers distributed the tablets at the schools. There were no significant group differences in age, gender, race, grade, or primary language at baseline. At the post-test, both groups showed a mean IQ score gain with a statistically significant difference ($p < .038$) of 2.47, favoring the multivitamin/mineral group. Subsequent analysis revealed that this difference was primarily attributable to a subset of the children whose increase in IQ score was greater than 15 points. Over a third of those randomized to multivitamins (35%) exhibited such an increase compared with only 21% of those given placebo ($p < .01$, chi-square test). The authors contended that the significant increase among the multivitamin group was likely attributable to improved nutrition

among a subset of poorly nourished children despite a lack of any evidence to support this claim. The fact that 21% of the placebo group showed similarly large IQ improvements (> 15 points) raises questions about underlying reasons, which may be related either to study design or implementation; these reasons may in and of themselves be both independent of nutritional status and a cause of the increase in the multivitamin group.

A recent macroanalysis of 13 trials concluded that the improved performance on nonverbal IQ tests in favor of multivitamin groups over controls was not due to chance ($p < .0002$).[88] In fact, when all of the data were aggregated from these 13 studies, the author reported a net gain of 3.2 IQ points among those given the multivitamin/mineral. Despite statistical significance, a difference of this magnitude is of questionable applied significance. Among the studies that showed no effects of multivitamin supplementation, several limitations were noted, including concerns regarding the measure of IQ and a design that varied between placebo and vitamin-supplemented groups. In addition, the author concluded that the reason for the nonsignificant differences between multivitamin/mineral supplementation and improvement in IQ in some studies was because of a lower sample size limiting statistical power, even though three of the five studies listed as having nonsignificant findings had larger sample sizes than others in which significant effects were found.[88] Despite a strong argument in support of an effect of multivitamin supplementation on nonverbal IQ, the author concluded that the most plausible explanation for the observed benefits was attributable to the large response of a subset of presumably malnourished children.[88]

In summary, available research does not support the contention that supplementation with multivitamins/minerals improves intelligence test scores of the general pediatric population. One finding that was common to several of the studies is that a subset of those supplemented exhibited a large change in test scores. It may well be that a subset of children are deficient in a specific nutrient or nutrients and hence respond favorably to treatment. However, although the data supporting this hypothesis are intriguing, they are by no means conclusive. Another consideration is the fact that none of the essential nutrients can be individually implicated. Indiscriminate supplementation of most essential vitamins and minerals is neither a feasible nor an acceptable public health practice.

To respond to these concerns, future research will need to use better designs that allow for a true test of the hypothesis. At a minimum, such studies should include (1) samples of deficient and nondeficient children, (2) multiple measures to assess nutritional status, (3) double-blind, randomized, placebo-controlled trials for both types of children, (4) randomization by initial nutritional status, and (5) assessment of both nutritional and cognitive outcomes.

Megavitamin/Megamineral Therapy

A related area of research has provided limited support for megavitamin therapy for two clinical conditions: autism and hyperactivity. Megavitamin therapy refers to the consumption of vitamins in amounts of more than 10 times the RDA, whereas megamineral therapy describes the consumption of minerals above the recognized biologic requirements.[94] One consideration in both the evaluation of the research in this area and its application to clinical practice is the potential toxicity of specific micronutrients in such large quantities.[95] Fat-soluble vitamins, particularly vitamin A, have shown toxic effects in large amounts, and although most water-soluble vitamins have been considered relatively safe, pyridoxine (vitamin B_6), a vitamin used frequently in megavitamin therapy, has produced ataxia and a severe sensory neuropathy in some individuals.[96] The basic assumption underlying this research is that the metabolic requirements of certain groups of children may be greater for certain nutrients, although there is little biochemical evidence to support this contention.

The arguments supporting the use of megavitamins with clinical populations date back to a study on autistic children showing a therapeutic effect of megadoses of vitamin B_6 on their behavior.[97] One complication of this study was that subjects had already been receiving megadoses of vitamin B_6 and other vitamins and medications prior to the experimental intervention. Therefore, children were randomly assigned to either a placebo, which meant taking them off the vitamin B_6, or varying doses of vitamin B_6 (75 to 3,000 mg). Although children's physical symptoms were reported to be significantly worse when on the placebo, other factors (ie, drug withdrawal), which were not well controlled in the study, could have been responsible for this deterioration. Furthermore, not all subjects were clinically autistic.[98]

Two studies have reported positive effects of combined treatment with vitamin B_6 and magnesium on the behavior of autistic children.[99,100] In a double-blind, randomized, placebo-controlled clinical trial, the effects of vitamin B_6 alone ($n = 37$) and vitamin B_6 in combination with magnesium ($n = 21$) were tested.[46] The combined treatment (vitamin B_6/magnesium) had a significant effect on 8 of 17 behaviors evaluated, but there was no effect of vitamin B_6 alone on any of the behavioral measures. In particular, positive benefits of the combined treatment compared with placebo were noted on behaviors reflecting interest in other people, verbal and nonverbal communication, and responses to the environment. In contrast, two other smaller studies, one that used lower doses of pyridoxine and magnesium than those used in the past, found no effect of the treatment on the behavior of autistic children.[101,102] Unfortunately, the small number of subjects in each of these studies increases the likelihood that the statistical power was inadequate to detect an effect even if it did exist, although one of the studies did find an improvement simply associated with being in the study.[100] Calcium and folic acid are two additional nutrients for which effects have been proposed; however, the research has been sparse.[103]

In a review of three well-controlled studies examining the effect of megavitamin supplementation on behavior in children with attention-deficit/hyperactivity disorder (ADHD), two showed no effect, whereas one reported adverse effects of supplementation.[98] The authors noted

that all of these studies employed a between-subjects analysis, that is, the response of the control group (those ADHD children on the placebo) was compared with that of the treatment group (those ADHD children given megavitamins), which may not be sufficiently sensitive to detect the effects of the supplement.[98] A fourth study assessed the impact of a megavitamin supplement (250 mg niacinamide, 250 mg ascorbic acid, 50 mg pyridoxine, 100 mg calcium pantothenate) on 12 children with ADHD, using a crossover design so that children would be exposed to both the vitamin and the placebo.[104] Unfortunately, because of parental refusals and one dropout, only seven subjects were included in the final analysis. Parent and teacher ratings were recorded weekly, and a trained behavioral observer recorded the child's behavior in the classroom, using the Stony-Brook Observational Code, for 30 minutes per week (at the same time of day). Despite the small sample size, several significant effects emerged; however, the direction of effects was not consistent. Teachers' reports of conduct problems and parental reports of hyperactivity and learning problems significantly declined while subjects were on the placebo. At the same time, teachers' reports of both inattentive and passive behavior and mothers' reports of psychosomatic complaints significantly decreased during the megavitamin treatment. Furthermore, there were some reported side effects of the megavitamin preparation, such as nausea and vomiting. These inconsistent findings are particularly important because the sample consisted solely of children who had responded to an open trial of megavitamin therapy, which should have maximized the probability of finding effects.

In summary, it does not appear that megavitamin supplementation has a consistent positive impact on the behavior of autistic or hyperactive children. For children with autism, supplementation with vitamin B_6 alone does not consistently improve behavior. Some evidence suggests that vitamin B_6 in combination with magnesium may have a positive impact on some aspects of behavior in autistic children, but this has not been demonstrated consistently. Further research using a greater number of children is needed to replicate such findings before recommendations can be made. In addition, the available evidence does not support the contention that megavitamin supplementation of children with attention-deficit disorder (ADD) or hyperactivity improves behavior. Furthermore, the fact that adverse side effects of such megavitamin preparations have been documented points to prudence in the scope of clinical use of such regimens.[104]

HUNGER: FASTING AND COGNITION

Hunger is typically defined as the "uneasy or painful sensation caused by a recurrent or involuntary lack of food…"[105] A related term, food insecurity, refers to the inability to acquire adequate and safe foods in socially acceptable ways. All people who experience hunger, that is, people who skip meals or reduce their food intake owing to a lack of necessary resources, are considered food insecure; not all of those who are food insecure experience hunger. Estimates for the year 2000 indicate that in the United States, approximately 13 million children under 18 live in food-insecure households and that approximately 4.1% of all children experience hunger.[106] With approximately 1 of every 6 children in the United States living in poverty, it is clear that hunger poses a serious problem for large numbers of children.[107]

In general, there seems to be a public perception that a relationship exists between hunger and psychosocial and academic functioning.[108–110] The potential mechanism to account for such delays is hypothesized to result from either the effects of deficient dietary intake over time or the more immediate metabolic or hormonal short-term effects of reduced food intake on cognitive functions, including but not limited to memory and attentional processes.[111] Methodologically, the association is difficult to establish because children who are at risk for hunger are frequently exposed to a wide variety of other risk factors (eg, poverty). In general, two types of designs have been used to assess the effects of hunger on cognition. The first refers specifically to whether the condition of hunger affects cognitive function, and the data come from a number of experimental studies that have measured children's response to fasting (eg, eating or not eating breakfast). The second refers to whether provision of food to children at nutritional risk can affect school performance and comes from food assistance and feeding programs that target low-income children in an attempt to reduce hunger and thereby improve school performance. In both types of studies reviewed, breakfast is the treatment variable. Breakfast has been shown to be a key component of a good diet by providing an important portion of the day's calories.[112,113] Its absence is considered to have potential effects on learning and school performance. Various surveys of children's eating habits suggest that anywhere from 5 to 26% of school-aged children frequently skip breakfast.[114,115]

Experimental Studies

In a series of clinical trials of short-term hunger in adequately nourished school-aged children, Pollitt and colleagues assigned children in random order to both a fasting and a breakfast condition, with each child serving as his or her own control.[116,117] Children were provided with dinner and spent the night in a controlled setting. Behavioral testing was conducted the following morning after 15 hours of fasting. Initial results showed no effect of missing breakfast, but differences emerged when IQ was considered in relation to test performance. Although missing breakfast had no effect on children whose IQ was above the median, children whose IQ fell below the median exhibited an increase in errors on the matching familiar figures tasks (MFFTs) in the absence of breakfast compared with the breakfast condition.[116] In contrast, on a memory test, subjects who had not eaten breakfast performed significantly better than those who had. Following similar procedures, the results of the second study showed statistically significant differences on the total number of errors in the MFFTs favoring the breakfast condition.[117] As in the first study, one measure of learning recall favored the no-breakfast (NBR) condition. In both studies, changes in performance (increase in errors)

were paralleled by physiologic responses to the feeding condition (glucose levels fell in NBR). The apparent benefits in incidental learning of the NBR condition were attributed to inefficient cognitive strategies.[116]

Two studies have explored the duration of fasting on cognitive function. In one study, the effects of increased duration of fasting were compared in well-nourished children under both BR and NBR conditions.[118] Although errors in performance on similar tests increased throughout the day for all children, children made fewer errors in the BR than in the NBR condition. On tests of arithmetic, between-group differences increased over the course of the morning, with BR-condition subjects performing significantly better than the NBR condition by midmorning. In a separate study, performance on a wide range of tests was compared between students who ate breakfast at home and those who ate breakfast at school.[119] Differences favoring the school breakfast condition were interpreted to reflect the benefits of eating within 30 minutes of the testing situation compared with the approximately 90-minute lag between breakfast eaten at home and testing. The study did not control for the nutritional content of home breakfast or the motivational effect for those children given breakfast at school.

Studies using healthy adolescents yield mixed results. In one, adolescents randomly assigned to a breakfast or a control group (given a very-low-calorie meal) showed no effects of hunger on cognitive function, including short-term memory, vigilance, impulsivity, and mood,[120] but another study reported that fasting resulted in slower word recall but no differences on spatial memory tasks compared with the breakfast group.[121] In two similar studies, students were allowed to eat their habitual breakfast (breakfast or not) and then were given either glucose or a placebo.[121] The results indicate that among students who had not eaten breakfast, glucose improved their word recall performance, whereas it had no effects on those who typically ate breakfast. There were no effects of breakfast or glucose on abstract reasoning.

A number of studies have focused specifically on glucose and cognition. It has been argued that because the brain has a high requirement for glucose relative to other organs,[122] the provision or availability of glucose prior to cognitive tasks may be particularly critical. The results of these studies are mixed, and weakness in study design further complicates their interpretation. In two studies, it was unclear whether subjects had eaten breakfast,[123,124] and in another, the nutritional content of the breakfast was not controlled.[125] Interestingly, research using animal models finds a U-shaped relationship between blood glucose and memory; at both high and low doses of glucose, the ability to retain learned information is impaired.[126] Although this type of relationship could account for the mixed findings, it is unclear whether this relationship would be replicated in children. Finally, other studies have reported a relationship between glucose tolerance and cognitive performance.[127] Given what is known about individual differences in diet and glycemic effect, research on glucose studies of fasting and cognition must include consideration of previous diet.

Research on fasting and cognition among low-income populations at nutritional risk reports mixed results. In Peru, using the same laboratory design used with well-nourished children, school-aged boys were categorized based on nutritional risk and then randomly assigned to a fasting or a breakfast condition, with each child serving as his own control.[128,129] The results showed no effects of fasting on tests of intelligence or vocabulary. In contrast, boys classified as at nutritional risk (low weight for height, low height for age) performed worse on a Stimulus Discrimination Task and the Sternberg Memory Search under fasting conditions compared with the breakfast condition. The authors concluded that attentional processes may be particularly sensitive to metabolic changes induced by the fasting condition.[130] Given that glucose levels were similar between the nutritionally at-risk youth and those considered not to be at risk, the mechanisms for such effects were unclear.

In Jamaica, Simeon and Grantham-McGregor tested the effects of missing breakfast on cognitive function among children of different nutritional histories: stunted, previously malnourished, and nonstunted controls.[131] All children were tested under both a breakfast condition and a tea-only condition. The results showed that both stunted and previously malnourished groups of children performed similarly and that missing breakfast resulted in lower test performance on verbal fluency and coding in these subjects. In contrast, the nonstunted controls' mathematics performance and MFFT efficiency scores improved as a function of missing breakfast. In a separate study, using a crossover design, poorly nourished Jamaican children performed significantly better on tests of verbal fluency (but not visual search, digit span, or speed of processing) after eating breakfast compared with well-nourished children.[132]

Finally, a study of school-aged children in Chile compared the effects of breakfast or no breakfast on the cognitive performance of normal, wasted, and stunted children and found no significant differences on any of the cognitive tasks.[133] Although this study was less controlled than those previously reviewed (randomization was only partially successful), the authors argued that testing children in the schools rather than a clinical laboratory may be a more valid test of the hypothesis. The absence of findings is attributed in part to the fact that highly motivating tasks, such as those employed in their study, may have masked potential between-group differences.

In summary, the results of well-controlled studies appear to indicate that fasting has effects on short-term memory that do not necessarily generalize to other domains of cognitive function. In addition, these effects likely vary as a function of previous nutritional risk.[130–132] Notably, it is unclear whether the reported effects are of meaningful magnitude, whether they can be sustained over time, or whether they are uniformly adverse. At least four studies have reported some small improvement in performance on certain tasks among healthy children under fasting conditions. Finally, although the results of several studies indicate that children at higher nutritional risk may be more susceptible to the effects of hunger,[131] this finding has not been consistent.[133]

School-Based Programs

One of the underlying assumptions of the school-based programs is the notion that children who come to school hungry will have a more difficult time attending to the learning process (see Chapter 9.1).[111] With the introduction of federally funded nutrition assistance programs in the schools and, in particular, the school breakfast program, investigators have been able to use these interventions as an alternative model to assess the effects of breakfast on school performance and to evaluate the effectiveness of the investment.

Data from evaluations of school breakfast programs have provided support for their benefits.[134] In one study, data on achievement, absenteeism, and tardiness collected prior to the initiation of school breakfast programs were compared with similar data after the school breakfast program. Compared with nonparticipants, children participating regularly in the school breakfast program showed significantly higher performance on the Comprehensive Test of Basic Skills (CTBS) and lower rates of absenteeism and tardiness. Most notably, even after controlling for a large number of potentially confounding variables (eg, sex, ethnicity, family size, income, pretest CTBS scores), the school breakfast program continued to show independent effects on the outcomes. One limitation of this study is that participation was voluntary, and this introduced a potential self-selection bias that could not be taken into account in the analyses.

In a two-state, three-school evaluation of the breakfast program, researchers found initial differences in academic performance between students with high participation in the school breakfast program (ie, those who typically ate school breakfast) compared with those with lower participation rates on a wide range of assessments, including test scores, indicators of depression and anxiety, hyperactivity, and attendance.[109] After introducing Universal School Breakfast (making the program free for all students in the school), program participation rates increased 100%. The authors reported that after 4 months of this breakfast program, students who frequently ate school breakfast showed improved rates of attendance and punctuality, decreased rates of psychosocial symptoms, and improved academic functioning (mathematics grades) compared with those who ate breakfast infrequently. Although suggestive, multiple methodologic problems (nonrandom design, small sample sizes, loss of subjects, and no control for usual breakfast consumption) prohibit the ability to establish any causal relationship between breakfast and student behavior. It is likely that children who choose to eat breakfast are significantly different in a number of ways from those who do not eat breakfast

Several studies from low-income countries suggest that children's performance and attendance improve with the introduction of a breakfast program, although, based on the designs, these effects are likely the result of increased motivation rather than any specific nutritional effect.[129,135,136] A comprehensive review of 15 school feeding programs in developing countries examined the association of school feeding with school attendance, participation, and achievement, with inconclusive results.[137,138] The results of this review highlight the difficulties associated with the implementation and evaluation of school feeding programs. Shortcomings likely to account for low program impact include inadequate targeting, food substitution rather than supplementation, inadequate supplementation (not meeting nutritional needs), poor administration and inefficient program implementation, and lack of nutrition education.

In summary, despite the absence of strong support for a direct impact of school feeding programs on school performance, consideration of the issues noted above in both programming and evaluation is likely to lead to more robust findings.[139] It should not be surprising that program evaluations of school feeding programs have not yielded strong effects on learning given the limitations of study designs available in school-based research. Furthermore, although one would expect that children at highest risk might benefit the most from such programs, this hypothesis has not been adequately tested. Finally, research on the effectiveness of such programs requires a recognition of the complexity of such relationships. Specifically, more attention needs to be focused on the multitude of factors (eg, attendance, absenteeism, time in school, time on tasks, etc) that mediate the relationship between school breakfast and school achievement (Figure 22-3).[134,137,138]

SPECIAL TOPICS

Sucrose

There is no shortage of literature attesting to the strongly held belief by parents and teachers that sugar causes behavioral alterations in children, particularly hyperactivity. However, most of the evidence to support such an association is purely correlational. The best test of the effects of sugar on behavior come from double-blind challenge trials that have shown an adverse effect of sugar on measures of sustained attention, performance on learning tasks, and play behavior.[140] At the same time, others have reported no effect of sucrose on behavior,[140,141] whereas still others have reported effects in the opposite direction as those hypothesized, that is, a decrease in activity and an increase in drowsiness in children after sugar ingestion.[141–143] Several potential explanations have been offered for this lack of uniformity in the research findings, including differences in subjects (ie, various ages and clinical status), state characteristics (fasting, nonfasting), study design issues (dosage of sucrose, differences in research settings, amount of time elapsed between challenge and testing, the placebo used), and the behavioral measures used. Furthermore, some researchers have failed to account for total energy intake, which is a potential confounder because of the inherent differences in energy content of sucrose and noncaloric sweeteners.[140] In addition, some but not all researchers have reported that aspartate, the most commonly used placebo, may also cause behavioral changes.[141,143,144]

One of the underlying assumptions of such research is that children with specific behavior problems such as ADD and hyperactivity may be particularly sensitive to the effects of sugar. Despite this assumption, many studies have examined samples composed primarily of normally active (without ADD or hyperactivity) children, whereas

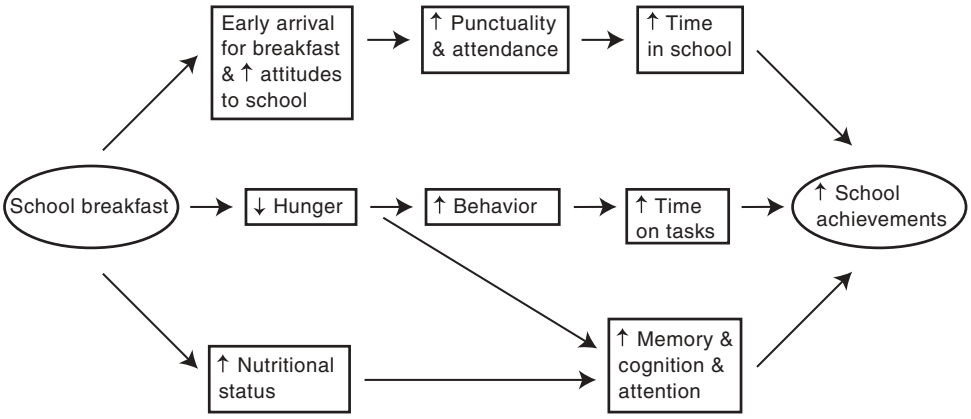

FIGURE 22-3 Possible mechanisms of the effect of school breakfast on school achievement. Reproduced with permission from Grantham-McGregor S, et al. Environmental effects on cognitive abilities. Mahwah (NJ): Lawrence Erlbaum Associates; 2001.

others have focused specifically on samples composed primarily of children diagnosed with ADD, with or without hyperactivity.

In six double-blind sucrose-challenge studies in normal children, two found no effects of sucrose on behavior,[140,144] two showed what might be considered positive effects,[141,143] and two others showed negative effects.[140,145]

Among the studies reporting adverse effects of sugar consumption, weaknesses in design may account for such findings. For example, in one study, after the high-sucrose challenge, girls (but not boys) made a greater number of errors on the paired associates task than when on the low-sucrose challenge; there were no differences between high sucrose and aspartate.[145] In addition, a global rating of children's behavior indicated that teachers perceived significantly greater activity in the high-sucrose versus low-sucrose challenge. There were no effects of the high-sucrose challenge on other cognitive measures, fidgeting, or the Abbreviated Conners' Teacher Rating Scale (used to diagnose hyperactivity). Of particular concern is that the significant differences were between high sucrose and low sucrose rather than the aspartate control, suggesting some mechanism other than sugar content (eg, perceived sweetness) as mediating the behavioral changes observed.

Studies that have examined the effects of sucrose on children diagnosed with ADD with or without hyperactivity have shown very little support of a causal association.[140,146,147] In a study of 7- to 10-year-old hyperactive boys, there was no effect of a sucrose challenge on performance on a sustained attention test (CPT), paired associate learning, matching familiar figures, fine or gross motor movements, or the draw-a-line slowly or draw-a-line fast tests.[140] Another study using hyperactive boys attending a day treatment program for hyperactive children reported no differences in behaviors during recreational periods, academic performance, or teacher ratings based on sucrose challenge.[140] In still another study that also used tests of attention among children with ADD, an oral 5-hour glucose tolerance test found no effect of glucose on the CPT, although, interestingly, the catecholamine response to the glucose was significantly lower in those with ADD than in the control group.[146] Finally, the results of a recent meta-analysis conclude that the available evidence does not support a relationship between sugar consumption and behavior or cognitive performance of children.[140] This conclusion is strengthened by the fact that only designs that met criteria of scientific rigor were included.

Despite all of the research to the contrary, there has been an obvious resistance of parents and teachers to fully accept such a conclusion. Some of this may stem from expectancy and common association (ie, high sugar consumption corresponding to events that may in and of themselves cause excitement in children). The results of one study illustrated the effect of parental expectancy on behavioral ratings.[148] Boys who were 5 to 7 years of age and who were reported to be sugar sensitive took part in a challenge study. Although all children received a placebo (aspartame), half of the mothers were told that their children were given a large dose of sugar and the other half were told that their children were given a placebo. Mothers who were told that their sons received sugar rated their children as significantly more hyperactive than those who were told that their children were given a placebo. Videotapes failed to corroborate their perceptions.[148]

In summary, research from well-controlled studies, including multiple outcomes and comparisons, does not support a consistent causal association between sucrose ingestion and children's behavior. These results are true for children diagnosed with ADD and/or hyperactivity and normally active children. Positive effects of elimination diets in treating ADD children may be attributable to the concurrent elimination of other substances such as caffeine or allergens and not the elimination of sucrose.[149] In addition, parental or teacher expectancy likely plays a role in reports of sugar sensitivity and in the perceived success of elimination diets. Whether a highly specific subgroup of children is sensitive to sucrose still is not supported by the bulk of the available research; however, this possibility cannot be definitely eliminated based on current research.

Food Additives

In addition to sugar, food additives have frequently been implicated as causes of children's behavioral problems, specifically hyperactivity. Although data from correlational

studies and open trials, in which normal diets are replaced with additive-free diets (the Feingold diet), have provided support for such an association, the evidence of a causal link is limited.[98] One of the major difficulties of such research is that neither the child nor the family is blinded to treatments involving changes in a child's diet. Furthermore, many other factors may also change with dietary manipulations, making it impossible to directly link food additives to behavioral change.

Two other types of studies offer a better test of the association between food additives and behavior: dietary studies and challenge studies. Dietary studies include two randomly assigned diets (one without additives and a placebo); in challenge studies, the subject is provided with either a food with additives or an additive capsule after being on a nonadditive diet for a specified period of time. Of 11 studies using these two techniques in children diagnosed with hyperactivity to test for the effect of a single or a class of substances (ie, artificial colors), only 3 found an effect of the challenge on the child's behavior.[150] In those studies, two showed effects on teachers' ratings of child behavior.[149]

More recently, studies have employed a standardized technique of double-blind, placebo-controlled food challenge to diagnose adverse food reactions.[151] This procedure includes an elimination diet and a subsequent reintroduction of the suspected food (or additive) and may also include allergy skin testing. Although a well-controlled design, this technique does not always allow the investigator to identify any one item or specific substance but rather to identify a food or a class of foods to which the individual may be sensitive.

Three studies using this technique provide limited support for either specific food sensitivities of some children with ADD and/or sensitivity to food additives,[152,153] although effects were often seen in only a subgroup of children.[150] In one study, differences in energy intake between diets may have affected the behavioral effects attributed to food additives.[150]

In summary, the available evidence does not support the notion that food additives adversely affect the behavior of hyperactive children. What does seem to be true, however, is that a small subset of hyperactive children may be particularly sensitive to some foods and/or food additives, and these children may benefit from a modified diet.

CHAPTER 23

ENERGY AND SUBSTRATE REGULATION IN OBESITY

Susan B. Roberts, PhD, Daniel J. Hoffman, PhD

Overweight and obesity are widely considered to be the major public health problem in affluent countries[1,2] and are becoming increasingly common in some economically disadvantaged societies as well.[3,4] Previously considered a problem mainly occurring in adults, overweight and obesity are now prevalent in children, with an estimated 18 to 28% of US children and adolescents thought to be affected.[5]

DEFINITION OF OBESITY

The definition of obesity is deceptively simple: it is a state of excessive accumulation of body fat. However, the translation of this simple definition into working standards for excess body fat and body weight has been complicated for several reasons. First, because body fatness is a continuum, the cutoff point for the definition of obesity is necessarily arbitrary.[1] In addition, controversy remains over what constitutes the optimal range of body fat in infants and children because of the normal developmental changes in adipose tissue mass that need to be taken into account. Finally, the harmful effects of obesity result primarily from the excessive accumulation of fat, but there is no simple method for the direct measurement of this body compartment in individuals of any age. These concerns notwithstanding, the Centers for Disease Control and Prevention (CDC) recently published new body mass index (BMI; kg/m^2) percentiles for children aged up to 20 years (see Appendix), together with useable definitions for "risk of overweight" and "overweight."[6] These definitions recognize that BMI is a better indicator of relative weight than weight for height, even if they are not precisely aligned with body fatness in all population groups.[7]

The new charts provide an improved set of reference growth data that have been updated and smoothed using statistical techniques. However, as reviewed elsewhere,[8] it should be noted that the latest national survey data for children ages 6 years and over were not included in the data set used to calculate the BMI percentiles because of the marked increase in weight of children 6 and older in the latest survey (Third National Health and Nutrition Examination Survey [NHANES III]) compared with previous surveys. The inclusion of the latest survey data would have shifted the percentiles up and resulted in a relative underclassification of the prevalence of overweight. Because the 85th percentile of BMI is used to classify risk of overweight and the 95th percentile is used to classify overweight,[7] the data used effectively define overweight as a fixed percentage relative to population surveys prior to NHANES III. Thus, the BMI charts can be considered more as recommendations for the healthy range of BMI rather than as current population values because they are designed primarily to provide a reference for the diagnosis of overweight. They can also potentially be used to diagnose underweight (eg, at the 10th or 5th percentiles), but accepted definitions for underweight are needed.

One concern with using BMI to identify overweight children is the potential for misclassification.[8] The relationship between weight and height and body fat content can be weak,[9] and, especially in children younger than 5 years when the high BMI percentiles are very close together, factors such as enhanced muscular development, large head size, and a high torso-to-leg ratio could all falsely elevate the BMI of a child with a healthy amount of body fat into an overweight range. For example, differences in head circumference between a 3-year-old child on the 10th head circumference percentile and one on the 90th percentile translate into a body weight difference of approximately 0.75 kg (assuming that the head weighs 1.7 g/cm^3 and is a sphere). A 3-year-old child's BMI would therefore vary by approximately 0.85 units depending on whether head circumference was on the 10th or 90th percentile. This could mean the difference between the 75th and 85th to 90th percentile for BMI—in other words, the difference between no weight concern and a diagnosis of risk of overweight. The effect of the relative length of torso and legs can also be predicted using theoretical calculations. Assuming that the proportion of standing height attributed to torso varies from 0.35 to 0.38 and that for a given contribution to height, torso weight is twice that of legs or neck,[10] BMI would vary by approximately 0.4 units. These calculations highlight the potential for misclassification of individuals, especially those between the 85th and

95th percentiles. Until improved methods for determining body fatness are routinely available, some individual judgment is needed in applying standard BMI definitions for overweight in individual children.

At the same time that the 2000 CDC percentiles were published, Cole and colleagues reported internationally derived, age-specific BMI values for children equivalent to BMI definitions of overweight (BMI = 25 or more) and obesity (BMI = 30 or more) in adults.[11] The adult cutoff values of 25 and 30 were originally developed based on increased health risks[12]; the theoretical advantage of creating equivalent values for children is that they would provide absolute standards for fatness rather than standards relative to population fatness at any given period of survey.[13,14] It should be noted that it is not currently known whether equivalent percentiles in childhood confer similar risk to those found in adults, but because BMI tends to track from childhood through adult life, the approach seems a reasonable one.

As reviewed elsewhere,[8] Cole and colleagues obtained national survey data from six countries (Brazil, the United Kingdom, Hong Kong, the Netherlands, Singapore, and the United States).[11] For each country, the percentiles equivalent to BMI values of 25 and 30 at age 18 years were determined, and then BMI values at different childhood ages were obtained for the same percentiles. There was substantial agreement in childhood BMI values among the six countries; thus, mean values for different ages were computed to give age-specific BMI cutoffs equivalent to adult BMIs of 25 and 30 kg/m^2. Figure 23-1 shows a comparison of the CDC 85th and 95th percentiles with the overweight and obesity cutoff points for BMI provided by Cole and colleagues. For both boys and girls, the 2000 CDC definition of overweight (95th percentile) is markedly higher than the Cole and colleagues[11] definition of overweight,[11] except for the period between age 4 and 5 years. In other words, by the current US definition, many fewer children in the United States and worldwide are overweight. In fact, the 2000 CDC definition of risk of overweight (85th percentile) most closely approximates the Cole and colleagues definition of overweight, with the Cole and colleagues values tending to be slightly higher for ages 2 to 10 years and slightly lower for 17 years and older.[11] In addition, the CDC BMI definition of overweight is not similar to the Cole and colleagues definition of either overweight or obesity, but the CDC 97th BMI percentile is similar to the Cole and colleagues definition of obesity for the period between 7 and 14 years.[11]

These comparisons raise the important issue that greater agreement is needed among national and international agencies with regard to definitions of what age-specific BMI values constitute risk of overweight and obesity. In the meantime, the 2000 CDC percentiles for BMI might be most appropriate for assessing different degrees of overweight in US children, and the BMI cutoffs of Cole and colleagues could be used for international comparisons of obesity prevalence.[11]

RISKS OF OBESITY

The short-term risks of overweight in children and adolescents extend to reduced scholastic performance, psychological problems, and a number of significant health risks, including hyperlipidemia.[15] In addition, obese children are at increased risk of becoming overweight or obese adults compared with children of normal weight[16] and therefore are at long-term risk of the substantially increased morbidity and mortality, psychological problems, reduced economic achievement, and discrimination that are seen in obese adults.[17] In a summary of 17 studies investigating the long-term risks of childhood overweight for the development of adult obesity, Serdula and colleagues observed that 26 to 41% of overweight preschool children go on to become obese adults, with the risk of adult obesity increased to 2.0 to 2.6 times that of nonoverweight children.[18]

The risk of adult obesity in overweight children increases progressively with age. Data from Braddon and colleagues[19] on changes in the risk of adult obesity according to the age

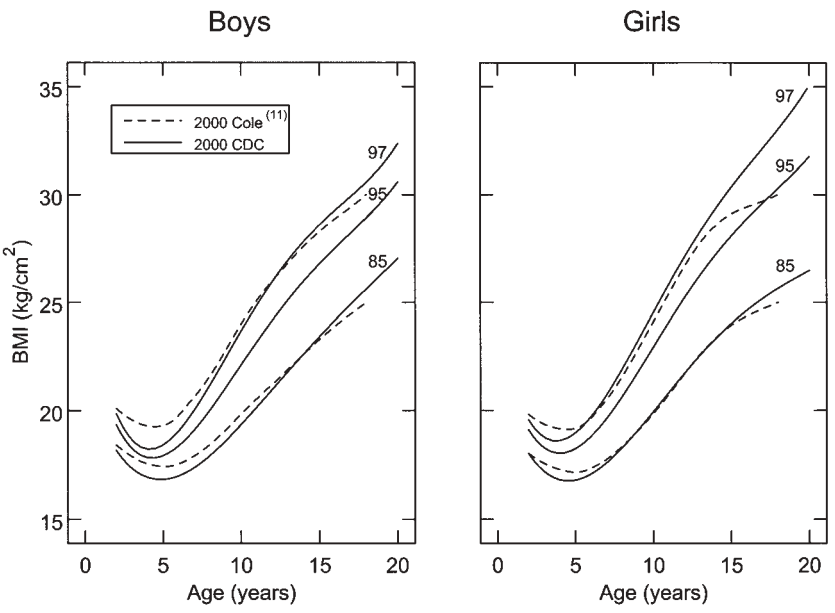

FIGURE 23-1 Comparison of Cole et al's[11] BMI definitions of overweight and obesity during childhood (*broken line*) with 2000 CDC 85th and 95th percentiles (defined as risk of overweight and overweight, respectively) and the CDC 97th percentile (*solid line*). Reproduced from Roberts SB and Dallal GE.[8]

of childhood manifestation are shown in Figure 23-2. In that study, which was conducted in a cohort of English children, the percentage of obese adults who were overweight at age 7 years was only 2.6% for men and 7.5% for women, whereas values increased to 13.9% for men and 25.5% for women who were overweight at age 14 years. In addition, these figures might substantially underestimate the true relationship between early fatness and later obesity because 28.6% of obese men and 36.5% of obese women were already obese or overweight by age 7, a substantially increased percentage relative to the group of children who were categorized as overweight, and again there was an increase in the number of obese adults who were overweight in childhood as age increased (Figure 23-2).

A further issue relevant to the risks of childhood overweight is that there is evidence to suggest that *severe* overweight developing early in life is particularly likely to lead to adult obesity. Whitaker and colleagues showed that childhood overweight was increasingly likely to predict adult obesity from age 3 years and older.[16] Similarly, Abraham and Nordsieck reported that 72.2% of severely overweight children (weighing more than 120% of the average for the population) became obese adults[20]; a similar result was found by others.[21] Although these data illustrate the substantial risk of childhood overweight leading to adult obesity, it is also important to note that many overweight children do not become obese adults. Data from Poskitt indicate that only one in nine overweight infants remain obese as adults in England,[22] whereas other studies similarly indicate that a minority of overweight children remain overweight.[19]

Recent studies have also raised the issue of whether, in addition to increasing the risk of adult obesity, obesity in childhood could also exert an independent influence on adult morbidity and mortality. In an analysis of longitudinal anthropometric data from the Third Harvard Growth Study (1922–1935), Must and colleagues observed that over a 55-year period, men who were overweight in adolescence had significantly increased all-cause mortality (relative risk 1.8) compared with men who were lean during adolescence.[23] This effect of adolescent weight, confirming a similar result found previously by Mossberg,[24] persisted even when weight at age 53 years was controlled. The implication of this finding is that the effects of adolescent weight on morbidity and mortality resulted from the adolescent obesity directly rather than from the effects of adolescent obesity on adult weight.[24] There was no association between adolescent weight and adult mor-

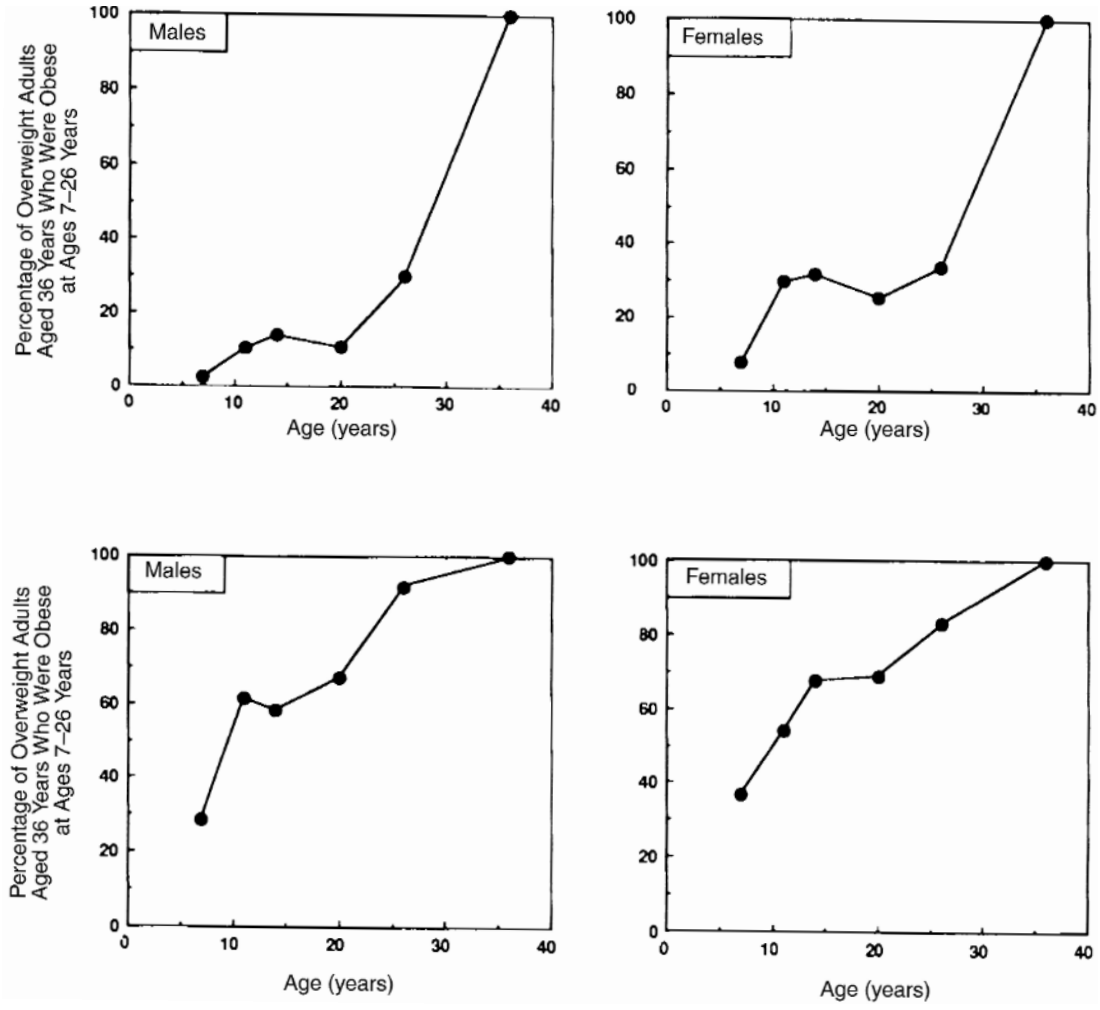

FIGURE 23-2 Percentage of obese men and women aged 36 years who were already obese (top) or either obese or overweight (bottom) by ages 7 to 26 years. Adapted from Braddon FEM et al.[19]

tality in females in the study of Must and colleagues,[23] and gender was not distinguished in the study by Mossberg.[24]

The mechanisms by which adolescent weight might exert an influence on adult morbidity independent of adult fatness in men and possibly in women are not known. However, reports of increased plaque deposition in the arterial walls of overweight children suggest that there could be long-term effects of early body weight on morphology or metabolism that are not easily reversible. Consistent with this suggestion is the fact that overweight girls have been shown to have a reduced age of menarche, a risk factor for developing breast cancer.[25–27] This effect appears to be primarily related to increased body size rather than to differences in dietary intake in the obese.[28–30] A study by Meyer and colleagues suggested that the lowered age of menarche in overweight girls might be associated with increased weight rather than with increased fat mass.[31]

It is important to note that not all studies of the relationship between childhood weight and adult morbidity have reported positive associations. The study of Barker and colleagues reported an opposite trend, with a negative association between weight at 1 year of age and vascular disease in adult life.[32] Further studies are needed to clarify this issue and in particular to determine whether the long-term effects of early obesity could be important at some ages during childhood but not at other ages.

GENETIC VERSUS ENVIRONMENTAL FACTORS IN THE DEVELOPMENT OF OBESITY

Studies in Animals

In animals, there is substantial evidence that obesity can be transmitted genetically.[33] Several genetically obese animal strains exist, such as the Zucker rat and the ob/ob mouse, which have substantially more adipose tissue than lean counterpart animals. The fat gain in genetically obese animals is caused by a variety of mechanisms, including hyperphagia and an increased efficiency of energy use. The increased energy efficiency can be attributed primarily to a reduced thermogenesis for body temperature regulation. It is likely that some degree of imbalance in the autonomic nervous system contributes to the defective thermogenesis, as indicated by reduced sympathetic nervous drive in response to mildly cold ambient temperatures and in response to overeating.[34] In addition, parabiotic studies, in which the circulatory systems of lean and genetically obese animals are joined, have indicated that unidentified circulating factors (or the ability to respond to them correctly) are also important in the development of obesity.[35]

Animal studies also demonstrate that obesity can result from environmental factors, most particularly the availability of high-fat or high-variety diets. Some—but not all—strains of laboratory rodents gain substantial weight and fat when offered cafeteria diets containing a variety of snack foods such as cookies, cheese, cakes, processed meats, nuts, and so forth. Similar results have also been produced by offering synthetic high-fat diets, as well as by providing sucrose solutions in addition to standard rat chow. It could be noteworthy that physical activity does not have as much of an influence on body fat content as does diet in these rodent species. The fact that only some strains of animals, and only some animals within a strain, are susceptible to this diet-induced obesity[36,37] strongly indicates that "environmentally induced" obesity occurs only in genetically susceptible individuals and should therefore really be viewed as a genotype–environment effect. In relation to this observation, it is important to note that the willingness to overconsume food is not entirely a result of absolute standards of taste in animals. Instead, in studies that have separated the process of eating from the process of digestion by the use of esophageal cannulae, it has been shown that unidentified postingestion factors play a dominant role in determining food preferences.[36]

Studies in Humans

Studies on the importance of genetic inheritance versus environmental factors in the development of overweight and obesity have been harder to conduct in humans. It is widely accepted that body fat mass and fat distribution are subject to significant familial transmission[38–43]; in other words, the body compositions of children to a large extent reflect those of their parents. There remains a great deal of uncertainty, however, over the relative importance of genetic inheritance and environmental transmission (transmission between generations through the sharing of common environmental circumstances) in determining body fat content. Reported values for genetic heritability range from negligible to 0.8, implying that genetic inheritance accounts for between 0 and 80% of the variability in body fat mass in the community, and rates of environmental transmission range almost as much.[39,41,43–55]

This uncertainty over the relative importance of genetic and environmental transmission probably relates in large part to the methods that have been used to measure body composition and to the populations that have been studied. Most previous studies have used simple anthropometric indicators of body fat mass (such as weight corrected for height or one or more skinfold thicknesses).[39,43–48,50–55] However, the relationship between anthropometric parameters and fat mass can be very weak.[9] In addition, muscle mass, bone size, and height appear to be strongly inherited.[43] This could help explain the genetic inheritance of indicators of apparent fatness based on weight and could indicate that weight measurements will tend to result in an overestimation of the genetic inheritance of fat mass.

Probably the best data available on the inheritance of body composition come from Bouchard and colleagues, who have been the only groups to use hydrostatic weighing (a gold standard method) for assessment of body composition.[49,56] Data from these investigations indicate that there are significant genetic and environmental components to the transmission of body density, with genetic inheritance accounting for 25% and environmental transmission for 30%. Thus, it appears that the family environment is at least as important as genetic inheritance in determining body fat mass.

Other lines of evidence from studies that effectively separate genetic inheritance from environmental factors confirm the importance of environmental factors in human overweight and obesity. For example, the body fat content of unrelated married couples becomes more similar over time.[40] In addition, the prevalence of obesity varies by the season of the year (it is highest in the fall and winter) and location within a country.[57] As further evidence, surveys show that the prevalence of childhood obesity has increased in the United States during the past two decades despite a relatively stable population pool.

METABOLIC PROGRAMMING IN THE DEVELOPMENT OF OBESITY

There is increasing awareness of the possibility that there might be critical periods during the life span when diet and other environmental factors exert a long-term influence on body fat content and the risk of adult obesity in humans,[58–61] a potential event that has been termed "metabolic programming." As emphasized by Lucas, the fact that this tremendously important issue has not yet been resolved reflects the relative lack of randomized dietary intervention trials with long-term follow-up in infants and children.[58,59] More studies of this type are needed despite the complex ethical issues involved.

Evidence consistent with the view that metabolic programming of adult body fatness might exist at different ages comes from several different sources, in particular indicating that either long-term energy insufficiency or long-term energy excess in childhood can lead to excess body fat content in adult life. In 1976, Ravelli and colleagues published the first study suggesting that nutrition of the mother during the intrauterine period might have a long-term influence on the risk of obesity.[62] Specifically, the investigators followed the incidence of obesity among men whose mothers lived in Holland during the Dutch "Hunger Winter," a time when the food supply was reduced in specific areas of the country at the end of the Second World War. A significant *increase* in the incidence of obesity at age 19 years was noted among the male offspring of mothers whose energy intake was reduced to famine levels (estimated at approximately 600 kcal/day) specifically during the first trimester of pregnancy, whereas a significant *decrease* in the risk of obesity was observed in women who had undergone energy deprivation during the third trimester. Although "metabolic programming" of intrauterine malnutrition can explain this result, it is also possible that other factors were important. For example, the mothers who were deprived of food might have been particularly concerned about feeding their infants substantial amounts of food after giving birth. In addition, the food provided by the Allied Forces after the famine was extremely high in fat, and the possibility cannot yet be ruled out that this might have had an important long-term effect.

Nevertheless, recent studies in animal models have also reported that malnutrition during the early part of pregnancy can be associated with increased body fat in adult life,[63,64] supporting the belief that long-term metabolic changes can be induced through diet. Although the mechanism for this effect is not known, Anguita and colleagues suggest that morphologic changes in the hypothalamus might be important.[64]

Similar to in utero energy insufficiency, childhood stunting (which is widely considered an indicator of chronic energy insufficiency during early childhood and typically occurs before age 5) has also been correlated with high BMI in several transitional countries, such as Brazil, China, and South Africa.[4,65–68] The risk for obesity and overweight for adults who were stunted as children and adolescents varies among countries but is consistently positive. The relative risk for obesity for an adult who was stunted in childhood is 1.7 in Brazil, 2.6 in South Africa, and 7.8 in Russia.[65] Mechanisms to explain these associations remain unclear; however, recent studies have offered possible metabolic as well as behavioral evidence that might explain part of this association.

In perhaps the first piece of evidence that early nutrition has long-term effects on metabolism that predispose a child to subsequent obesity, Hoffman and colleagues reported that nutritionally stunted children have a higher respiratory quotient and lower fat oxidation compared with healthy children from the same environment (Figure 23-3).[69] In the same series of experiments, stunted children also appeared to have impaired regulation of food intake compared with control children from the same environment,[70] resulting in greater energy consumption per kilogram of body weight when the stunted children were exposed to an abundant, ad libitum diet (Table 23-1). The results of this study need to be replicated but are consistent with the hypothesis that exposure to food insecurity early in life can disrupt normal perceptions of hunger and satiety. Taken together, these studies provide multiple lines of evidence consistent with

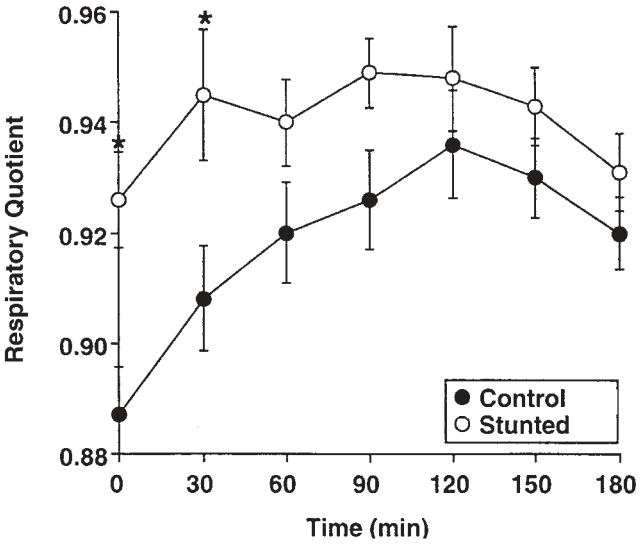

FIGURE 23-3 Fasting and postprandial respiratory quotient (RQ) in stunted and control children.[69] Values are means ± SEM. The stunted children had a significantly higher fasting RQ compared with control children (t = 0) and postprandially at t = 30 minutes ($p < .05$). The average postprandial RQ was not significantly different between the two groups ($p = .10$). Reproduced with permission from Hoffman DJ et al.[69]

the suggestion that undernutrition during early life can have long-term metabolic effects that can promote obesity later in life.

The first months after birth have received considerable attention as another potential time when metabolic programming, through the choice of diet (breast milk or formula) and the time of weaning, could have a long-term influence on body fatness. In particular, although several studies have suggested no effect of formula feeding on body fatness, the more recent studies have consistently indicated that breast-fed infants tend to become leaner adults.[71–79] The finding of a tendency for formula feeding to promote later body fatness in full-term babies is consistent with preliminary findings from randomized studies in preterm infants[80] and also with the well-known effect of early overfeeding in rodent models (resulting in a permanent increase in body weight and fat content).[81] Additionally, similar results have been demonstrated in nonhuman primates.[82]

Further studies are needed to determine whether metabolic or behavioral influences of formula versus breast-feeding are responsible for the differences observed. However, of potential relevance to this issue is the fact that Singhal and colleagues conducted a prospective study of preterm infants who were fed either a standard infant formula, banked breast milk, or an enriched preterm formula (5 g protein/L and 9 g fat/L greater than the standard formula) to examine long-term effects on circulating leptin.[80] Between the ages of 13 and 16 years, the children were measured for body fatness and leptin concentrations. It was found that the children who had received the preterm formula had a 30% higher ratio of leptin to fat mass compared with both of the other groups,[80] suggesting that the excess energy intake or altered nutrient composition of the preterm formula might have programmed higher circulating leptin during adolescence.

ENERGY AND SUBSTRATE REGULATION IN OBESITY

Energy Regulation

Average nonoverweight children consume more than 2 million kilojoules a year, but their body fat stores increase only modestly if growth is normal and energy expenditure approximates energy intake. A change of only 10%, either in intake or output, can lead to a 15-pound change in body fat in a single year, in addition to that deposited as a normal consequence of growth. The majority of children, who are of normal weight, do not exhibit such undesirable changes in body weight and fat, implying that normal energy regulation must be remarkably sensitive.

Until recently, our understanding of the underlying cause of this sensitive energy regulation was dominated by the guiding principle of energy balance:

Energy stored = Energy intake – Energy expenditure

Thus, it has been recognized that high levels of body fat (ie, energy) cannot have been accumulated without energy intake being unusually high or energy expenditure being unusually low, or a combination of these two options. Similar calculations to those given above can illustrate that the dysregulation of energy in obesity needs to be only very small for excess adipose tissue to accumulate. For example, a child who becomes 100 pounds overweight by the age of 15 years needs to have eaten less than an extra ≈ 100 MJ per day between the ages of 5 and 15 years. There has been considerable interest in defining whether energy intake or energy expenditure is the primary factor determining this energy dysregulation in obese individuals, as well as seeking to identify metabolic mechanisms that determine the separate regulation of these parameters. As described below, most of the investigations conducted in children have been cross-sectional in nature, that is, comparing measurements of energy intake and expenditure between lean and obese individuals or examining the relationship between these parameters in groups of individuals differing widely in body composition.

TABLE 23-1 Energy Intake and Ratio of Energy Intake to Resting Energy Expenditure

Energy Intake

The energy intake of an individual is usually understood to be that energy available to the body after obligatory losses of energy in urine and stools. Although complex metabolic balance studies are needed to precisely determine this "metabolizable energy," it can also be predicted from the dietary intakes of protein, fat, carbohydrate, and alcohol using the standard conversion factors of 4.0, 9.0, 4.0, and 7.0 kcal/g, respectively, which take into account the obligatory losses.

The regulation of food intake clearly plays an important part in the sensitive energy regulation in children of normal weight. More than 70 years ago, Davis demonstrated that very young children of normal body weight are capable of choosing a balanced diet and maintaining normal growth without dietary intervention from adult caregivers.[83] This remained true over periods of several days or longer, although food choices at individual meals were frequently extremely erratic. Recently, Birch and colleagues[84] and Shea and colleagues[85] provided additional strong evidence in support of an important role for the regulation of food intake in the energy regulation of young children of normal body weight. These investigators showed that although there might be substantial meal-to-meal fluctuations in energy and nutrient intakes, prompt and appropri-

ate compensation occurs spontaneously so that the 24-hour energy intake remains relatively stable. A further report by Birch and colleagues also demonstrated that young children are able to compensate for the inclusion of low-calorie fat substitutes in a meal to maintain a constant energy intake.[86]

These studies clearly demonstrate that in children of normal body weight, energy regulation through the regulation of food intake occurs and plays an important role in the maintenance of a stable pattern of body composition change throughout childhood. However, a caveat to these studies is that the observed capacity for normal energy regulation may occur only when relatively healthy foods are offered, and the ability of young children to accurately regulate energy intake when offered many highly energy-dense foods of low nutritional value has not been systematically explored.

Individual studies of differences in reported energy intake between overweight and nonoverweight children have been conflicting, but taking all of the data together, reported energy intakes of overweight children are not significantly greater than those of nonoverweight children of the same age and are significantly less when expressed in relation to body weight.[29,85,87–105] However, it is known that overweight individuals, including adolescents,[106] underreport their energy intake to a greater degree than do individuals of normal weight, which indicates that the finding of normal food intake in overweight children might be owing to methodologic error.

In contrast to the studies of reported energy intake, studies from psychological investigations of eating behavior in overweight children suggest that already-overweight children consume more total energy than do nonoverweight subjects. Studies by several groups have suggested that overweight children and adolescents are faster eaters, chew less, prefer high-fat foods, and do not exhibit the normal pattern of decelerating eating toward the end of a meal, as seen in children of normal weight.[107–110] Furthermore, obese parents have been reported to give more encouragement to their children to eat than do parents of nonobese children and serve them larger portions of food.[111] These findings are also consistent with results from studies in adults.[112] In addition, overweight children may have an abnormal pattern of energy consumption within the day, with a reduced percentage of calories being consumed at breakfast.[113] As described below, studies of total energy expenditure (TEE) might be more reliable for estimating the energy intake of overweight children than studies of reported energy intake and confirm that already-overweight children consume more total energy than children of normal weight.

Energy Expenditure

The TEE of an individual, which is equal to the metabolizable energy intake when body energy stores remain constant, can be divided into compartments that relate to the different types of energy expenditure measurements that are made. Typically, three major compartments are defined. The resting energy expenditure is the energy expended at rest after an overnight fast and is the major compartment, comprising at least half of the TEE in a typical individual. The thermic effect of feeding is the increase in energy expenditure above baseline resulting from the consumption and processing of food and comprises 7 to 15% of TEE on average. This thermic effect of feeding has been further subdivided into facultative and obligatory components, where obligatory energy expenditure is the expenditure for necessary aspects of digestion and assimilation, whereas the facultative component has been proposed as a form of energy wasting that can perhaps serve to burn off surplus dietary energy. The final component of TEE is the energy expended for physical activity and arousal, which is generally the second-largest component of TEE and the most variable because to a large extent it is under voluntary control.

The role of energy expenditure in the regulation of energy balance remains controversial. Studies in both adults[114–117] and adolescents[118] have suggested that humans have a relatively limited capacity for dissipating surplus dietary energy by thermogenesis. In these studies, subjects have been overfed, and changes in energy expenditure and energy storage have been measured to assess the fate of the excess dietary energy. In all carefully controlled studies, the ability to dissipate excess energy, seen as an increase in TEE or components of energy expenditure, has represented a relatively minor component of the excess dietary intake.[114–117] Thus, the majority of the surplus energy was stored, primarily in the form of additional body fat. Studies of this kind highlight the importance of the regulation of food intake, rather than thermogenesis, in the short-term regulation of energy balance.

It is possible, however, that energy expenditure plays other critical roles in energy regulation that these studies do not address. In particular, it has been speculated that low energy expenditure in one or more of the components of expenditure could have an association with increased body fatness over the long term. This could be a result of the low energy expenditure promoting increased fatness or of an underlying mechanism promoting fat gain that precipitates low energy expenditure to provide the surplus energy needed for the weight gain. Studies of differences in components of energy expenditure between obese and nonobese children are discussed below. These cross-sectional studies do not define the causal role of energy expenditure in obesity but do serve to define the energy expenditure of children who are already obese in relation to normal values. Prospective studies that have investigated the role of energy expenditure in the weight gain in obesity are discussed below under "Roles of Energy Intake and Expenditure in the Development of Obesity."

Concerning resting energy expenditure, a summary of studies in otherwise healthy overweight and nonoverweight children reveals that the overweight individuals do not have reduced resting energy expenditure. In relation to age, the resting energy expenditure of overweight children appears to be within the normal range at 8 to 10 years and increases subsequently compared with values of normal children (Figure 23-4). Values for energy expenditure per unit of fat-free mass (the metabolically active component of the body

because fat mass is relatively metabolically inactive) are somewhat lower in overweight compared with nonoverweight children. However, this is an inappropriate method of expressing resting energy expenditure in individuals of different sizes because there is a wide variability in the energy expenditure of different tissues that comprise the lean mass. Tissues such as brain and heart have a very high energy expenditure and tissues such as muscle have a low energy expenditure. It appears that overweight and nonoverweight individuals have more similar amounts of tissues with high energy expenditure than they have tissues with low energy expenditure. Thus, it is more appropriate to examine the relationship between fat-free mass and resting energy expenditure than to compare resting energy expenditure per unit of fat-free mass between different groups.

As seen in Figure 23-5, neither the intercept nor the slope of the relationship differs between obese and nonobese individuals, demonstrating that there is no difference in the resting energy expenditure of overweight and nonoverweight children when the data are appropriately normalized for metabolically active tissue. This result, obtained by combining data from studies in which data from at least two groups of subjects were available, is compatible with results from regression analyses in a group of children with a wide range of body compositions,[119] as well as with results of numerous studies in adults.[120]

Several studies on the thermic effect of feeding demonstrate a normal energy expenditure in overweight compared with nonoverweight children and adolescents,[118,121,122] a result that contrasts with the numerous studies that indicate a reduced thermic effect of feeding in obese adults.[123,124] There is one report of a reduced thermic effect of feeding in obese children,[125] and the duration of obesity has been implicated as a possible explanation for differences in results among different studies.[121] This explanation could also help explain the fact that the thermic effect of feeding is reduced in obese adults.

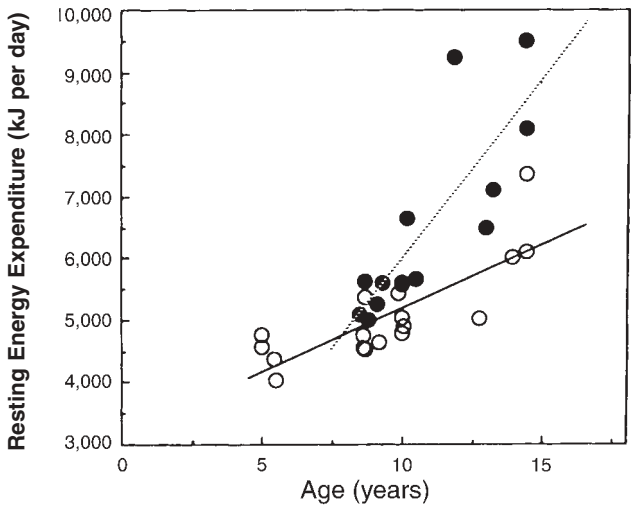

FIGURE 23-4 Relationship between resting energy expenditure (in kJ/d, where 1 kJ = 0.239 kcal) and age in nonoverweight (*solid line*) and overweight (*broken line*) boys and girls aged 5 to 15 years.[171] Data points are group means reported between 1989 and 1994.[92,103,122,132,137,141,144,172–178] There was a significant effect of obesity status on the relationship between resting energy expenditure and age ($p < .001$), and the relationship between resting energy expenditure and age was significant in both nonoverweight ($r^2 = .630$, $p < .000$) and overweight children ($r^2 = .682$, $p < .000$).

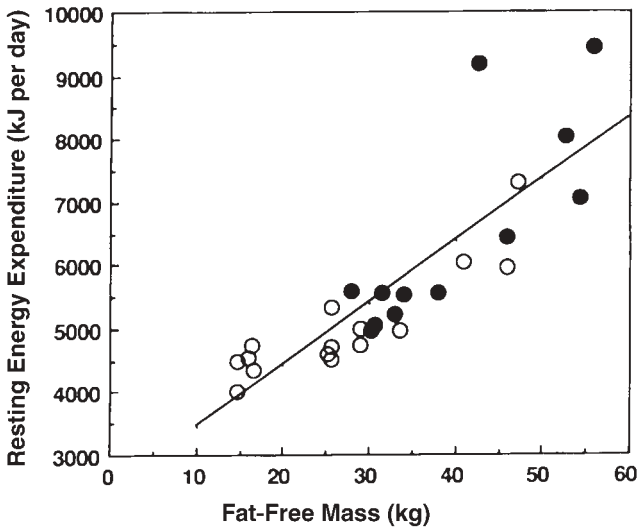

FIGURE 23-5 Relationship between resting energy expenditure and fat-free mass in nonoverweight and overweight boys and girls aged 5 to 15 years.[171] Data points are group means (in kJ/d, where 1 kJ = 0.239 kcal) reported between 1989 and 1993.[103,122,132,141,144,172–178] There was no significant effect of overweight status on resting energy expenditure in multiple regression analyses, including fat-free mass as an independent variable. The relationship between resting energy expenditure and fat-free mass is significant ($r^2 = .712$, $p < .000$).

Concerning physical activity, several studies have reported no difference in physical activity between lean and overweight children,[71,87,126,127] whereas other studies have reported low[128–131] or even high[132] levels of physical activity in overweight children relative to nonoverweight controls. Television viewing has also been investigated separately as a marker for low physical activity and for its relationship to body composition in children.[133] Although the mechanism by which television viewing might influence body fat mass is not known, a reduction in physical activity is strongly implicated as part of the mechanism because television viewing is a sedentary activity that might replace more strenuous ones, together with the possibility that dietary intake could be increased as well.[134,135] Studies in this area have not produced consistent results, with some studies reporting a negative association between the time spent watching television and body fatness[134] and other studies failing to substantiate this result.[127,136]

This controversy might reflect the fact that inactivity during television viewing can potentially be compensated for by strenuous activity at other times; more research is needed to elucidate the relationship between body fat mass and physical activity in children as well as in adults. A further unresolved aspect of the literature on television viewing is that there are reports of both a decrease[126] and normal[137] resting energy expenditure during television viewing in obese children compared with nonobese controls. On the basis of the studies described above, it cannot

be concluded that the obese child is necessarily inactive, or that inactivity is an important cause of obesity. However, this conclusion does not exclude an important role for physical activity in obese children, and further studies are needed to clarify this important issue.

Studies on TEE as determined using the doubly labeled water technique[138,139] have been conducted as a way to examine the combined effects of different components of energy expenditure in normal-weight and overweight children and also as a more accurate way to assess energy expenditure for physical activity (when combined with measurements of resting energy expenditure). Using this method, several studies in children and adults have indicated an inverse association between energy expenditure for physical activity and body fat mass when values for physical activity are normalized for body size by the use of the ratio of total to resting energy expenditure as a physical activity index.[106,140,141] The mechanism of this association is not known but is likely to include the fact that inactivity promotes insulin resistance and could enhance fat oxidation.[142] Although this ratio of total to resting energy expenditure is reduced with increasing body fat content, the TEE for physical activity is typically high. This is because resting energy expenditure and the energy costs of most activities increase with body size. These consistent findings contrast with the substantial controversy over the effects of obesity on physical activity when studies using reported estimates of physical activity are considered.

Doubly labeled water measurements of TEE have also been used to examine differences in energy intake and energy requirements between normal-weight and overweight children. The recent Dietary Reference Intakes for Macronutrients[143] summarized all available data on TEE in childhood to report that there is no substantial difference between normal-weight and overweight children in the relationship between TEE and body weight, height, and age, with equations suitable for all children based on summaries of all available doubly labeled water data:

$$\text{TEE (kcal/day)} = 89 \times \text{weight (kg)} - 100 \text{ (boys and girls 0–2 years)}$$

$$\text{TEE} = 88.5 - 61.9 \times \text{age (years)} + \text{PA} \times 26.7 \times \text{weight (kg)} + 903 \times \text{height (mm)} \text{ (boys 3–18 years)}$$

$$\text{TEE} = 135.3 - 30.8 \times \text{age (years)} + \text{PA} \times 10.0 \times \text{weight (kg)} + 934 \times \text{height (mm)} \text{ (girls 3–18 years)}$$

where PA is a physical activity coefficient used for children 3 years and older:

PA = 1.00 if physical activity level is sedentary
PA = 1.13 if physical activity level is low
PA = 1.27 if physical activity level is active
PA = 1.45 if physical activity level is very active

TEE does not equal energy intake in children because there is additional consumed energy used for growth that is deposited in the form of lean tissue and fat. However, except during the early months of life and during the peak of pubertal development, energy used for energy deposition is only 20 to 25 kcal/day[143]; thus, TEE closely reflects energy intake. The equations given above indicate that children who are overweight do indeed need more energy to maintain current body weight than do normal-weight children. For example, a child more than 3 years of age who is already overweight by 10 kg compared with normal-weight children will have increased TEE and hence energy intake of 100 to 267 kcal/day. Table 23-2 summarizes estimated energy requirements for children of reference weights, based on the above equations with an increment added for the energy deposition in normal growth.

A final issue to consider when comparing differences in energy expenditure between lean and overweight individuals is the energy expenditure response to overfeeding. As detailed above, an ability to burn off surplus dietary energy has been suggested as potentially important in the regulation of energy balance. However, in a study of overweight and nonoverweight adolescents, Bandini and colleagues found no difference between groups in the ability to dissipate excess energy intake.[144] This finding is consistent with the view, outlined above, that diet-induced thermogenesis plays only a small role in the regulation of energy balance.

Substrate Balance

As an extension of the energy balance principles detailed above, it has been suggested that body carbohydrate balance could play a critical role in overall energy regulation.[145] The basic principle behind this theory of energy regulation, which is in keeping with the earlier glucostatic theory of energy regulation, is that balance of the primary energy substrates, fat and carbohydrate, have to be considered separately.[145] Thus:

$$\text{Fat stored} = \text{Fat intake} - \text{Fat oxidation}$$

$$\text{Carbohydrate stored} = \text{Carbohydrate intake} - \text{Carbohydrate oxidation}$$

Because the energy in carbohydrate stores is very small in relation to that in fat stores, the carbohydrate stores have a high turnover rate and are liable to be depleted quickly and frequently. The essential requirement of key tissues for glucose suggests that signals should exist to efficiently monitor and correct body carbohydrate balance. An extension of this theory of nutrient regulation is that dietary macronutrient composition plays an important role in determining body fat content.[145] This is because the higher the dietary fat content, the more total food (and energy) needs to be consumed to maintain carbohydrate intake and therefore carbohydrate stores, and the fatter the individual will be because of increased energy intake.

Flatt has also suggested that the increase in body fat induced by a high-fat diet could be self-limiting because reduced insulin sensitivity and increased circulating free fatty acids tend to occur with increased body fat content, promoting increased fat oxidation and preservation of carbohydrate stores, resulting in a stabilization of hunger and

*Values are estimated average requirements from Dietary Reference Intakes.[143]

satiety signals from body carbohydrate stores and stability of food intake and body fat stores.[145] This model provides a potential explanation for body fat regulation that does not rely on the concept of a novel "signal" from fat stores that detects and corrects a body set point.

Support for the importance of nutrient balance in the overall regulation of energy balance can be derived from several sources, although there is currently little information available on infants and children. Flatt has demonstrated in mice the critically important idea that energy balance is indeed adjusted on a day-to-day basis to maintain stable body carbohydrate balance, through adaptive fluctuations in food intake.[145] Studies in humans have indicated that carbohydrate balance is more closely regulated than is fat balance.[146,147] Concerning the effect of dietary composition on energy intake and body composition, animal studies have repeatedly demonstrated that hyperphagia and obesity can be induced in many strains of normal-weight rodents by feeding a high-fat diet as described above.[36]

In humans, results from some,[148–151] although not all,[152–154] short-term intervention studies in adults indicate that energy intake increases with consumption of a high-fat diet. The fact that not all human studies have found an increase in energy intake with consumption of a high-fat diet does not invalidate the nutrient balance theory of energy regulation because a high-fat diet could induce positive energy balance by decreasing energy expenditure, rather than increasing energy intake as suggested by both animal and adult human studies.[155,156] Also consistent with the nutrient balance model are the data from cross-sectional studies that indicate that consumption of a high-fat diet is frequently associated with high body fat mass in adults.[157–161] Thus, as predicted by the nutrient balance model above, obese and overweight adults tend to consume a higher-fat diet than do nonobese subjects and, at least in the short term, might be hyperphagic.

Some,[131,132] but not all,[87] studies in children and adolescents support the view that high dietary fat intake is associated with obesity. It is possible that this controversy could be owing to the fact that the fiber content of the diet and its energy density might have significant effects on food intake. Although high-fat diets tend to be low in fiber and have a high energy density, this is not always so, and differences in these aspects of the diet (unreported in the studies described above) might have been important. An additional important consideration in relation to dietary intake is that on theoretical grounds, saturated fat can be expected to have more adverse effects on body fat mass than other fats do because of its influence on insulin sensitivity.[142] Consistent with this suggestion are the results of a recent study that observed increased intake of saturated fat as well as increased total fat intake in obese boys and girls compared with normal control subjects.[132] Also consistent with the nutrient balance theory of energy regulation is the fact that obese adults do tend to have reduced insulin sensitivity and increased circulating levels of free fatty acids (which could be interrelated, as predicted by the hypothesis of Randle and colleagues[162]). Furthermore, the increased circulating levels of free fatty acids promote fat oxidation in the fasting state and are associated with increased body fat,[163] and reduced-obese adults have reduced rates of fat oxidation.[164]

ROLES OF ENERGY INTAKE AND EXPENDITURE IN THE DEVELOPMENT OF OBESITY

As described above, the majority of published investigations into the causes of early overweight have been cross-sectional in nature, that is, they have related measurements of body fat mass to energy expenditure or other parameters measured at the same time. This approach provides important information on energy intake, energy expenditure, and substrate oxidation in individuals who are already obese but does not address the question of what happens during the development of the obese state. A finding, for example, of high energy intake in overweight children does not preclude the possibility that energy intake was normal or even low during the period of excess weight gain. Recent prospective studies have addressed the issue of causality in overweight by investigating whether energy expenditure is low in individuals with increased susceptibility to overweight (because of parental obesity). However, the results have been conflicting, with reports of both low energy expenditure[165–167] and normal energy expenditure[168–170] in the pre-overweight state. These conflicting reports emphasize the potential for both high energy intake and low energy expenditure to contribute to the overweight state. Additional research is currently under way by several groups to investigate this important issue, as well as to investigate the role of impaired fat oxidation in the development of overweight in children.

SUMMARY AND IMPLICATIONS FOR THE TREATMENT OF OBESITY

The excess fat mass that characterizes obesity is attributable to both genetic susceptibility and environmental factors and results from energy intake exceeding energy expenditure plus the energy requirement for normal growth over a prolonged period of time. However, this increment in energy intake over energy expenditure can be as little as 400 MJ/day or less if it persists over a period of years. The studies summarized in this chapter do not provide definitive evidence as to whether this differential between energy intake and energy expenditure is caused primarily by decreased energy expenditure or by increased energy intake. However, the weight of evidence currently indicates that both overeating and underexpending can be primary causes of overweight in childhood, and that once a child is overweight, energy intake is higher than that of normal-weight children. In addition, dietary fat, in particular saturated fat, can promote fat deposition through its influence on energy intake.

Further studies are needed in this area, in particular to delineate the usual roles of high energy intake and low energy expenditure as causal factors in excessive weight gain leading to overweight in childhood. Current prescriptions for the treatment of childhood overweight, taking into account the degree of caution that is appropriate for a disorder in which the treatment can itself have detrimental consequences, should be based on individualizing for each child a decrease in energy intake relative to energy expenditure by a combination of moderate dietary therapy and promotion of energy expenditure from physical activity (see Chapter 54, "Evaluation and Management of Obesity").

CHAPTER 24

MATERNAL NUTRITION AND PREGNANCY OUTCOME

Theresa O. Scholl, PhD, MPH

Adverse pregnancy outcomes such as preterm delivery, intrauterine growth restriction, and low birth weight are increased two- to threefold among infants born to poor urban women from countries such as the United States.[1] Other factors affecting outcome include inadequate gestational weight gain, inadequate prenatal care, smoking, drinking alcohol, and substance abuse.[2,3] A history of spontaneous abortion or other poor outcome in a prior pregnancy plays a role by increasing risk in the current pregnancy.[3] Poor maternal intake of micronutrients, iron, folic acid, calcium, and zinc in particular also is associated with an increased risk of adverse events in the course and outcome of pregnancy.[2] However, apart from rare occurrences, inadequate intake of a single nutrient does not occur in isolation. Unlike in animal studies that involve experimentally induced deficiencies of single nutrients, the link between maternal nutritional status and the course and outcome in human pregnancy is less secure. Apart from its immediate effects, maternal nutrition during pregnancy also has important implications for risk of chronic disease development in later life (see Chapter 25, "Fetal Nutrition and Imprinting").

IRON AND ANEMIA

Iron is essential for the formation of hemoglobin, which transports oxygen, and for the synthesis of enzymes that use oxygen to provide cellular energy.[2] Iron deficiency is defined by three stages of increasing severity: depletion of iron stores (Stage 1), impaired hemoglobin production (Stage 2), and iron deficiency anemia (IDA) (Stage 3). Anemia is an abnormally low concentration of hemoglobin (or hematocrit). Specific cutpoints have been formulated for its diagnosis by age and sex and by trimester during pregnancy.[2]

The increase in anemia during pregnancy is partly an artifact of maternal plasma volume expansion, a normal physiologic response to pregnancy.[4] Although the maternal red blood cell mass also increases during gestation, its expansion and the expansion of the plasma volume occur at different times.[2,5] During the first and second trimesters, hemoglobin concentration declines, reaches a low point early in the third trimester, and rises thereafter. Consequently, depending on the stage of gestation when anemia is assessed, it can be difficult to separate truly anemic women from those whose anemia occurs as a result of hemodilution.

Supplementation with iron is recommended during pregnancy to meet the demands of both the mother and the rapidly growing fetus.[2] Table 24-1 shows the intakes that are currently recommended by the Institute of Medicine for iron and other nutrients during pregnancy (on-line at <http://www.nap.edu>). Anemia (low hemoglobin levels) and IDA sometimes also serve as indicators of overall maternal nutritional status during pregnancy. When overall dietary intake is inadequate, risk of anemia is increased.[6–8]

Maternal anemia and hemoglobin (or hematocrit) concentration are linked with an increased risk of poor pregnancy outcome. Evidence suggests that anemia and iron deficiencies are associated with an increased risk of low infant birth weight, preterm delivery, and perinatal mortality. The relationship between maternal hemoglobin and pregnancy outcome is U shaped, with "low" hemoglobin probably reflecting a mix of true and physiologic anemia and "high" hemoglobin reflecting hypovolemia—failure of the plasma volume to expand in association with maternal pathology—maternal hypertension, preeclampsia, or diabetes.[9,10] Poorly nourished animals have reduced maternal plasma volume expansion during pregnancy and low cardiac output, lower uteroplacental blood flow, and reduced

nutrient transmission to the fetus.[11] Thus, it is possible that hypovolemia has nutritional antecedents.

Maternal anemia, when diagnosed before midpregnancy, is associated with an increased risk of preterm birth, fetal growth restriction, and low birth weight. Murphy and colleagues studied 44,000 singleton pregnancies in women from Cardiff, Wales, who sought prenatal care by 24 weeks gestation.[9] The prevalence of anemia based on "low" hemoglobin before week 24 (hemoglobin < 104 g/L) among these women was 3.9%. Increased risk of preterm birth (before 37 weeks) was associated with low hemoglobin when women entered care before week 13 or after week 20. For those who entered between 20 and 24 weeks, risk also was increased when hemoglobin was high. Risk of low birth weight (< 2,500 g) was increased for women entering care before 20 weeks gestation. A high maternal hemoglobin concentration (> 145 g/L) was also associated with hypertension and pregnancy-induced hypertension (PIH), both of which could reflect inadequate expansion of the maternal plasma volume.

Garn and colleagues analyzed data from more than 50,000 consecutive pregnancies that were followed as part of the Collaborative Perinatal Project (CPP) using the lowest hematocrit anytime during pregnancy, thus confounding the effects of true and physiologic anemia.[12] Low (< 0.29) and high (> 0.39) hematocrit were associated with increased risk of fetal death, preterm delivery, and low birth weight. At the lowest hematocrit (< 0.25), risks of preterm delivery, low birth weight, and fetal death were increased approximately two- to threefold for the white women in the study. For black women, only the risk of fetal death was raised substantially. Overall, for both black and white gravidas, the risk of fetal death was increased appreciably when hematocrit levels were very high (> 0.41).

Steer and colleagues studied a multiethnic sample of women from the Northwest Thames region of London.[13] For all ethnic groups, there was an increased risk of preterm delivery and low infant birth weight when the hemoglobin level during pregnancy was either low (< 85 g/L) or high (> 115 g/L).

Meis and colleagues analyzed data from the Cardiff Birth Survey, a population-based survey of data on the pregnancies of more than 25,000 Welsh women.[14] Both low (< 104 g/L) and high (> 135 g/L) maternal hemoglobin at entry to care increased risk of preterm delivery. After controlling for other potential confounding variables, high hemoglobin remained a significant risk factor, whereas low hemoglobin did not. However, early-pregnancy bleeding, a factor that often gives rise to anemia and lowers hemoglobin concentration, was associated with nearly a twofold increase in risk of preterm birth.

Lieberman and colleagues examined the association of hematocrit at delivery with spontaneous preterm birth in a sample of approximately 8,000 Boston women.[15] Each 5-point drop in hematocrit was associated with an approximately twofold increase in the risk of preterm delivery. Maternal anemia and socioeconomic factors accounted for the twofold difference in preterm delivery for blacks compared with whites.[16]

Klebanoff and colleagues attempted to replicate the above results using prospective data from the CPP.[5] They regarded the strong association between maternal anemia and preterm delivery as a time-of-sampling artifact caused by the changes in hemoglobin and hematocrit over the course of pregnancy. That is, when sampled at the time of delivery a lower hematocrit and an increased risk of anemia characterize pregnancies that are delivered late in the second or early in the third trimester, whereas a higher hematocrit (and lower anemia risk) characterized those pregnancies that are delivered at later gestations. When data were examined prospective to delivery, anemia diagnosed at any time during the late second to early third trimester was associated with a modestly increased risk of preterm delivery, which diminished substantially after adjustment for maternal race, education, and age.[5] A subsequent prospective study gave a consistent result.[17]

Lu and colleagues examined the relationship of maternal hematocrit to pregnancy outcome in approximately 17,000 iron- and folate-supplemented Alabama women, delivered between 1983 and 1988.[18] Low hematocrit before midpregnancy was associated with a modestly increased risk of preterm delivery and fetal growth retardation. After

TABLE 24-1 Dietary Reference Intakes or Adequate Intake and Upper Limit of Intake during Pregnancy

	Dietary Reference or Adequate Intake	*Upper Limit of Intake*
Minerals		
Iron	27 mg*	45 mg
Zinc	12 mg,† 11 mg‡	34 mg†, 40 mg‡
Calcium	1,000 mg	2,500 mg
Phosphorus	700 mg	3,500 mg

midpregnancy, the relationship between maternal hematocrit and risk of preterm delivery became inverse, although the relationship was weak.

Higgins and colleagues reported findings from supplemented Montreal women that suggested some potential benefit for a low maternal hematocrit level late in pregnancy.[19] They found a weak effect of initial hemoglobin on infant birth weight but a strong, inverse relationship after 33 weeks gestation, when the highest infant birth weights were associated with the lowest third-trimester maternal hemoglobin levels (< 110 g/L). There was also a relationship between birth weight and the change in hemoglobin level between entry to care and the third trimester; women with the greatest decrements gave birth to the largest infants.

Zhou and colleagues described the relationship between maternal hemoglobin levels during the first trimester and poor pregnancy outcome in 829 Shanghai women.[20] In this population, other risk factors associated with poor pregnancy outcome (eg, smoking, alcohol use) were uncommon, and women enrolled for care early in the first trimester (6 to 8 weeks). The risk of preterm delivery was increased about twofold when hemoglobin was between 100 and 109 g/L, increased nearly threefold when hemoglobin was 90 to 99 g/L, and increased approximately fourfold for hemoglobin below 90 g/L.

Recently, Scanlon and colleagues used data from Pregnancy Nutritional Surveillance to examine the relationship between maternal anemia (severe or mild) and pregnancy outcome (preterm delivery or fetal growth restriction) in 173,031 low-income gravidas.[21] Because Z scores were used to define hemoglobin levels of interest, cutpoints varied with gestation but were always less than 110 g/L during trimesters 1 and 2. Whereas preterm delivery was increased for anemic women and women with low hemoglobin levels during the first or second trimesters, for women with moderate to severe anemia, risk was approximately doubled. For the others, risk of preterm delivery was increased between 10 and 40%. During the third trimester, the association reversed: anemia and low hemoglobin levels were each associated with a decreased risk of preterm birth and there was little association between high maternal hemoglobin levels and preterm delivery or fetal growth restriction. However, throughout trimesters 1 and 2, high hemoglobin was associated with a 30 to 80% increase in fetal growth restriction. The association of maternal anemia in early pregnancy to preterm delivery and other poor outcomes has been confirmed in recent studies from countries in the developing world, including Nepal and Egypt.[22,23]

In Camden, New Jersey, Scholl and colleagues combined anemia with low serum ferritin to index IDA.[6] Data from more than 800 women in the Camden Study were used to examine total anemia, IDA, and anemia from causes other than iron deficiency at entry to prenatal care as risk factors for preterm delivery. They found a better than twofold increased risk of preterm delivery and a threefold increase in low birth weight with IDA. When vaginal bleeding was present at or before entry to care, risk of preterm delivery was increased fivefold for IDA and twofold with anemia from other causes. However, later in pregnancy (after week 28), maternal IDA did not increase risk of preterm birth or low birth weight.[24] Consistent data were obtained from Papua, New Guinea, where severe anemia (hemoglobin < 80 g/L) that was attributable to iron deficiency and occurred early in pregnancy increased risk of low birth weight about sixfold among primiparous women.[25] Risk was not increased with IDA at delivery. Thus, it seems reasonable to presume that some, but not all, maternal anemia and IDA is attributable to the expansion of maternal plasma volume. At present, this state is poorly differentiated from anemia or IDA late in pregnancy but is easier to differentiate in the first or second trimesters.

Allen recently reviewed the mechanisms and changes that underlie the relationship between maternal anemia and pregnancy outcome.[26] The link between maternal anemia in the first and second trimesters and preterm delivery and other outcomes might involve alterations in the growth and development of the placenta. Severe maternal anemia is associated with increased placental weight and size as well as functional changes that permit the placenta to carry more oxygen.[27,28] Maternal iron stores affect the growth of the placenta even when the mother is not anemic. In one study of more than 500 British gravidas, placental volume measured by ultrasonography at 18 weeks gestation was inversely related to the maternal hemoglobin and ferritin levels 4 weeks earlier.[29] This relationship was recently confirmed by data from more than 1,600 gravidas.[30] Maternal ferritin levels at entry to care (mean, 12.9 weeks) correlated negatively with placental weight at term, controlling for factors also associated with placental size (maternal weight, height, parity, and smoking).

In a subsample (n = 17), serum ferritin correlated with capillary surface area of the placenta and the proportion of terminal villi that was capillary. These results suggest that maternal iron stores in the low-normal range are associated with increased placental size and with changes in the oxygen-carrying ability of the placenta. Interestingly, shorter gestation duration was associated with a higher ratio of placental weight to birth weight among deliveries in that study.[30]

During pregnancy, low intakes of two micronutrients, zinc and folate, have been associated with IDA at entry to care.[7,8] Recommendations for intake of these nutrients during pregnancy, along with information about the upper limit considered safe, are given in Table 24-1. Zinc is an element involved either directly as a metalloenzyme in the production of enzymes, which include deoxyribonucleic acid (DNA) and ribonucleic acid polymerase, or as a catalyst in the synthesis of other enzymes.[2] Folic acid functions as a coenzyme in the transfer of single-carbon atoms from donors such as serine and histidine to intermediates in the synthesis of amino acids, purines, and thymidylic acid.[2] Although many other nutrients in addition to these two would be limited in a marginal maternal diet, inadequate intake of either zinc, folate, or both potentially leads to impaired cell division and alterations in protein synthesis. Such alterations are most notable and have the greatest

potential to do harm during times of rapid tissue growth, such as pregnancy.

ZINC

Neggers and colleagues demonstrated a positive association between maternal serum zinc at 16 weeks gestation and birth weight in a large population of low-income Alabama women.[31] Serum zinc in the lowest quartile was associated with an eightfold increase in risk of low birth weight, suggesting a threshold effect for circulating zinc levels during pregnancy. Kirksey and colleagues examined the relationship of maternal zinc nutriture to birth weight and found that plasma zinc concentrations in the second trimester, along with pregnancy weight at 3 months gestation, formed the best predictor model of birth weight for these pregnancies, accounting for 39% of the variance.[32]

Scholl and colleagues examined dietary zinc intake in 818 Camden women and reported increased risks of complications and adverse pregnancy outcomes in association with low intakes of dietary zinc (6 mg/day or less).[7] These complications included decreased gestational weight gain and an increased risk of IDA at entry to care. Poor outcomes associated with low zinc intake included risk of low birth weight, preterm delivery, and very preterm delivery that were two to three times greater than in controls. In the presence of IDA, the risk of very preterm delivery was greater than fivefold higher. Others have also reported a positive relationship between low serum zinc and reduced birth weight or an increased risk of low infant birth weight.[33–35] However, the finding of inverse relationships between maternal zinc levels and birth weight could also suggest greater fetal uptake of maternal zinc by larger infants.[36–38]

Tamura and colleagues used data from more than 3,400 gravidas to examine the relationship between pregnancy outcome and zinc in the first to early third trimesters.[39] They found no relationship between maternal plasma zinc and risk of fetal growth restriction, preterm delivery, or selected pregnancy complications and no significant correlation with birth weight or gestation duration. However, women with plasma zinc below the median had been removed from the sample and enrolled in a clinical trial that demonstrated a positive effect of zinc on gestation duration and birth weight.[40] Thus, prescreening might have removed vulnerable women from the population at risk.

Because serum or plasma zinc represents less than 1% of the total body zinc pool, it might not be the most reliable indicator of zinc status. Meadows and colleagues were the first to demonstrate that both lower leukocyte zinc concentration in maternal serum and in cord blood were associated with impaired fetal growth.[41,42] No differences were noted between the mean leukocyte zinc concentrations of women delivering preterm appropriate for gestational age and normal-weight infants. Wells and colleagues also noted an association between maternal leukocyte zinc and lower birth weight.[43] Simmer and Thompson measured maternal concentrations of zinc in polymorphonuclear and mononuclear cells within 48 hours of delivery and found lower zinc levels associated with fetal growth retardation.[44] Adeniyi reported the opposite: maternal leukocyte zinc and placental zinc concentrations were lower in preeclamptic women with normal birth weight infants compared with women delivering lower birth weight infants.[45]

Inconsistencies in the relationship of zinc and pregnancy outcome could arise from the fact that there is no agreed upon indicator of zinc status; maternal serum or plasma zinc might not reliably assess zinc nutritional status. Clinical trials of zinc supplementation have focused on entire groups of low-income women in which the mean zinc intake is low. These trials have also yielded equivocal results, perhaps because of an approach that selects a population, as opposed to individuals, at risk.

Two trials have shown effects that were conditional on maternal weight, that is, a lower rate of preterm delivery in zinc-supplemented women who were not overweight.[40,46] Cherry and colleagues reported a response to supplementation status for pregnant adolescents at less than 25 weeks gestation.[46] Low serum zinc concentrations were more common in underweight and multiparous women. The frequency of preterm delivery was less in the zinc-treated normal-weight women compared with the placebo group. Zinc treatment of underweight multiparous women was associated with a gestational age increase of nearly 3 weeks. Zinc supplementation was also associated with a reduced need for assisted respiration in newborns of normal-weight women.

The trial conducted by Goldenberg and colleagues took a more targeted approach and recruited women with plasma zinc levels below the median and randomly assigned them to zinc or placebo.[40] The analysis was stratified after the fact by body mass index (BMI) above or below 26 kg/m^2. Zinc supplementation was associated with longer gestation duration—by approximately half a week (p = .06)—and increased birth weight, mainly because of longer duration of gestation. Women with BMIs of less than 26 benefited most from zinc treatment, experiencing a 248 g increase in infant birth weight and a 0.7 cm increase in infant head circumference. Consistent with prior results, effects were increased for women with lower pregravid BMIs. In addition, Kynast and Saling found that zinc treatment between 20 and 34 weeks gestation was associated with lower incidences of preterm labor, placental abruption, vaginal bleeding, fetal acidosis, and fetal growth retardation when zinc-supplemented gravidas were compared with control subjects.[47]

In contrast, two recent trials from the developing world (Peru and Bangladesh), where one might suppose that zinc deficiency would be prevalent, did not show this.[48,49] It is possible that if gravidas from the developing world have multiple nutritional deficiencies, these might reduce the bioavailability of zinc or otherwise limit fetal growth. Low plasma zinc, however, has a number of potential causes.[50] It is of interest that when Bangladeshi women were screened for low plasma zinc, less than 4% had levels at or below the median plasma zinc cutpoint used to enrol women from the United States in Goldenberg and colleagues' trial.[40,49] In addition to its effect on protein synthesis, zinc also has an antiseptic action.[50] In theory, a low

zinc intake could be associated with an increased risk of infection during pregnancy, leading to fragile fetal membranes (and premature rupture of membranes); conversely, a low plasma zinc level might be an acute-phase response to a stressor such as maternal infection.

FOLIC ACID

Folate is critically important for development and is a cofactor for many essential cellular reactions, including the transfer of single-carbon units; it is required for cell division because of its role in DNA synthesis.[51,52] Folate also is a substrate for a variety of reactions that affect metabolism of several amino acids, such as the transmethylation and transsulfuration pathways. A central feature of fetal development is widespread and sustained cell division. Because of its role in nucleic acid synthesis, the need for folate increases during times of rapid tissue growth. During pregnancy, folate-dependent processes include increase in the red cell mass, enlargement of the uterus, and growth of the placenta and fetus.

It is recommended that pregnant women consume 600 μg folic acid per day, which includes 400 μg of synthetic folic acid from supplements or fortified cereals, to reduce risk of neural tube defects (see Table 24-1). Recent data suggest that less than one-third of women in their reproductive years consume this amount.[53] Fortification of flour and cereal products in the United States with folic acid (since 1998) has been associated with a 19% decline in risk of liveborn infants with neural tube defects, along with changes in biomarkers of folate status, including increases in serum and red cell folate and a decline in homocysteine levels.[54,55]

Serum folate is a sensitive indicator of the folate available to replicating cells with high turnover rates, whereas red cell folate reflects folate status over preceding weeks. A metabolic effect of folate deficiency is an elevation of homocysteine.[56] Hyperhomocysteinemia can occur when dietary folate intake is low. In other cases, genetic factors and the interaction between genes and the environment increase the metabolic requirement for folate, increasing risk of spontaneous abortion and fetal growth restriction and decreasing gestation duration.[57]

More than three decades ago, Hibbard described an increased risk of placental abruption in gravidas with abnormal formiminoglutamic acid (FIGLU) excretion and attributed it to a defect in folate metabolism.[57] Hyperhomocysteinemia, a risk factor for cardiovascular disease, is now known to cause vascular damage.[56] About half of the pregnancies occurring in women with hereditary homocystinuria terminate in fetal demise.[52] High levels of homocysteine also might do injury in the course of pregnancy, increasing the risk of serious complications such as pregnancy-induced hypertension and placental abruption.[58] Both are risk factors for adverse outcome, increasing intrauterine growth restriction and with it the possibility of preterm delivery, in particular, preterm delivery that is medically indicated.

The role of folic acid in DNA synthesis and cell replication suggests its potential to have an important effect on birth weight, gestation duration, or both. An absolute deficiency of folate—from a diet inadequate to meet the needs of pregnancy—in theory interferes with growth of the conceptus. The influence of dietary and circulating folate on preterm delivery and low infant birth weight was studied in 832 women from Camden, one of the poorest cities in the continental United States.[8] Low intakes of folate from diet and supplements were associated with maternal characteristics reflecting poorer maternal nutritional status, including lower caloric intake, low rate of gestational weight gain, and a higher frequency of IDA at entry to prenatal care. After controlling for gestation at entry and the time in pregnancy when the samples were drawn, there was a significant relationship between dietary folate intake and serum folate at week 28. Low folate intake (< 240 ng/day) was associated with a greater than threefold increase in the risk of low infant birth weight and preterm delivery, after controlling for maternal age, parity, ethnicity, smoking, rate of gestational weight gain, and intake of energy and other nutrients (zinc, fiber, and vitamin B_{12}). Circulating folate at week 28 also was associated with risk; the adjusted odds for low birth weight increased by 1.5%, and preterm delivery increased by 1.6% per unit decrease in serum folate at week 28 after controlling for potentially confounding variables. Thus, lower concentrations of folate at week 28 were associated with a greater risk of preterm delivery and low birth weight.

Goldenberg and others presented data from a cohort of approximately 1,200 Alabama women with risk factors for intrauterine growth restriction.[59–62] Most analyses involved data from a subsample (n = 289) for whom circulating levels also were assayed. There was a significant and positive correlation within the subsample between maternal folate intake from diet and supplements and serum folate at weeks 18 and 30. Using data from the cohort as a whole, adjusting for gestation, smoking, ethnicity, infant sex, pregravid weight, and gestational weight gain, there was a significant increase in infant birth weight among infants of mothers whose folate intake was above the 90th percentile compared with those below the 10th percentile.[62] A psychosocial score, which encompassed measures of maternal depression, anxiety, mastery, stress, and social support, correlated positively with supplement use but did not confound the association between folate and infant birth weight.[60]

Likewise, studies by Frelut and colleagues showed a positive bivariate correlation between maternal red cell folate (at week 32) and infant birth weight in 21 infants (r = .48).[63] Ek found a positive relationship (bivariate) between maternal red cell folate and birth weight and birth length in 147 infants at delivery.[64] Whiteside and colleagues reported that shorter gestation duration (< 39 weeks) and reduced infant birth weight were associated with lower serum folate at week 26.[65] In two studies, Tchernia and colleagues found that shorter gestation correlated with lower serum folate and red cell folate.[66] Rondo and colleagues, after examining more than 700 mother-infant pairs comparing growth-restricted and normally grown infants, found a greater percentage of growth-restricted infants with abnormally low or high red cell

folate in cord blood but detected no difference in maternal red cell folate at delivery.[67]

In their case series, deVries and colleagues reported increased frequency of hyperhomocysteinemia (24% versus the 2 to 3% expected) among women with serious complications of pregnancy (placental abruption, fetal demise, or intrauterine growth retardation [IUGR]).[68] Growth-restricted infants averaged 1327 ± 498 g at birth, and most were delivered preterm. Likewise with placental abruption, mean birth weight was low (1,518 ± 981 g) and gestation was shortened (30.8 ± 5.7 weeks).

Further, preeclamptic gravidas from Rajkovic and colleagues' study had significantly higher plasma homocysteine levels and delivered at an average of 35 ± 4 weeks' gestation compared with 40 ± 1 weeks among controls.[69]

Malinow and colleagues assessed the influence of maternal homocysteine and serum folate at term (37 to 42 weeks) on infant birth weight and gestation duration in 35 healthy nulliparas.[70] They reported that higher maternal homocysteine was associated with significantly lower infant birth weight and shorter gestation, whereas higher maternal folate correlated with increased birth weight (univariate analyses). A concentration gradient was detected; homocysteine declined from maternal vein to umbilical vein to umbilical artery by approximately 1 μmol/L for each phase, suggesting uptake of maternal homocysteine by the fetus.

Burke and colleagues, however, failed to detect differences in fasting homocysteine among women giving birth to growth-restricted infants (n = 37) compared with controls (n = 35).[71] Inadequate statistical power, along with the use of a less-sensitive test (fasting versus postload homocysteine), posed limitations to this research.

Recently, maternal homocysteine levels measured in more then 5,800 women aged 40 to 42 were linked to past data on pregnancy outcome contained in Norwegian birth registries.[72] Higher maternal homocysteine correlated with older age at delivery, higher cholesterol levels, less multivitamin use, and lifestyle factors (cigarette smoking and high coffee consumption). Women with currently high homocysteine levels were more likely to have had a reproductive history that included preeclampsia, preterm delivery, low birth weight, or fetal growth restriction.

Unlike in observational studies, randomized trials of supplementation with folic acid have shown less uniform benefit. Fleming and colleagues enrolled 146 Australian women before midpregnancy (week 20) into a randomized trial with five arms:

1. Placebo
2. Folic acid (0.5 mg)
3. Iron sulfate (60 mg)
4. Iron in combination with low-dose folate (0.5 mg)
5. Iron combined with high-dose folate (5 mg)

A total of 89 women completed the study with sample sizes of 15 to 20 per group; there were no significant differences in placental weight, birth weight, or gestation duration among the groups.[73] Small sample size and associated statistical power would limit the ability to detect an effect of folate, if any.

Fletcher and colleagues conducted a randomized, controlled study comparing iron (200 mg ferrous sulfate) with iron with folate (5 mg). Supplements were administered to 643 London women at entry to care.[74] No significant differences in birth weight, gestation, or incidence of congenital defects were found.

Giles and colleagues performed a double-blind, randomized, controlled trial of 692 women in Melbourne, Australia, assigned to folate (5 mg/day) or placebo.[75] Four groups were stratified by gestation at entry from less than 10 weeks to greater than 30 weeks. Outcomes, examined in babies born alive and well, suggested small differences in birth weight and gestation among groups and in multiparas between the index and penultimate pregnancies. None, however, were statistically significant.

Baumslag and colleagues administered iron alone (200 mg) or in combination with folic acid (5 mg/day) or with folate and vitamin B_{12} (50 μg/day) to South African women who had been allocated to one of these three groups.[76] There was no effect of the folate among the white women who were studied, but among Bantu women, who subsisted primarily on maize porridge, the risk of bearing an infant of less than 1,870 g was reduced fourfold by folic acid supplementation.

Iyengar and Rajalakshmi allocated 500 poor Indian women alternately to either iron alone (60 mg as ferrous fumarate) or in combination with folate (500 μg/day). Of these, 239 delivered in hospital; 189 had data included in the analysis.[77] There was a significant difference between folate and iron supplementation, favoring folate in infant birth weight (+ 200 g) and placental weight (+ 61 g). Risk of low infant birth weight was nearly twice as high among iron-supplemented (34%) compared with folate-supplemented (18%) gravidas.

Rolschau and colleagues studied 40 Danish women, matched for age, parity, smoking, pregravid weight, and housing conditions and allocated them to iron (200 mg ferrous fumarate) plus multivitamins with and without folic acid (5 mg).[78] Among the folate-supplemented subjects, serum and red cell folate increased significantly, infant birth weight was greater by more than 400 g, and placental weight was higher by almost 50 g.

Blot and colleagues assigned 200 French women to iron (105 mg elemental iron) alone or in combination with folic acid (350 mg/day).[79] Of these, 109 were re-evaluated at delivery. Women treated with folate had higher serum and red cell folate at delivery. Gestation duration was increased among supplemented women (40.7 ± 1.2 versus 39.9 ± 1.2 weeks), as were birth weight (3,461 ± 430 g versus 3,303 ± 375 g) and placental weight (660 ± 130 g versus 604 ± 115 g). In this study, the main effect of folic acid was to extend gestation by nearly 1 week.

Finally, Czeizel and colleagues reported the effect of periconceptional supplementation (from more than 28 days before conception to second missed menstruation) with folate-containing multivitamins (0.8 mg folate) or trace minerals.[80–82] After the randomized periconceptional period, about 60% of each group was prescribed multivitamins with folic acid or folic acid alone

during pregnancy. Thus, only the effect of periconceptional folic acid supplementation on pregnancy outcome was addressed. In addition to increasing the number of recognized conceptions, supplementation with multivitamins containing folic acid increased the likelihood of multiple births, fetal demise, and female births. In the analysis that included both singleton and multiple births, there was a small but statistically significant excess of low birth weight infants among the folic acid–supplemented subjects compared with the trace mineral group. The increased risk of IUGR and preterm delivery among multiple pregnancies is well known. When the analysis was confined to singletons, however, the excess in low birth weight infants persisted in the folate group but was no longer statistically significant.

In summary, although observational studies of folate and pregnancy suggest a potential benefit of folate supplementation during pregnancy—a decrease in serious complications and an improvement in birth weight and gestation—randomized trials imply that routine folate supplementation might not benefit all pregnant women. Some who are at risk, either because of common genetic polymorphisms that alter folate metabolism or because of environmental factors associated with a diet low in folate, would seem to benefit the most.

MULTIVITAMIN AND MINERAL SUPPLEMENTS

In the United States, about one-quarter of women (26% of white women and 15.5% of black women) in their reproductive years regularly take vitamin or mineral supplements.[83] In one study, 16% of low-income gravidas in Massachusetts took vitamins before pregnancy.[84] In Camden, New Jersey, 17% of low-income minority gravidas reported using supplements before they became pregnant.[85] Preconceptional supplement use was more likely to occur in women with a history of spontaneous abortion or other poor pregnancy outcome.

Information on recommended dietary intakes for pregnant women in the United States are given in Table 24-1. However, information on the effects of prenatal multivitamin and mineral supplements on pregnancy outcome is limited. The women in Canada who used such supplements during pregnancy had a reduced risk of preterm delivery (twofold lower than controls) and very preterm delivery (fourfold reduction in risk with first trimester use; twofold reduction with second trimester use); low infant birth weight was also decreased.[85]

Fawzi and colleagues examined the effect of supplementing more than 1,000 human immunodeficiency virus–positive women from Tanzania with multivitamins, vitamin A, and placebo in a double-blind, placebo-controlled trial.[86] Multivitamin supplementation decreased the risk of very preterm delivery (an approximately twofold reduction) along with decreasing risk of low infant birth weight and fetal growth restriction. The multivitamin supplement had the bonus of increasing CD4, CD8, and CD3 counts in the women.

A third study examining multivitamin use from survey data (the 1988 National Maternal and Infant Health Survey) reported no effect of multivitamin use on pregnancy outcomes, including preterm delivery; multivitamin use also did not amend the effect of maternal smoking on the fetus.[87] However, these conclusions are limited by the fact that the survey questionnaire was geared toward regular multivitamin use (3 days/week or more) and did not differentiate women who used vitamins from those who did not.

An increasing number of individuals are using megadoses of vitamin or mineral supplements—5.5% in 1997, up from 2.4% in 1990.[88] The use of megadoses of nutritional supplements by pregnant women and their effect on the course and outcome of pregnancy have not been investigated. The upper limit of nutritional intake is the highest level considered safe for use. The recommendations of the Institute of Medicine for the upper limits of nutritional intake during pregnancy are given in Table 24-1.

HERBAL PRODUCTS

Herbal products are considered nutritional supplements. They are used during pregnancy primarily for relief of nausea and vomiting (eg, ginger, raspberry leaf, chamomile) and closer to term to ripen the cervix and to stimulate labor (eg, black cohosh, blue cohosh, raspberry leaf, castor oil, evening primrose oil).[89–92] Little is known of their safety and efficacy. There is also a serious bias in prevalence estimates. One cross-sectional survey of pregnant women from San Francisco reported a response rate of 24%, and surveys of nurse-midwives had responses of 34% and 68%.[89,91,92] The largest survey to date was done by telephone and, although not limited to pregnant women, had an estimated response of 60%.[88] Thus, use of herbal remedies by pregnant women could be much different (higher or lower) than the published literature currently suggests.

FISH OIL SUPPLEMENTS

Consumption of supplements that contain fish oil, as well as eating a diet rich in marine foods that contain omega-3 fatty acids, is also associated with longer gestation duration. The clinical trial conducted by the People's League of Health on 5,022 women in London in 1938 and 1939 suggested that supplementing a diet that was not markedly deficient with minerals, vitamins, and halibut oil extended gestation.[93] Fewer infants were born before the fortieth week of gestation to the supplemented women (20% among supplemented subjects versus 24% among the unsupplemented), although there was no difference in mean birth weight.

A trial of 533 Danish women who received fish oil, olive oil, or no supplement by 30 weeks gestation showed that women taking the fish oil supplement had longer average gestations (by 4 days) and bore infants with higher average weights (+107 g), which was mostly attributable to the change in gestation.[94] The effect of fish oil was strongest for women with low fish consumption at entry to care and amounted to an increase of 7.4 days gestation in this group.

There was little effect of the supplement on women with high fish consumption at entry (–1.6 days). Thus, the hypothesized effect of omega-3 fatty acids on gestation appears to have a threshold and to be specific to the initiation of idiopathic preterm labor.

Recently, a multicenter trial of high-risk women enrolled gravidas with a history of preterm delivery, fetal growth restriction, or preeclampsia. Some of the centers enrolled women with threatened preeclampsia or suspected fetal growth restriction. Women were randomized to either fish oil or olive oil. Fish oil reduced the recurrence risk of preterm delivery approximately twofold but did not alter the recurrence of the other poor pregnancy outcomes.[95] A recent prospective and observational study of seafood intake in early pregnancy bolstered this relationship: risk of preterm delivery was increased nearly fourfold among women with little or no intake of fish by 16 weeks gestation.[96]

Finally, ecologic studies have indicated that the consumption of large quantities of fish during pregnancy is associated with lower blood pressure and thus, in theory, with a lower incidence of pregnancy-induced hypertension. Consistent with this is the reduction in the incidence of preeclampsia in the People's League of Health Study.[93] However, because of the multiple supplementation regimen, it could not be attributed to the use of the fish oil per se. The recent multicenter trial of fish oil showed no effect on the recurrence risk of preeclampsia or on blood pressure.[95]

CALCIUM

The skeleton acts as the calcium reservoir of the body (99% is stored there), and when dietary calcium intake is low or poorly absorbed, calcium is withdrawn from bone to support serum calcium homeostasis.[2] During pregnancy, retention of an estimated 30 g of calcium, most of which is transferred during the third trimester, is needed to mineralize the fetal skeleton.[2] Although it is often assumed that pregnancy, like lactation, might be a setting for bone mass loss because of this requirement, this might be buffered by a 60 to 70% enhancement in intestinal calcium absorption during pregnancy.[97]

Although several studies have examined longitudinally the change in bone mass with pregnancy, only two have examined the influence of dietary calcium on bone mass as an independent variable.[98,99] Lamke and colleagues evaluated 14 mature pregnant women in the second trimester and postpartum and reported a significant decrease in trabecular bone and a small gain in cortical bone.[98] Christiansen and colleagues studied serial changes in radial bone mass in 13 Danish women during pregnancy and found no change.[99] These women were, however, ingesting an average of 650 mg/day in calcium supplements, apart from their diet. Sowers and colleagues found no change in femoral bone mineral density in 32 women, aged 20 to 40 years, with measurement prior to pregnancy and following delivery, compared with matched controls, but again the average calcium intake exceeded the Recommended Dietary Allowance (RDA) for both groups.[100] Drinkwater and Chestnut studied changes in bone mineral density (pregravid and 6 weeks post partum) in 6 women who experienced pregnancy and 25 controls; mean calcium intake was high (> 1,500 mg/day) in each group.[101] Despite this, pregnancy was associated with significant decrements in bone at the femoral neck and radial shaft; increased bone density was found for the tibia.

One reason for the limited number of subjects and studies during pregnancy is risk of radiation exposure, making ultrasonography desirable for measuring bone change during pregnancy. Several recent studies have measured change in either the os calcis or the phalanges, and all have reported significant decreases in ultrasonographic measures of bone density during pregnancy.[102–105] The largest of these, with a sample size of 250 gravidas, reported a quantitative ultrasonographic index 3.6% lower at 6 weeks postpartum than at entry.[102] Although the amount of bone lost was small, it is consistent with the fetal demand for calcium. In this study, there was no relationship between dietary calcium intake and bone loss. However, Aguado and colleagues detected an overall decrease in bone propagation (phalanges 2 to 5) as seen by ultrasonography during the second and third trimesters that was greater for gravidas with low dietary calcium intake (< 1,000 mg/day). Decreases in maternal bone propagation were paralleled by increases in markers of bone turnover.[103]

Calcium intake, particularly during growth, could be an important determinant of bone mineralization and thus bone density.[106] Higher calcium intakes during childhood and adolescence are associated with higher bone mass at maturity.[107] Maternal growth and pregnancy often coincide, and approximately half of all pregnant teenagers continue to grow while pregnant.[108] Recently, Sowers and colleagues reported that ultrasonographic bone measures of the os calcis during pregnancy showed that bone loss was greater for growing teenage gravidas (–5.5%) than for mature women (–1.9%).[102] In the case of pregnancy in a still-growing girl, calcium nutriture might be limited by maternal diet but simultaneously driven by the need to retain enough calcium to mineralize two skeletons.

Presumably, continued maternal growth could affect the risk of osteoporosis and osteoporotic fractures in later life, particularly if the maternal diet was deficient in calcium during childhood and adolescence. Sowers and colleagues, in a cross-sectional study of two Iowa communities, reported that women with a first pregnancy before age 19 had, at maturity, a bone mass (measured at the middistal forearm) that was –0.52 standard deviation units (SDU) below that of other women.[109] Calcium consumption was also related to bone density (– 0.68 SDU for lower intakes), and the joint effect for early pregnancy and lower calcium intake, assuming additivity, exceeded –1 SDU in bone mass. A longitudinal study from a third community carried out 5 years later also showed that bone mass was significantly reduced in those with a teenage birth.[110] A cross-sectional study by Fox and colleagues yielded similar results in perimenopausal women.[111]

Another approach has been to examine the cross-sectional relationship of parity to bone mineral density or risk of fracture. In general, cross-sectional studies of bone

mass and parity, usually confined to mature white women, have shown increased bone mass, decreased fracture risk, or no effect of parity on bone mass.[112] Lower bone mineral density has been reported in parous minority women compared with controls of the same ethnic group. Goldsmith and Johnston reported lower radial bone densities in 52 parous black women compared with black nulliparas. Among whites, parous women had a bone density 1% higher than nulliparous controls.[113] Carter and Haynes showed that lower bone density was present in adults with scoliosis.[114] Parous black women were more likely to have scoliosis than were nonparous blacks. However, parity does not measure the effects of pregnancy but the cumulative effect of the reproductive experience, along with antecedents and consequences. For example, a positive correlation between parity and bone density could reflect greater antecedent hormonal integrity and possibly increased body weight of women who bear children compared with women who are infertile. It is uncertain the extent to which small decrements in bone mass with parity among black women reflect an overrepresentation of women with adolescent childbearing.

Maternal calcium metabolism is altered during pregnancy, and these alterations could be involved in the etiology of preeclampsia. During pregnancy, maternal serum calcium levels fall and urinary calcium excretion rises, whereas serum ionized calcium remains unchanged. Preeclampsia and gestational hypertension are marked by aberrations involving calcium: affected women have hypocalciuria, low levels of ionized calcium, lower levels of 1,25-dihydroxyvitamin D, elevated levels of parathyroid hormone, and increased intracellular concentrations of calcium in erythrocytes, platelets, and lymphocytes.[115] Thus, preeclampsia might be a pathologic manifestation of a calcium-conserving mechanism. Calcium supplementation might reduce smooth muscle reactivity, including the reactivity of uterine and vascular smooth muscle by reducing parathyroid hormone and intracellular calcium levels.[116] On the other hand, disturbances in calcium metabolism could be a marker for preeclampsia, a response to an unknown and underlying metabolic perturbation.

Diets low in calcium, especially during pregnancy, have been associated with increased blood pressure levels through heightened smooth muscle reactivity (see Table 24-1 for recommended dietary intake of calcium and other nutrients during pregnancy). The pathogenesis of PIH may or may not involve calcium in the maternal diet. Belizan and Villar reported an inverse relationship between toxemia and dietary calcium from ecologic-level data.[117] More recently, gestational hypertension (but not preeclampsia) and maximum diastolic pressure were found to be weakly associated with low dietary calcium intakes.[118] Several smaller-scale clinical trials have confirmed that calcium supplementation is associated with decreased blood pressure during pregnancy, consistent with reports of an inverse association between calcium and systolic blood pressure in nonpregnant subjects.[119–120]

A meta-analysis of 14 randomized, controlled trials of calcium supplementation involving more than 2,400 pregnant women showed statistically significant reductions in systolic and diastolic blood pressure with the administration of calcium salts (375 to 2,000 mg/day elemental calcium).[121] Risk of preeclampsia was reduced more than twofold among women supplemented with calcium during these trials. Duration of treatment ranged from 10 to 22 weeks, with most studies starting the supplement during the second trimester. Although differences in the risk of preeclampsia were significant in the aggregate, only two of the nine studies showed statistically significant differences.

A large, randomized, double-blind, placebo-controlled trial of 5,489 low-risk nulliparous women showed no effect of calcium supplementation.[122] Pregnant women were enrolled at centers throughout the United States and prescreened for compliance with supplement use and for conditions associated with abnormal calcium metabolism or increased risk of preeclampsia. Women were supplemented with 2 g of elemental calcium (or placebo) beginning at 13 to 21 weeks gestation and continuing until they delivered. Calcium supplementation did not significantly reduce the risk of preeclampsia, gestational hypertension without preeclampsia (either mild or severe), or pregnancy-associated proteinuria without hypertension. Blood pressure was also unaffected. Between 20 and 40 weeks gestation, systolic pressure was lower by 0.3 mm Hg and diastolic pressure was 0.03 mm Hg higher among the calcium-supplemented subjects; these small differences were not statistically significant. Likewise, risk did not differ when data were examined according to hypothesized moderating variables: quintile of dietary calcium intake at baseline, maternal age, urinary calcium excretion, or gestation at entry to the study. These results suggest no effect of calcium supplementation on preeclampsia; however, participants' dietary intake of calcium was high, averaging about 1,100 mg/day.[122]

Recently, an Australian trial of calcium supplementation in gravidas ($N = 456$) with dietary calcium intakes (median, 1,100 to 1,200 g/day), maternal characteristics, and pregnancy outcomes very similar to those in the US trial reported a positive effect of supplementation.[116] Calcium supplementation (1.8 g/day from week 24) resulted in a greater than twofold reduction in the risk of preeclampsia. Although the proportion of women with pregnancy-induced hypertension (PIH), severe PIH, and severe preeclampsia was slightly less in the treatment group, differences from placebo were not statistically significant.

During pregnancy, an increased risk of PIH associated with lower calcium intake could result in an increased risk of preterm delivery because an indicated preterm delivery is one method of reducing the maternal–fetal morbidity and mortality associated with preeclampsia and eclampsia. Consequently, supplementation with calcium during pregnancy could have a side effect of reduced preterm birth risk. Preeclampsia involves the failure to adequately perfuse many organs, including the placenta, and is also associated with fetal growth restriction and low infant birth weight (< 2,500 g).

Two calcium supplementation trials among high-risk women showed promising results. In Ecuadorian women

with low calcium intake, gestation duration increased by 1.8 weeks ($p < .01$) for the calcium-supplemented subjects ($n = 22$).[123,124] Among teenagers from Baltimore, the calcium-supplemented group had a lower incidence of preterm delivery compared with the placebo group.[119] Further, life-table analysis demonstrated an overall shift to a higher gestational age with calcium. Another randomized, controlled trial of supplementation of 260 pregnant Ecuadorian teenagers (age 17.5 years and less) with 2,000 mg/day elemental calcium increased gestation duration from 38.7 weeks (0.3 weeks) for placebo to 39.6 weeks (0.4 weeks) with calcium supplement. Risk of PIH was reduced by 80% in this trial with calcium supplementation.[125] Baseline dietary calcium intake was low and amounted to less than 50% of the RDA for pregnancy. The more recent clinical trial from Australia also showed a reduction in the risk of preterm delivery from 10% (placebo) to 4.4% (calcium supplemented) as well as for low birth weight (7.4% versus 2.6%).[116] There were also reductions in admissions for threatened preterm labor ($p = .03$) and in preterm premature rupture of membranes ($p = .08$) for gravidas assigned to calcium.

A large calcium supplementation trial of more than 1,000 women from Argentina, however, showed a decrease in the incidence of PIH but no effect on preterm delivery.[120] The meta-analysis cited above also showed no effect of calcium intake on preterm delivery or fetal growth restriction.[121] Likewise, the US clinical trial performed by Levine and colleagues, discussed above, also found no effect of calcium supplementation on obstetric outcomes, including preterm delivery, and perinatal outcomes, including birth weight, low birth weight, or fetal growth restriction.[122] Thus, effects might be confined primarily to teenage gravidas or to gravidas with a very poor dietary intake of calcium.

DIET AND GESTATIONAL WEIGHT GAIN

The bulk of the research on gestational weight gain has focused on the relationship between total weight gain and birth weight. The body of evidence on this topic has been extensively reviewed by the Institute of Medicine and recently updated by Abrams and collegues.[2,126] Studies from developing countries and among different ethnic groups have been virtually unanimous in showing a positive relationship between weight gain and birth weight.[127,128] Maternal pregravid weight or BMI and weight gain appear to have independent and additive effects on birth weight. Correlations between weight gain and birth weight range between .20 and .30. The average magnitude of the effect on birth weight (in women with a normal weight for height) is, assuming a base birth weight of about 3,000 g, approximately 20 g of birth weight for every 1 kg of total gain; pregravid weight for height is a strong effect modifier on birth weight.[128] The relationship between gestational weight gain and preterm delivery appears more complex and more controversial. A current review concluded that most studies showed that a slow rate of gain, particularly in the second half of pregnancy, was associated with an increased risk of preterm birth.[129]

A poor or otherwise inadequate gestational gain could reflect an inadequate dietary intake. The first report of a positive relationship between diet and weight gain was made by Thomson, who found a correlation of .30 between caloric intake and weight gain in Scottish primigravidas eating "to appetite."[130] Among Camden gravidas, a significantly lower caloric intake was associated with an inadequate gestational gain.[131] This relationship was confirmed subsequently with three 24-hour dietary recalls taken during the course of pregnancy.[7] A diet that is low in energy is often one that is of poor quality with a low nutrient density. Thus, low intakes of the micronutrients iron, zinc, and folate are associated with inadequate gestational weight gain as well as with an increased risk of poor pregnancy outcomes.[6–8]

CHAPTER 25

FETAL NUTRITION AND IMPRINTING

Hilton Bernstein, MD, Donald Novak, MD

The fetus exists in utero in a dynamic environment that attempts to protect the fetus from noxious insults, while, at the same time, providing adequate nutrition and oxygenation to ensure the delivery of a healthy baby at the end of pregnancy. The mechanism by which the fetal milieu is maintained is delineated in subsequent chapters. It has become increasingly evident, however, that insults impacting the fetus and its environment can have significant consequences, not only during the immediate postnatal period but also during adult life. This chapter attempts to summarize the evidence supporting the relationship between events in fetal life and long-term health, in humans as well as in animal models.

BARKER HYPOTHESIS

In the late 1980s, David Barker and colleagues began to uncover data that, considered in totality, have become known as the "fetal origins" or "Barker" hypothesis.[1] It proposes that alterations in fetal nutrition and/or endocrine status result in developmental adaptations that may permanently change an individual's body structure, physiology, and metabolism, thereby predisposing individuals to cardiovascular, metabolic, and endocrine disease in adult life. The hypothesis suggests that insults to the fetus, occurring at sensitive (critical) periods of development, may eventually manifest in chronic diseases of adulthood, including, among others, type 2 (non–insulin-dependent) diabetes mellitus (NIDDM), coronary artery disease (CAD), hypertension, and stroke (Table 25-1). The term "fetal programming" has been coined in relation to this effect. It has been further hypothesized that, during periods of rapid growth, fetal adaptations meant to counteract malnutrition in utero can negatively influence long-term health.[2] This "thrifty hypothesis" posits that adaptations undergone by the fetus in utero to become "thrifty," that is to say efficient in the use of scarce metabolic fuels, may, in fact, be counterproductive when the organism, after birth, is exposed to an environment in which resources (such as food) are plentiful.[2,3] Support for this hypothesis has been found in large population studies, such as those involving the Pima Indians of North America.[4,5] These groups have, over generations, become adept at survival under subsistence conditions. When suddenly introduced to an environment containing abundant food—the so-called "Western diet"—the incidence of diseases including NIDDM and CAD has become epidemic.

Early evidence for the relationship between conditions in utero and later health can be found in the work of Rose, who, in 1964, described high rates of stillbirth and infant mortality among siblings of adults with CAD.[6] Subsequently, Forsdahl, in 1977, showed that areas of Norway with the highest rates of CAD had had relatively high infant mortality rates 50 years previously.[7] Barker and Osmond, in 1986, demonstrated similar findings in a British population.[8] Much of the information provided subsequently by Dr. Barker and colleagues has been derived from extensive retrospective analyses of adult British men and women who, as infants, had birth measurements recorded. In one such cohort, from Hertfordshire, Great Britain, data on approximately 16,000 subjects born between 1911 and 1930 were available.[9–13] In this group, birth weight has been noted to be inversely proportional to subsequent mortality from CAD (Figure 25-1). This relationship held over a range of "normal" birth weights ranging from 5.5 to 9.5 pounds: over 9.5 pounds, death rates attributable to heart disease rose, presumably because of the inclusion of infants of diabetic mothers in this group.[13] These findings have subsequently been replicated in a variety of other populations.[14–16] Ultimate mortality rates in infants born small were higher in those men in whom poor growth had persisted at 1 year of age, as well as in women who were of above-average weight by 1 year of age.

The connection between small size at birth and subsequent mortality from CAD has subsequently been extended to include enhanced risk of stroke, hypertension, and NIDDM.[17] Martyn and colleagues have demonstrated that the eventual risk of stroke is associated with diminished

TABLE 25-1 Reported Associations with Small Size at Birth

Increased risk of
Type 2 diabetes mellitus
Hypertension
Death from coronary artery disease
Stroke
Hypercholesterolemia

birth weight and placental size in the setting of a relatively preserved head size.[18] An inverse relationship between size at birth and serum cholesterol values in adult life has also been reported.[10,19] Hypertension during adult life has been associated with birth size in many studies[10,20–22]; this relationship may be manifest during childhood.[23] The impact of birth weight on eventual blood pressure has been of variable degree; placental size has also been reported to directly correlate with systolic blood pressures.[20] Perhaps the most intriguing association noted thus far is that between low birth weight and NIDDM, first noted by Hales and coworkers in 1991.[12] This association has been confirmed in other populations in Great Britain,[10,24] as well as in other, although not all, regions worldwide.[25–30] The association between insulin resistance in later life and birth weight is strongest in infants born relatively "thin" (low ponderal index),[29] as well as in adults who are obese. In fact, the interaction between adult weight and the conditions described above has caused debate regarding the robustness of these findings.[31] Nonetheless, at present, the bulk of available evidence supports an association between fetal growth and later health. Timing of the insult also influences the body habitus of the baby at birth. Various epidemiologic studies have shown that if the insult occurs early in pregnancy, babies tend to be proportionate with regard to weight for length (thinness) and may be more prone to develop hypertension as adults.[14] Insults in the second or third trimester result in asymmetric babies who are thin (diminished weight for height); these babies are thought to be more likely to suffer long-term abnormalities of the glucose-insulin axis.[10] Infants with small abdominal circumferences are hypothesized to have suffered an insult during hepatic organogenesis; resultant long-term changes in hepatic function may result in abnormal cholesterol and fibrinogen levels.[19] Barker and others have also shown that lifestyle factors such as obesity are additive to the effect of intrauterine environment.[9] Less certain, perhaps, is the relationship between inadequate fetal nutrition and low birth weight. Genetic influences may play a significant role. In particular, Vaessen and colleagues have reported a polymorphism in the promoter region of insulin-like growth factor I, an important fetal growth factor. Those homozygous for deletion of this 192-basepair region have a significantly enhanced risk of low birth weight, NIDDM, and CAD.[32,33] This deletion may account for a significant proportion of the findings related above.

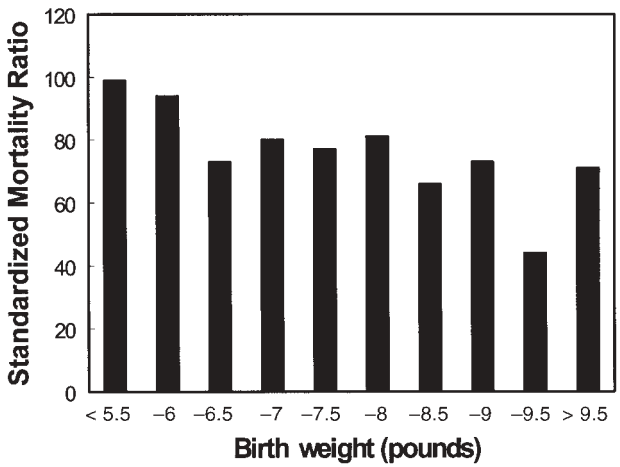

FIGURE 25-1 Standardized mortality ratio for men by birth weight in Hertfordshire study. Adapted from Osmond C et al.[13] Reproduced with permission from McClellan R, Novak D. Fetal nutrition: how we become what we are. J Pediatr Gastroenterol-Nutr 2001;33:233–44.

Convincing evidence for the association between intrauterine nutrition and later health can, however, be found through the study of infants exposed to malnutrition during times of famine. Under normal circumstances, fetal nutrition, perhaps as impacted by diminished uterine blood flow, as may be noted in preeclampsia, is difficult to estimate. During the extreme conditions found during famine, however, poor fetal nutrition is intuitive. The Dutch famine of 1944 to 1945 is an unfortunate but, given the excellent birth records kept in the country, instructive example of such a tragedy. Near the end of the Second World War, Allied Forces mounted a campaign into Nazi-occupied Holland, called Operation Market Garden. When the Dutch resistance called a general railway strike to support this campaign, German authorities retaliated by terminating food shipments into the region. This, combined with the severe winter of 1944 to 1945, resulted in severe famine. Food allowances dropped to levels approaching 300 to 600 calories per person per day during the height of the famine in December 1944 through April 1945. Infant weights fell in accordance with the caloric restriction. Infants born after exposure to famine in late gestation weighed an average of 3,133 g (n = 307), approximately 300 g less than infants conceived and born after the famine (average 3,413 g).[34] Infants born after exposure during midgestation weighed an average of 3,217 g (n = 297), whereas those children exposed only in early gestation weighed an average of 3,470 g (n = 217), more than control infants. It is unclear whether this increase in weight compared with that of the control group represents the end result of an early, biologic compensation to nutrient restriction gone awry when nutrients became abundantly available or is merely the result of available food and supranormal intakes during late gestation by the children's mothers. These children were again studied at approximately 50 years of age. Keeping in mind that clinically overt cardiac disease, as well as NIDDM, often does not present until after 50 years of age, those exposed to famine in mid- or late gestation had evidence of glucose intolerance, based on 2-hour plasma glucose values after glucose load. Elevations of serum insulin values were also noted in those exposed to famine during late gestation.[35] Those exposed in early gestation appeared to have an increased incidence of CAD, as well as a more "atherogenic" serum lipid profile.[34,36,37] Blood pressures were elevated compared with those of controls in a subgroup of individuals whose mothers had ingested a diet disproportionately deficient in protein.[38] These data generally support the "thrifty hypothesis," although further follow-up as the cohort ages will be necessary to appreciate the full impact of famine on their long-term health. It should also be pointed out that,

despite the extreme nature of the maternal dietary restriction during the famine, the impact on progeny was really quite minimal, demonstrating the extraordinary capacity of pregnant women to maintain fetal homeostasis. It is also noteworthy that the results of these studies are not universal; although methodologically limited, studies of infants born during and after the Leningrad famine of World War II have not demonstrated differences between adults exposed to famine in utero and those born later.[39]

There is evidence that insults in utero can be propagated beyond the first, directly impacted generation. Klebanoff and colleagues have shown that mothers born small for gestation are more likely to have children who themselves are small for gestation[40]; others have shown that mothers born either small (under 2,000 g) or large (over 4,000 g) suffer higher subsequent infant mortality rates than do controls.[41,42] This information must be interpreted in light of the fact that small mothers tend to have relatively small babies, suggesting a strong maternal genetic influence, independent of fetal nutrition.[43–45] This influence has been reproduced in an animal model.[46] There is some information suggesting that perinatal nutrition may influence growth beyond the first generation. Stewart and colleagues administered a low-protein (LP) diet to a colony of rats over 12 generations. LP diet–fed animals were approximately 67% of control size. When a regular (high-protein) diet was then introduced at weaning, weights did not "catch up" to control values for three generations. Of interest, however, when pregnant animals were switched to a regular diet during pregnancy, offspring rapidly caught up to and, indeed, surpassed control weights.[47] These data are strikingly similar to those reported in humans as a result of the Dutch famine and confirm the disparate impact of malnutrition in utero at different segments of pregnancy.

The role of neonatal nutrition on eventual health during adult life has also been examined. Serum cholesterol values appear to be influenced by breast-feeding: both Marmot and Fall and their colleagues have shown that exclusive breast-feeding can be associated with lower serum cholesterol values during later life.[48,49] These findings have been replicated by others.[50–52] Less consensus exists regarding the relationship between adult blood pressure and mode of feeding. Lucas and Morley, in a prospective study of low birth weight infants, documented lower arterial blood pressures in infants who had been exclusively breast-fed, at least until hospital discharge, compared with those given formula, at 13 to 16 years of age but not at 8 years of age.[53] Other studies have both supported and cast doubt on the benefits of breast-feeding with regard to eventual blood pressure.[54–57] Exclusive breast-feeding for a period of at least 2 months has also been shown to diminish the likelihood (compared with exclusive bottle feeding) of developing NIDDM in Pima Indians.[58] Although intriguing, this association has not been replicated in other populations.

The remainder of this chapter focuses on work done in animal models, thus beginning to explore the mechanisms by which in utero environment influences postnatal outcomes.

MECHANISMS UNDERLYING "PROGRAMMING": ANIMAL MODELS

Exploration of the mechanisms underlying the "programming" of physiology during fetal life has generally involved the use of animal models of growth retardation. Although many such models are available, the most widely used are those in which maternal diet is modified, thus causing malnutrition and subsequent growth retardation. This can be done either by limiting total caloric intake, similar to the situation seen during human famine, or by limiting a specific component of the maternal diet in a controlled way, for example, use of a diet low in protein. In this case, caloric intake may be held constant through an increase in the other components of the diet, that is, carbohydrates and fats. This method, although perhaps less "physiologic," allows insight into the mechanism by which changes observed may be produced. Still another method by which growth-retarded animals may be produced is limitation of uterine blood flow, mimicking preeclampsia in the human. This may be done in sheep through selective removal of placental subunits, or caruncles, whereas in the rodent, ligation of the uterine artery is most often performed, although the acute nature of this intervention, usually performed late in gestation, casts doubt on its applicability to the human situation. Other models, including that produced by heat stress[59] or by genetic manipulation, also exist.[60–64] We will focus primarily on work done in dietary and uterine artery ligation models, largely because the majority of published work has involved their use.

Perhaps the most attention has been paid to the relationship between in utero nutrition and subsequent hypertension in animal models. In a series of articles exploring this phenomenon, Langley-Evans and colleagues have demonstrated that the progeny of pregnant rats fed an LP diet throughout gestation develop systolic blood pressures that exceed those of controls.[65–70] These effects are noted at the time of weaning, last through approximately 5 months of life, and typically are in the range of 15 to 30 mm Hg. The changes noted are, to some degree, specific to the diet used. Specifically, LP diets varying in carbohydrate, fat, and amino acid content may not have similar effects, despite similar total protein contents.[71] Rats made small by maternal uterine artery ligation are not hypertensive, whereas sheep fetuses made small by placental embolization are.[72,73] Thus, the hypertension observed after administration of an LP diet to pregnant rats is not simply the result of small fetal size but rather seems related to a combination of variables, which have been elucidated only on a superficial level. More progress has been made toward determining the mechanisms of hypertension in this model. Specifically, in utero exposure to maternal glucocorticoids seems to be of key importance. The placenta normally contains an 11β-hydroxysteroid dehydrogenase activity that converts maternal glucocorticoids to inactive forms, thus protecting the fetus from their effects. Exposure of the mother to an LP diet is associated with an attenuation in the placental activity of this enzyme, as well as with increases in the activities of fetal and placental glucocorticoid inducible enzymes.

Treatment of pregnant rats with dexamethasone, which is not substantially inactivated by 11β-hydroxysteroid dehydrogenase, produces hypertension in offspring,[74,75] as does the administration of an inhibitor of 11β-hydroxysteroid dehydrogenase, carbenoxolone.[76,77] Administration of metapyrone, an inhibitor of corticosteroid synthesis, to pregnant rats fed an LP diet abolished elevated blood pressures in the offspring, unless the mothers were supplemented with exogenous glucocorticoid.[68] Postnatally, glucocorticoids are required for LP diet–associated hypertension to develop; adrenalectomy of hypertensive animals restores blood pressure to control levels.[67] Bertram and colleagues have shown that maternal LP diet administration is associated with enhanced expression of the glucocorticoid receptor in the offspring.[78] This alteration may account for some of the phenotypic differences noted. Langley-Evans and Jackson have also demonstrated alterations in the activity of the renin-angiotensin system in association with maternal LP diets. Activity of angiotensin-converting enzyme (ACE) is consistently increased in the offspring of LP diet–fed dams.[79,80] Captopril, an ACE inhibitor, and losartan, an inhibitor of the angiotensin II receptor, are both effective in reversing the hypertension brought about after in utero exposure to an LP diet, either temporarily, if given after weaning, or permanently, if given before weaning.[67,79,81,82] These results appear specific to drugs that have their effects on the renin-angiotensin system; Ca channel inhibitors were ineffective in this regard.[81]

Exposure to an LP diet in utero also appears to have long-term effects on renal morphology and function. Nephron numbers are diminished postnatally, and renal function, as determined by measurement of creatinine clearance, is diminished at 4 weeks of age. Older animals demonstrate increased urinary albumin excretion and blood urea nitrogen, suggesting that renal abnormalities persist past the immediate postnatal period.[83,84]

In summary, there is significant evidence that, in animal models, nutrition in utero has an impact on blood pressure postnatally, analogous to the situation documented above in humans. Although a variety of mechanisms by which this hypertension may occur have been suggested, the manner by which altered nutrition effects these changes remains elusive.

IN UTERO NUTRITION AND GLUCOSE INTOLERANCE

The impact, in animal models, of in utero nutrition on the pancreas and, more specifically, on pancreatic insulin secretion has been known for many years. Winick and Noble, in 1966, demonstrated that nutrition had an effect on cell number within the pancreas, and Swenne and colleagues showed that protein malnutrition in the weanling period was associated with glucose intolerance and impaired insulin secretion.[85,86] Snoeck and colleagues, in 1990, showed that B-cell proliferation and islet size were diminished in the pancreas of neonates exposed to an LP diet in utero, as was islet vascularization.[87] Dahri and colleagues, in 1991, continuing this work, demonstrated abnormalities in insulin secretion from these abnormal islets.[88] When animals were maintained on an LP diet into adulthood, glucose tolerance was impaired. Even when a normal diet was administered after birth, however, insulin secretion in response to a glucose load was abnormal in female rats tested at 70 days of age.[89] Others have shown that although glucose tolerance is roughly equivalent to that of controls at 3 months of age, impairment is clearly noted by 15 months of age, suggesting an ongoing or "programmed" response to in utero undernutrition.[90] Petrik and colleagues have subsequently shown that exposure to an LP diet through weaning is associated with increased pancreatic B-cell apoptosis, in association with diminished rates of proliferation and insulin-like growth factor II expression.[91] Studies of offspring at 3 months of age have shown that hepatic glucose output in response to glucagon is diminished compared with controls, whereas a paradoxical response, that is, an increase in hepatic glucose output, was noted in response to insulin, despite an increase in hepatic insulin receptors.[92] Hepatic glucokinase activity is decreased, whereas phosphoenolpyruvate carboxykinase (PEPCK) activity is increased,[93] contributing to an increase in hepatic gluconeogenesis noted in the offspring of protein-deprived mothers.[94] Peripheral adipocyte size was reduced compared with controls; adipocyte insulin receptor content was increased.[95] Insulin-induced suppression of lipolysis was diminished in the LP adipocytes.[96] Basal and insulin-stimulated glucose transport activities are enhanced in the LP group, and alterations in the insulin signaling pathway mediated by insulin receptor substrate 1–associated phosphatidylinositol 3-kinase have been documented.[96,97] In skeletal muscle, insulin receptor density and basal glucose uptake are enhanced compared with controls; however, stimulation with insulin has less impact on maximal transport, perhaps because the insulin-responsive glucose transporter 4 is already maximally translocated to the plasma membrane in the LP group.[98]

Offspring of mothers fed an LP diet through pregnancy and lactation may themselves have abnormal glucose tolerance during pregnancy.[99] Although this finding has not been universal,[100] abnormalities in fetal pancreatic insulin content, glucose turnover, and glucose use have been documented in the second- and even third-generation offspring, despite receipt of a normal diet throughout.[99,100] These data have been bolstered by those obtained in other complementary models. Provision of dexamethasone to pregnant rats produces growth retardation, with subsequent hyperglycemia and hyperinsulinemia in adult offspring, in association with increased PEPCK messenger ribonucleic acid and activity.[101] These findings, similar to those noted after LP diet exposure, suggest that some of the effects of LP diet on later glucose homeostasis may be mediated by maternal glucocorticoids. Others have used the uterine ligation model to examine long-term impacts on glucose homeostasis. Simmons and colleagues have demonstrated that animals born to mothers who underwent uterine artery ligation at day 19 of gestation develop fasting hyperglycemia by 10 weeks of age. Cell mass diminishes after 7 weeks of age, having been normal up until that point.[102] When these

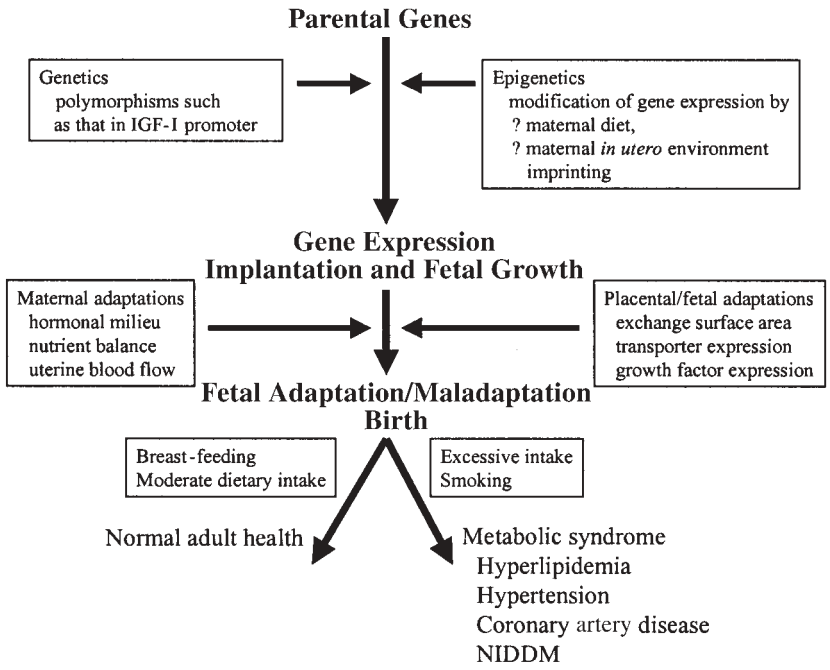

FIGURE 25-2 Proposed schema by which maternal, fetal, and environmental factors interact to produce adult disease. IGF = insulin-like growth factor; NIDDM = non–insulin-dependent diabetes mellitus. Adapted from Bertram CE, Hanson MA. Animal models and programming of the metabolic syndrome. Br Med Bull 2001;60:103–21.

animals become pregnant, their offspring develop glucose intolerance early in life and frank diabetes by 26 weeks of age.[103] Thus, there is significant evidence that nutrition in utero, in the animal as in the human, is capable of "programming" subsequent glucose homeostasis. The mechanisms underlying these phenomena, as delineated above, are beginning to be elucidated.

CONCLUSION

There is now clear evidence both from human epidemiologic studies and animal models that in utero conditions impact, in a significant way, postnatal health. Less certain is the manner by which these changes occur; a proposed algorithm is shown in Figure 25-2. As is depicted in other chapters, placental nutrient transfer is a complex process, the regulation of which, whether by genetic or environmental factors, remains poorly understood. As a result, the definition of and, if necessary, the augmentation of in utero nutrition continue to be a topic of intense investigation.

CHAPTER 26

DEVELOPMENT OF THE FETUS: CARBOHYDRATE AND LIPID METABOLISM

William W. Hay Jr, MD

The rapid rates of metabolism and growth of the placenta and fetus require ready sources of carbon for energy production and deposition in energy stores (adipose tissue and glycogen) and for structural tissues (proteins). Maternal plasma glucose provides most of the carbon for placental and fetal energy requirements. As much as 20 to 30% of the amino acids taken up by the fetus can be oxidized, however, providing most of the additional carbon necessary to meet fetal requirements for oxidation. Glucose carbon also gets to the fetus as lactate that is produced in the placenta. Between 20 and 40% of glucose carbon also is deposited in growing body tissues; most of this goes to glycogen, some to protein, and some to adipose tissue. Lipid, on the other hand, appears to be directed primarily to growth as there is little capacity to oxidize long-chain fatty acids in fetal tissues. Lipids account for fetal growth through the provision of essential fatty acids supplied to developing structural membranes. Fatty acids also account for fetal growth through adipose tissue development and growth.[1–5]

Based on experimental data from late-gestation fetal sheep and estimated data from full-term human fetuses, it is possible to construct reasonable estimates for the rates of carbon supply to the fetus from glucose (including products of glucose metabolism in the placenta, such as lactate and fructose) and amino acids, as well as for fatty acids, and to compare these rates with requirements for energy production and storage. Such estimates are shown in Table 26-1.[5–7]

CARBOHYDRATES

Sources of Glucose for the Placenta and Fetus

Maternal Glucose Supply Maternal plasma glucose provides all of the glucose for the placenta and fetus, except under relatively uncommon conditions of prolonged maternal hypoglycemia or fetal hypoxia, when the fetus can produce its own glucose by glycogenolysis or gluconeogenesis. The placenta also can use its own glycogen for glycolysis, but insufficient glucose-6-phosphatase has been found in the placenta for its glycogen to be available for production into the fetal circulation.

Qualitative evidence demonstrating that maternal glucose is the sole source of glucose for the placenta and fetus under normal conditions comes from studies in which tracers of glucose that are infused into the mother have the same specific activity or enrichment (ratio of tracer glucose to unlabeled glucose) in blood sampled from the fetus, indicating no dilution of fetal glucose with glucose other than from the maternal circulation.[8,9] Quantitative evidence to support these observations has come from tracer studies in fetal sheep during fed, normoglycemic conditions.[9–11] In these studies, net uptake of glucose by the fetus from the placenta equals fetal glucose use, that is, there is no source of glucose for fetal glucose use other than what comes from the mother by way of the placenta.

Fetal Glucose Production Only after prolonged periods (several days) of decreased fetal glucose supply, producing sustained fetal hypoglycemia and hypoinsulinemia, does fetal glucose use exceed supply, demonstrating a new source of fetal glucose production.[12] A natural onset of fetal glucose production does tend to develop in late gestation.[13] Most species appear to have sufficient functional activities of hepatic gluconeogenic enzymes in late fetal life, except the rat, in which mitochondrial phosphoenol pyruvate carboxykinase (PEPCK) develops only after birth.[14] Thyroid hormone also is essential for glucogenesis, acting on both the hepatic glucogenic pathways and on the mechanisms activating glucogenesis. These thyroid effects include up-regulation of catecholamine secretion and effects and increased or maintained concentrations of enzymes necessary for glucose production, such as glu-

cose-6-phosphatase, fructose diphosphatase, and alanine transaminase.[15]

In the case of selective hypoinsulinemia, produced, for example, by injection of streptozocin, a drug that destroys the pancreatic insulin-producing beta cells,[16] or by fetal pancreatectomy,[17] fetal glucose concentration actually increases. At the same time, the fetal glucose use rate remains near normal, despite a reduction of up to 70 to 80% in glucose supplied by the placenta. Infusion of glucose into these animals increases the glucose use rate but does not appear to decrease the rate of fetal glucose production. Only by reinfusion of insulin to normal or higher-than-normal levels can this glucose production by the fetus be diminished. Thus, fetal plasma insulin concentration appears to be a more important and more specific regulator of fetal glucose production than is fetal glucose supply or concentration.

Fetal glucose production also can come from glycogenolysis. The principal source of fetal hepatic glycogen is fetal plasma glucose. Circulating lactate[14] and certain amino acids, such as alanine,[18,19] serine,[20] and glutamine,[21] can label fetal glycogen. In vivo and in vitro studies with magnetic resonance spectroscopy using ^{13}C-labeled glucose indicate that only about 10% of glycogen (at least in fetal sheep) could come from nonglucose precursors, that is, by the indirect pathway of reverse glycolysis (DiGiacomo, Battaglia, Shapiro, et al, unpublished data). Glycogen accumulates progressively toward term in most organs.[22] Lung glycogen content decreases late in gestation, however, presumably as part of surfactant production, although this issue is controversial. Glycogenolysis in the fetus is rapidly activated by catecholamine infusion, glucagon injection, and hypoxia or ischemia[23]; all of the enzymes necessary for glycogenolysis are present early in gestation.[24]

Mechanisms of Placental Glucose Uptake and Transport

A principal action of fetal glucose production, regardless of cause or mechanism, is to divert uterine glucose supply to the placenta. As shown in Figure 26-1, an increase in fetal glucose concentration that is independent of the maternal glucose concentration can separately regulate the partition of uterine glucose uptake into glucose transfer to the fetus and uteroplacental glucose consumption. This observation demonstrates complex regulation of glucose uptake, metabolism, and transfer to the fetus by the placenta.

Maternal Glucose Concentration Glucose enters the placenta and fetus from the maternal circulation according to concentration-dependent mechanisms, making maternal plasma glucose concentration the principal regulator of placental and fetal glucose supply.[25] Maternal glucose concentration tends to decrease slightly during the second half of gestation[26] as a result of the balance of two opposing forces: (1) it tends to decrease because of the increasing consumption of glucose by the growing placenta and fetus and (2) it tends to increase from the development of maternal insulin resistance and glucose intolerance caused by certain hormones (perhaps, for example, placental lactogen, progesterone, prolactin, estrogen, and glucocorticoids)[27] and certain competitive substrates (eg, fatty acids).[28] In women who develop overt diabetes mellitus with insulin resistance and glucose intolerance during late gestation, the insulin resistance appears to be the primary defect. Studies by Catalano and colleagues,[29] Shao and colleagues,[30] and Barbour and colleagues[31] indicate that the mechanism for this insulin resistance involves alterations in the insulin signal transduction cascade independent of hormonal influence, as well as potentially significant effects of placental growth hormone.

Placental Glucose Transporters Glucose uptake and transport by the placenta are mediated by facilitative transporter proteins. Both GLUT 1 (all species) and GLUT 3 (human, rat, and sheep) isoforms have been identified at both the maternal-facing microvillous trophoblast membrane and the fetal-facing basal trophoblast membrane,[32] although quantitative distribution has varied among studies and species.

GLUT 4 also has been found in the human placenta, but there is no evidence that insulin signal transduction activates its translocation or increases glucose uptake. One recent study, however, showed increased glucose uptake in perfused human placentas from insulin-treated diabetic women; the mechanism for such an effect is not known.[33] In another study, JAr placental cells showed stimulation of mitogenesis via the MAPK signaling pathway but did not show insulin stimulation of PI3-kinase-dependent protein kinase B activation sufficient to stimulate glucose transport or glycogen synthesis, highlighting the placenta as a nonclassic target organ of insulin regulation of glucose metabolism.[34]

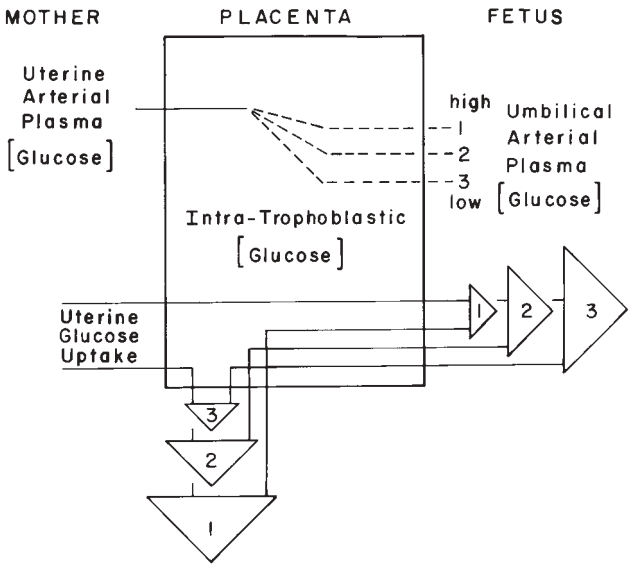

FIGURE 26-1 Schema of effects of fetal glucose concentration of placental glucose transfer to the fetus and uteroplacental glucose consumption, adapted from data in sheep. A decrease in fetal glucose concentration relative to maternal glucose concentration promotes maternal-to-fetal glucose transfer at the expense of uteroplacental glucose consumption. These findings demonstrate a reciprocal relationship between placental glucose transfer and uteroplacental glucose consumption that is determined by the fetal glucose concentration. Reproduced with permission from Hay WW.[2]

In the human placenta, GLUT 1 is the principal transporter at the maternal-facing microvillous membrane, whereas GLUT 3 occurs more on the fetal-facing basal membrane or localized in extravillous trophoblast and villous cytotrophoblast cells.[35] Hahn and colleagues found that hyperglycemia down-regulates the GLUT 1 glucose transport system in full-term placental trophoblast studied in vitro by down-regulating both GLUT 1 protein concentration and translocating membrane GLUT 1 protein to intracellular sites, where they would be less—or not at all—effective in mediating glucose.[36] In contrast, Illsely and others have suggested that hyperglycemia in diabetic pregnancies enhances fetal glucose-stimulated insulin and insulin-like growth factor (IGF)-I production, the latter acting to promote GLUT 1 at the fetal-facing basal trophoblast membrane, thereby maintaining an increased placental glucose transport capacity.[37–39] To date, however, there is no in vivo evidence for this mechanism, except for increased fetal-facing basal membrane GLUT 1 protein concentrations in placentas from diabetic pregnancies.

Hyperglycemia itself also can promote further hyperglycemia in pregnancy. For example, women with gestational diabetes mellitus release greater amounts of tumor necrosis factor α (TNF-α) from both the placenta and maternal adipose tissue in response to high glucose. TNF-α specifically interrupts the insulin signal transduction pathway leading to insulin resistance, glucose intolerance, and progression of hyperglycemia.[40,41] In other species, different patterns have been observed. For example, in sheep, chronic hyperglycemia was associated with reduced GLUT 1 and GLUT 3 concentrations and with increased glucose uptake by the uteroplacenta from the mother. There was no change in fetal glucose uptake, however.

In contrast, chronic hypoglycemia decreased placental GLUT 1 concentrations but did not appear to change placental GLUT 3 concentrations, although uterine, uteroplacental, and fetal glucose uptake rates were decreased.[42] Obviously, change in transporter expression can occur in response to changes in glycemia, particularly when the glycemic changes are chronic, but the impact of such changes in placental GLUT expression is not necessarily directly related to placental glucose transport to the fetus, which appears to exert independent control over its rate of glucose uptake.

Nutritional patterns during gestation also affect the expression of placental glucose transporters. In sheep, for example, early gestational nutrient restriction decreases placental size, but there is no change in placental weight-specific GLUT 1 transporter abundance. When such sheep were refed later in gestation, placental mass and GLUT 1 abundance both increased with sufficient feeding, but neither increased if the ewes were overfed.[43]

Nutrient restriction studies in the rat have shown no change in placental GLUT 1 expression but did show reduced GLUT 3 expression. However, there was no change in fetal glucose concentration.[44] An additional study compared rodent and ovine placental GLUT 1 responses to changes in glucose.[45] In rats, 6 days of sustained hyperglycemia caused no change in GLUT 1 protein levels, whereas 3 days of intrauterine growth retardation (IUGR) with fetal hypoglycemia and ischemic hypoxia decreased GLUT 1 levels by 50%. In pregnant sheep, maternal and fetal hyperglycemia caused an initial threefold increase in GLUT 1 with a persistent decline over the next 2 to 3 weeks, whereas maternal and fetal hypoglycemia led to a 30 to 50% decline in placental GLUT 1 levels. In a rat placental cell line, high glucose concentrations decreased GLUT 1 concentrations, which was counteracted in part by exposure to low oxygen concentrations.

Clearly, there is considerable need for more research into the regulation of placental glucose transporter expression and related placental glucose uptake, metabolism, and transport to the fetus because there are demonstrable differences among isoform specificity, time-dependency, and species.

The arrangement of glucose transporter proteins on both sides of the trophoblast allows bidirectional transport of glucose across both membranes, as well as across the whole placenta.[11] Thus, placental glucose transfer to the fetus is regulated by the combined effects of the concentrations of glucose in the maternal and fetal plasma and the kinetic function of the glucose transporter proteins at both the maternal- and fetal-facing trophoblast membranes.[46]

Transplacental Glucose Concentration Gradient Net transport of glucose from mother to fetus across the placenta requires a net maternal-fetal plasma glucose concentration gradient. In all species studied, including humans, the fetal plasma glucose concentration has been observed to be significantly lower than that measured in a simultaneously obtained blood sample from the mother.[47] In addition, a significant linear relationship has been observed

between the prevailing glucose concentration in the mother and that in the fetus.[11,48] This linear relationship between maternal and fetal glucose concentration covers the physiologic range of glycemia but experimentally has been seen during acute hyperglycemia induced by glucose infusion to the mother and during hypoglycemia induced by insulin infusion to the mother.[49]

Placental Glucose Consumption The transplacental glucose concentration gradient is produced by both placental and fetal glucose consumption. The contribution by the placenta is large because the placenta is a highly metabolically active organ; in pregnant sheep near term, for example, the placenta can consume almost twice as much glucose as does the fetus, even though the placental-to-fetal weight ratio is only about 1:10.[50] Thus, a large part of uterine glucose uptake is consumed by placental glucose metabolism, which contributes significantly to the physiologic hypoglycemia of the fetus and helps to establish the transplacental glucose concentration gradient; without placental glucose consumption, fetal arterial glucose concentration would more than double.[25] Glucose use in the placenta also contributes to glycogen formation via glycogenin.[35] There is no evidence, however, that this glycogen serves other than local purposes as the amount of glucose-6-phosphatase in the placenta appears insufficient to release enough glucose into the fetal circulation to account for any significant portion of fetal glucose use.[51]

Placental Glucose Transport Kinetics The relationship between the rate of placental glucose transfer to the fetus and the maternal-fetal plasma glucose concentration gradient is complex. Placental and fetal glucose consumption rates vary independently of each other. Furthermore, in vivo studies in sheep have shown that the glucose transporter proteins at both maternal and fetal placental membranes demonstrate saturation kinetics (Figure 26-2).[52–54] In these studies, glucose clamp experiments produced steady-state net fluxes of glucose into and across the placenta and into the fetus at different concentrations of glucose in the maternal and fetal circulations. Uptake and net consumption of glucose by the uteroplacenta demonstrated saturation kinetics with a V_{max} of about 0.23 mmol/min. K_m (maternal arterial glucose concentration at $V_{max}/2$) and K_s (maternal arterial glucose concentration at which V_{max} is reached) were 2.8 mmol/L and 8.0 mmol/L, respectively—not significantly different from the same parameters for uterine glucose uptake. Similar results have been measured in a variety of in vitro perfusion experiments in human placentas, although V_{max} in the human placentas studied in vitro is several-fold higher than under normoglycemic conditions.

Summary of Placental Glucose Uptake, Consumption, and Transport

Figure 26-3 summarizes the regulation and quantitative aspects of placental glucose uptake and transport. First, uterine, placental, and fetal glucose uptake are directly related to maternal glucose concentration (Figure 26-3A).[54] Second, fetal glucose uptake is separately regulated by fetal glucose concentration, by which a relatively lower glucose concentration in the fetus establishes a larger maternal-fetal glucose concentration gradient and thus increased transfer of glucose to the fetus (Figure 26-3B).[54] In contrast, at any

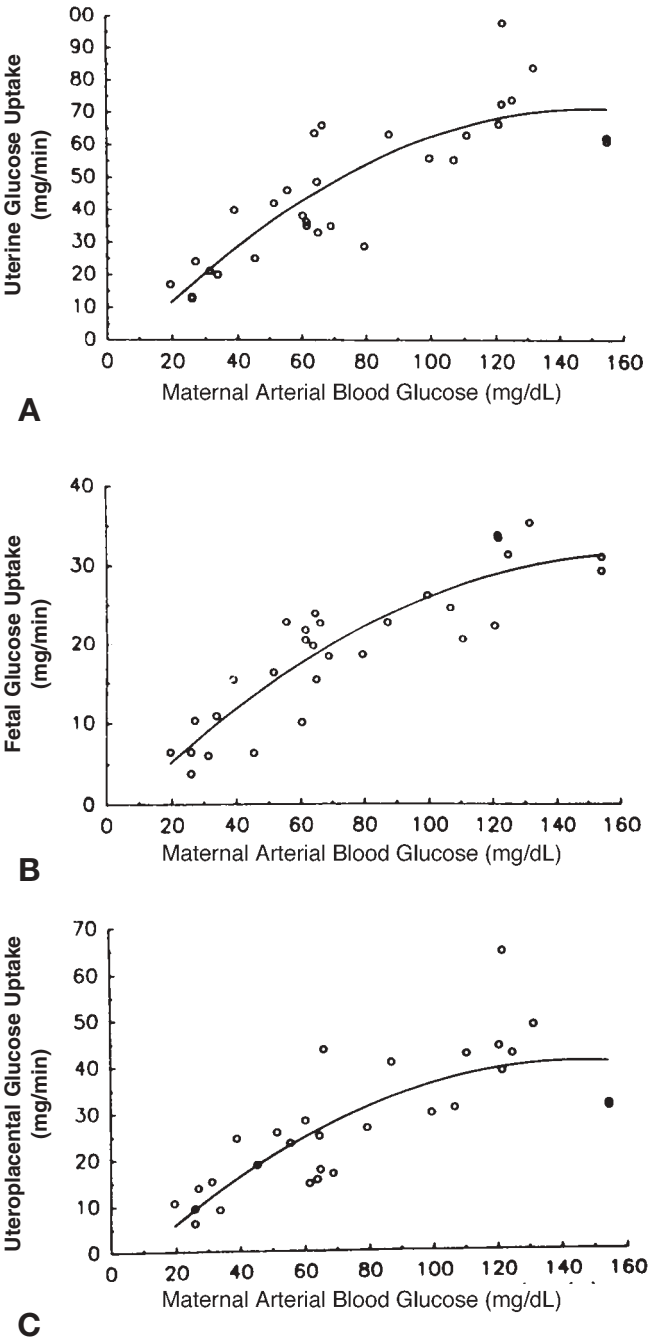

FIGURE 26-2 Relationship between maternal glucose concentration and the net uptake of glucose by the uterus, fetus, and uteroplacenta. Glucose was infused into pregnant sheep after an overnight fast to produce a large variety of maternal arterial blood glucose concentrations. Net glucose uptake rates by the uterus (*A*), fetus (*B*), and uteroplacenta (*C*) were quantified by the Fick principle. All three relationships show saturation kinetics with an approximate K_m value (a measure of the sensitivity of the transport processes to maternal glucose concentration) in the physiologic range of maternal glucose concentration (about 50 to 60 mg/dL [2.8 to 3.3 mM]). These results show that maternal glucose concentration determines the entry of glucose into the uterus, uteroplacenta, and fetus. Reproduced with permission from Hay WW and Wilkening RB.[54]

maternal glucose concentration, placental glucose consumption is directly related to fetal arterial plasma glucose concentration (Figure 26-3C).[46] In fact, the fetal side of the placenta has a capacity to take up glucose eightfold greater than that of the maternal side, so that changes in fetal glucose concentrations have a strong influence on placental glucose flux and metabolism.

Fetal Glucose Use

Kinetics of Glucose Use Placental glucose transfer to the fetus also is attributable to the saturation of the capacity for glucose use in the fetus. This capacity itself is variable as increased fetal glucose supply from the placenta and increased fetal plasma glucose concentration act to increase fetal insulin secretion. In turn, increased fetal insulin concentration augments fetal glucose use and plasma clearance, effectively limiting the increase in fetal glucose concentration as maternal glucose concentration and maternal-to-fetal glucose transfer increase.[16]

Effects of Plasma Glucose and Insulin on Glucose Metabolism The rate of fetal glucose metabolism (total use as well as the rate of fetal glucose oxidation) depends directly on the simultaneous interaction of fetal plasma glucose and insulin concentrations (Table 26-2). An example in near-term fetal sheep depicting the effect of glucose and insulin concentrations simultaneously on fetal glucose use, measured as the rate of glucose oxidation to CO_2, is shown in Figure 26-4.[55] Although both glucose and insulin act independently (ie, additively) to increase glucose use and oxidation in the fetus according to saturation kinetics, the relative proportion of glucose oxidized during short-term (3- to 4-hour) studies (about 55% in fetal sheep) does not change significantly over the entire range of glucose used.

Thus, the principal metabolic effect of insulin in the fetus is to increase the permeability of insulin-sensitive cells to glucose, enhancing glucose uptake and use in general, and oxidation of glucose in proportion to uptake and use, rather than differentially affecting intracellular pathways of glucose metabolism. This is true on balance for the whole fetus; individual tissues and metabolic pathways can vary significantly in their responsiveness to insulin. Such a permissive role for insulin in fetal sheep is different from that in adult humans, in whom higher rates of glucose use are partitioned more into glucose storage (fat and glycogen) than into oxidation. The same could be true in the human fetus, which, like the human adult, has the capacity to synthesize fat to a greater extent than does the leaner fetal sheep. In fetal sheep, the disposition of nonoxidized glucose-carbon is less certain. Recent studies, however, have demonstrated significant contributions of glucose-carbon to the formation of glycogen in the liver, heart, and lung, and a significant contribution to the carbon contained in amino acids and synthesized proteins (DiGiacomo, Carter, Battaglia, and Hay, unpublished data, 1990).

Glucose Transporters and Glucose Uptake and Metabolism Glucose is transported into cells in the fetus, just as in the newborn and adult, by a family of structurally related membrane-spanning glycoprotein transporters.[56–59] GLUT 1 is the predominant fetal glucose transporter isoform.[60–62] It is found in abundance in most fetal tissues.[60,62,63] In contrast, tissue-specific isoforms, such as the neuronal GLUT 3 in brain,[64] GLUT 2 in hepatocytes and pancreatic beta cells,[65] and GLUT 4 in insulin-responsive tissues such as skeletal muscle, heart, and adipose tissue,[66] are expressed in smaller amounts in fetal tissues than is GLUT 1.[64–66] Stud-

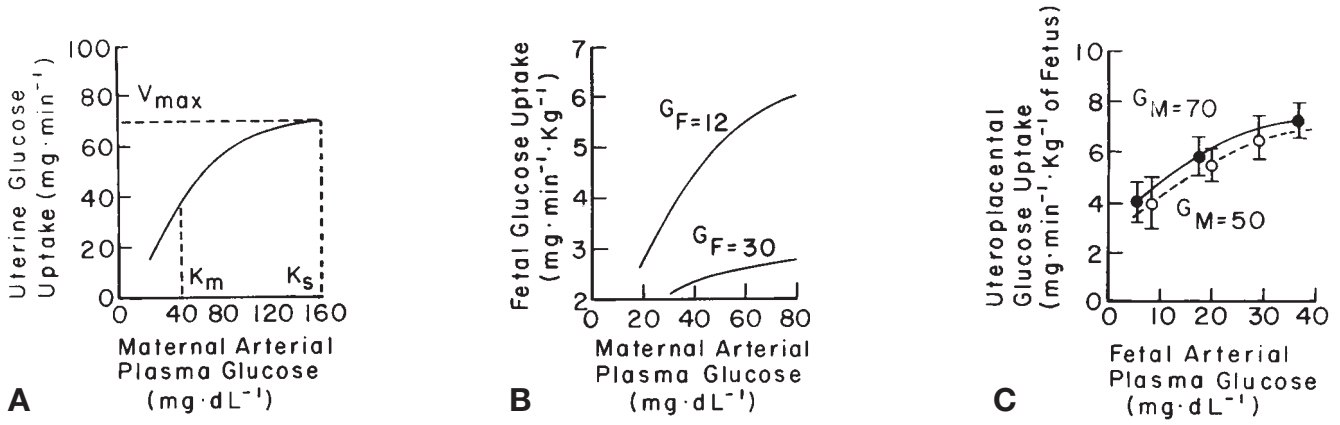

FIGURE 26-3 *A*, Net rate of glucose transfer into the uterus from the maternal plasma versus maternal plasma glucose concentration. V_{max} is the maximum rate at which glucose can enter the uterus; K_m is half of V_{max} and a measure of the sensitivity of uterine glucose uptake to maternal glucose concentration; K_s is the maternal glucose concentration at which V_{max} is reached. *B*, Net rate of glucose transfer into the fetus from uteroplacenta versus maternal plasma glucose concentration; a lower fetal glucose concentration relative to any maternal glucose concentration produces a greater maternal-fetal glucose concentration gradient and a higher rate of placental-to-fetal glucose transfer (upper curve versus lower curve). *C*, Net rate of uteroplacental glucose consumption versus fetal plasma glucose concentration; at any maternal glucose concentration (data for maternal glucose concentrations of 50 and 70 mg/dL are shown), uteroplacental glucose consumption is directly related to fetal glucose concentration. These data show that maternal glucose concentration determines the rate of glucose entry into the uterus (and thus the fetus and placenta), but the rate of uteroplacental glucose consumption is regulated by fetal glucose concentration. Adapted from Hay WW et al[46] and Hay WW and Meznarich HK.[54]

TABLE 26-2 What Glucose and Insulin Do in the Fetus

Glucose
Enters fetus from placenta according to transplacental, maternal-fetal plasma glucose concentration gradient
Enters fetal tissues (via glucose transporters) according to saturation-limited (Michaelis-Menten) kinetics, independent of and additive to that of insulin (in sheep)
Promotes its own oxidative and nonoxidative metabolism to equal extents in fetal sheep; perhaps more to nonoxidative fat deposition in humans
Increases fetal oxidation and oxygen consumption
Inhibits protein breakdown
Contributes most of the substrate for fetal glycogen formation
Increases insulin production and secretion
Maintains fetal growth
Insulin
Increases glucose uptake into insulin-sensitive (via GLUT 4 transporters) tissues according to saturation-limited (Michaelis-Menten) kinetics, independent of and additive to that of glucose (in sheep); perhaps more into adipose tissue in humans
Increases plasma glucose clearance
Produces hypoglycemia
Increases transplacental maternal-fetal glucose concentration gradient and thereby increases the transfer of glucose across placenta and into fetal plasma
Inhibits glucose production
Inhibits protein breakdown (most likely through increased glucose use)

ies in the fetal sheep have demonstrated time-dependent universal suppression of fetal peripheral tissue GLUT 1 and GLUT 4 concentrations by chronic hyperglycemia.[63] These observations in sheep mimic results obtained in the rat fetus exposed to a diabetic maternal environment.[67] Because the results varied in the rat depending on the timing and duration of exposure to hyperglycemia,[67,68] there obviously are independent effects of glucose and insulin on fetal glucose transporters, particularly GLUT 1.

Both acute and chronic changes in fetal glucose and insulin concentrations have been studied in fetal sheep to address the interrelationships among absolute changes in glucose and insulin concentrations, duration of change in glucose and insulin concentrations, expression of glucose transporter concentrations, and glucose use rates in the fetus. In chronic studies lasting 2 to 4 weeks in late gestation, sustained hyperglycemia was associated with a progressive decrease to normal or subnormal insulin concentrations.[69] Under these conditions, there was a transient increase in brain GLUT 1 but not in GLUT 3 concentrations and a progressive decline in liver and adipose tissue GLUT 1 and myocardial and skeletal muscle GLUT 1 and GLUT 4.[67]

Further studies showed that the chronic hyperglycemia and reduction in GLUT 4 correlated with the development of insulin resistance.[70] Chronic hypoglycemia (produced

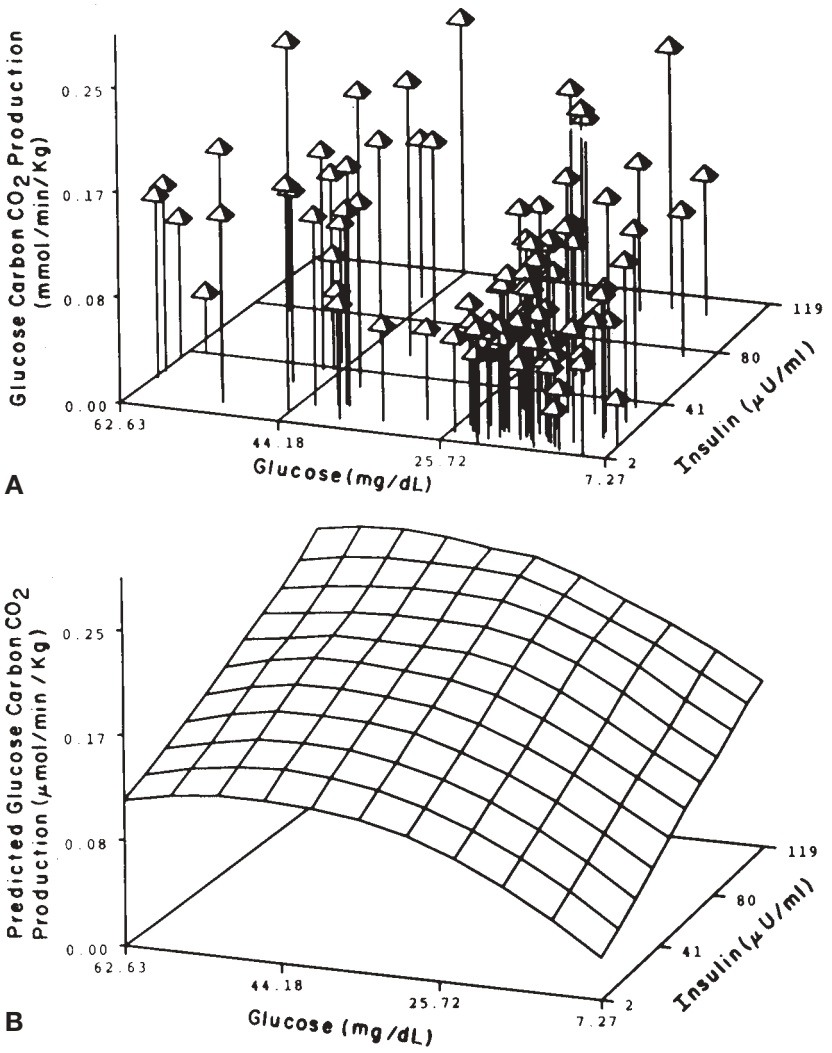

FIGURE 26-4 Data from fetal sheep showing the additive effects of plasma glucose and insulin concentrations on fetal glucose oxidation rate measured as CO_2 production rate. *A*, Three-dimensional plot of individual values of the rate of glucose oxidation to CO_2 at different concentrations of glucose and insulin. *B*, Predicted values of the rate of fetal glucose oxidation to CO_2 displayed as a three-dimensional glucose × insulin surface from the values in *A*. Reproduced with permission from Hay WW et al.[55]

by maternal insulin infusion) produced a decline in brain GLUT 3, an increase in brain GLUT 1, and a subsequent decline in liver GLUT 1 but no significant change in insulin-sensitive myocardium, skeletal muscle, or adipose tissue GLUT 1 or GLUT 4 concentrations.[67] These time-dependent and tissue- and isoform-specific changes in response to altered circulating glucose or insulin concentrations, or both, showed that cellular adaptations in GLUT 1 and GLUT 3 are geared toward protecting the fetus from perturbations in substrate availability, and the adaptations in GLUT 4 are geared toward development of insulin resistance.

In acute studies, expressions of GLUT 1, GLUT 3, and GLUT 4 were studied in response to 1, 2.5, and 24 hours of selective hyperglycemia or hyperinsulinemia.[71] Hyperglycemia initially increased the fetal glucose use rate associated with an increase in GLUT 1 and GLUT 3 isoforms, which mediate basal glucose use, but made no change in GLUT 4, which mediates insulin action. Fetal glucose use rates returned to normal values by the end of 24 hours. These results contrast with the tissue-specific effects of selective hyperinsulinemia, which produced a sustained increase in fetal glucose use rate associated with a sustained increase in hepatic GLUT 1 and a myocardial-specific emergence of mild insulin resistance associated with a down-regulation of GLUT 4. In skeletal muscle specifically, there was a lack of sustained temporal association between the increases in transporter proteins and glucose use rates.[72] This observation indicates that subcellular localization and activity of transporters or tissues other than skeletal muscle contribute to net fetal glucose use rate.

These observations support an immediate but transient cellular adaptation of augmented glucose uptake associated with a transient increase in GLUT 1 concentration in response to an acute hyperglycemic perturbation in the intrauterine milieu. In contrast, alterations in the hormonal milieu (specifically of insulin) did not demonstrate any acute effects on the mechanisms underlying insulin-induced cellular glucose transport, except for a sustained increase in hepatic GLUT 1 concentrations and an increase in skeletal muscle GLUT 4 concentrations. Whether chronic hyperinsulinemia in the presence of hyperglycemia or euglycemia leads to adaptations of fetal ovine glucose transporter proteins aimed at enhancing or limiting intracellular substrate delivery remains unknown, as do the mechanisms, such as GLUT gene transcription or translation and post-translational protein stability, that underlie both acute and chronic adaptation to changes in circulating glucose and insulin concentrations.

Basal Insulin Concentration The basal concentration of insulin in the fetus probably has a role in fetal glucose use, but direct evidence for this is not as convincing as the effect of hyperinsulinemia. For example, an acute decrease of fetal plasma insulin concentration with somatostatin infusion does not appear to affect fetal glucose concentration or glucose use.[39,73] In contrast, a chronic decrease of fetal plasma insulin concentration, either by pancreatectomy or streptozocin injection into the fetus, reduces fetal growth[17,74] and decreases umbilical glucose uptake in relation to fetal hyperglycemia. The hyperglycemia results from decreased peripheral tissue insulin sensitivity and glucose use and from the release of insulin's normal inhibition of hepatic glucose.

Interaction between Glucose and Alternative Carbon Substrates for Oxidative Metabolism With markedly reduced rates of glucose supply to the fetus, fetal glucose use rate decreases proportionally.[46,54] Under such short-term conditions, fetal oxygen consumption remains near normal,[55] indicating active reciprocal oxidation of other substrates, at least over the short term, such as glucose released from glycogen, lactate, amino acids, fatty acids, and keto acids. Over longer periods (more than 3 weeks) of reduced glucose supply, fetal oxygen consumption tends to decrease by 25 to 30%. Because the rate of fetal growth decreases at the same time and to the same extent as the decrease in oxygen consumption, the reduction in fetal oxygen consumption probably represents the oxidative requirements of the decreased protein synthetic activity.[74]

Glucose Use Rates Quantitative aspects of fetal glucose use have been studied in several large animal models. In most studies, fetal glucose use is about 5 mg/min/kg fetal weight near term, down from values nearly twice as high in midgestation,[75] when fetal growth and metabolic rate are as much as twice as great as they are closer to term. In humans, based on the increase in total maternal glucose production in late gestation, fetoplacental glucose use is estimated to be about 5 to 6 mg/min/kg fetal weight.[8] This rate is similar to that measured in normal full-term infants.[76] Table 26-3 presents estimated rates of glucose use in several fetal organs and the remaining carcass of fetal sheep in late gestation. The fraction of glucose oxidized versus that entering tissue accretion pathways in these organs has not been determined, and the factors that regulate glucose uptake in specific organs remain poorly studied. Most organs appear dependent on plasma glucose concentration for their specific rate of glucose uptake, and certain organs,

TABLE 26-3 Fetal Metabolic Rates That Account for Glucose Use*

	Glucose Use Rate (mg/min/kg fetus)	*Percent of Total*
Whole fetus (sheep, measured)	5.0	100
Whole fetus (human, estimated)	6.0–8.0	100
Brain (sheep, measured)	0.8	16
Brain (human, estimated)	4.0	50–67
Heart (sheep, measured)	0.65	13
Lungs (sheep, estimated)	0.1	2
Liver (sheep, measured)	0.1	2
Red blood cells (human, estimated)	0.1	2
Gut (sheep, estimated)		
Carcass/skeletal muscle (estimated, sheep)	3.25	65
Total of organs accounted for		
Sheep	5.0	100
Human	8.2	103–137

*Based on data in fetal sheep and estimates for human fetuses for brain.

such as skeletal muscle and probably the heart and liver, are insulin sensitive (at least in sheep studied in vivo).

Gestational Development of Placental Glucose Transport and Fetal Glucose Use The fetus grows severalfold in size over the second half of gestation and so does its absolute rate of glucose use. Placental glucose transfer to the fetus, therefore, must increase to meet the increasing metabolic requirements for glucose of the larger, growing fetus. The increase in placental glucose transport occurs for two reasons: (1) the transplacental glucose concentration gradient increases as the fetal glucose concentration decreases relative to maternal glucose concentration (Figure 26-5A), and (2) the placental transport capacity itself increases (Figure 26-5B).[75]

Placental glucose transport capacity develops primarily by an increase in the total amount,[77] rather than the affinity, of glucose transporters.[75] The number of glucose transporter proteins can increase via an increase in the trophoblast membrane surface area, an increase in the concentration of transporters per unit of membrane area, or both. Although there is some evidence from in vitro studies that glucose concentration can regulate placental glucose transporter expression, either directly or through IGF-I action,[78] GLUT 1 messenger ribonucleic acid (mRNA) can vary independently of GLUT 1 protein. For example, GLUT 1 protein decreases over gestation in rats, but it parallels GLUT 1 protein in sheep. There is no evidence, however, that such changes affect the actual rate or the capacity (maximal rate) of placental glucose transport. In fact, in vitro perfusion studies in human placentas and in vivo studies in humans and sheep indicate that placental glucose transport capacity is much greater than actual transport rates, indicating that small changes in placental glucose transporter content might have little or no effect on the rate of placental glucose transport.[53,54] By late gestation, however, glucose transport capacity by the placenta has a dominant role in the regulation of glucose transport to the fetus (Figure 26-5C).

Fetal glucose concentration can decrease relative to maternal glucose concentration over the second half of gestation for several reasons. First, fetal cellularity increases over this period, as does the fraction of body weight that consists of insulin-sensitive tissues (eg, skeletal muscle and adipose tissue).[79] Second, fetal insulin concentration increases, developmentally and in response to glucose and other secretagogues.[80] Third, insulin-sensitive GLUT 4 transporters on fetal skeletal muscle and adipose tissue cell membranes also increase over gestation, at least as a result of the increase in the relative body content of these insulin-sensitive tissues. The result is an increase in the effectiveness of insulin to promote fetal glucose use and glucose clearance, thereby reducing the relative fetal plasma glucose concentration. On balance, however, by late gestation, the increasing gradient of glucose concentration across the placenta contributes only limited control over placental transport of glucose to the fetus. The combination of these developmental processes and how they interact to promote net glucose transfer to the fetus by the placenta are summarized in Figure 26-6.[46]

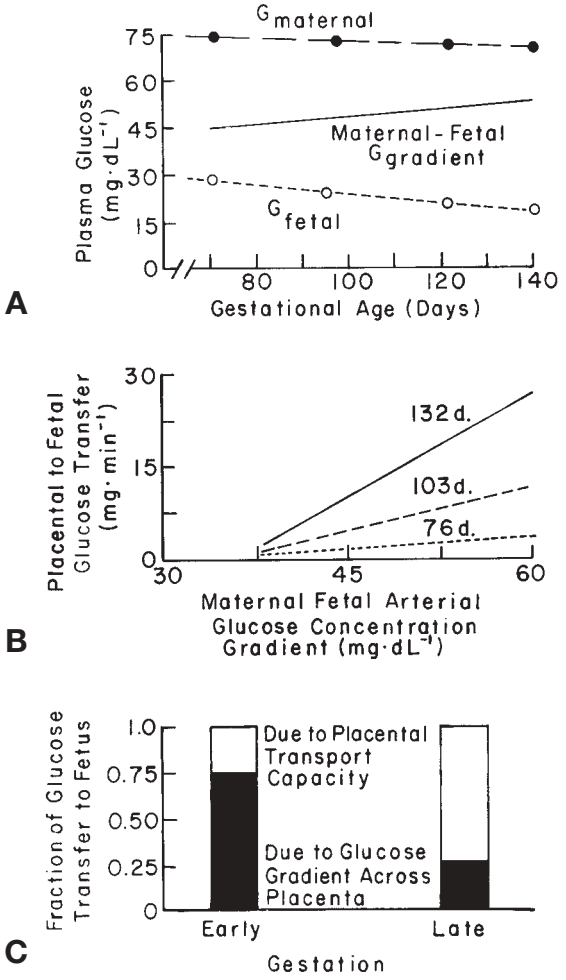

FIGURE 26-5 *A*, Plasma glucose concentration tends to decrease in fetal sheep (-○-) over the second half of gestation relative to maternal plasma glucose concentration (-●-). This increases the maternal-fetal plasma glucose concentration gradient or the driving force for transplacental glucose transfer (—). *B*, Placental-to-fetal glucose transfer (PGT) increases about eightfold over this same period. This increase in transport largely reflects transport capacity, shown by the increasing slope of PGT as gestational age increases. *C*, At midgestation, most of PGT is attributable to the maternal-fetal glucose concentration gradient, whereas by term, the placental transport capacity for glucose accounts for most of PGT. Adapted from Molina RD et al.[75]

Fetal Insulin Secretion

Many studies have addressed the onset and development of insulin secretion from the fetal pancreas. The fetal pancreas develops in the late first to early second trimester of pregnancy, producing measurable insulin concentrations by midgestation. As noted above, there is a gradual increase in basal insulin concentration and glucose- and arginine-induced insulin secretion toward term.[80] In the rat, very little insulin is secreted in the fetus,[81,82] whereas in the human fetus, which normally does not secrete much insulin,[49,83] sustained hyperglycemia in pregnant diabetics,[84] particularly when the hyperglycemia is pulsatile, produces considerable insulin.

Fetal sheep are somewhere in between, showing downregulation of glucose-induced and basal insulin secretion in the presence of chronic, sustained, marked hyper-

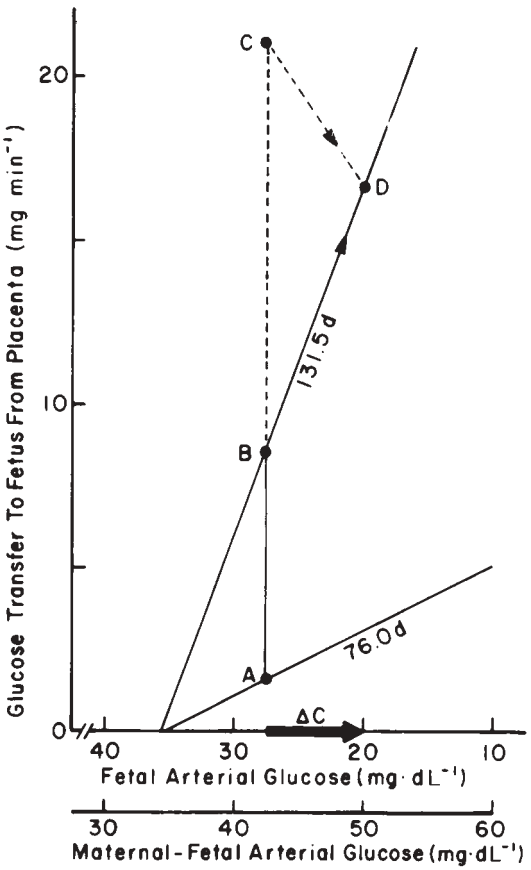

FIGURE 26-6 Graphic illustration of interrelationships among developmental changes in placental glucose transport capacity, fetal glucose demand, and fetal glucose concentration from mid- to late gestation in sheep. Placental glucose transfer capacity increases over gestation, shown by the increased slope of the 131.5-day gestational age line versus the slope of the midgestation, 76-day line, supplying more glucose to the fetus (A to B). Fetal growth demands more glucose, however, represented by point C. Additional glucose is provided by the simultaneous decrease in fetal glucose concentration relative to that of the mother, which increases the transplacental glucose concentration gradient (x-axis segment ΔC). Although fetal hypoglycemia increases fetal glucose uptake, it also tends to decrease disposal of glucose into fetal tissues from fetal plasma. These opposing forces combine to produce the actual glucose supply to the fetus at point D. Reproduced with permission from Hay WW et al.[46]

glycemia, as seen in rats,[68] but increased insulin secretion with pulsatile hyperglycemia, as seen in humans.[85] Hypoglycemia decreases basal and glucose-induced insulin secretion,[86] perhaps a fundamental aspect of how intrauterine growth retardation (IUGR) with fetal hypoglycemia decreases fetal pancreatic development and insulin secretion capacity. Clearly, fetal insulin secretion responds variably to changes in glucose concentration that are dependent on the absolute change in glucose concentration, its magnitude, and its pattern.

Alternate Carbohydrates Produced in the Placenta

The fetal glucose/oxygen metabolic quotient is less than 1.0,[5] which means that glucose does not (in fact, could not) account for all of the carbon necessary for the rate of fetal oxidation. Furthermore, tracer studies in fetal sheep have shown that the fraction of fetal glucose use that does produce CO_2 is only about 0.5 to 0.6.[38] Thus, there remains a need for carbon substrates other than glucose to meet the oxidative requirements imposed by the fetal respiratory rate (VO_2 or net rate of oxygen consumption), even if all of the glucose consumed by the fetus was oxidized. To meet at least part of the need for other carbon substrates, the placenta plays an important role by metabolizing glucose to lactate (in most or all species) and fructose (in ruminants).

Lactate and fructose are produced directly in relation to placental glucose supply.[87,88] Based on preliminary observations, approximately 50 to 70% of uteroplacental glucose consumption goes to lactate (at low and high values, respectively, of maternal and fetal glucose concentrations and the rate of placental glucose consumption), and 3 to 5% goes to fructose under the same conditions. Lactate produced in the placenta enters both maternal and fetal circulations at about equal rates under normal conditions,[87] whereas fructose produced in the placenta enters only the fetal circulation.[88] At normal rates of lactate and fructose uptake by the fetus and their oxidation fractions in fetal tissues measured in late-gestation sheep,[89] these two substrates could supply carbon sufficient to account for another 20 to 30% of the carbon requirements for fetal oxygen consumption above that provided by glucose. Amino acids and perhaps fatty acids and keto acids are the only other substrates available to make up the balance.

Adaptations to Changes in Glucose Supply

Hypoglycemia Short-term maternal hypoglycemia has been studied in late-gestation sheep.[90] As shown in Figure 26-7,[90] several days of fasting-induced hypoglycemia produce proportional reductions in glucose uptake by maternal nonuterine tissues, the fetus, and the uteroplacenta. Similar changes in glucose use by these tissues have been found with acute, insulin-induced hypoglycemia of several hours duration.[54] At the same time, however, the uteroplacental oxygen consumption rate does not change. Thus, even with hypoglycemic conditions, other substrates must substitute for glucose to maintain oxidative metabolism. Recent studies demonstrate that as glucose use by the placenta is decreased, so is uteroplacental production of lactate and fructose.[87,88] There is little or no change in placental use of free fatty acids, keto acids, or amino acids. Thus, uteroplacental oxygen consumption can be maintained by a balance in which a decreased supply of glucose to the fetus also results in decreased production of exported products of glucose metabolism, allowing glucose carbon to be used preferentially for oxidative metabolism.

This pattern is maintained with much longer periods of hypoglycemia, but two other adaptations develop under chronic conditions as well. First, fetal glucose production develops.[74] This increases the fetal glucose concentration relative to that of the mother and shifts the balance of glucose uptake by the uterus more to placental glucose consumption and less from glucose transfer to the fetus (see Figure 26-1). Fetal glucose production thus

serves two purposes: (1) the maintenance of fetal glucose metabolism and (2) the diversion of diminished glucose supply to the uterus into placental metabolism.[12] Fetal glucose production, therefore, maintains the glucose metabolic requirements of the fetus and placenta without further drain on the diminished availability of glucose in the mother; this could represent a simple "survival" adaptation (Table 26-4).

The second adaptation to chronic hypoglycemia in late gestation is a reduction in placental and fetal growth rates, resulting in lower fetal and placental weights.[74] Because placental glucose transfer capacity does not change at the same time, placental weight reduction, or failure to maintain weight, does not appear to include a reduction in placental membrane surface area or glucose transporter number or affinity. The advantage of a smaller placenta is not clear, but because the overall carbon balance in the placenta is maintained, it provides additional evidence that with chronic hypoglycemia and decreased placental glucose supply, placental glucose carbon is shunted to oxidative metabolism, that is, it is not shunted to nonoxidative processes such as the production of placental tissue and the production of normally exported products of placental glucose metabolism, such as lactate and fructose. It is interesting to speculate that all of these activities take place to substitute reduced rates of fetal and placental growth for reduced substrate supply, maintaining normal fetal and placental tissue-specific rates of metabolism and preserving their function and viability without further demands on maternal metabolism.

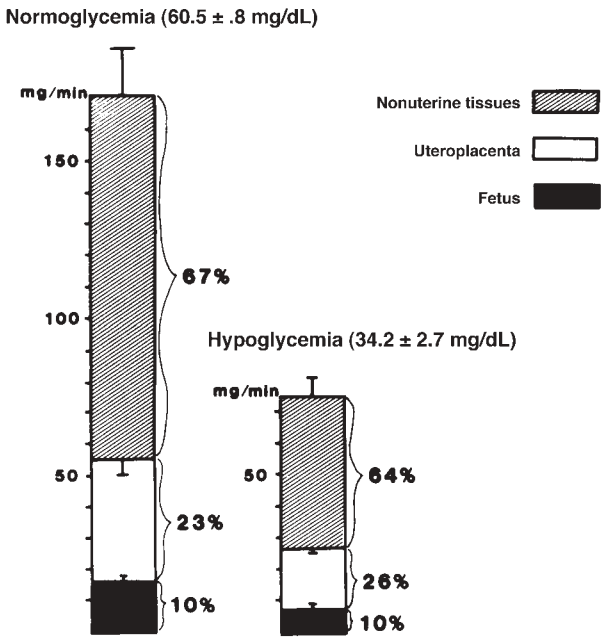

FIGURE 26-7 Fractional partition of maternal glucose production to nonuterine maternal tissues, uteroplacenta, and fetus in normoglycemic sheep (first column) and hypoglycemic sheep (second column), showing that in the short term there is no change in the relative proportions of glucose used by these three sets of tissues. Thus, fetal and placental glucose needs are dependent on the supply of glucose from the maternal plasma glucose pool; with maternal glucose deficiency, either the fetus must use its own sources of glucose (glycogenolysis or gluconeogenesis) or rely on other substrates, such as amino acids, for carbon balance. Reproduced with permission from Hay WW et al.[90]

TABLE 26-4 Fetal Responses to Decreased Glucose Supply and Hypoglycemia

Acute
Decreased glucose uptake
Decreased insulin production and secretion
Hypoinsulinemia
Decreased glucose use
Increase in rate of placental glucose transfer to fetus because fetal hypoglycemia tends to increase maternal-fetal glucose concentration gradient
Decreased placental lactate production
Decreased fetal lactate uptake and use
Substitution of other substrates to main oxidative metabolism
Chronic
Initial increase in fetal glucose production, then return toward normal condition of little or no fetal glucose production
Initial increase in amino acid oxidation, then return to normal rates
Decreased insulin sensitivity
Increased ratio of fetal to maternal glucose concentration
Increased ratio of placental glucose consumption to placental glucose transfer

Intrauterine Growth Retardation IUGR is a unique example of how fetal glucose metabolism and its regulatory mechanisms adapt to glucose deficiency and hypoglycemia to maintain normal fetal glucose metabolism. Regardless of the model (Table 26-5), when the fetus is deprived of glucose by placental insufficiency or maternal hypoglycemia, the fetal weight-specific glucose use rate is not very much different from the normal rate.[91]

This indicates that part of the mechanism to enhance glucose uptake by the fetus from the placenta is the production of further hypoglycemia, thereby increasing the maternal-fetal glucose concentration gradient. To do this, there must be an increase in the fetal tissue capacity for glucose uptake, use, or both. This could come about by increased concentrations, activity, or plasma membrane localization of glucose transporters; by increased insulin signal transduction and thereby increased effectiveness at promoting GLUT 4 (and perhaps GLUT 1) translocation to the cell membrane; or by mechanisms of insulin metabolism into oxidative and/or nonoxidative pathways. In both fetal sheep and fetal rats with IUGR, GLUT 1 and GLUT 4 concentrations in myocardium, adipose tissue, and skeletal muscle do not decrease with sustained hypoglycemia,[63,65,66] perhaps a positive adaptation to maintain glucose use despite hypoglycemia. It has not been determined if this maintenance of glucose transporter concentration is sufficient by itself to maintain glucose use at normal rates. More studies are necessary to sort out this fascinating and complex adaptation to glucose deficiency among the many tissues in the fetus.

Hyperglycemia Acute maternal hyperglycemia produces an increase in uteroplacental glucose uptake with saturation kinetics that parallel those of the fetus (Table 26-6). At the same time, uteroplacental oxygen consump-

tion rate does not change[54]; thus, increasing amounts of glucose consumed by the placenta are shunted into nonoxidative pathways. These include increased rates of lactate and fructose production, as well as increased use of glucose carbon for placental tissue, particularly glycogen.

With chronic hyperglycemia in the mother, produced by glucose infusion or experimental diabetes, similar patterns of glucose metabolism in the placenta have been observed. Fetal adaptations produce other changes as well. For example, in experimental animals, chronic fetal hyperglycemia in response to chronic maternal hyperglycemia eventually appears to down-regulate fetal pancreatic insulin secretion.[92] This involves the basal rate of insulin secretion and also appears to later involve the secretion of insulin in response to acute hyperglycemia.[93] As a result of the relative decrease in circulating insulin concentrations in the presence of hyperglycemia, fetal hyperglycemia is exaggerated, shifting the increased rate of uterine glucose uptake more into uteroplacental glucose consumption. Oxidative metabolism, measured as the uteroplacental rate of oxygen consumption, still does not change. Thus, uteroplacental glucose metabolism increasingly enters nonoxidative pathways.

The particular metabolic pathways of glucose carbon under these conditions have not been explored. Placental size is not dramatically increased, suggesting that export of placental glucose carbon into lactate and fructose and perhaps other products accounts for the balance of glucose carbon not used for oxidative metabolism. Of course, glucose carbon could substitute for the oxidation of carbon normally provided by other substrates, including keto acids and fatty acids, but principally the amino acids. Normally, the glucose oxidation fraction in the placenta of sheep in late gestation, corrected for lactate carbon and fructose carbon export, is still only about 50%. Thus, half of placental oxidative metabolism must be supplied by other substrates.

Some amino acids, such as leucine and serine, can be oxidized within the placenta directly as they are taken up from the maternal plasma and concentrated within the trophoblast cytosol. In contrast, glutamate is produced in the fetal liver from glutamine and then taken up by the placenta, where as much as 70 to 80% is oxidized.[94] It is certainly possible, therefore, that under hyperglycemic conditions, excess glucose carbon could substitute for carbon that is derived from amino acids, keto acids, and fatty acids under normoglycemic conditions. Thus, there are clear interrelationships among a variety of carbon substrates that can act as sources of carbon for placental oxidative metabolism, and placental glucose supply appears to regulate these interrelationships.

Summary of Placental and Fetal Glucose Metabolism

Acute and chronic adaptations to extreme changes in glucose supply to the placenta involve active and complex adjustments in the patterns of placental metabolism and growth. The one constant is placental oxidative metabolism, which, on a weight-specific basis, appears to be maintained in spite of major shifts in the relative supplies of substrate carbon and the rate of placental growth.

LIPIDS

Considerably less is known about placental lipid uptake, metabolism, and transfer to the fetus than is known for glucose, principally because most experimental animal models, especially sheep, demonstrate little capacity for lipid uptake, metabolism, and transport by the placenta. Also, lipid transport by the human placenta has not been

TABLE 26-6 Fetal Responses to Increased Glucose Supply and Hyperglycemia

Acute: Mild to Moderate
Increased glucose uptake
Increased insulin production and secretion
Hyperinsulinemia
Increased glucose use
Increased fetal oxygen consumption
Mild arterial hypoxemia
Respiratory acidosis
Increased placental lactate production
Increased fetal lactate uptake and use
Acute: Severe
Arterial hypoxemia

Increased erythropoietin
Increased fetal oxygen consumption
Metabolic acidosis
Decreased placental perfusion
Fetal demise
Chronic
Decreased insulin secretion and/or synthesis
Decreased peripheral insulin sensitivity
Increased ratio of placental glucose consumption to placental glucose transfer

studied in vivo, and there is large variation in the data obtained from human placental tissue studied in vitro. Even so, the human placenta appears to have considerable capacity for lipid transfer. Transporters for specific fatty acids are primarily involved. More complex pathways include lipoprotein dissociation by placental lipoprotein lipase activity (although the exact cellular source of lipoprotein lipase in the placenta remains in question), triglyceride uptake and metabolism (including metabolic pathways of oxidation, chain lengthening, synthesis, and interconversion pathways), and release into the fetal plasma as free fatty acids or lipoproteins.[95]

Placental Lipid Uptake, Metabolism, and Transfer to the Fetus

Importance of Placental Lipid Metabolism to Fetal Lipid Supply The amount and type of fatty acids or complex lipids transported by the placenta vary among species; it is greatest in the hemochorial placenta of the human, guinea pig, and rabbit and least in the epitheliochorial placenta of the ruminant and the endotheliochorial placenta of the carnivores. Furthermore, it is interesting that fetal fat content at term varies among species reasonably directly with the lipid transport capacity of the placenta.[96] There are many lipid substances in the plasma that are transported across the placenta; they are essential for placental and fetal development even if they do not contribute to nutritional or energy metabolism. Also, brown fat is common to all fetuses; it is essential for postnatal thermogenesis even if the neonate is not "fat" with white adipose tissue. Furthermore, many lipid substances entering the fetus are qualitatively different from those taken up by the uterus and uteroplacenta, implying active placental metabolism of individual lipid substances. Placental lipid metabolism, therefore, is qualitatively and, in some cases, quantitatively important for fetal development and growth, even if the fetus does not get very fat.

Uptake, Synthesis, Metabolism, and Hydrolysis of Fatty Acids A schema of lipid uptake, metabolism, and transport in the human placenta is shown in Figure 26-8.[4,95] After entering the placenta, fatty acids can be used for triglyceride synthesis, cholesterol esterification, membrane biosynthesis, direct transfer to the fetus, or oxidation. The most important factor that regulates the flux of lipids into the placenta and into the various pathways of transport and metabolism is the concentration of maternal plasma lipids, including free fatty acids and triglycerides. For example, placental triglyceride content increases in women who are fasting, who deliver preterm infants, or who have diabetes mellitus—all conditions in which maternal plasma free fatty acid concentrations are increased.

Placental tissue from different species has been shown to express lipoprotein lipase activity as well as phospholipase A_2.[97–104] Maternal plasma triglycerides are hydrolyzed by these enzymes, and the fatty acids that are released are then taken up by the placenta. In the trophoblast cells, the fatty acids are then re-esterified and further hydrolyzed, facilitating their diffusion into fetal circulation. Cultured placental trophoblast cells have shown that esterified intracellular lipids provide a reservoir of fatty acids that can be released into the medium.[105]

All fatty acids cross lipid bilayers, such as those in the syncytiotrophoblast, by simple diffusion. Partition studies in pure phospholipid bilayers indicate that this diffusion is rapid, on the order of 20 to 30 milliseconds.[106] In addition, fatty acid transport across membranes is facilitated by fatty acid binding proteins (FABPs), which aid in intracellular channeling of fatty acids.[107–111] The main membrane-associated FABPs are the plasma membrane fatty acid binding protein (FABPpm) and the fatty acid transfer proteins (FAT/CD36 and FATP).[107] These transfer proteins have been found on both the maternal-facing microvillous and fetal-facing basal membranes of the placental trophoblast, whereas a placenta-specific protein, p-FABPpm, has been found exclusively on the microvillous membrane.[112] p-FABPpm has a unique amino acid composition that enhances the binding affinity and capacity of this protein for arachidonic acid and docosahexaenoic acid (DHA) compared with linoleic and oleic acids.[113–115] The syncytiotrophoblast also contains cytoplasmic binding proteins, which appear to act by removing fatty acids from the inner membrane and channeling them to their respective metabolic fates.[107,109,116]

Fatty acid transport into the fetal circulation is largely determined by the transplacental gradient of nonesterified fatty acids (NEFAs) relative to available circulating binding protein concentrations and the activity and availability of their binding sites. The concentration of NEFAs in the maternal plasma at term is about three times that in the fetal circulation, but the concentration of albumin, the primary carrier protein for NEFAs, is actually 10 to 20% higher in fetal than maternal circulation.[117] Thus, the ratio of plasma NEFAs to albumin on the fetal side of the placenta is about 25% of that on the maternal side at term.[118] The higher concentration of NEFAs relative to available binding sites on albumin, α-fetoprotein, and other lipoproteins in the maternal compared to the fetal plasma is reflected in the concentration of unbound NEFAs, which is greater in maternal (12 nM) than fetal (9 nM) circulation.[119] Human cordocentesis data from 18 to 36 weeks gestation indicate an exponential decrease in the concentration of NEFAs in the fetal circulation over this period,[120] presumably because of increasing use of fatty acids in the fetus for rapidly growing structures such as the brain and adipose tissue.

Although most fatty acids appear to be transported by diffusion and direct carrier-mediated mechanisms, some studies suggest that chain-altering metabolism in intratrophoblast peroxisomes could lead to a greater transfer of medium-chain fatty acids into the fetal circulation.[121] This might be advantageous to fetal lipid metabolism, which appears to be limited in its capacity for oxidation of long-chain fats, an apparent result of low cytosolic or mitochondrial carnitine concentrations or both.[122] Fatty acids also can be esterified to di- and triglycerides and to phospholipids. These can be stored transiently or for the long

term or hydrolyzed by phospholipases and acylglycerol lipases to release fatty acids into the fetal circulation.

Additional evidence for the hypothesis that transient placental esterification of fatty acids occurs during transport of fatty acids by the placenta comes from measurements of the activities of enzymes required for the isolation of glycerol-3-phosphate.[123] Such enzymes are located in the endoplasmic reticulum and have been identified in placental trophoblast cells. Although enzyme-specific activity and total enzyme content do not necessarily reflect metabolic flux, the presence of these enzymes indicates that fatty acid esterification followed by hydrolysis is a reasonable hypothetical pathway for placental lipid metabolism and transport.

Fatty Acid Synthesis Fatty acids also are synthesized in the placenta. Significant fatty acid synthesis has been measured in placental tissue and cultured trophoblast cells from human,[124] sheep,[125] and pig placentas.[126] Primarily long-chain fatty acids (oleic, palmitic, and palmitoleic acids) are formed.[105] Radiolabeled palmitate can be incorporated rapidly into triglycerides in human placental slices, and studies of human trophoblast cells in culture have shown that incubation with albumin-bound ^{14}C-oleate produces ^{14}C-labeled cellular triglycerides. Similar observations have been made in 21-day pregnant rats studied in vivo, showing incorporation of ^{14}C-palmitate into placental triglycerides and phospholipids.[127]

Lipoprotein Synthesis There is conflicting evidence regarding the synthesis of lipoproteins by placental tissue and their use for transport of fatty acids to the fetal circulation. By day 21 of gestation in the rat, the placenta appears to synthesize apoprotein B, which is normally an integral part of the major plasma lipoprotein carriers of triglycerides.[127] Such observations have not been made in the human placenta, which might secrete lipoproteins only during the early part of gestation, if at all.[128] Small amounts of low-density lipoprotein (LDL) and very-low-density lipoprotein (VLDL) have been identified in human amniotic fluid, but their source has not been determined.[105]

Cholesterol Metabolism and Transfer Low-density lipoprotein cholesterol is taken up by endocytosis into trophoblast cells and degraded by lysozymes.[129] LDL cholesterol appears to be the major precursor for placental production of progesterone and estrogen. High-density lipoprotein (HDL) cholesterol also contributes to placental progesterone production in cultured human trophoblast cells. Some of this cholesterol is transferred directly to the fetus, although the role of this transport is uncertain, given the large capacity and rate of cholesterol synthesis in the fetal liver.[130]

Nonessential Fetal Lipid Supply The bulk of placental lipid transport is dependent on maternal plasma fatty acid and lipid concentrations and maternal-fetal plasma fatty acid concentration gradients. In humans, concentrations of free fatty acids are higher in maternal blood than in fetal blood, and their concentrations are highly correlated. Under normal circumstances, the fetal-maternal ratio of free fatty acids is less than 0.5.[131] In humans, fetal patterns of essential fatty acids and structural lipids correlate directly with the fatty acid/lipid composition of the maternal plasma (and, indirectly, the maternal diet).[52] This direct correlation could be unique to humans because of the high lipid transport capacity of the human placenta. Sheep, for example, transport very little total lipid across the placenta, except for some long-chain essential fatty acids, and horses produce a lipid profile in fetal plasma that is qualitatively and quantitatively different from that in maternal plasma; this is perhaps the product of placental metabolism or different rates of transfer for different chain lengths of fatty acids.[132]

In fetal plasma, the fatty acids are bound to albumin and α-fetoprotein and transported to the liver, where they are synthesized into triglycerides and released into the fetal circulation. Because maternal triglyceride concentration determines the activity of placental lipoprotein lipase and

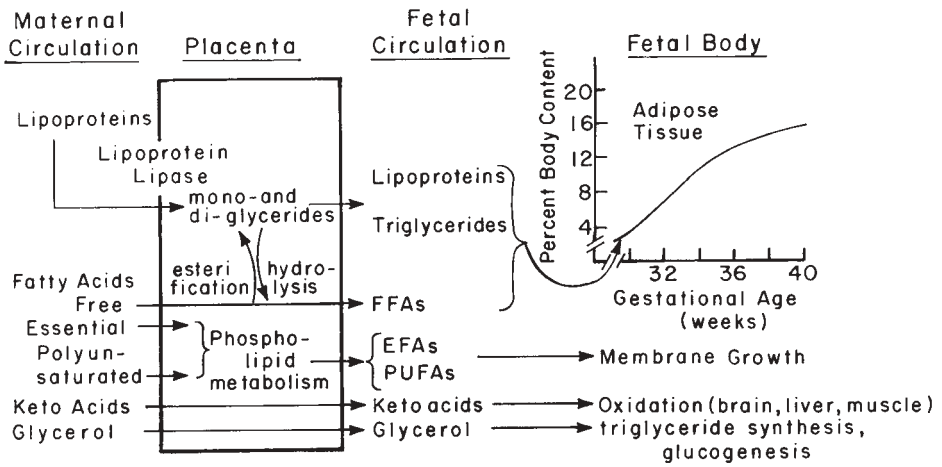

FIGURE 26-8 Schematic of placental-fetal interrelationships in humans for various aspects of placental lipid metabolism, fetal lipid uptake and metabolism, and fetal lipogenesis into adipose tissue. Adapted from Hay WW[4] and Coleman RA.[95]

fatty acid transport across the placenta is concentration dependent, there is a direct relationship between maternal and fetal plasma triglyceride concentrations, even though there is no direct uptake and transfer of intact triglycerides by the placenta.

The impact on the fetus of maternal plasma free fatty acid and lipid concentrations also is reflected in fetal lipid content and adipose tissue development. Fatter human fetuses develop in women who have higher plasma concentrations of fatty acids and other lipids. Experimentally, diabetic rats (induced by streptozocin) have increased free fatty acids, and their fetuses have carcass and hepatic lipid contents that are increased twofold above normal.[133] Similarly, rabbits fed oil-rich diets show increased neonatal adipose stores.[134]

In humans, umbilical venous–arterial fatty acid concentration differences in cord blood samples show that the net flux of free fatty acids into the fetus from the maternal circulation can account for the fetal requirement of fatty acids during the end stages of pregnancy.[135] In contrast, the perfused human placenta can transfer fatty acids at a rate that can account for only about 20% of what is required for the accumulation of fetal adipose tissue deposited during the third trimester.[72] Other estimates, based on fetal lipid accumulation as well as on in vitro transfer experiments, estimate that as much as 50% of fetal fatty acid requirements is transferred across the human placenta.[95] Similar estimates have been made in rats using the incorporation of ^3H from ^3H_2O into fatty acids, indicating that fatty acids are derived about equally from the mother and from fetal fatty acid synthesis.[137] Estimates in the rabbit[138] and the monkey[139] indicate that in these species, placental fatty acid transfer across the placenta could account for all fetal fat deposition in late gestation. Overall, therefore, it appears that there is a general relationship between the permeability of the placenta to lipids, especially fatty acids, and the adiposity of the fetus at term, with human fetuses developing the most fat (15 to 18% of body weight at term),[140] guinea pigs second at about 12%, and rabbits third at about 7% (Figure 26-9).

Availability of Essential Fatty Acids to the Fetus

Essential Fatty Acid Metabolism and Transfer by the Placenta The supply of essential fatty acids and long-chain polyunsaturated fatty acids (LCPUFAs) is critical and central to the synthesis of structural lipids and, hence, to normal development of the fetus. Linoleic acid (18:2 omega-6) and α-linolenic acid (18:3 omega-3) are the only fatty acids known to be essential for complete nutrition and must be supplied in the diet. All of the omega-6 and omega-3 fatty acid structures acquired by the fetus must, therefore, come from the mother via the placenta, either in the form of these two essential fatty acids or their LCPUFA derivatives, of which arachidonic acid (20:4 omega-6) and docosahexaenoic acid (22:6 omega-3) are metabolically the most important.[141]

Essential fatty acids are readily transferred to the fetal plasma in all species studied so far. Cultured trophoblast cells incubated with ^{14}C-acetate do not label arachidonic acid, however, and delta-5 and delta-6 desaturase activities in human placental microsomes are absent, at least early in gestation,[142,143] consistent with the absence of measurable conversion of γ-linolenic acid to arachidonic acid.[144] This emphasizes the requirement for direct transfer of the essential LCPUFAs to the fetus from the maternal plasma. In fact, higher concentrations of these essential fatty acids are found in the fetus than in the mother.[145–148] These results suggest that fetal arachidonic acid is either transferred directly from the mother or has a higher binding capacity in the fetal plasma but do not exclude the possibility that some might be synthesized from linoleic acid in the fetal liver.

Although formation of arachidonic acid and DHA from essential fatty acid precursors has been shown in term and preterm infants,[149–155] the degree to which the fetus is capable of fatty acid desaturation and elongation is not clear. Fetal baboons can synthesize both DHA and arachidonic acid from their precursors, α-linolenic acid and linoleic acid, respectively.[156,157] A low enzymatic activity of delta-5 desaturation has been proposed as one factor limiting arachidonic acid synthesis,[158] and although high delta-5 and delta-6 desaturase activities in the liver of one 18-week and two 22-week fetuses,[141] which were close to those found in adult liver,[159] have been reported, human fetal liver desaturase-elongase chain reactions have not been clearly demonstrated in physiologic conditions

Maternal Diet and Essential Fatty Acid Supply In general, reduced maternal essential fatty acid nutrition has been correlated with reduced neonatal growth and head circumference in humans.[160] Significant linear correlations between the mother and fetus or newborn have been found for both LCPUFAs and essential fatty acids in healthy women eating normal, unsupplemented diets.[161–163] Parallel increases in plasma DHA in the mothers and newborns also have been found after fish oil supplementation during pregnancy.[164,165] These observations show the importance of maternal dietary fatty acids to regulate the availability of

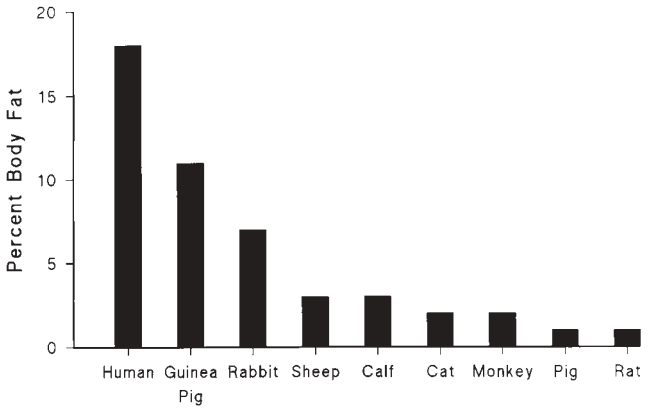

FIGURE 26-9 Fetal fat content at term as a percentage of fetal body weight among species. Adapted from Hay WW,[2] Hay WW,[4] Battaglia FC and Meschia G,[5] Sparks JW et al,[7] and Widdowson EM.[96]

LCPUFAs to the fetus and newborn. In fact, because the developing fetus depends primarily on the maternal supply of essential fatty acids, maternal dietary supplementation with LCPUFA-rich oils during the last trimester of pregnancy to increase levels in neonates has been advised.[164,165]

The competitive desaturation of the omega-3 and omega-6 series by delta-6 and delta-5 desaturases, however, is of major significance because of their controlling role in the desaturating and elongating pathways of the parent essential fatty acids.[166] Thus, excessive dietary intake of linolenic acid from vegetable oils, particularly safflower, sunflower, and corn oil, can inhibit delta-6 desaturase and decrease the formation of DHA from α-linolenic acid. Similarly, arachidonic acid formation is lower when excessive linolenic acid is provided, as seen in enterally or parenterally fed infants receiving corn or safflower oil as the predominant source of fatty acids.[167–170] Further, the inhibitory effect of eicosapentaenoic acid on delta-5 desaturase activity has been considered to be responsible for the lower plasma arachidonic acid found when fish oil, high in eicosapentaenoic acid and DHA, is consumed.[166] Also, excessive fish oil intake can inhibit intake of linolenic acid from vegetable oils, particularly safflower, sunflower, and corn oil; fish oils inhibit delta-6 desaturase activity and decrease arachidonic acid levels.[171,172] The consumption of fish oils modifies membrane phospholipid composition, increasing eicosapentaenoic acid and DHA concentrations at the expense of arachidonic acid content. Adverse effects of low arachidonic acid concentration in serum and red blood cell phospholipids on growth during infancy have been reported.[173–175]

Arachidonic acid status in preterm infants also has been correlated with birth weight.[173,176,177] Foods containing lipid peroxides are potentially toxic, and the higher the content of LCPUFAs in the diet, the more likely that peroxidation will occur.[178–180] Thus, excess intake of PUFAs could reduce antioxidant capacity,[181] enhancing susceptibility to oxidative damage,[182] a condition that has been shown to be responsible for fetal damage during pregnancy in rats.[183–185]

Dietary olive oil appears to protect the LCPUFA series better than fish oil does.[186] Olive oil also does not affect arachidonic acid concentrations[187–189] and is much more resistant to lipid peroxidation.[180,190,191] The effect on the fatty acid profile and vitamin E concentration in a diet supplemented with 10% fish oil versus the same amount of olive oil during pregnancy has been studied in rats. A decrease in both arachidonic acid and α-tocopherol concentrations, as well as delayed postnatal development, was found in the offspring of rats fed the fish oil–rich diet.[192] The study was extended to determine whether dietary supplementation with either vitamin E or γ-linolenic acid as a precursor of arachidonic acid could ameliorate these changes. Arachidonic acid concentrations and postnatal development indices, but not α-tocopherol concentrations, were improved when the fish-oil diet was supplemented with γ-linolenic acid.

In contrast, postnatal development indices were not improved when the fish oil–rich diet was supplemented with sufficient exogenous vitamin E to normalize α-tocopherol levels.[192] Thus, although feeding a fish oil–rich diet during pregnancy and lactation decreased both α-tocopherol and arachidonic acid concentrations, the latter deficiency rather than the former seemed to be responsible for delayed postnatal development of rat pups. In this same study, another group of pregnant and lactating rats fed the fish oil–rich diet received a supplement with arachidonic acid instead of γ-linolenic acid, and although both treatments restored brain phospholipid content and arachidonic acid content in the pups, improvements in growth rate and neurodevelopment indices were more efficient in the γ-linolenic acid group. The only difference between the two groups was the absence of linoleic acid in brain phospholipids when rats were supplemented with arachidonic acid, whereas it was present at a normal level in those supplemented with γ-linolenic acid.[192] These findings agree with previous findings in humans fed diets rich in arachidonic acid; the proportion of linolenic acid in plasma phospholipids decreased,[193] likely a consequence of replacing linolenic acid with arachidonic acid in tissues.[194]

These observations in humans and experimental animals emphasize the exquisite sensitivity of endogenous LCPUFA metabolism to changes in maternal dietary fatty acid composition during perinatal development and the quite remarkable consequences to fetal and neonatal development. Because the benefits and risks of modifying maternal fat intake in pregnancy and lactation are not yet completely established and the safety of high intakes of LCPUFAs during pregnancy is still unclear,[195–197] further studies are required before recommendations to increase LCPUFA intake in pregnancy can be made.

Placental Uptake, Metabolism, and Transfer of Essential Fatty Acids Maternal plasma essential fatty acids are the fetus's principal source of LCPUFAs.[117,143,147] Cellular uptake of free fatty acids occurs by facilitated transmembrane transport involving a FABPpm.[198–202] The preference for human placental transfer from the maternal to the fetal circulation has been reported to be DHA to α-linolenic to linoleic > oleic > arachidonic acid.[203] Arachidonic acid, however, has the highest accumulation of all of these fatty acids in the placenta.[203] Arachidonic acid uptake by placental syncytiotrophoblast membranes is highly dependent on adenosine triphosphate and sodium,[204] implying an active transport mechanism for this fatty acid. Selective LCPUFA placental transfer also is attributable to trophoblast cellular metabolism; for example, a certain proportion of arachidonic acid is converted to prostaglandins in the placenta.[143] Also, a selective incorporation of certain fatty acids into phospholipids has been found in the ovine placenta,[205] and selective placental trophoblast fatty acid oxidation[206] and lipid synthesis have been reported.[105,207,208]

Fetal Accumulation of Essential Fatty Acids Requirements for omega-6 and omega-3 fatty acids in the human fetus during the last trimester of fetal development and through the early weeks of life have been estimated to be 400 mg/kg/day and 50 mg/kg/day, respectively.[209,210] In tissues such as the brain, where lipids constitute about 50%

dry weight, almost half the total lipid content is composed of LCPUFAs.[211] Both arachidonic acid and DHA are readily incorporated into the structural lipids of the developing brain,[212] where, besides their role in maintaining membrane fluidity, permeability, and conformation, they play an important functional role. For example, once released from phospholipids by the action of phospholipase A_2, arachidonic acid is the main precursor for eicosanoids, prostaglandins, and leukotrienes[213] and is essential for fetal and neonatal growth[214]; DHA has a key role in the development of visual function.[145,215,216]

Although the relative rates of desaturation by rat liver and brain differ between adult and 10-day-old animals,[217] the degree to which the human fetus is capable of desaturation and elongation is not clear. It is normally believed that the supply of essential fatty acids and LCPUFAs is critical and central to the synthesis of structural lipids and hence to normal fetal development.[146,149,218]

Fetal Lipid Metabolism

Physiologic changes that develop in the fetus in late gestation and increase nutrient use, such as the increase in plasma insulin concentration, act to enhance net maternal-to-fetal fatty acid and lipid transport by increasing fatty acid use in the fetus (largely to develop adipose tissue, it appears). Increased use of fatty acids by fetal tissues lowers fetal plasma fatty acid concentrations relative to those in the maternal plasma and increases the maternal-to-fetal fatty acid concentration gradients. For example, human maternal venous blood concentrations of fatty acids are directly related to umbilical artery free fatty acid concentrations, and umbilical vein–artery differences in concentration of free fatty acids.[140]

Similar observations have been made in the rabbit[138] and the guinea pig,[219] including evidence in the latter that experimentally lowering the fetal fatty acid concentration relative to that in the maternal plasma independently increases fatty acid transfer across the placenta (using an in situ perfusion model). Even at the same concentrations, furthermore, naturally occurring or experimentally increased fetal plasma concentrations of albumin directly increase the transfer of fatty acids across the placenta; this observation is based on data from both in vitro perfused human placentas[220] and in situ perfused guinea pig placentas.[219] The effect of albumin seems to be one of simply providing increased esterification capacity in the fetal plasma to bind free fatty acids transferred directly across the placenta.

When the processes of fatty acid transfer to the fetus by the placenta and fatty acid incorporation into fetal tissues actually begin during gestation and whether or not they occur with simultaneous development of placental fatty acid transporters and placental lipid metabolic capacity remain to be determined, although human fetal fat accretion develops primarily in the third trimester.[7] During late gestation, maternal lipid metabolism changes to a catabolic state,[221] as shown by increased adipose tissue lipolysis and reduced uptake of circulating triglycerides.[222] The reduced uptake is the result of decreased adipose tissue lipoprotein lipase activity.[223]

There also is an overproduction of triglycerides by the liver and enhanced absorption of dietary lipids. Together, these changes in maternal lipid metabolism produce increasing concentrations of nearly all types of circulating plasma lipids as late gestation proceeds, including free fatty acids, glycerol, and triglyceride-rich VLDL and chylomicron particles. When the pregnant mother is well fed, plasma concentrations of keto acids (β-hydroxybutyrate and acetoacetate) are not increased, although during fasting, when concentrations of these substrates do increase, they also can contribute significantly to the supply of nutrient substrates to the uteroplacenta and fetus.

Fetal Leptin

Leptin mediates a multitude of biologic actions in the adult, including regulation of weight by controlling hypothalamic mechanisms involved in food intake[224] and regulation of insulin secretion,[225,226] insulin action to promote peripheral glucose use,[227,228] and metabolic rate.[229,230] Emerging evidence supports roles for leptin in the fetus as well, including enhancement of growth.[231] Umbilical cord leptin concentrations correlate with birth weight,[232,233] being higher in macrosomic infants of diabetic mothers[232] and lower in infants with IUGR,[233] indicating that the fetal metabolic and hormonal milieu independent of fetal fat content could regulate leptin synthesis and circulating concentrations. In fetal sheep, fetal white adipose tissue leptin mRNA amounts increase with fetal development and gestational age and with basal insulin concentrations.[234] Glucose infusions producing hyperglycemia and hyperinsulinemia and insulin infusions producing hyperinsulinemia alone also increased circulating leptin concentrations, showing that insulin itself can affect fetal leptin production, which thus could mediate at least some of insulin's influence on fetal growth.

Summary of Placental and Fetal Lipid Metabolism

The transport of fatty acids and other lipid substances across the placenta and the deposition of lipids in adipose tissue are late-gestation phenomena and are highly species-specific. The human hemochorial placenta transfers the most lipids and produces the fattest of all land mammals at birth. Essential fatty acid transport, however, occurs in all species and begins early in gestation, allowing membrane lipids, particularly those of neurons, to develop throughout gestation. At preterm birth, however, the human newborn is in a precarious balance with respect to lipid metabolism. Failure to provide sufficient nonprotein energy will lead to increased rates of lipolysis and fatty acid oxidation. This might or might not result in breakdown of membrane lipids for oxidation, but certainly it produces a metabolic situation in which essential fatty acids will be oxidized along with other fatty acids to produce necessary energy in preference to membrane deposition. This could lead to deleterious alteration in the amount and structure of critical membrane development in the brain, potentially leading to abnormal neurologic function and long-term outcome.[235]

CHAPTER 27

AMINO ACID NUTRITION IN UTERO: PLACENTAL FUNCTION AND METABOLISM

Timothy R. H. Regnault, PhD, Frederick C. Battaglia, MD

This chapter reviews placental function and metabolism as it relates to the issue of fetal amino acid nutrition. The review includes information available in human pregnancy, although, of necessity, most of the in vivo information has been collected in various animal species, and this, too, is reviewed. In all mammalian species, the 20 amino acids of the genetic code are required for net protein accretion. The rate of protein accretion, which varies among mammals, is based primarily on fetal growth rate. The nutritional supply of amino acids for growth is defined as the net umbilical uptake of amino acids, representing the net transfer from the placenta to the fetus, including backflux from the fetus to the placenta of essential and nonessential amino acids. In the ovine fetus, where these data are available, the quantity taken up by the fetus clearly exceeds requirements for growth[1–4] and is associated with a high rate of fetal amino acid oxidation. This review aims to detail aspects of fetal amino acid requirements, placental transport, and metabolism of amino acids and to highlight factors influencing these processes, such as fetal growth restriction (FGR). In addition, umbilical uptake, interorgan cycling, and fetal and placental amino acid use, including specifically fetal hepatic and hindlimb amino acid metabolism, are discussed. In conclusion, this chapter deals with the neonatal implications of fetal amino acid metabolism.

PLACENTAL DELIVERY OF FETAL AMINO ACID REQUIREMENTS

The primary source of nitrogen for the growing mammalian fetus is the circulating maternal free amino acid pool. In considering the primary role of the placenta in the delivery of amino acids to the fetus, it is important to consider the multiplicity of factors that may affect these overall delivery rates. Figure 27-1 presents in diagrammatic form the potential fate of an amino acid that has been transported across the plasma membrane of the microvillous maternal surface into the trophoblast cytosol, prior to its entry into the fetal circulation through the basal membrane. Pathway 1 represents the direct transplacental flux of an amino acid from the maternal circulation across the plasma membranes on the maternal and fetal surfaces of the trophoblast and into the fetal circulation. Pathway 2 represents the delivery of an amino acid that has entered the intracellular pool via protein turnover within the trophoblast. Pathway 3 represents the backflux from the fetal circulation into the trophoblast of the same amino acid, and pathway 4 refers to the transformation of the amino acid to a metabolite, which can then enter the fetal circulation. The latter example would be the transamination of leucine to ketoisocaproic acid, which can then be delivered to the fetus. The algebraic sum of these fluxes represents the net umbilical uptake, which is the nutritionally important measurement because it represents the net supply of the amino acid delivered to the fetus. The relative importance of each of the pathways in determining the umbilical uptake differs among amino acids. Examples of amino acids that are used extensively within the placenta (such as glutamate) or are synthesized at a relatively high rate within the placenta (such as glycine) are described in the following sections. There is already ample evidence to show that for different amino acids, one or another of these pathways may predominate.

It is becoming apparent that the fetus not only accrues nitrogen in the new tissues formed during growth but also extensively metabolizes its nitrogen source by synthesizing, oxidizing, and transaminating amino acids.[5] The current estimate of ovine fetal uptake of nitrogen is approximately 0.9 g/kg/day, which is approximately equal to the estimated fetal nitrogen requirement.[4] Therefore, the quantity of amino acids transported is sufficient to meet the current estimation of fetal nitrogen requirements. This estimation includes the fate of amino acids metabolized and excreted as ammonia or urea from the fetoplacental unit.[3,6–8] Other potential sources of nitrogen, such as intact proteins or peptides, which may be important in embryogenesis, do not appear to be required to meet fetal nitrogen needs.

Estimations of fetal protein synthetic rates have been performed in fetal sheep using a variety of methodolo-

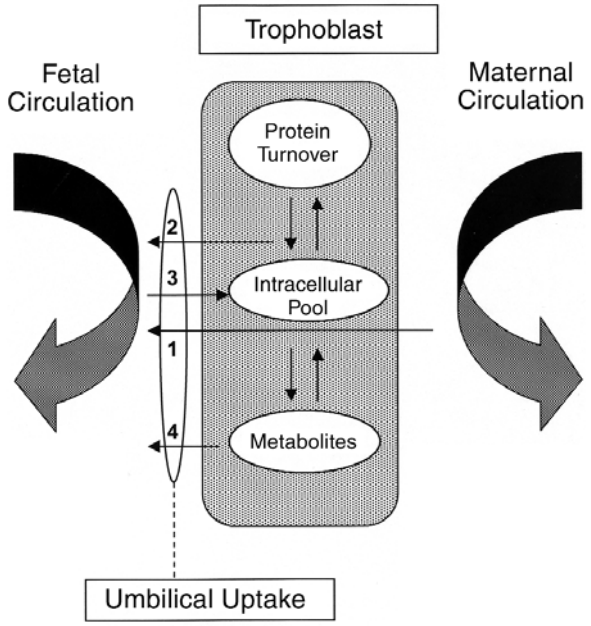

FIGURE 27-1 A diagrammatic representation of potential pathways for the delivery of an amino acid into the fetal circulation. See text for full description of pathways.

gies.[9–14] Leucine was used as a tracer amino acid in chronically catheterized fetal sheep to assess protein synthetic rates at different gestational ages.[9,14] These studies demonstrated that the absolute fractional protein synthetic rate (K_s) decreased from midgestation to term and that this decrease was greater than that seen in the fractional protein accretion rate. Figure 27-2 demonstrates the inverse relationship noted between the fetal K_s and fetal age. Therefore, protein breakdown, defined as the difference between protein accretion and synthesis, also appears to decrease in late gestation. The higher protein synthetic rate of the midgestation fetus is proportional to the higher metabolic rate at that stage of gestation. Absolute fractional protein synthetic rate declines at a rate similar to fetal O_2 consumption (VO_2), giving a relatively constant ratio of K_s/VO_2.[9] Thus, protein synthesis per millimole of oxygen consumed is quite constant from midgestation until term.[9] Fetal metabolic studies have advanced our conceptual framework of the key factors that alter metabolic rate per kilogram of body weight during development.[9,10,15–18] Because many metabolic variables, such as protein synthetic rate, lactate use rate, and urea production rate, bear a relationship to metabolic rate, studies of the ontogenetic changes in fetal metabolic rate have helped to clarify the developmental changes in metabolic measurements such as protein synthetic rate.[15,17,19]

PLACENTAL AMINO ACID TRANSPORT

In recent years, both in vivo and in vitro studies have brought out the complexity of the placenta as an organ for amino acid transport and metabolism.[2,4,20–35] It is important to emphasize that unlike an organ such as the liver, the placenta must function as an organ of transport, delivering amino acids from the maternal circulation into the fetal circulation. The complexity of the organ stems not only from the different cell types required to effect such net transport but also from the capacity of the placenta to metabolize or synthesize various amino acids. The human placenta has at least two cell types that are critically important in determining its overall transport characteristics: the trophoblast and the endothelium. In other species, additional cell layers may be present; for example, in the epitheliochorial placenta of sheep and goats, there is an endometrial cell layer as well.

The concentration of most amino acids, including some of the essentials, is higher in fetal than in maternal plasma,[2,4,36] consistent with a process of active transport of amino acids across the placenta. An increased fetomaternal ratio of plasma amino acid concentrations has been documented for humans,[37,38] primates,[39] rats,[40] guinea pigs,[41–43] sheep,[1,2,4,22] and cows.[44] Although the fetomaternal concentration ratio is greater than 1.0 for most amino acids measured, there are quantitative differences among species. For example, the fetomaternal ratio in human whole blood for the cationic amino acids lysine and histidine is consistently greater than 1.0, whereas in the sheep, the ratio is less than 1.0.

This concept of active transport has been corroborated by a variety of experiments. Studies of placental tissue cultured in vitro with nonmetabolizable amino acid analogues, for example, α-aminoisobutyrate (AIB), as well as other amino acids, have shown the concentration of those substances intracellularly to be a level several times greater than extracellular maternal concentration.[45–51] Placental tissues have also been found to have extremely high levels

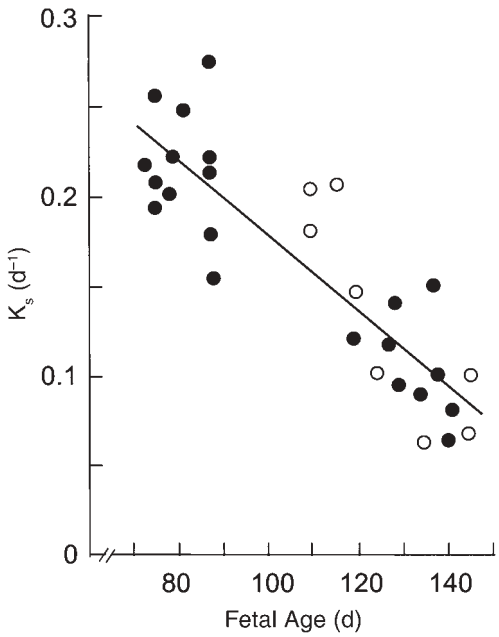

FIGURE 27-2 In chronically catheterized fetal sheep, the protein synthetic rate (K_s) was noted to decrease with fetal age. Protein synthetic rates were determined using [1-^{13}C]-leucine (*dots*) and [U-^{14}C]-lysine (*open circles*). Regression line (r = –.87) was drawn according to the equation: y = 0.39 – 0.02Ix. Adapted from Kennaugh JM et al.[9]

of the amino acids taurine, glutamate, and aspartate, as well as moderately high levels of alanine, glycine, serine, glutamine, and threonine,[38] when compared with maternal or fetal concentrations. It should be emphasized that measurements of placental tissue amino acid concentrations have not been corrected for extracellular fluid content of the tissue. Therefore, the intracellular tissue concentrations are likely to be considerably higher than the values in the literature.

The uptake of amino acids occurs through active transport, and mammalian transport systems have been characterized over the years by such general properties as ion dependence, kinetics, substrate specificity, and regulation of activity, and this has allowed the description of multiple transport systems for neutral, anionic, and cationic amino acids.[52,53] Studies in human and rat trophoblasts have yielded much information concerning the location and functioning of amino acid systems; however, care must be taken in the interpretation of data from different species. Figure 27-3 represents a summary of amino acid transport systems described for the maternal and basal membranes of the trophoblast. Each system is distinct but exhibits some overlapping substrate specificity.

System A is a sodium-dependent, unidirectional transporter with a characteristic affinity for *N*-methylated substances, and system A activity has been demonstrated in both microvillous and basal membranes.[54–56] Its activity is increased as an adaptation to cellular depletion of amino acid substrates, similar to that described for system X_{AG}^-.[57,58] System ASC has been described for neutral amino acid transport, specifically alanine, serine, and cysteine, as well as for some anionic amino acids.[54,55,59,60] It is a sodium-dependent obligate exchanger localized at the basal membrane, although studies using BeWo cells suggest that system ASC transporters may be present on the microvillous membranes as well, but after differentiation and syncytial formation, such activity is lost.[61] A sodium-independent group of transporters (Asc) has also now been reported to exist in placental tissue.[62,63] In addition, the broad-scope sodium-dependent transporter B^o is responsible for neutral amino acid transport, including branched-chain amino acids (BCAAs), and has been localized to the microvillous and basal membranes.[64–67] The β-amino acid taurine uses the system β transport system. Studies have demonstrated that this β transport system is a sodium-dependent transporter, found on both membranes,[68–73] although with a greatly reduced basal membrane activity compared with the microvillous membrane.[71]

System L (or l) transporters are sodium independent and have been localized to both trophoblast membranes.[54,74,75] They play a major role in the transport of essential amino acids, having a high affinity for leucine and

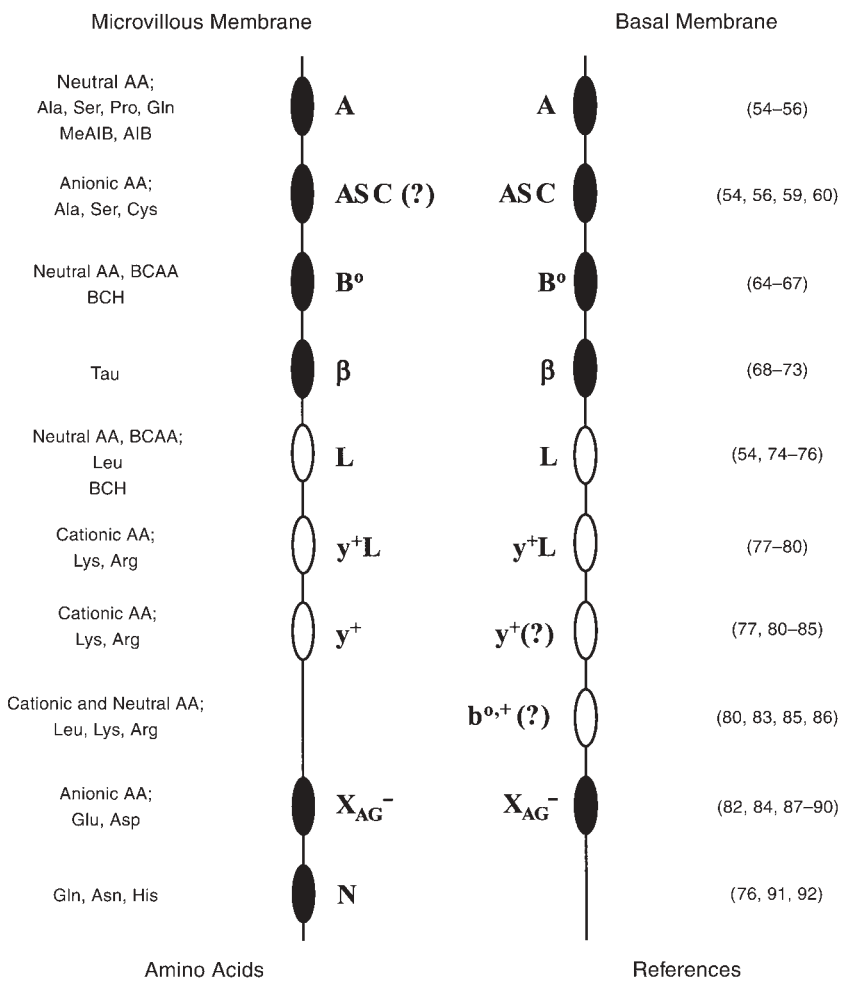

FIGURE 27-3 Schematic representation of the sodium-dependent (*closed ovals*) and sodium-independent (*open ovals*) amino acid transport systems for both the microvillous (maternal) and basal (fetal) membranes of the trophoblast. Amino acid substrates are listed on the left and references on the right. AA = amino acid; AIB = α-aminoisobutyric acid; BCAA = branched-chain amino acid; BCH = 2-aminobicyclo-(2,2,1)-heptane-2-carboxylic acid; MeAIB = methylaminoisobutyric acid.

other BCAAs.[76] The cationic amino acid transport system y^+L is considered a low-capacity, high-affinity system that exchanges cationic amino acids for neutral amino acids, and its activity is localized to both the microvillous membrane and the basal membrane.[77–80] A proposed hypothesis is that this transporter system in the basal membrane is the major supply route of cationic amino acids to the fetus through the uptake of neutral amino acids from fetal circulation, in exchange for cationic amino acids from the placenta.[80] The sodium-independent low-affinity, high-capacity y^+ transport system is a high-capacity system that transports cationic amino acids such as arginine, lysine, and ornithine in a sodium-independent manner. It is considered to be the major cationic transport system in placental tissues[80–82] and is localized to the microvillous membrane[77,80,83,84] and possibly to the basal membranes.[85] A role for the related $b^{o,+}$ system in placental tissues has been reported[83,85,86]; however, further vesicle studies suggest that there is no functional evidence for this system in either term microvillous or basal membrane.[80]

The placenta takes up the anionic amino acids glutamate and aspartate from the maternal and fetal circulations but does not actively transfer these amino acids from mother to fetus. Recent studies using isolated human and rat placental membrane vesicles have revealed the presence of a high-affinity transport system for aspartate and glutamate via the sodium-dependent X_{AG}^- system within both the microvillous and the basal plasma membranes.[82,84,87–90] This system may mediate the concentrative uptake of anionic amino acids from the maternal and fetal circulations into the placenta. System N transports neutral amino acids but differs from systems A and ASC in that it displays a preference for amino acids containing nitrogen-bearing side chains, transporting only glutamine, asparagine, and histidine.[76,91,92]

PLACENTAL AMINO ACID TRANSPORTER PROTEINS

Historically, placental amino acid transport has been described in terms of transport systems based on competitive inhibition studies, although it is now becoming possible to move to a more precise description of the protein chemistry of the transporter system. The ability to clone, sequence, and study the expression of transporters has led to an explosion of data concerning the molecular basis of amino acid transport systems and their potential in vivo function.[93–95] It is now clear that some placental transporters exist as a monomeric protein, whereas other transport systems exist as a heterodimeric complex.[94,96,97] Those monomeric transport systems induce amino acid uptake in a similar manner to the amino acid uptake associated with permeases described in microorganisms,[98–101] although the regulation of placental membrane acquisition of monomeric systems has not yet been studied. Heterodimeric systems involve the grouping together of two proteins to facilitate amino acid transport. In placental tissues, monomeric transport systems are believed to include y^+[102] and most likely the X_{AG}^- system, whereas heterodimeric transport systems include system L, y^+L,[103] and the Asc system.[63,104] Those systems that operate in a heterodimeric manner are generally made up of a common heavy chain, specifically one of the type II membrane glycoproteins, 4F2hc (comparable to the CD98 surface antigen CD98hc),[105–107] the neutral and basic amino acid transport (NBAT; equivalent to rBAT or D2[108–111]) protein, or as yet undefined proteins,[62] which associate with one of a variety of light-chain transport proteins, providing a range of amino acid transport systems.[97,103,104,106,112] There is also evidence that these heavy chains may interact with themselves and each other to form homodimers and/or heterodimers before interacting with a specific light chain to induce activity.[80] A summary of the traditional transport systems and their heavy- and light-chain associations that have been reported in placental tissues and membranes is presented in Table 27-1.

The 4F2hc messenger ribonucleic acid (mRNA) is ubiquitously expressed,[113] although whereas 4F2hc is expressed in placental tissues throughout pregnancy, NBAT expression appears only in first- and early second-trimester placentae and is not in term tissues.[80,114,115] During human and rat pregnancy, whole-tissue studies have demonstrated 4F2hc predominantly in the microvillous membrane, with the content increasing as gestation advances.[80,107,115] However, 4F2hc has not been detected in the human basal membrane,[80,107] despite reports of 4F2hc mRNA in rat basal membrane preparations[115] and evidence that 4F2hc plays a role in basal membrane amino acid transport in other tissues, including the intestine and kidney.[111]

The glycosylated 4F2hc protein is composed of a single transmembrane region with a large C-terminal extracellular domain.[106,116,117] Because mammalian substrate transporters appear to have multiple transmembrane helices, it is unlikely that the 4F2hc protein is capable of inducing amino acid transport alone.[118] It is postulated that 4F2hc is, in fact, the modulator of heterodimeric transport systems and acts as a "guidance molecule," translocating the nonglycosylated light chains to the plasma membrane, after which disulfide linkage between 4F2hc and the light chain occurs.[97,119–121] This movement is independent of the formation of the disulfide bonds, which suggests a noncovalent steric association.[121] Functional transport may then occur as both heavy- and light-chain expression and interaction are required for transporter function.[97,114,122] The expression of the heavy chain and not that of the light chains is best correlated with placental amino acid transport system activity.[102,106]

Neutral Amino Acid Transporter Light-Chain Proteins

The subcellular location of the light-chain proteins and their interaction with 4F2hc protein is not well defined. Presently, the model of interaction involves an intracellular pool of light chains that are available for incorporation with the membrane-bound heavy chain.[102,106] Several specific light chains and their amino acid transport systems have been identified. Currently, three subtypes of the amino acid system A have been cloned: amino acid transporter (AT) A-1, ATA-2, and ATA-3. The ATA-1 (or GlnT[123,124]) system has

a limited tissue expression, being expressed predominantly in the human placenta and heart, and is responsible for the transport of small short-chain neutral amino acids, such as alanine, serine, methionine, asparagine, and glutamine.[123] The functional characteristics of ATA-2 are similar to those of ATA-1, although found in a wider range of tissues, including the placenta.[123,125] ATA-3 appears to have a unique tissue distribution predominantly in hepatic and skeletal muscle tissues.[126,127]

The ASCT-1 (SATT),[118,128,129] a component of the ASC transport system, has been localized to human placenta tissue, although its expression is very low.[129] Another component of the ASC system, ASCT-2, has also been cloned,[130] although this complementary deoxyriboncleic acid (cDNA) is currently thought to code protein for the related transport family, the B^o system.[65,66] The B^o system is a sodium-dependent neutral amino acid transport system for which the related gene, *hATB°*, is proposed to represent the B^o system in the human placental choriocarcinoma cell line, JAR, and isolated human placental Poly(A)$^+$ mRNA.[65,131] The B title represents this system's broad substrate preference, and the capital status indicates its sodium dependence. The superscript ^{o} defines it as accepting zwitterionic or neutral amino acids, which distinguishes it from the $B^{o,+}$ system, which also accepts cationic amino acids.[65,132] These systems are differentiated from the $b^{o,+}$ system, which also transports neutral and cationic amino acids, but in a sodium-independent manner. This latter system has been reported in basal membrane preparations,[85] although, recently, this localization has been questioned, with its activity attributed instead to the y^+L system.[80] The sodium-independent transport of small neutral amino acids is carried out by the Asc system, composed of the proteins Asc1 and Asc2, both of which have been identified in placental mRNA.[62,63] Asc1 forms a heterodimeric complex with 4F2hc,[63] whereas Asc2 appears to interact with a presently unknown heavy chain.[62] System N activity was first found in the liver but has also been localized to the human placenta.[91] Recently, complementary DNAs (cDNAs) encoding two subtypes of system N, SN1 and SN2, have been described,[133,134] although expression of these subtypes in placental tissues has not yet been reported. The β transporter for taurine has displayed activity in placenta preparations,[68–73] and presently, this activity is associated with an mRNA encoding TAUT in human placental Poly(A)$^+$ mRNA.[135]

Light chain proteins also associate with 4F2hc to form the functional L transport system,[114,122] catalyzing the uptake of neutral amino acids in a sodium-independent manner. Two light-chain proteins have been reported to determine L system activity, system L-amino acid transporter (LAT) 1 and 2. The 4F2hc/LAT1 transport activity displays a narrow specificity toward neutral amino acids, uninfluenced by pH, whereas 4F2hc/LAT2 activity has a broad specificity and is stimulated by decreasing pH.[136] Both LAT1 and LAT2 have been reported in placental samples.[102,104,107,113,122,137–139] Immunologic and functional studies suggest that, at term, the light chain, LAT1 is located predominantly in the microvillous membrane and the syncytiotrophoblast layer of the villi.[107,139] Furthermore, the L transport system phenotype associated with that of the placental microvillous membrane is found to occur when the LAT1 and not the LAT2 catalytic subunit is coexpressed with the 4F2hc.[140] In a similar manner, human LAT2 mRNA has been identified in the choriocarcinoma BeWo cell line and placental villous tissues,[104,140] although it is localized to the basal membrane and not the microvillous membrane, as is the case for LAT1.[122,140,141] These studies suggest that the localization of system activity may be further defined through specific light-chain location.

Cationic Transport System Light-Chain Proteins

Transport of cationic amino acids is believed to occur through the y^+L and y^+ systems. Placental y^+L system activity is determined by which light chain, system y^+L-amino acid transporter-1 (y^+LAT1) or y^+LAT2, forms a heterodimer with the membrane-bound 4F2hc. Human placental preparations contain y^+LAT1 mRNA,[103,112] and when this mRNA is coexpressed with 4F2hc in *Xenopus laevis* oocytes, amino acid uptake characteristics similar to that of system y^+L are displayed.[112] Presently, it is unclear if system y^+LAT light-chain proteins display a tissue distribution pattern similar to that displayed by the LAT proteins. The related system y^+ activity depends only on the expression of monomeric proteins (or *CAT* gene products),[142] which, unlike systems L and y^+L, require expression of both a common heavy chain and a related light chain.[102,112,136] Currently, there are three known mRNAs that encode for proteins related to this cationic amino acid transport system in placental tissues, namely, the cationic amino acid transporters (CATs) 1 CAT 2B, and 4.[80,81] Recently, kinetic and substrate inhibition studies and reverse-transcriptase polymerase chain reaction studies localizing CAT4 mRNA in human placental tissue suggest that y^+ activity is limited to the microvillous membrane and not the basal membrane.[80]

Anionic Transport System Light-Chain Proteins

Five cDNAs encoding proteins capable of mediating high-affinity sodium-coupled transport have been reported, and three of these have been cloned from both rat and human placenta.[45,66,89] These placental proteins, excitatory amino acid transport (EAAT) 1 (GLAST1), 2 (GLT1), and 3 (EAAC1), are known to mediate placental sodium-dependent D-aspartate–inhibitable anionic amino acid transport or system X_{AG}– activity.[90] EAAT1 and EAAT3 have been detected in human placental tissue,[143,144] whereas these two and EAAT2 have been detected in rat placenta tissues.[89,145] The regulation of these proteins appears to be under the control of growth hormone and insulin-like growth factor family members,[145] and up-regulation of the system has been demonstrated through cell density and nutrient deprivation studies in muscle and placental cell lines.[57,89] These latter studies demonstrated that EAAT1 and EAAT3 play a key role in the basal anionic amino acid transfer, whereas EAAT2 may be involved in conditions of amino acid depletion.[89]

Alterations in Amino Acid Transporter Proteins and Disease

The importance of the heavy- and light-chain proteins in placental amino acid transport and metabolism is highlighted by studies showing that alterations in 4F2hc and/or y^+LAT1 expression may be responsible for lysinuric protein intolerance,[112,146] cystinuria,[147] alterations in maternal-to-placenta essential amino acid supply,[120,139] and maternal immune response failure during implantation.[148–150] The identification of individual transporter proteins in the trophoblast will be expanded considerably as sequence data for specific transporters permit rapid identification of other members of the same family of transporters. Thus, the information provided in Table 27-1 and Figure 27-3 should be regarded as an interim report in a rapidly changing field.

AMINO ACID TRANSPORT SYSTEMS AND FGR

In clinical studies, the concentration of amino acids has been observed to be lower in the fetal and maternal plasma of pregnancies that were complicated by FGR,[151–153] suggesting alterations in amino acid delivery. This depression in amino acid concentrations is true regardless of whether fetal concentrations were determined at the time of delivery or many weeks prior to delivery. Recently, these same investigators demonstrated that lower amino acid concentrations were found in FGR pregnancies even if the fetus had normal fetal heart rate and velocimetry measurements, suggesting that this may antedate other clinical pathologic findings.[151–154] Studies in human FGR demonstrate that system A may be impaired.[155] An in vitro study using microvillous membrane vesicles from the placentae of appropriate for gestational age (AGA) and small for gestational age (SGA) babies demonstrated markedly lower activity (by 63%) of the A system transporters in the SGA compared with the AGA membrane vesicles,[156] suggesting a positive association between fetal growth and system A activity. In human FGR, the transport of taurine from maternal to fetal circulation is reduced, thereby affecting fetal taurine concentrations.[71] In addition, studies inducing FGR through maternal protein deprivation in rats have demonstrated a down-regulation of placental amino acid transport, specifically system A, and also systems X_{AG}^- and y^+.[84,157] Inhibition of system A transport in rat pregnancies has also been associated with decreases in fetal weight, demonstrating a role for system A transport in maintaining normal fetal growth.[158] With regard to system X_{AG}^- transport, the basal membrane activity of EAAT1 is reduced in an FGR rat model, which could impact placental glutamate uptake from the fetal circulation.[84]

The microvillous membrane system y^+ and y^+L activity is not altered in human FGR,[79,159] although basal membrane transport of lysine is reduced as represented by reduced mediated lysine uptake and a reduced maximum velocity for the y^+L system.[79] Reductions in the uptake of leucine in both microvillous and basal membrane preparations of FGR placentae highlight possible alterations in the L transport system.[79] These changes in basal membrane transport properties could be an important adaptive response by the trophoblast, limiting the backflux of amino acids from the fetal circulation to the placenta. In vivo studies of ovine FGR placental transport have indeed shown a reduced backflux of leucine and threonine from the fetal circulation to the placenta, suggesting that changes in basal membrane function may have occurred.[160,161] At steady state, the fetomaternal enrichment ratio of leucine in normal human pregnancies is approximately 0.8, a much higher ratio than the 0.4 ratio in sheep.[160,162] However, in both species, this ratio is significantly lower in FGR pregnancies. In the ovine FGR model, the reduction in fetomaternal ratio was attributable to a significant reduction in transplacental leucine flux,[160]

which is probably also the mechanism in human FGR pregnancies. Furthermore, the magnitude of the leucine ratio reduction correlates with a clinical classification of FGR severity based on a completely different set of clinical data, namely, fetal arterial velocimetry and fetal heart rate data.[154] In addition, recent clinical studies have shown that the leucine and phenylalanine (fetomaternal) enrichment ratio is significantly lower in human FGR compared with normal pregnancies.[79,162,163]

OTHER FACTORS REGULATING PLACENTAL AMINO ACID TRANSPORT

As pregnancy advances, the increasing nutrient demands of the developing conceptus must be met through an appropriate increase in placental nutrient transport. This enhanced performance is facilitated through alterations in placental perfusion and changes in membrane exchange surface area. Recent studies in human pregnancies have shown that umbilical blood flow increases during gestation in a pattern similar to fetal growth rate. The relationship between blood flow and body size is quite good, although not perfect. As shown in Figure 27-4, when blood flow is expressed per kilogram fetal weight, it falls slightly throughout gestation. This pattern of decline is similar to the changes in fetal heart rate in human pregnancies, which decreases as gestation advances. Heart rate is closely linked to metabolic rate. Thus, the changes in blood flow and in fetal metabolic rate appear to be reasonably well linked in human pregnancies. The decrease in umbilical blood flow per kilogram fetal weight in human pregnancies does not present a problem in terms of supplying amino acids to the fetus as it grows. This is not the case as changes in blood flow are compensated for by an increase in placental surface area and presumably an increase in the number of membrane-bound transporters available for delivery of amino acids. Between the sixteenth week of pregnancy and term, human fetal weight increases approximately 20-fold, whereas the peripheral villous surface area increases only ninefold.[164–167] More importantly, the multiplication factor of nine actually decreases in late gestation.[167] It should be emphasized, however, that there are only a few careful ontogenetic studies of how total surface area, including microvillous surface, changes over gestation.[167,168] The increases in total surface area of the placenta alone cannot account for the exponential fetal growth occurring over this time period. These data suggest that fetal growth is supported not by changes in villous surface area alone; rather, the total transport capacity of the trophoblast is likely to be determined by total villous surface area, placental permeability, and the concentration of specific amino acid carrier proteins on cell membrane surfaces, as well as the affinity characteristics of these proteins and the circulating amino acid concentrations at both the maternal and fetal surfaces.

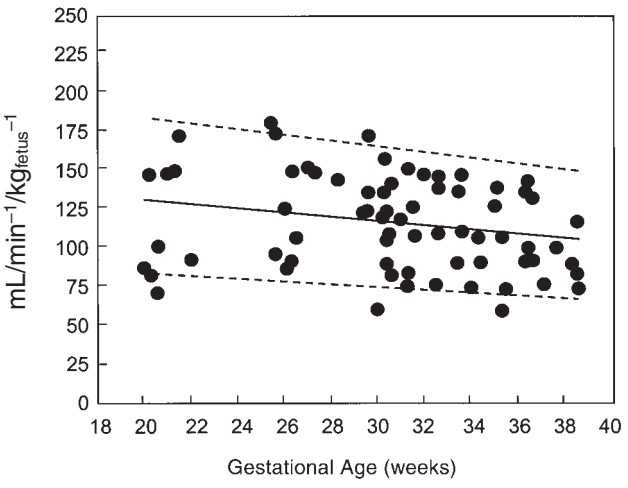

FIGURE 27-4 Umbilical vein blood flow per kilogram of fetal weight plotted against gestational age for human pregnancies. Slight linear decrease observed was not significant. (y = –1.3636x + 155.9964). Both 5th and 95th percentiles are shown (*dashed lines*). Adapted from Barbera A et al.[234]

The observations of differences in amino acid transport activity in the FGR placenta highlight the important point that the activity of transport systems must be considered in conjunction with other contributors to amino acid flux. In studies comparing normal and FGR placentae, there are reported reductions in total villous surface area,[168,169] suggesting that morphometric changes contribute to the overall reduction in placental amino acid transport capacity. Placental permeability is also suggested to play a role in amino acid transport, although in FGR vesicle studies, the composition and permeability of placental plasma membrane are not altered.[170] However, this is most likely not the case in vivo. Thus, at the present time, it appears that both reductions in surface area for exchange and reductions in specific transporter number and activities contribute to the reduction in amino acid transport in FGR pregnancies.

Accompanying the maturational changes in trophoblast surface area, amino acid transport systems are reported to have differing expression and transport parameters through gestation.[56,80,83,107,171,172] For example, in term placenta, L-arginine transport in microvillous membrane preparation is through both y^+ and y^+L systems, whereas in the basal membrane, transport may be restricted to the y^+L system.[80] Furthermore, the functional properties of transport systems may also change as gestation advances. For example, first-trimester microvillous membrane has increased transport activity compared with term placental vesicles,[172] and 4F2hc protein levels differ between early/midpregnancy and term placenta.[80,107] Early in gestation, the K_m of the microvillous high-affinity system y^+L is significantly less than in term preparations.[80] Such studies highlight the complex interactions that occur between developing microvillous membrane and basal membrane, within the trophoblast and between the two circulations, to facilitate an increase in nutrient delivery to the growing fetus as gestation advances.

Another factor to consider is the fact that placental tissue contains a number of hormone receptors (ie, for insulin, gonadotropins, growth factors, somatomedins, β-adrenergics, cholinergics, opiates). How hormones interact with the regulation of amino acid transport is incom-

pletely understood at present. There is some evidence, however, that insulin infusion may enhance placental amino acid uptake, concentration, and transport to the fetus.[173,174] Karl and colleagues found that AIB uptake by cultured trophoblast cells was enhanced by insulin as well as by dexamethasone, glucagon, and 8-Br cyclic adenosine monosphosphate.[173] They postulated that because trophoblasts are known to produce insulin-like growth factor (IGF)-I, insulin may initially enhance AIB uptake via IGF-I. Insulin receptor concentrations were found to be markedly reduced in placentas from SGA infants, and AIB uptake was decreased in the cultures of these trophoblast cells.[156,173,175,176]

MULTIPLE ROLES OF AMINO ACIDS

Since the first description of amino acids as important neuroexcitatory or neuroinhibitory compounds in the brain, it has become increasingly clear that amino acids serve important functions beyond that of components of proteins and/or as metabolic fuels for tissues. Even in the latter role, their importance had been underestimated by studies that examined the contribution of amino acids to total CO_2 production in the whole organism. It took some time to appreciate the fact that oxidation may be organ specific. Thus, glutamate/glutamine oxidation by the small bowel may represent a relatively minor contribution to total CO_2 production in humans but may be crucial to meeting energy requirements of the gastrointestinal tract. The oxidation of glutamate appears to be important not only in the small bowel but in the heart and in the placenta as well. Similarly, amino acids whose intracellular concentrations may change rapidly can play an important role as idiogenic osmoles in regulating water balance across tissues.[177] The interorgan shuttling and interconversion of amino acids may also play an important role for purposes not directly related to providing carbon and nitrogen for growth or as metabolic fuels.[93] Traditionally, we have come to appreciate the role of alanine and glutamine in shuttling carbon from skeletal muscle to the liver, where it is used for glucose production. Recent studies have brought out the importance of glutamate cycling between the fetal liver and placenta.[178–180] Normally, in fetal life, there is no significant rate of gluconeogenesis in the fetal liver. This is useful to the fetus because it permits the fetus to meet its glucose requirements by obtaining glucose from the maternal glucose pool via transplacental transport, but the large amount of carbon coming to the fetal liver would require oxidation if no alternative carbon was released from the liver instead of glucose. In fetal life, glutamate serves this important function. The fetal liver releases a large amount of glutamate into the circulation, which reduces the fetal hepatic oxygen requirement for the metabolism of glutamate. The glutamate is taken up almost in a first-pass clearance by the placenta, where it is used as a mitochondrial fuel.[181] In this sense, the placenta assists the liver by reducing its oxygen requirement significantly. Such interorgan transport and interconversion of nutrients may serve other functions as well. The placental oxidation of glutamate provides a source of reduced nicotinamide-adenine dinucleotide phosphate, which can be used in steroidogenesis.[181–183] These additional roles of interorgan shuttling between the fetal liver and placenta are also evident in serine and glycine metabolism.[184–186] Serine is another amino acid that is released from the fetal liver and is taken up from the fetal circulation into the placenta, where it is used for glycine production. This pathway provides a supply of methylene tetrahydrofolate within the placenta, as is discussed later in this chapter. More recently, attention has focused on the role of the interconversion of arginine and citrulline in providing substrate for nitric oxide synthase leading to nitric oxide production, a potent vasodilator.[187] Other functions of nitric oxide as a signaling compound are being described.[159] Its role in regulating insulin release from beta cells is under investigation and may provide a link between amino acid metabolism and endocrine regulation of carbohydrate metabolism. The work in fetal metabolism has only served to further strengthen the concept that amino acids play multiple roles in the body and that their metabolism and use tend to be organ specific.

PLACENTAL AMINO ACID METABOLISM

The amino acid requirements of the placenta for energy and for protein accretion during its growth are not well known. The placenta contains enzymes related to carbohydrate and amino acid metabolism that give it the capacity to oxidize a number of amino acids as well as perform glycolysis, glycogenolysis, and glycogen, protein, and fatty acid synthesis.[188,189] Four amino acids (alanine, glutamine, threonine, and serine) that are found in high concentrations in placental tissues and are known gluconeogenic precursors are transported by the three transport systems, A, L, and ASC.[5] This could be a protective mechanism to ensure adequate fetal supply of these important amino acids. Preincubation of placental tissue for several hours in amino acid–free medium leads to an increased concentrating capacity of the placental tissues for AIB.[25,190] This increased concentrating capacity can be blocked by inhibitors of protein synthesis, indicating that the placental vesicles respond to hypoaminoacidemia by up-regulation of the A system transporters. Far less is known about the placental vascular endothelium. Although still in debate, it may share at least one characteristic with that of the cerebral circulation, namely, the absence of system A transporter.[191] The metabolism of amino acids within the placenta during transport has not been well studied.

So far, amino acid oxidation by human placental mitochondria has been demonstrated for alanine, aspartate, glutamate, and glycine.[183] Given the data on the large uptake of glutamate by the placenta from the fetal circulation, it is likely that glutamate is the predominant amino acid functioning as a metabolic fuel for the placenta.[179] Placental metabolic requirements are very large. In vivo estimates of its oxygen consumption are approximately equal to those for the brain, and oxidation of amino acids is a major metabolic function of the brain and placenta.[192] In vivo, there is a significant production and excretion of ammonia into

both uterine and umbilical circulations by the ovine placenta.[6,7] The absolute rate of uteroplacental ammonia production, approximately 25 μmol/minute in the ovine pregnancy at midgestation (73 to 97 days, term 147 ± 3 days), is approximately equal to that of the term placenta. Because in vitro data indicate that there is minimal urea cycle activity within the placenta,[193] this suggests that ammonia and not urea is the end product of amino acid deamination within the placenta. Some of the ammonia produced by the placenta is consumed by the fetal liver, and in fetal sheep near term, the uptake by the fetal liver is approximately 1.5 to 1.8 times that taken up by the umbilical circulation from the placenta.[6,7,193] This indicates that fetal tissues, as well as the placenta, produce ammonia, and uptake of ammonia by the fetal liver undoubtedly contributes to its high rate of urea production.

In part, the ammonia production by the placenta is derived from the transamination of BCAAs.[194] The activity of the branched-chain aminotransferases is high in the placenta, and because the activity of α-keto decarboxylases is low, it is clear that the α-keto acids derived from the BCAA are not oxidized further. These α-keto acids represent part of a group of compounds that are produced in the placenta and are delivered into both uterine and umbilical circulations. These compounds include ammonia, lactate, and one of the polyols, sorbitol (Figure 27-5). The placental production of glutamate as a consequence of transamination of α-ketoglutarate from BCAA[93] and the placental uptake of fetal plasma glutamate at 4.8 μmol/min/kg fetus represent the two major influxes of glutamate into the ovine placenta. Although the ovine placenta contains the enzyme glutamine synthetase, only a small fraction of glutamate that is taken up by the placenta from fetal circulation is returned to the fetus as glutamine.[181,195] It is the oxidation of glutamate that appears to be the predominant pathway of placental glutamate disposal.

It is likely that placental ammonia production is not confined to the epitheliochorial placenta of the sheep. It has been described for the perfused human placenta, and a net efflux of ammonia from the pregnant uterus into the maternal circulation has also been found in rabbits, guinea pigs, and sheep.[19,194,196–198] It is intriguing to speculate on the possible biologic significance of mammalian fetuses growing and developing in an environment of an elevated ammonia concentration. Ammonia can affect hepatic metabolism and may play a role in glial development and in the development of other tissues rich in glutamine synthetase. Ammonia is now one of a number of compounds that have been shown to be produced in the ovine trophoblast and delivered into both fetal and maternal circulation. The enzymes involved in these pathways have been found in the human trophoblast, although, in most instances, studies that document the production of these metabolites in human trophoblast in vivo are lacking.

UMBILICAL UPTAKE OF AMINO ACIDS

Measurements of unidirectional flux are currently available only for the ovine species and not for other mammalian species. A number of studies involving examination of the umbilical uptake of amino acids in chronic, unstressed sheep models have revealed that most amino acids (particularly the neutral amino acids) are delivered into the fetal circulation in amounts that exceed their net rates of accretion.[2,4,16,199,200] The most complete data on the uterine and umbilical uptakes of amino acids are presented in Figure 27-6.[200]

Several studies of the umbilical uptake of amino acids under normal conditions have shown that there is no measurable uptake of aspartate and, in fact, a significant net uptake from the fetal circulation into the placenta of serine and glutamate. Thus, for these three amino acids, it is clear that fetal requirements must be met by production within fetal tissues. Stegink and colleagues infused labeled tracer isotopes of glutamate and aspartate into both fetal and maternal circulations of rhesus monkeys and found essentially no transfer of the compounds across the placenta.[201,202] Schneider and colleagues, using an in vitro perfused human placenta preparation, found significant uptake of glutamate from the fluid perfusing the fetal side of the placenta rather than a net transfer of glutamate from the maternal to the fetal side.[203] Not surprisingly, because amino acid requirements and protein synthetic rates are linked to fetal metabolic rates, the umbilical uptake or dietary supply of amino acids per kilogram of fetal body weight is much

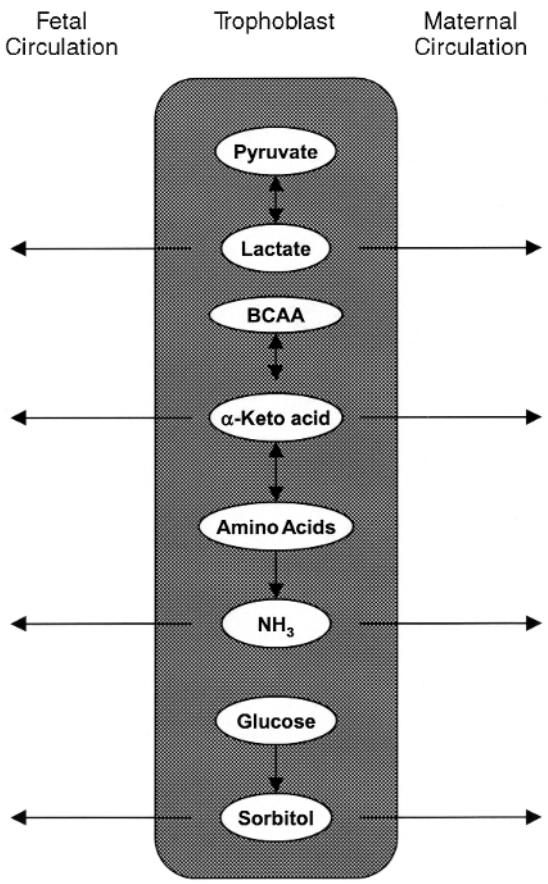

FIGURE 27-5 A schematic representation of some of the metabolites produced in the placenta, which are then delivered into both the maternal and fetal circulations. BCAA = branched-chain amino acid.

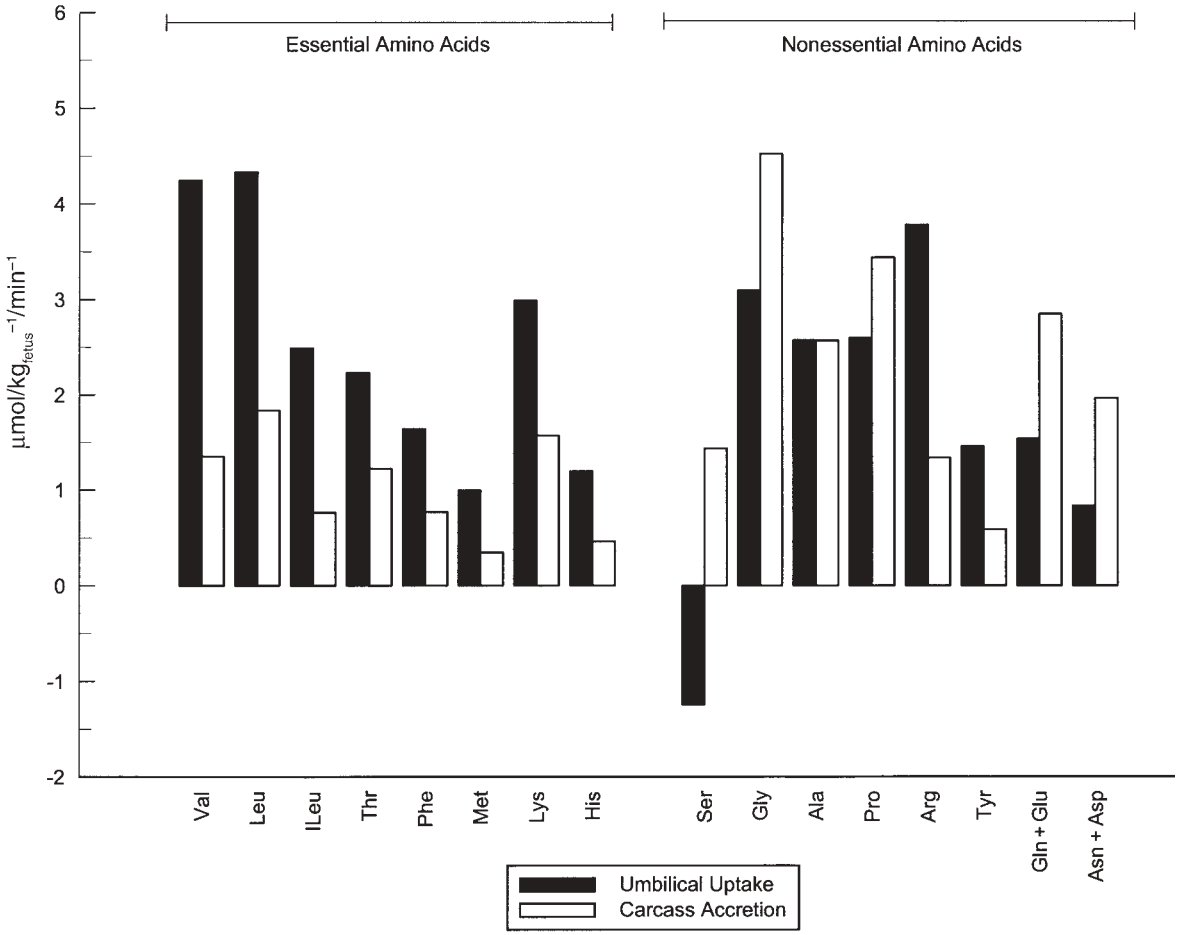

FIGURE 27-6 Comparison between mean umbilical uptakes and estimated normal fetal accretions of amino acids. For pairs of amino acids (glutamine + glutamate and asparagine + aspartate), individual accretion rates are not known. Adapted from Chung M et al.[200]

higher in early gestation compared with term.[16] A key question in fetal nutrition is how maternal concentrations of amino acids are related to the umbilical uptake. This question is important because it would help define the extent to which changes in maternal amino acid concentrations could impact the fetal delivery of amino acids. The question has been studied in both ovine pregnancies and human pregnancies by infusions of amino acids into the maternal circulation with measurements of their umbilical uptake. The relationship between maternal concentration and umbilical uptake is a complex one. In ovine studies, the flux from the maternal circulation to the fetal circulation is most rapid for five amino acids, and for those five, differences in their fluxes are directly attributable to differences in their normal maternal plasma concentrations,[204] as shown in Figure 27-7. In human pregnancies, it is possible for most amino acids to increase the fetal delivery by increasing the maternal concentration.[198] This has been shown for both normal pregnancies and pregnancies complicated by fetal growth restriction.[163] However, for some amino acids, this has not been possible when an infusion of many amino acids is given to the mother presumably owing to competitive inhibition by other amino acids in the infusate.

It is clear that the umbilical uptake of amino acids cannot be considered solely a reflection of the amino acid supply derived from the maternal plasma pool via transplacental transport but also may include a contribution derived from production within the placenta or release from placental protein breakdown. It is important to understand which amino acids are provided to the fetus primarily through placental production versus placental transport because differing forms of placental pathology may adversely affect the mode of delivery of those amino acids to the fetus.

FETAL AND PLACENTAL OXIDATION

The use of multiple-tracer methodology in animal models has allowed further elucidation of amino acid metabolism within the placenta and the fetus. Fetal and placental metabolism of the essential amino acids leucine and threonine have been studied in some detail.[160,161,205] For leucine, Loy and colleagues were the first to demonstrate that even for an essential amino acid, there may be extensive catabolism both within the fetus and within the placenta.[205] They found that 20 to 25% of the (1-^{14}C) leucine infused into the fetus could be accounted for as $^{14}CO_2$ produced by the fetus. Unlike glutamate, there was no measurable oxidation of leucine within the uteroplacental tissues. This indicated an extensive use of leucine as a fetal but not a placental fuel. The extensive fetal catabolism of leucine can be better

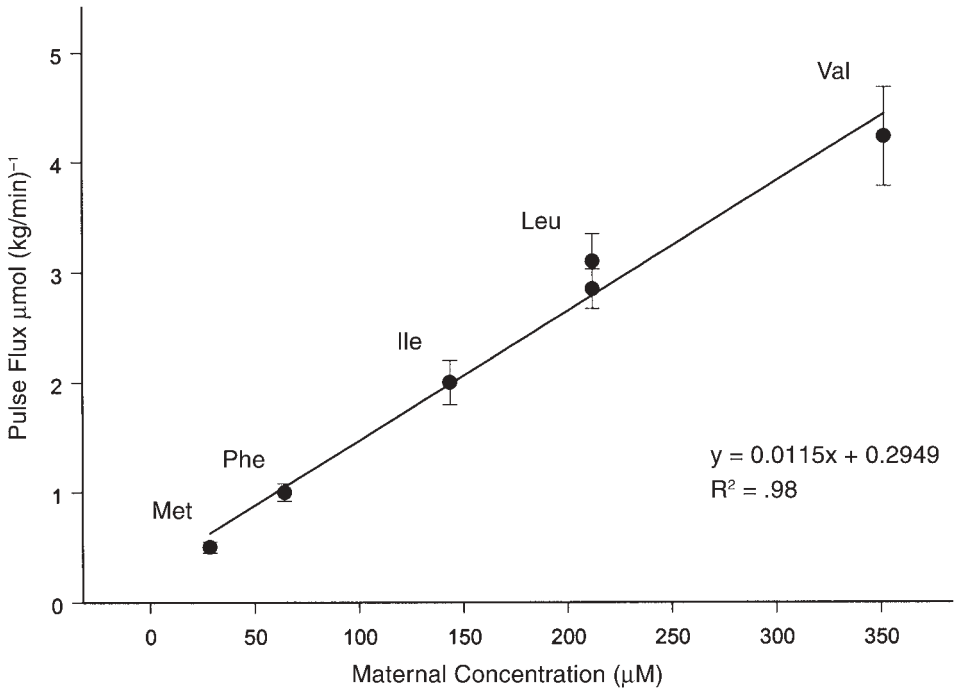

FIGURE 27-7 Pulse flux calculated over the first 10 minutes after the bolus versus maternal plasma arterial concentration for the five essential amino acids that have high and similar pulse flux clearances. The two leucine data represent two separate studies. Adapted from Paolini CL et al.[204]

appreciated by a comparison of its supply to the fetus via the placenta and its rate of oxidation and of accretion in tissue protein. The total umbilical uptake of leucine is approximately 4.9 µmol/minute/kg, and net accretion of leucine in tissue proteins accounts for only 2.0 µmol/minute/kg in late gestation. On the other hand, the rate of leucine oxidation is 2.8 µmol/minute/kg or 57% of its uptake. Thus far, the fetal and placental metabolism of other essential amino acids has not been studied in such detail.

The oxidation rates in the fetus and/or placenta have been measured for leucine, lysine, threonine, alanine, glycine, serine, and glutamate,[160,161,181,204,206,207] and it is apparent that fetal oxidation of amino acids is not confined to the nonessential amino acids. In fact, it is an important safety feature for fetal nutrition that amino acids are provided in amounts that exceed their rates of accretion.[4,5] This mandates a fairly high oxidation rate for most amino acids, including the essential amino acids. It is not surprising, therefore, that there is a relatively high rate of urea production by the fetus. This has been directly measured in the ovine fetus and estimated for the human fetus.[8,208]

In FGR, the oxidation of amino acids is decreased, sparing the amino acids for protein synthesis. The principal amino acid used as a metabolic fuel by the ovine placenta appears to be glutamate.[181] There are no data in other species, but an uptake of glutamate from the fetal plasma into the placenta has been shown for human pregnancies. This observation supports the idea that it probably plays a similar role for the human placenta.

FETAL HEPATIC CIRCULATION AND AMINO ACID METABOLISM

Probably no area of fetal physiology and metabolism has progressed more rapidly since the last edition of this book than fetal hepatic physiology. The advances are both in studies relating to the perfusion of the fetal liver and in studies of fetal hepatic metabolism of amino acids.

Fetal Hepatic Circulation

The umbilical vein carries the most oxygenated and nutrient-rich blood of the fetus, and a large fraction of this blood perfuses the fetal liver. Thus, the fetal liver, in contrast to the postnatal liver, is a site of preferred oxygenation. It is a vitally important defense for the fetus during periods of chronic or acute hypoxia because it continues to take up lactate from the fetal circulation and release pyruvate. The pyruvate can then be metabolized by other fetal tissues. For human pregnancies, the percentage of umbilical blood flow shunted away from the fetal liver through the ductus venosus has now been measured.[209,210] The shunt gradually decreases from 40 to 15% over a gestational age range from 20 weeks to term. In some FGR pregnancies, this shunt is significantly increased.[209,211] Because other studies have shown a reduction in umbilical blood flow per kilogram fetal weight in FGR pregnancies,[212] this, in itself, reduces perfusion of the fetal liver. However, if the reduction in umbilical flow is coupled with an increased ductus venosus shunt, the decrease in hepatic perfusion can be profound. These changes in the fetal circulation must be kept in mind in terms of its potential importance on fetal hepatic metabolism.

Hepatic Amino Acid Metabolism

Fetal hepatic uptake of amino acids has been studied in late-gestation fetal lambs, and fetal hepatic uptake and the umbilical uptake of amino acids have been compared. A large hepatic uptake of all of the essential and most of the nonessential amino acids by both lobes of the fetal

liver has been reported.[4] During normal fetal development, there is no appreciable rate of fetal gluconeogenesis. This is understandable because fetal hepatic glucose production would be self-defeating for the fetus. It would increase plasma glucose concentration, which would reduce the transplacental glucose gradient leading to a reduced umbilical glucose uptake from the mother. The absence of fetal gluconeogenesis is not accompanied by a reduced amino acid uptake in the fetal circulation from the placenta,[178] as shown in Figure 27-8. There is a large uptake of amino acids, including all of the gluconeogenic amino acids, as well as a large fetal uptake of lactate.[178] In fetal life, the carbon is released primarily as glutamate and pyruvate, with a smaller contribution coming from the hepatic release of serine, ornithine, and aspartate. This is in contrast to what occurs in postnatal life, where the carbon from these amino acids is released from the liver solely as glucose.

The hepatic uptake of lactate and release of pyruvate are of special interest because of the importance of these compounds during fetal hypoxia. As mentioned earlier, the fetal liver is a site of preferred oxygenation because it is perfused with oxygen-rich umbilical venous blood. This is quite different from hepatic perfusion in postnatal life. The uptake of lactate and release of pyruvate continue under conditions of fetal hypoxia providing pyruvate, which can be metabolized by nonhepatic tissues even under hypoxic conditions.[213]

The interorgan shuttling of the two amino acid pairs, glutamate and glutamine and serine and glycine, plays an important role in this overall carbon balance for the fetus. The release of glutamate, serine, and pyruvate effectively replaces the glucose carbon release characteristic of the liver in postnatal life. This is clearly brought out in Figure 27-8, which shows what happens when gluconeogenesis is triggered in the fetal liver by the infusion of glucagon.[178] With the advent of net glucose released from the liver, the efflux of glutamate, serine, and pyruvate is markedly reduced, and the overall carbon balance is maintained. The exchange of glutamate and glutamine between the fetal liver and placenta does not represent a cycling of carbon between the two organs. Glutamate is largely oxidized in the placenta and in the fetus. The exchange of glutamate and glutamine changes quite markedly during parturition and during glucocorticoid or glucagon administration to the fetus.[179,180] Under these conditions, there is a decrease of fetal hepatic glutamate release, which results in a decrease of placental glutamate uptake. What role these metabolic changes in the fetal liver play in parturition is not yet established. Studies have shown that FGR is also associated with changes in fetal and placental glutamate metabolism. Fetal plasma glutamate concentrations are significantly lower in ovine FGR pregnancies compared with normal pregnancies.[214]

Glycine and serine are another metabolically related pair of amino acids that demonstrate a similar pattern of release and uptake across the ovine fetal liver and placenta.[4,184,186] The fetal glycine oxidation rate is high, and glycine is almost totally oxidized within the fetal liver. Fetal hepatic glycine oxidation and serine production from glycine are linked in the fetal liver by the enzyme systems glycine oxidase and serine hydroxymethyltransferase.[186,206,215] The combined action of these enzymes is the production of one mole of CO_2 and one mole of serine for every two moles of glycine consumed.[184,85] This is also true in adult tis-

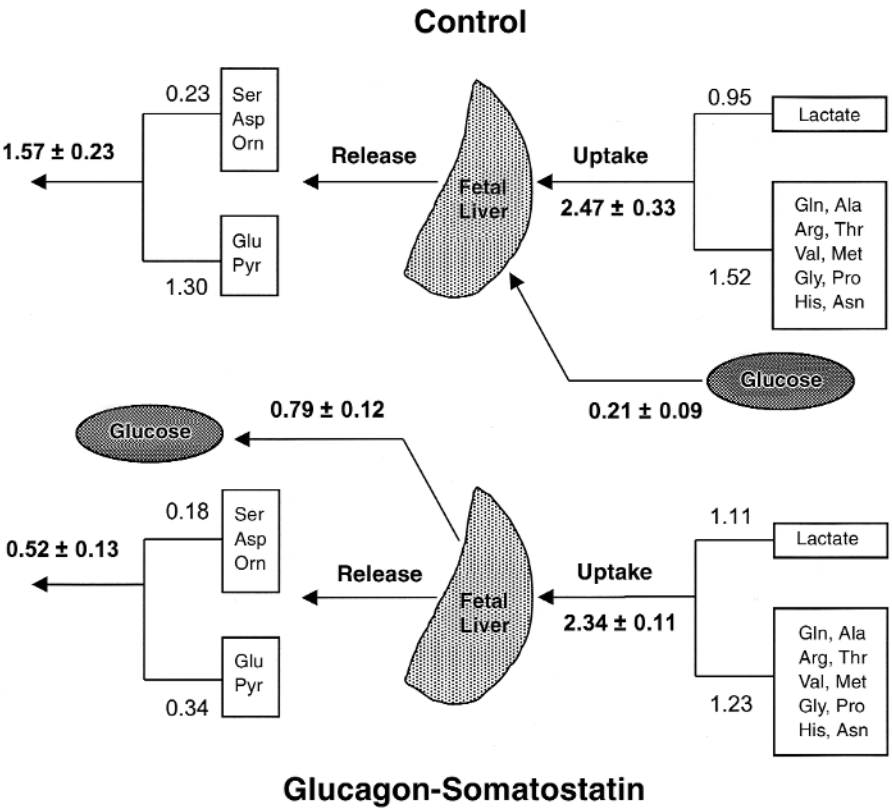

Figure 27-8 Fetal hepatic uptake and output of glucose carbon and glucogenic substrate carbon under normal physiologic conditions (Control) and during a fetal glucagon somatostatin infusion. Each number represents a substrate carbon to oxygen uptake ratio. Adapted from Teng C, et al.[178]

sues,[216,217] although adult liver is not normally a site of net serine release.[218]

Infusion of tracer serine into the fetus has demonstrated a rapid bidirectional transport of serine between the fetal blood and placenta, as well as placental conversion of fetal plasma serine to glycine.[185] In contrast to glycine oxidation, the bulk of fetal plasma serine oxidation occurs in extrahepatic tissues. Moores and colleagues infused labeled serine into the maternal circulation of pregnant sheep and found that, despite high maternal enrichments of serine, there was no fetal plasma enrichment evident.[206] However, the infusion of maternal tracer serine did lead to the appearance of labeled glycine in the fetal circulation. Thus, placental glycine production uses serine derived from both the maternal and fetal circulations. This brings out the complexity of pathways by which an amino acid such as glycine is delivered to the fetus from the placenta. The pathway for glycine production from serine is thought to be via serine hydroxymethyltransferase (SHMT) because ovine placental tissue is known to have moderately high activity for the mitochondrial isoform of this enzyme.[186] A by-product of placental glycine production via SHMT is methylenetetrahydrofolate, which could be involved in a variety of methylation reactions within the placenta.[186,206] These examples of placental-fetal interorgan shuttling of amino acids, particularly between the fetal liver and placenta, are now recognized to be an important and unique aspect of fetal metabolism.

FETAL HINDLIMB METABOLISM OF AMINO ACIDS

Several laboratories have studied the amino acid uptake by the fetal ovine hindlimb as being representative of the fetal carcass/extrahepatic tissues. Its metabolism has been evaluated under normal, maternal fasting and fetal euglycemic hyperinsulinemic states.[219,220] Under normal physiologic conditions, the hindlimb of a growing fetus shows a net uptake of both essential and nonessential amino acids from the fetal circulation.[220] This is in contrast to adult hindlimb studies that show a large output of alanine and glutamine.[221] It is theorized that the high amino acid uptake by the fetal hindlimb could be explained by the relatively high nitrogen accretion rate of the fetus.[220] There is a net uptake across the hindlimb of two amino acids that are not supplied by the placenta: glutamate and serine. It is estimated that the net fetal hepatic output could account for the combined uptake of glutamate by the placenta and the hindlimb.[220] Given the large uptake of alanine by the fetal liver, it is interesting that the fetal hindlimb shows no net release of alanine.

Theoretically, these amino acids could not be taken up by the fetal liver and be used for glucose production during a state of reduced umbilical glucose uptake (ie, maternal fasting).[222] Liechty and colleagues reported a relatively high activity for keto acid carboxylase activity in fetal skeletal muscle.[223] In pregnant sheep, after fasting, there is an approximate fivefold increase in the use of glutamine and a twofold increase in the use of the BCAAs by the uteroplacental tissues, suggesting a possible interorgan cycle between hindlimb and placenta, with the hindlimb supplying glutamine during the maternal fasted state.[224] Under euglycemic, hyperinsulinemic conditions, fetal lambs were noted to have significantly decreased arterial concentrations of most amino acids; a significantly increased limb uptake of alanine, asparagine, glycine, isoleucine, methionine, and tyrosine; and a decreased uptake of aspartate, but with no significant change in net total nitrogen uptake.[220] These studies show that the stimulation of alanine uptake by insulin is opposite to the effect of maternal fasting, suggesting that insulin or IGFs may play a role in regulating an alanine exchange between fetal circulation and nonvisceral fetal tissues.[220]

NEONATAL IMPLICATIONS OF FETAL AMINO ACID SUPPLY AND METABOLISM

One may ask what studies of amino acid nutrition and metabolism during fetal life can contribute to our approach to optimal nutrition for very premature infants in a neonatal intensive care unit. First, it is important to recognize that normal fetal development and postnatal development are vastly different biologic states. Not only are there profound endocrine changes triggered by delivery and its associated separation from the placenta, but the interorgan cycling of amino acids between the fetal organs and placenta is abruptly terminated. However, certain principles of amino acid metabolism during early development still apply. To summarize, during fetal development, amino acids are taken up in amounts that exceed their requirements for growth. This leads to a high rate of amino acid oxidation and a relatively high rate of urea production. A second general characteristic is the absence of gluconeogenesis, which leads to a hepatic production and release of serine and glutamate. It is important to emphasize that the requirements of amino acids change quite markedly with increasing gestational age and also on whether there has been normal or abnormal fetal growth. In the normal term newborn, the rate of net protein accretion in utero is quite low, with fat accretion dominating growth. In FGR fetuses, there are changes in plasma amino acid concentrations reflecting the reduced placental supply. There may also be vascular changes that lead to hepatic injury.

The delivery of optimal nutrition to the small premature infant is a critical factor to its overall care. Very premature infants have been delivered before they have gone through the phase of in utero development associated with rapid accretion of fat depots and glycogen stores. Preterm infants are born at gestational ages associated with rapid accretion of protein in utero. This has led to a neonatal nutritional approach that emphasizes the early provision of amino acids to very preterm babies. It should be emphasized, however, that this makes an assumption of good liver perfusion and the absence of any prenatal liver injury. Neither of these conditions necessarily applies to an individual newborn in the immediate neonatal period. The best guideline for assessing the nutritional status of the low birth weight infant is not clear. However, one approach

would include achieving a postnatal growth that approximates the in utero growth rate of a normal fetus.[225] By this guideline, the intrauterine accretion rate of amino acids becomes a reference point defining the minimal requirements in the neonatal period. As delineated in the previous discussion, the mammalian fetus uses the circulating maternal free amino acid pool as its primary nitrogen source for growth with certain conspicuous exceptions. Because amino acid oxidation is linked to hepatic gluconeogenesis in postnatal life and because gluconeogenesis is a requirement for postnatal adaptation, one would expect amino acid oxidation to be sustained during postnatal development, significantly increasing amino acid requirements. For the premature infant, the primary sources of nitrogen are obtained from a parenteral nutrition composition, human breast milk, or premature infant formulas. Current nutritional management for preterm and FGR infants aims at early provision of amino acids.

Recommendations for the quantity of protein delivery include 3.6 to 3.8 g/kg/day gross protein intake for the stable growing infant at < 27 weeks gestation and < 1,000 g and 3.0 to 3.6 g/kg/day for the 1,000 to 1,750 g infant at 28 to 34 weeks gestation. Although the exact quantity is debated (ie, European versus American guidelines), it is generally accepted that the stable growing low birth weight infant requires, on average, a parenteral amino acid intake of 3.0 g/kg/day to ensure accretion of nitrogen at the intrauterine rate of approximately 300 mg/kg/day. This amino acid intake, plus an energy intake of 80 to 100 kcal/kg/day, results in a weight gain that approximates the intrauterine rate of 15 g/kg/day.[226] However, the studies of the fetal circulation in FGR pregnancies make it clear that the general recommendations should be used with caution in newborns of any weight or gestational age when there is evidence of circulatory compromise in utero. A high carbohydrate and relatively low nitrogen intake is prudent. Certainly, if a high nitrogen intake is given to such infants, there should be an assessment of ammonia and urea levels as well as measurement of amino acid concentrations to ensure that the nitrogen load is not compromising the infant. This caution reflects the fact that there are still no ideal approaches to assess both the quality and the quantity of amino acids provided as protein in milk feedings to low birth weight infants. Breast milk provides a large array of compounds not included in formula feedings. Some of these compounds, such as glycoproteins and peptides, contain amino acids. However, owing to the instability of glutamine, it is currently omitted from parenteral nutrition solutions and infant formulas. Glutamine has recently been found to be an important metabolic fuel for lymphocytes[227,228] and intestinal epithelial cells[229] and is supplied to the fetus in large amounts throughout gestation.

It has already been demonstrated that formula-fed, very low birth weight infants whose weight gain was comparable to that of a normal fetus retained the same amount of protein (approximately 1.9 g/kg/day) but accumulated fat at approximately three times the rate of the fetus. This indicates that the body composition of the premature infant will differ from that of the comparable placentally nourished fetus.[230] How this will impact on long-term growth and neurodevelopment is unclear and a matter of much debate.[231–233]

As the complex interplay among fetus, placenta, and maternal dietary supply of amino acids becomes increasingly clear, it is hoped that this information can be used to understand more completely the remarkable process of fetal growth and maturation. This, in turn, will then be invaluable information in the further modification and design of feeding regimens for premature infants to optimize growth and long-term neurodevelopment.

CHAPTER 28

THE LOW BIRTH WEIGHT INFANT

Richard J. Schanler, MD

In the neonatal period, low birth weight (LBW) infants have greater nutritional needs to achieve optimal growth than at any time in their life. Many LBW infants either are born at the beginning of the third trimester of pregnancy or are products of pregnancies complicated by diminished uterine blood flow. These circumstances result in decreased nutrient deposition in the fetus. Thus, many LBW infants are growth restricted at birth.[1] In addition, their medical condition postnatally may contribute to increased nutrient needs. Impediments to growth include the stress of common pathophysiologic events (hypotension, hypoxia, acidosis, infection, surgical intervention) and their therapies (corticosteroids), as well as physiologic immaturity (decreased gastrointestinal motility and enzyme immaturity).[1] There also is a fear that aggressive feeding may produce pathology (feeding intolerance, necrotizing enterocolitis) and that some nutritional regimens may produce toxic effects on organ development. Lastly, intense support is needed to correct growth restrictions at birth and to continue appropriate weight gain, which is nearly double that of a term infant.[2,3] Thus, the LBW infant requires specialized nutritional support to meet these great demands for growth.

Special considerations regarding nutrient needs of LBW infants begin at birth. Because of limited body stores, increased expenditure, severity of illness, and/or immaturity, LBW infants may be given parenteral glucose solutions immediately from birth. Enteral feedings often are precluded because of the multiplicity of medical problems. Thus, immediately after birth, total parenteral nutrition (TPN) is initiated, consisting of intravenous glucose, amino acids, electrolytes, vitamins, and lipid. Subsequently, minimal enteral nutrition is added to provide small, trophic quantities of milk. As the infant matures physiologically and the medical condition stabilizes, TPN is slowly replaced with enteral nutrition. This chapter describes the nutritional needs and goals for LBW infants. Both parenteral and enteral nutritional needs are addressed (Table 28-1).

GOALS FOR NUTRIENT INTAKES

The nutritional reference standard for the term newborn is the exclusively breast-fed infant. A similar standard is not available for LBW infants. Instead, the reference standard for the LBW infant is the estimated intrauterine nutrient accretion rate at corresponding stages during the last trimester of pregnancy. We use the data on the nutrient composition of the fetus derived from chemical analyses of fetal cadavers to determine the net deposition or retention of particular nutrients during the last trimester of pregnancy.[4,5] From analyses of smoothed curves, these data have been computed on a daily basis per kilogram body weight (Table 28-2). Although the original data were derived from fetal carcass analyses, the data for several minerals have been corroborated by noninvasive neutron activation techniques.[6]

TABLE 28-1 Comparison of Suggested Parenteral and Enteral Fluid, Energy, and Nutrient Intakes for Low Birth Weight Infants

Component, Units	*Parenteral Intake Unit/kg/d*	*Enteral Intake Unit/kg/d*

The intrauterine accretion data provide a reference for nutrient deposition. To determine the advisable intake needed for a particular nutrient, we use the factorial approach.[7] This method includes a summation of the quantity of the nutrient deposited and an estimate of nutrient losses (Table 28-3). For infants receiving TPN, the advisable intake includes estimates of nutrient deposition, cutaneous and urinary losses, and an additional allowance to account for variability. For enteral nutrition, the factorial approach is amended to account also for the bioavailability of the particular nutrient. For example, the average calcium absorption from preterm formulas is approximately 50%. To provide a best estimate for calcium intake, we use the following factorial approach (see Table 28-3).

ENERGY

Based on a series of observations, the daily energy need for the growing LBW infant has been summarized (Table 28-4).[8] The values are not absolute. The range in resting energy expenditure has been reported from 49 to 60 kcal/kg/day at 8 to 63 days postnatal age.[9] When nourished parenterally, the LBW infant has less fecal energy loss, generally fewer episodes of cold stress, and somewhat lesser activity so that the actual energy needs for growth are lowered to approximately 80 to 100 kcal/kg/day. In circumstances of chronic disease, such as bronchopulmonary dysplasia, the resting energy expenditure rises significantly.[10,11] Total energy needs in LBW infants with bronchopulmonary dysplasia (BPD) are increased because of greater energy expenditure, activity, and possibly fecal energy losses. It is not surprising to find that these infants require 150 kcal/kg/day to achieve weight gain.

The distribution of nonprotein calories, the quantity of calories derived from fat and from carbohydrate, should be considered. A balanced distribution between calories derived from glucose and fat is appropriate to avoid potential effects on respiratory metabolism, especially in infants who are ill and receiving TPN. A distribution of calories favoring glucose (therefore low fat), or a surplus of glucose calories such that glucose is converted to fat, will increase the production of carbon dioxide, increase the partial pressure of carbon dioxide, increase alveolar minute ventilation, raise the respiratory quotient, and may increase the oxygen consumption.[12,13] In addition, a balanced distribution of glucose-lipid calories favors protein accretion, whereas glucose-only solutions are associated with protein oxidation.[14] Daily monitoring of the intakes for all energy sources in TPN is essential to ensure a relatively balanced distribution of calories derived from glucose and fat. One example of the computation of calorie distribution is provided in Table 28-5.

PARENTERAL NUTRITION

AMINO ACIDS

The essential amino acids include isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. For the LBW infant, several investigators also consider histidine, tyrosine, cysteine, taurine, arginine, glycine, and glutamine to be conditionally essential amino acids.[15] The content of specific amino acids also varies among the representative preparations. For example, tyrosine and cysteine are not present in all preparations, principally because of difficulties in solubility.[15–17] Taurine and glutamic acid are not present in all solutions.[15,18] Because of the high proportion of essential and conditionally essen-

TABLE 28-3 Computation of Net Enteral and/or Parenteral Nutrient Need Based on the Factorial Approach Using Data from Rates of Fetal Nutrient Accretion

Net fetal Ca deposition = 105 mg/kg/d
Postnatal urinary losses = 5 mg/kg/d
Postnatal cutaneous losses = 2 mg/kg/d
Subtotal (parenteral need) = 112 mg/kg/d
Assume net absorption (%) = 50%
Total (enteral need) = 224 mg/kg/d

tial amino acids, commensurate with the initiation of TPN in the first days after birth, a previously elevated blood urea nitrogen may decline more rapidly.[19] Although several amino acid solutions are available for parenteral nutrition, the percentage of essential/total amino acids is variable (Table 28-6): 53% (TrophAmine, Braun, Bethlehem, PA), 48% (FreAmine III, Braun, Bethlehem, PA), 48% (Aminosyn PF, Abbott Park, IL), 44% (Novamine, Fresenius, Lexington, MA), and 40% (Travasol, Clintec, New Providence, NJ).

It is known that there is a direct relationship between the quantity of nitrogen (amino acids) provided in TPN and nitrogen balance or retention.[20,21] It is also known that specific amino acids may affect nitrogen balance, a fact that has been useful in determining the essentiality of particular amino acids. Malloy and colleagues observed that the addition of cysteine hydrochloride to TPN increased plasma free and total cyst(e)ine and urinary cyst(e)ine concentrations.[22] Zlotkin and colleagues, however, were unable to demonstrate a significant effect of increasing cysteine intake on nitrogen balance or weight gain.[23] Cysteine also serves as a precursor of glutathione. In vitro studies suggest that, even in LBW infants, cysteine is an ideal substrate for glutathione production.[24] Thus, cysteine hydrochloride is added to TPN solutions, not only to meet cysteine needs and to enhance glutathione synthesis but also because it lowers the pH of the solution, which, in turn, enhances the solubility of the calcium and phosphorus salts.[25,26]

Glutathione is the major intracellular antioxidant, and its primary function is to protect the cell against free radical damage (eg, from peroxides). The liver synthesizes glutathione from cysteine, glutamine, and glycine. Not only is cysteine considered rate limiting for glutathione synthesis, but a lack of glutamine also may affect the rate of glutathione production.[27] Glutamine is abundant in muscle and plasma. It has a role in intestinal cell growth, a particularly important concern in parenterally nourished infants when the gastrointestinal tract is not being used. Plasma glutathione concentrations increase when glutamine is added to TPN solutions.[27] In extremely LBW infants, one study reported a shorter time to full feedings, fewer days of TPN, and less need for prolonged mechanical ventilation with the addition of glutamine to TPN.[28] A large, multicenter randomized trial, however, failed to identify a benefit of parenteral glutamine supplementation with respect to growth, protein synthesis, or host defense.[29] Routine parenteral nutrition solutions do not contain significant quantities of glutamine. Current formulations of the amino acid are not stable for prolonged periods in TPN mixtures, necessitating daily preparation.

Nitrogen retention can be augmented either by providing the best mixture of essential/nonessential amino acids, increasing the nitrogen intake, or within a narrow range by increasing the energy intake (from approximately 50 to 80 kcal/kg/d).[20] The positive relationship between energy intake and nitrogen balance for any given nitrogen intake is linear within the usual intakes of nitrogen and energy. Nitrogen balance (retention) increases markedly as energy intake is increased from 50 to 90 kcal/kg/day at the same nitrogen intake.[20,30] Understanding these principles is important when intakes of nitrogen are limited or when energy intakes are not maximized.

The use of TrophAmine and FreAmine III has been evaluated in LBW infants of 32 weeks gestation.[31] The group receiving TrophAmine had significantly greater gain in body weight and net nitrogen balance than the group receiving FreAmine III. It appears that the plasma amino acid pattern is directly related to the composition of the parenteral amino acid solution.[32] Because it was developed to ensure optimal levels, plasma amino acid patterns in

LBW infants receiving TrophAmine appear to be more "balanced" than plasma amino acid patterns of other formulations.[15,31,33,34] Thus, the importance of selecting the optimal mixture cannot be underestimated.

Serial balance studies were conducted for 3 weeks in a longitudinal study of TPN (using TrophAmine 2.2% at 130 mL/kg/day [2.9 g/kg/day] and Intralipid 20% at 20 mL/kg/day [4.0 g/kg/day]) in LBW infants.[25] Significant positive relationships were observed between nitrogen retention and intake. Based on those relationships, Table 28-7 depicts the amino acid concentration and intake needed to meet the intrauterine accretion rate for nitrogen. These and other investigations suggest that an amino acid intake of approximately 3 to 3.5 g/kg/day is appropriate for LBW infants receiving TPN.[15,25]

The use of a combined glucose and amino acid source for TPN may be initiated soon after birth.[19,35] The provision of this combination of nutritional support reverses the negative nitrogen balance attributed to a constant urinary nitrogen loss,[19,25,35,36] increases the serum concentration of essential amino acids,[19,37] and increases the rate of protein synthesis.[35,38] Doses of 1 to 3 g/kg/day have been used immediately after birth (Table 28-8).

Intravenous Lipid Emulsions

Essential fatty acids, linoleic acid ($C_{18:2\ \omega\text{-}6}$) and linolenic acid ($C_{18:3\ \omega\text{-}3}$), cannot be synthesized and thus need to be provided to the LBW infant. Without provision of these fatty acids, essential fatty acid deficiency, characterized by dermatitis, thrombocytopenia, infection, and failure to thrive, may manifest in the first week after birth. Classically, essential fatty acid deficiency is assessed by measuring the plasma triene-to-tetraene ratio. As a deficient intake results in decreased arachidonic acid (tetraene, $C_{20:4\ \omega\text{-}6}$) relative to a normal triene ($C_{20:3\ \omega\text{-}9}$) ratio, an abnormal state is characterized by a triene-to-tetraene ratio > 0.2 to 0.4. Small amounts of essential fatty acid (~ 4% of total calories or 0.5 g/kg/day) are required to prevent essential fatty acid deficiency.

Intravenous lipid emulsions containing soybean oil (or safflower oil) with glycerin and egg yolk phospholipids as emulsifiers added to the parenteral nutrition regimen in the first few days will prevent essential fatty acid deficiency,[39,40] provide needed energy for tissue healing and growth, and equalize the distribution of nonprotein calories (see Tables 28-1 and 28-9). Intravenous lipid emulsion has been used in sick LBW infants beginning on the day of birth without short-term adverse effects.[41] Intravenous lipid reportedly protects the lung from oxygen toxicity by increasing the content of polyunsaturated fatty acids in the lung.[42] This finding may be especially important in ventilator-dependent LBW infants.

The concentration of the lipid emulsion (10% versus 20%) affects the infant's tolerance of the lipid preparation. Despite similar or even greater doses of lipid, there is better tolerance of the 20% intravenous lipid solution. LBW infants receiving the 20% solution at the same or even greater lipid intakes had lower serum concentrations of triglycerides, cholesterol, and phospholipids than similar infants receiving the 10% solution.[43,44] Given the same dose of lipid, the greater volume required for the 10% solution contributes more phospholipid, cholesterol, and liposomes, which accumulate to form lipoprotein X. Lipoprotein X particles compete with lipoprotein lipase to reduce the clearing of triglycerides.[15,43,44] Thus, regardless of the dose of lipid or the age of the infant, LBW infants should receive the 20% solution.

The method of lipid infusion also affects triglyceride clearance. Intermittent infusion may produce higher serum triglyceride concentrations than continuous infusion (over a 24-hour interval) of the same dose.[45] The use of intermittent infusions and lipid-free intervals does not appear to be justified in routine circumstances.[46,47] Indeed, deleterious effects on pulmonary function have been demonstrated in adults who received large bolus doses of intravenous lipid, resulting in markedly elevated (> 300 mg/dL) plasma triglyceride concentrations.[48] For any given dose of lipid, triglyceride concentrations in LBW infants are more elevated at 1 week postnatal age than 2 to 3 weeks postnatal age.[49] Most authorities suggest using plasma triglyceride concentrations to monitor lipid tolerance. A plasma triglyceride concentration > 150 mg/dL usually is avoided. Plasma free fatty acid concentrations provide a more direct measure of lipid tolerance. Because of the complexity of the assay, however, this method is not performed routinely.

TABLE 28-7 Suggested Intakes of Parenteral Nutrients Available for Low Birth Weight Infants

Heparin	1 U/mL	100 U
Lipid (by separate infusion)	5 mL/kg/d	1 g

Adapted from Nutrition and Gastroenterology Clinical Review Committee.[102]
Contains no electrolytes, phosphorus, magnesium, trace elements, or cysteine. Monitor glucose to determine whether to increase glucose infusion rate and electrolytes, phosphorus, and magnesium to determine when these are to be added. When phosphorus is added, ensure that cysteine has been added so that the solubility of minerals is optimized.

There have been some concerns regarding the worsening of pulmonary function and the potential for oxidant toxicity as a result of the use of intravenous lipid.[50–52] In vitro studies suggest that the formation of hydroperoxides in the lipid emulsion may be deleterious to lung function.[53] Clinical studies, however, do not indicate an increased risk from the administration of intravenous lipid emulsions.[54] Indeed, the concern actually may focus on the lack of appropriate antioxidants to protect the infant.[55] The use of intravenous lipid emulsion, even when administered within 12 hours of birth, was not associated with either an increase in oxygen requirement or the development of chronic respiratory disease in infants who were extremely LBW.[52] It appears that the benefits of intravenous lipid outweigh the potential risk.

Intravenous Carnitine

Carnitine is one of several conditionally essential nutrients that may be included in TPN solutions for neonates. Carnitine, present in all milks fed to infants but not included in usual TPN mixtures, has a role in fatty acid transport into the mitochondria, fatty acid oxidation, and ketogenesis. Supplementation of TPN with L-carnitine (8 to 10 mg/kg/day) results in greater plasma total and acylcarnitine concentrations in premature infants compared with control infants receiving TPN without carnitine.[56,57] Study infants who were supplemented with carnitine also appeared to have greater fatty acid oxidation as evidenced by increased ketone production.[57] Supplementation with high doses of carnitine (48 mg/kg/day), however, results in a slower weight gain and an anomalous increase in protein oxidation.[52] Thus, parenteral carnitine intakes range in doses of 10 to 20 mg/kg/day and are used until any milk is provided.

Minerals: Calcium, Phosphorus, and Magnesium

The LBW infant is prone to several clinical conditions that cause or result in abnormalities in mineral metabolism, for example, hypocalcemia, hyperphosphatemia, and hypermagnesemia. These conditions may affect how parenteral nutrition is provided. In the fetus, calcium (Ca) is transported actively from the mother, under the influence of parathyroid hormone–releasing peptide (PTHrP). Most transplacental transfer of Ca occurs in the last trimester. Postnatally, serum Ca declines, and the LBW infant may not have compensatory mechanisms to increase serum Ca. Parathyroid hormone response to hypocalcemia appears to be blunted, and some investigators report elevated calcitonin levels in LBW infants. Thus, Ca must be provided in the early postnatal period to prevent and to treat hypocalcemia. Because there is a transient period of oliguria and renal insufficiency, postnatal serum phosphorus (P) values may rise in some LBW infants. Yet, with renal maturation, serum P concentrations decline. Therefore, P must be provided in parenteral nutrition solutions. Ca and P must be provided together for optimal bone deposition; without P, bone Ca deposition is blunted, and hypercalcemia and hypophosphatemia will be manifest. Hypermagnesemia in LBW infants is not an uncommon finding following maternal magnesium therapy. However, once serum magnesium (Mg) concentrations normalize, parenteral Mg should be provided.

Inadequate intakes of Ca and P result in the spectrum of bone undermineralization, osteopenia of prematurity, rickets, and fractures in LBW infants.[58,59] Osteopenia may potentiate chronic lung disease because undermineralization affects chest wall stability. An increasingly more compliant chest wall leads to atelectatic changes in the lung.[60] P deficiency has been associated with diaphragmatic paralysis and respiratory failure in adults.[61] Ca and P deficiency also result in hypercalciuria and, in combination with the use of diuretics, may result in nephrocalcinosis.[62,63]

Although the direct relationship between intake and net retention aids in determining optimal intakes of these minerals, intakes are limited by the solubility of Ca and P in solution. Careful attention to pH, amino acid concentration and source, and temperature must be given to provide a recommendation for the appropriate quantity of Ca and P in TPN.[64,65] To optimize solubility further, during preparation of TPN, the P is added first and the calcium is added as the last step.

Proportional increases in Ca and P, up to 76 and 45 mg/kg/day, respectively, are retained by the infant.[65] Prestridge and colleagues demonstrated increased net retention, without increased urinary losses, when Ca intakes were increased from 60 to 80 mg/kg/day and P intakes were increased from 55 to 80 mg/kg/day, respectively.[66] The effects of the greater Ca and P intakes also were manifest by increased bone mineral content during and well beyond the 3-week TPN study interval.[66]

Daily intakes of Ca and P can be increased if each is delivered separately.[67] However, alternate-day infusion methods result in hypercalciuria and hypercalcemia when P is omitted and hyperphosphaturia and hyperphosphatemia when Ca is omitted. The two minerals, therefore, must be delivered together for deposition into bone. Indeed, abnormal serum Ca and P concentrations are observed when one of the two minerals is omitted in the

TPN solution. If P is omitted from TPN, the resulting biochemical pattern is observed: hypophosphatemia, hypophosphaturia, hypercalcemia, and hypercalciuria.

The optimal ratio of Ca to P in TPN for LBW infants is generally Ca:P ≥ 1:1 (molar).[59,68] Ratios of Ca:P < 1:1 result in elevated urinary P and serum P concentrations, suggestive of inadequate P use because of inadequate Ca intake.[66] However, it appears that the absolute quantity of Ca and P is more important than the ratio. If the quantity is limited, the ratio will affect net retention as much as an increase in the intake of the two minerals. Table 28-7 depicts the intake required to achieve the intrauterine accretion rate for Ca, P, and Mg. However, as mentioned earlier, solubility issues prevent the achievement of these intakes with current formulations. A plan for Ca and P concentrations in TPN is found in Table 28-10. Note that recommendations for Ca and P depend on the quantity of amino acids in the solution.

Early, immediate provision of parenteral nutrition solutions is provided to LBW infants. In addition to glucose, amino acids, and lipid, Ca is added to prevent/treat hypocalcemia. Generally, doses of elemental Ca of 25 to 75 mg/kg/day are used.[69] P may not be needed in the first 1 or 2 days, until the serum P normalizes (see Table 28-8).

The parenteral intakes of Mg needed to meet intrauterine accretion rates were derived in a longitudinal study evaluating serial Mg balance studies using TrophAmine 2.2% (130 mL/kg/day) and Intralipid 20% (20 mL/kg/day).[25,66] As elevated serum Mg concentrations and net retention were observed with intakes of 12 mg/kg/day, the linear relationship between intake and net retention suggested that a lower parenteral Mg intake was appropriate (see Table 28-7). That intake derived for Mg is easily attainable (see Table 28-10).

Electrolytes

Serum sodium (Na) is a useful indicator of hydration in LBW infants. Sodium needs in the early days postnatally may be determined by the serum Na. The usual parenteral needs for Na and potassium (K) are determined in each clinical circumstance, with a range of intakes recommended (see Table 28-1). Serial balance studies were conducted for 3 weeks in a study of TPN (using TrophAmine 2.2% at 130 mL/kg/day and Intralipid 20% at 20 mL/kg/day) in LBW infants.[25] It was also noted that the majority of the Na intake was derived from common medications received by the LBW infant. Significant relationships were determined between specific nutrient intake and net retention for Na and K. Thus, a derived intake for these electrolytes takes into account all potential sources for Na and K (see Table 28-7).

A relative degree of acidosis, manifest by a low serum bicarbonate concentration and a borderline low serum pH, also may occur with TPN. The LBW infant has decreased renal reabsorption of bicarbonate. Moreover, the use of amino acid solutions with low pH (generally 5.5 to 6.5) and the use of cysteine hydrochloride further reduce the pH.[15] The addition of acetate to the solution, as either the Na or K salt, has been reported to correct the acidosis. The small quantity of acetate, 1 to 2 mEq/kg/day, has not been observed to affect the solubility of the minerals in TPN solutions containing TrophAmine and cysteine hydrochloride.[26]

Trace Elements

Suggested parenteral intakes of copper (Cu) and zinc (Zn) for LBW infants have been evaluated from serial balance studies (using TrophAmine 2.2% at 130 mL/kg/day and Intralipid 20% at 20 mL/kg/day) conducted during the first 3 weeks postnatally.[18] Net retention and urinary excretion did not increase over the 3 weeks of study, suggesting that the elements were used by the infant during the early period of postnatal life.[25] As intakes were correlated with net retention, the estimated intake needed to meet the intrauterine accretion rate was determined (see Table 28-7). Estimated parenteral intakes of Zn have been reported, which are in a similar range of 350 to 450 g/kg/day.[68,70] A greater dose may be indicated in LBW infants with ongoing intestinal losses of Zn. Estimated parenteral intakes of Cu were similar to those reported by Zlotkin and Buchanan and slightly greater than those reported by Greene and colleagues.[68,70] Differences in recommendations may arise owing to the various sources of amino acids used and medical conditions of the infants studied.

An estimate of Zn status can be obtained from serum Zn concentrations that range between 70 and 120 μg/dL in adults. Severe Zn deficiency generally is associated with plasma zinc concentrations below 20 to 30 μg/dL.[68] Copper status is more difficult to define with serum indices.[71] Plasma Cu and ceruloplasmin concentrations increase with postmenstrual age.[68] At 30 weeks, plasma Cu concentrations are 35 μg/dL and at 40 weeks are between 50 and 60 μg/dL. Cu needs are increased in cases of excess biliary losses and in patients with jejunostomies. It is important to recognize that impaired biliary secretion, however, will lead to a build-up of Cu. Therefore, it is advised that Cu intakes be reduced in patients with impaired biliary excretion, such as that which occurs in cholestatic syndromes.[68]

Selenium (Se) is a component of glutathione peroxidase, and its absence from long-term TPN solutions results in a deficiency of the element.[72–74] Approximately 75% of an absorbed dose is excreted by the kidney, so Se intake should be reduced in patients with impaired renal function. The recommended intake of 2 mg/kg/day is derived from the Se intake of the term breast-fed infant.[68]

Recommendations for manganese (Mn) intakes are not clearly defined.[68] The ratio of Mn to Zn in the available trace

TABLE 28-10 Calcium, Phosphorus, and Magnesium in Total Parenteral Nutrition

*mmol (mg)/dL.
Short term assumes total parenteral nutrition (TPN) with ≥ 2.4% amino acids + cysteine; long term assumes TPN with > 2.5% amino acids + cysteine; special assumes TPN with > 3% amino acids + cysteine.

element solution used for LBW infants provides a greater intake of Mn than presumed to be needed. Mn excretion is diminished markedly in cholestatic syndromes. The use of Mn in cholestatic disease should be avoided.

Chromium (Cr) needs may be associated with insulin activity at the receptor level.[68] Cr deficiency, therefore, may result in impaired glucose tolerance. High doses of Cr may accumulate in the body.[75] A recommended intake of approximately 0.3 μg/kg/day appears to be appropriate.

Vitamin A

Vitamin A has diverse functions, being essential for vision, growth, reproduction, cell differentiation, and immunocompetency.[76] Retinol is the dietary component present as retinyl esters (palmitate, stearate) in animal sources, and betacarotene is the vitamin A precursor of plant origin. The amount of vitamin A in the diet is quantitated as retinol equivalents (REs): 1 RE equals 1 μg all-*trans* retinol or 3.33 IU vitamin A; 6 μg betacarotene equals 1 μg retinol.

Carotene and retinyl esters are converted to retinol in the proximal small intestine. Retinol is absorbed into intestinal cells, esterified, and incorporated into chylomicrons that are transported via the lymphatics to the circulation and eventually taken up by the liver. In the liver, the vitamin is esterified and stored as retinyl palmitate.[76] Retinol is mobilized from the liver to the circulation bound with retinol-binding protein and transthyretin. More than one-third (37%) of LBW infants were found to have hepatic vitamin stores < 20 μg/g, signifying deficiency, whereas more than three-fourths (76%) had stores of < 40 μg/g.[77] Vitamin A also is stored in the lung and may be involved in growth and differentiation of the lung.[77] Therefore, LBW infants may be vitamin A deprived and their lungs susceptible to the effects of this deficiency.[77]

Photodegradation of retinol occurs when milk or an intravenous solution is exposed to light during continuous infusions, so increased light exposure should be avoided.[78,79] In addition, between 30% and 75% of the original retinol is lost by adsorption to the tubing before it reaches the infant. Greater plasma retinol concentrations occur when the vitamin is mixed with intravenous lipid emulsion or with the use of retinyl esters.[80,81]

Plasma vitamin A concentrations in LBW infants receiving TPN are low. When receiving 455 μg/day, there is no change in plasma vitamin concentrations over baseline.

Infants developing BPD reportedly have lower plasma vitamin A concentrations at 4, 14, 21, and 28 days of age compared with infants not developing BPD.[82] Randomized controlled trials of vitamin A supplementation in LBW infants susceptible to BPD have been reported.[83] In a randomized comparison of vitamin A intakes from all sources over the first month, an intake of 510 μg/kg/day was associated with less plasma vitamin A deficiency and less BPD than control infants receiving 130 μg/kg/day. Vitamin A–supplemented infants also had less airway infection and retinopathy of prematurity than control infants.[77]

Not all randomized studies observe a significant effect of vitamin A supplementation on BPD outcomes.[84] However, a recent meta-analysis suggests that supplementation with vitamin A is associated with a modest reduction in oxygen requirement at 36 weeks postmenstrual age (summary RR 0.85 [0.73, 0.98]) and a trend toward a reduction in retinopathy of prematurity.[83] Despite high vitamin A intakes in a recent large multicenter study, 24% of the supplemented group had plasma concentrations < 20 μg/dL. The authors concluded that because of the modest decrease in chronic lung disease, the safety, lack of toxicity, and low cost, further investigations using higher doses of the vitamin were warranted.[85]

Guidelines should be adopted and parenteral preparations reformulated to provide intakes that approximate 500 μg/kg/d for vitamin A, initiated within the first 12 hours after birth.[68]

Vitamin E

Vitamin E functions in humans as a biologic antioxidant: a free radical scavenger that inhibits the naturally occurring peroxidation of polyunsaturated fatty acids, components of the lipid layer of cell membranes.[86]

Daily parenteral administration of 2.1 mg is associated with normal plasma vitamin E concentrations by 48 hours.[87] Mixing the vitamin E dose with intravenous lipid increases plasma vitamin E concentrations. Early use of TPN-containing multivitamins is effective in raising plasma vitamin E concentrations to physiologic ranges within the first 24 hours.[88] Current TPN regimens recommend vitamin E intakes of 2.8 mg/kg/day (40% of a vial of MVI-Pediatric, Astra Pharmaceuticals) for infants below 2.5 kg and 7 mg/day (1 vial of MVI-Pediatric) for infants greater than 2.5 kg.[68]

Data from randomized trials in LBW infants suggest that there may be a relationship between pharmacologic doses of vitamin E and the entities of retinopathy of prematurity, BPD, and intraventricular hemorrhage. The incidence of severe retinopathy of prematurity (stage 3+plus) was 2.4% with vitamin E supplementation and 5.3% in the control group, a modest effect despite pharmacologic doses of the vitamin.[89–92] Despite initial studies demonstrating a modest effect on the reduction of BPD, pharmacologic vitamin E supplementation has not been demonstrated to reduce the severity of the disease.[93–95] If given within 12 hours of birth, vitamin E administration is associated with a reduction in the incidence and severity of intraventricular hemorrhage.[96,97] Studies demonstrating an effect of intramuscular vitamin E on intraventricular hemorrhage have suggested a target plasma concentration > 1.0 mg/dL by 24 hours and > 2 mg/dL at 3 days.[98] Those plasma vitamin E concentrations can be achieved with TPN-containing multivitamins if initiated soon after birth. Guidelines should be adopted and TPN preparations reformulated to provide intakes that approximate 3 mg/kg/day for vitamin E, which should be initiated soon after birth.

Water-Soluble Vitamins

Current formulations generally provide more water-soluble vitamins than are needed by LBW infants. Plasma ascorbate (vitamin C) and vitamin B_2 (riboflavin) concen-

trations reportedly were elevated in LBW infants receiving TPN.[80,99,100] The elevated riboflavin concentrations appear paradoxical in view of the known degradation of the vitamin under infusion and nursery lighting conditions. Thus, significantly lower doses of some of the water-soluble vitamins are indicated (Table 28-11). When used in a dose of 2 mL/kg/day (40% of the vial MVI-Pediatric), no deficiencies of thiamin or riboflavin were detected, and plasma concentrations of folate and vitamin B_{12} indicated sufficient status.[101]

Summary of Parenteral Nutrient Needs

Parenteral nutrient needs consider the needs for growth and greater energy expenditure and potential for nutrient losses as a result of illness. LBW infants receiving TPN should have biochemical monitoring to avoid excesses or deficiencies of particular nutrients (Table 28-12). Complications related to TPN therapy are recognized (Table 28-13). Early, immediate use of parenteral nutrition is important to prevent deficiencies in LBW infants. A general protocol has been devised (see Tables 28-8 and 28–14).[102]

GASTROINTESTINAL PRIMING

The lack of enteral nutrients poses several problems for the development of the intestinal tract. In several animal species, the absence of enteral nutrients is associated with diminished intestinal size and weight, atrophy of intestinal mucosa, delayed maturation of intestinal enzymes, and increases in permeability and bacterial translocation. A lack of enteral nutrients also affects intestinal motility, perfusion, and hormonal responses. The hormonal response to feeding premature infants has been evaluated by measuring the plasma concentrations of a variety of gastrointestinal hormones in response to milk feeding during the first week after birth.[103] Significant hormonal surges are noted after milk feeding, but no response is observed in absence of feeding. The responses to feeding are observed both in healthy premature infants and those with respiratory distress. Hormonal responses to small quantities of milk (24 mL) are noted for gastrin, gastric inhibitory polypeptide (GIP), and enteroglucagon, but the motilin response is not observed until the cumulative milk intake is 700 mL.[103]

The above observations prompted prospective randomized clinical studies of small volumes of milk as early minimal enteral nutrition, or gastrointestinal priming, in premature infants. When studied in the first or second week after birth, infants given "early" priming milk feeding had a better feeding tolerance when feedings were advanced, required a shorter duration of parenteral nutrition, and had a lower incidence of conjugated hyperbilirubinemia compared with similar infants given only parenteral nutrition during the same interval (Table 28-15).[104,105] Probably because of better tolerance to feeding, premature infants receiving the trophic feedings had cumulatively greater milk intakes, which was associated with lower serum alkaline phosphatase activity.[104] The lower alkaline phos-

phatase activity, primarily of bone origin, was observed for 14 weeks, well beyond the initial intervention in the first week. Significant stimulation of gastrointestinal hormones, such as gastrin and GIP, also was reported following the early feeding of small quantities of milk.[106] Intestinal motility patterns matured more rapidly in premature infants receiving early enteral feeding.[107] Subsequent investigations demonstrated that trophic feeding was associated with greater absorption of Ca and P, greater lactase activity, and a reduced intestinal permeability.[108–110] The meta-analysis of several studies of gastrointestinal priming indicated that its use was associated with a shorter time to regain birth weight, fewer days when feeding was withheld, and a shorter duration of hospitalization but no increase in the incidence of necrotizing enterocolitis.

Noteworthy in the studies of minimal enteral nutrition is that the subject population consisted of premature infants selected because they had the greatest risk of feeding intolerance and necrotizing enterocolitis. For example, feedings were administered during mechanical ventilation and while umbilical arterial and venous catheters were in place.[104,105,111] The infants also had the usual morbidities of patent ductus arteriosus, intraventricular hemorrhage, and systemic hypotension. These data suggest that by the end of the first week after birth, in the absence of major cardiovascular instability (severe acidosis, hypotension, hypoxemia), the intestinal tract of the premature infant can be primed with small volumes of milk. In general, for infants who are ill, the small volumes of 10 to 20 mL/kg/d continue for approximately 4 to 7 days before there is any consideration of advancing the milk volume.[108] The decision for advancement of feedings, however, is made after clinical feeding tolerance is proven and clinical stability is achieved.

ENTERAL NUTRITION

PROTEIN

Milk Composition In the first few weeks after birth, the protein content of milk from mothers who deliver premature infants (preterm milk) is greater than term milk, the milk obtained from women delivering term infants.[112] The protein content in both milks declines, such that beyond 2 weeks, it levels off to what we call mature milk (Table 28-16). The quality of protein (eg, the proportion of whey and casein) in human milk is particularly suitable for the premature infant. Human milk contains 70% whey and 30% casein, whereas bovine milk contains 18% whey and 82% casein. A whey- and/or casein-dominant commercial formula, therefore, refers to these proportions of bovine milk. The whey fraction of milk consists of soluble proteins that are digested more easily. Human milk and then whey-dominant bovine milk, in that order, promote more rapid gastric emptying than casein-dominant milk.[113] Ele-

Safety

vated concentrations of potentially toxic amino acids (phenylalanine, methionine, and tyrosine) are reported in premature infants fed formulas with high casein contents.[114,115] Hepatic enzyme immaturity may explain the higher plasma amino acid concentrations. Because we infer that elevations of particular amino acids may be toxic to brain development, there may be a concern when feeding premature infants a casein-dominant milk, especially at a high protein intake.

The composition of the whey fractions of human and bovine milks differs significantly. The major human whey protein is α-lactalbumin, a nutritional protein for the infant and a component of mammary gland lactose synthesis. Lactoferrin, lysozyme, and secretory immunoglobulin A (IgA) are specific human whey proteins that are particularly resistant to hydrolysis and, as such, line the gastrointestinal tract to play a primary role in host defense.[116] These proteins, therefore, may be suitable for the premature infant who is exposed to multiple pathogens in the nursery environment. The three host defense proteins are present only in trace quantities in bovine milk. The major whey protein in bovine milk is α-lactoglobulin, the protein often blamed for bovine milk protein allergy and colic.[117]

The major amino acid for the fetus and in human milk is glutamine, which is not found in commercial formula because of problems with stability of the free amino acid. Glutamine, however, is an important amino acid for cell growth, specifically intestinal epithelial growth, has a role in immune function, and is a precursor in glutathione synthesis. When commercial formula was supplemented with glutamine under experimental conditions, premature infants had better feeding tolerance and a significantly lower incidence of sepsis than infants fed unsupplemented formula.[118] Further research efforts are under way to define how to supply this amino acid if human milk is not fed.

Protein Needs The quantity and quality of protein needed for premature infants have been investigated.[119] Formulas providing protein intakes of 2.25 and 4.50 g/kg/day as either whey- or casein-dominant preparations and pasteurized human milk with a protein intake of approximately 1.6 g/kg/day were compared. Although absolute growth rates reportedly were similar during the in-hospital study, hospital duration was longer for the infants fed human milk, suggesting a slower rate of weight gain than infants fed formula.[114,115] Those infants receiving protein intakes of 4.5 g/kg/day, as well as infants given casein-dominant milk, had more abnormalities in plasma amino acids and protein indices of nutritional status (elevated blood concentrations of urea nitrogen and ammonia, acidosis, lethargy, and fever), suggesting excessive protein intake.[120] Although generally considered excessive protein intake, 4.5 g/kg/day were provided with relatively low energy (115 kcal/kg/day) and mineral intakes. Some investigators comment that energy and mineral intakes may have limited the ability to use the protein and that such intakes may be appropriate if the total diet is adjusted.

The appropriate protein intake for premature infants has been defined further from evaluations of weight gain, nitrogen retention, and serum biochemical indicators of protein nutritional status.[121,122] Protein intakes of 2.2 and 2.8 g/kg/day resulted in lower serum indices, weight gain, and nitrogen retention, and intakes of 3.8 g/kg/day appeared somewhat excessive. Therefore, protein intakes of approximately 3.5 g/kg/day at 120 kcal/kg/day seem appropriate for the otherwise normal premature infant.[121]

An alternate way to compute the protein needs of the premature infant is to use the factorial approach to add the needs for tissue deposition, derived from intrauterine accretion rates of 1.8 to 2.2 g/kg/day, to the postnatal losses of protein from the skin (approximately 0.2 g/kg/day) and the urine (1.0 g/kg/day). As approximately 85% of the protein is absorbed, the calculated enteral protein intake is 3.5 to 4.0 g/kg/day. A range of protein intakes is found if all

products available are considered (Table 28-17). However, the above computations provide the basis on which to select products designed for LBW infants (fortified human milk and preterm formula).

The above studies were conducted using formulations with whole or intact protein. Although fetal nitrogen uptake is composed primarily of amino acids, no data suggest that postnatal formulations include hydrolyzed proteins or free amino acids. Whey-dominant protein formulations are well absorbed, and the provision of hydrolyzed protein formulations, usually casein derived, for the otherwise healthy premature infant is not indicated (Table 28-18).

Protein needs should be considered in conjunction with energy. Protein synthesis requires energy. If energy intake is inadequate, protein synthesis may be depressed and amino acid oxidation may increase.[123] Protein retention, or balance, generally is a function of protein intake if energy intake is adequate.[20] Excessive protein intake is more of a risk if energy intake is limited.

Human Milk Protein Needs The aforementioned studies demonstrated that the lowest plasma concentrations of amino acids, albumin, and urea nitrogen and the slowest rates of weight gain were found in the human milk–fed premature infants.[119,124] These observations suggest that after the early 2 weeks of feeding, the lower protein intakes in human milk–fed premature infants may become a concern. To meet protein needs, the human milk–fed premature infant needs a protein supplement (see Table 28-16). Growth rates and serum protein and urea nitrogen concentrations in premature infants increase when human milk is fortified with protein to achieve a protein intake of at least 3 to 3.5 g/kg/day.[125] This range of protein intake is adequate assuming that no protein deficit has arisen as a result of a prolonged or deficient parenteral nutrition phase. For this reason, greater intakes of protein may be necessary for premature infants to allow for catch-up protein nutritional support. Thus, intakes closer to 4 g/kg/day, with adequate energy and mineral intakes, often may be indicated.

FAT

Human Milk Lipid Composition The lipid system in human milk is structured in a way that facilitates fat digestion and absorption; there is an organized human milk fat globule containing an outer protein coat and an inner lipid core. The pattern of fatty acids (high in palmitic $C_{16:0}$, oleic $C_{18:1}$, linoleic $C_{18:2\ \omega\text{-}6}$, and linolenic $C_{18:3\ \text{-}3}$), their distribution on the triglyceride molecule ($C_{16:0}$ at the 2-position of the molecule), and the presence of bile salt–stimulated lipase.[126] Because the lipase is heat labile, the superior fat absorption from human milk is reported only when unprocessed milk is fed.[126]

The most variable nutrient component in human milk is fat, the major energy source, comprising nearly 50% of the calories. The fat content of human milk varies among

women, changes during the day, rises slightly during lactation, and increases dramatically within a single milk expression (Table 28-19).[127] The variability in total fat content is unrelated to maternal dietary fat intake. Because it is not homogenized, on standing, the fat separates out of human milk. The separated fat may adhere to collection containers, feeding tubes, and syringes. The loss of fat, therefore, robs the premature infant of needed energy. The greatest losses of fat occur from continuous milk infusion systems. Care should be taken when using the continuous milk infusion system to ensure the inclusion of only a short length of tubing. If the system contains a cassette interface, much of the fat will be lost when the tubing system is changed. Milk infusion systems that use a syringe and small infusion pump, where the syringe is oriented upright, will allow more complete delivery of fat.[128] Fat loss was reduced from 48% to less than 8% with the change in methods of continuous infusion.

Manufacturers of infant formulas modify their fat blends to mimic the fat absorption from human milk. This accounts for the differences in the constituent fatty acids between human milk and cow's milk–based formulas. Generally, commercial formulations have a greater quantity of medium-chain fatty acids (MCFAs) to compensate for the absence of lipase and the unique structure of triglyceride in human milk.[126,129] In human milk, saturated fatty acid, particularly palmitic acid, is esterified in the 2-position of the triglyceride molecule. The end product of digestion of the triglyceride is a 2-monoglyceride and minimal free fatty acid. The 2-monoglyceride is absorbed better than with the free fatty acid. This is important because free palmitic acid has a great tendency to bind with minerals to form soaps. In that case, both fat and mineral absorption would be limited. Thus, the overall structure of human milk is designed to provide optimal fat and mineral absorption.

Hindmilk The variability in the fat content of human milk may be made advantageous for the premature infant. Most milk transfer during a feeding occurs in 10 to 15 minutes, but continued milk expression yields a milk with a progressively higher fat content (hindmilk) than the earlier foremilk. The fat content of hindmilk may be 1.5- to 3-fold greater than that of foremilk. The use of hindmilk in selected cases may provide the premature infant with additional energy. Fractionation of each milk expression into two portions, foremilk and hindmilk, is practical if the mother's milk production is greater than needed by her infant. The additional fat and therefore energy intake from hindmilk has been shown to improve the body weight gain in premature infants.[130] The composition of foremilk and hindmilk has been examined (see Table 28-19). No differences between fractions were observed for the contents of nitrogen, Ca, P, Na, or K. Cu and Zn concentrations declined by approximately 5% from foremilk to hindmilk.

The differences between foremilk and hindmilk also should be considered in terms of the distribution of calories. Fat and protein comprised 42% and 12% of calories in foremilk and 55% and 9% of calories in hindmilk, respectively. Theoretically, the long-term feeding of hindmilk could exert a negative effect on protein status. A greater proportion of protein calories (10 to 12%) is recommended for premature infants. Usual commercial human milk fortifiers (see Tables 28-16 and 28-19), when mixed with hindmilk, raise the proportion of protein calories in hindmilk to approximately 12%. The use of hindmilk, therefore, can be recommended for premature infants whose rate of weight gain is low (below 15 g/kg/day).

TABLE 28-19 Composition of Foremilk and Hindmilk (Mean ± SD)

	Foremilk (U/dL)	*Hindmilk (U/dL)*
Energy (kcal)	63 ± 11	82 ± 8

Essential Fatty Acids The essential fatty acids, linoleic and linolenic acids, are present in ample quantities in human milk and commercial formula. Without an adequate intake of these fatty acids, essential fatty acid deficiency (thrombocytopenia, dermatitis, increased infections, and delayed growth) develops in 1 week. Approximately 0.5 g/kg/day (~4% of total energy intake) of essential fatty acids will prevent the deficiency.[40] Derivatives of linoleic and linolenic acids are arachidonic acid ($C_{20:4\ \omega\text{-}6}$) and docosahexaenoic acid ($C_{22:6\ \omega\text{-}3}$). The very long-chain polyunsaturated fatty acids (LCPUFAs), which are found in human but not bovine milk, are components of phospholipids found in brain, retina, and red blood cell membranes.[131,132] Arachidonic and docosahexaenoic acids functionally have been associated with body growth, vision, and cognition.[132,133] In addition, the fatty acids are integral parts of prostaglandin metabolism. When their diet was supplemented with LCPUFAs, formula-fed premature infants had red blood cell concentrations of $C_{22:6\ \omega\text{-}3}$ that parallel those of similar infants fed human milk.[131] Follow-up studies of such supplemented infants suggest improvements in visual acuity and short-term neurodevelopmental measures compared with unsupplemented infants but of similar magnitude to infants fed human milk.[133–135] The consensus is that premature infants should receive LCPUFAs via either human milk or supplemented formula.

Medium-Chain Fatty Acids The proportion of MCFAs, here defined as carbon length 6:0 to 12:0, is below 12% of total fatty acids in human milk but approaches 50% in preterm formulas (see Table 28-17). MCFAs are not essential fatty acids. Previous reports suggested that MCFA were absorbed passively and to a greater extent than long-chain fatty acids (LCFAs) and affected growth and mineral absorption positively.[136,137] Data comparing premature infants receiving MCFAs at 42% versus 7% of total fatty acids in a

crossover design demonstrated no differences in either the absorption of fat or weight gain.[138] Similarly, no differences in nitrogen retention, weight gain, and energy digestibility, expenditure, and storage were found in premature infants participating in a randomized, crossover study of formulas with MCFAs at 46% versus 4%.[139] Other reports also confirm the lack of effect of MCFAs on weight gain and mineral absorption compared with exclusively LCFA diets.[140] When used in a high proportion, MCFAs may be incompletely oxidized and contribute to increased urinary dicarboxylic acid excretion and metabolic inefficiency compared with LCFAs.[141,142] When added exogenously to milk, MCFAs have been reported to adhere to feeding tubes and diminish fat delivery to the infant.[143] Thus, there are no compelling data to suggest that a high proportion of MCFAs is needed for preterm formulas. Indeed, formulas containing a very high proportion of MCFAs (> 80%) may produce essential fatty acid deficiency if fed for a prolonged period of time.

Carnitine Carnitine is synthesized from lysine and methionine and serves as an important effector of fatty acid oxidation in the mitochondria. The provision of carnitine in the diet results in improved fatty acid oxidation.[57] Human milk contains abundant carnitine, and all infant formulas are supplemented with carnitine.

Carbohydrate

The carbohydrate fraction of human milk is composed of lactose (90 to 95%) and oligosaccharides (5 to 10%). The lactose content of human milk rises from 55 g/L in colostrum to 70 g/L in mature milk. Although studies in term infants demonstrate a small proportion of lactose in the feces, the presence of lactose is assumed to be a normal physiologic effect of feeding human milk. A softer stool consistency, more nonpathogenic bacterial fecal flora, and improved absorption of minerals have been attributed to the presence of small quantities of unabsorbed lactose in feces.[144] Dietary lactose also has been associated with increased mineral absorption.[145] Theoretic concerns that lactose may not be digested adequately by premature infants less than 34 weeks postnatal age may be unfounded as clinical studies indicate that they tolerate the feeding of lactose-containing milk. Premature infants absorb > 90% of the lactose in human milk.[146] The feeding of milk, in particular human milk, in premature infants stimulates intestinal lactase activity compared with no feeding or formula feeding.[109] Thus, early feeding of human milk also may be beneficial to promote better lactose use.

Because of conflicting data regarding lactose use by premature infants, and as a result of attempts to reduce the osmolality of the milk, preterm formulas contain a large proportion of carbohydrate as corn syrup solids (glucose polymers).[145] The usual lactose-to-glucose polymer mixture is 50:50. Glucose polymers are well absorbed by premature infants.

Calcium and Phosphorus

Ca and P are primary components of the skeleton, accounting for 99% and 85%, respectively, of bone mass. The goal for premature infant nutrition is to achieve a bone mineralization pattern similar to the fetus and to avoid osteopenia and fractures. Preterm human milk contains approximately 250 mg/L and 140 mg/L, respectively, of Ca and P.[147] In contrast, the Ca and P content of enteral products designed for premature infants in the United States is significantly greater (see Tables 28-17 and 28-18). In human milk, Ca and P exist in ionized and complexed forms that are easily absorbed. The salts in commercial formulas, however, are relatively insoluble. Thus, in the design of commercial formulas, greater quantities of these minerals are added to compensate for their poorer bioavailability. However, distinct from the term infant, the premature infant requires significantly greater quantities of Ca and P than can be provided in human milk.

For the human milk–fed premature infant, Ca and P intakes are deficient throughout lactation and far below those necessary to achieve respective intrauterine accretion rates.[148] Skeletal radiographs may reveal poor bone mineralization, rickets, and fractures in the premature infant fed human milk.[149] Deficient intakes of Ca and P are associated with biochemical markers, such as low serum and urine P concentrations, elevated serum alkaline phosphatase activity, and elevated serum and urine Ca concentrations.[150] Usually, serum P concentrations are the best indicator of Ca and P status in human milk–fed premature infants.[151] Prolonged deficiency of these minerals tends to stimulate bone resorption to normalize serum Ca concentrations. This bone activity often is correlated with elevated serum alkaline phosphatase activity. It has been reported that the majority of premature infants having an elevated serum alkaline phosphatase activity were those fed human milk.[152] Moreover, follow-up of the same infants at 9 and 18 months noted that linear growth was significantly lower in the group that had the higher serum activity of alkaline phosphatase in the neonatal period.[152] A high alkaline phosphatase value in the neonatal period is a negative predictor of height in 9- to 12-year-old adolescents.[153]

The supplementation of human milk with both Ca and P not only improves the net retention of both minerals but also improves bone mineral content.[154,155] Current management of human milk–fed premature infants emphasizes the need for supplements of both Ca and P.[156] A linear relationship exists between Ca (or P) intake and net retention in enterally fed premature infants.[157] Premature infants receiving unfortified human milk never achieve intrauterine accretion rates for Ca and P. Intakes of Ca and P of approximately 200 and 100 mg/kg/d, respectively, can be achieved with the use of specialized human milk fortifiers and preterm formulas, thus making it possible to meet intrauterine estimates (see Tables 28-17 and 28-18). However, term infant formulas and specialized (not "preterm") formulas provide inadequate quantities of Ca and P to meet the needs of growing premature infants (see Table 28-18). Several factors affect the absorption of Ca and P, including postnatal age and intake of Ca, P, lactose, fat, and vitamin D. Vitamin D, however, is responsible for only a small component of Ca absorption in premature infants.[158]

The time to supply sufficient Ca and P stores for premature infants is during the initial hospitalization, before their discharge and the beginning of exclusive breastfeeding. However, because of prolonged parenteral nutrition and the inability to provide "catch-up" quantities of Ca and P in milks, some infants may benefit from additional Ca and P after hospital discharge.

Magnesium

Approximately 60% of body Mg is in bone. Preterm human milk contains approximately 30 mg/L of Mg.[147] The absorption of Mg is significantly greater in unfortified human milk (73%) compared with formula (48%).[157] Net Mg retention in human milk–fed premature infants meets intrauterine estimates. Thus, the data from balance studies and biochemical monitoring suggest that Mg supplements are not needed for premature infants fed human milk.[159] Similar studies in premature infants fed preterm formulas indicate that, despite lower absorption compared with human milk, intrauterine estimates for Mg accretion are surpassed.

Trace Elements

Zinc Several factors affect the zinc needs for the enterally fed premature infant. Fetal accretion of zinc is approximately 0.85 mg/kg/day. Growth is a major determinant of zinc needs. The major excretory route is via the gastrointestinal tract. Infants with large gastrointestinal fluid losses may become Zn deficient. Premature infants receiving pooled pasteurized human milk (Zn intake approximately 0.7 mg/kg/day) are in negative Zn balance for 60 days postnatally and never meet the intrauterine accretion rate.[160] In contrast, intakes of 1.8 to 2 mg/kg/day are associated with net retention of Zn that surpasses intrauterine accretion rates.[161–163] The classic signs of Zn deficiency include an erythematous skin rash involving perioral, perineal, and facial areas, as well as the extremities.[123] Although there are limitations to the assay, plasma Zn values < 50 μg/dL are highly suggestive of deficiency.[123] A very low serum alkaline phosphatase activity, a Zn-dependent enzyme, also is suggestive of deficiency. Reports of symptomatic Zn deficiency in unsupplemented human milk–fed premature infants remind us of the decline in milk Zn concentration as lactation advances. The infants reported to be Zn deficient were several months of age.[164]

Copper There are no universally accepted methods to assess Cu status clinically. Balance study data provide only an estimate of Cu retention at one point in time. Premature infants receiving pooled pasteurized human milk (Cu intakes approximately 85 μg/kg/day) are in negative Cu balance for 30 days postnatally and never meet the intrauterine accretion rate.[160] Fortified human milk provides a Cu intake of as much as 180 μg/kg/day, and balance study data surpass intrauterine accretion rates.[163] Cu retention is quite variable from formula providing intakes of 200 to 300 μg/kg/day.[161,163] Several premature infants with those intakes, however, achieve the intrauterine accretion rate. Symptoms of Cu deficiency include osteopenia, neutropenia, and hypochromic anemia. As Cu is excreted in bile, cases of severe cholestasis warrant limiting Cu intakes.

Iron The iron (Fe) needs of the premature infant are determined by birth weight, initial hemoglobin, rate of growth, and magnitude of Fe loss and/or transfused blood.[123] There are three phases of postnatal Fe metabolism. In the first phase, there is decreased erythropoiesis. The hemoglobin concentration declines to a nadir, "physiologic anemia of prematurity," which is at approximately 2 to 3 months postnatal age. In the second phase, the hemoglobin rises as active red cell production is occurring. This phase needs Fe. The third phase is an exhaustion of Fe stores, or "late anemia of prematurity," observed if Fe supplementation is inadequate.[123]

The concentration of Fe in human milk declines through lactation, from approximately 0.6 mg/L at 2 weeks to 0.3 mg/L after 5 months of lactation.[165] The absorption of Fe is affected adversely by blood transfusion.[166] Premature infants fed human milk are in negative Fe balance, which, if untransfused, corrects with Fe supplements.[166] Fe absorption also appears to be facilitated by a modest degree of anemia.[167] Thus, the usual recommendations for premature infants suggest delaying Fe supplementation until 2 to 3 months postnatal age, a time when hemoglobin concentrations are at a nadir.[168] However, the provision of small doses of Fe at 2 mg/kg/day beginning 2 weeks postnatally has been demonstrated, in the absence of blood transfusions, to prevent the development of Fe deficiency at 3 months postnatal age.[168] When recombinant erythropoietin for the treatment of anemia of prematurity is used, higher doses of Fe are needed, in the range of 6 mg/kg/day, to support the more rapid rate of erythropoiesis.[169]

Generally, ferrous sulfate (25 mg/mL, 2 mg/kg/day) drops are used in human milk–fed premature infants beginning soon after the achievement of complete enteral feedings. Formula-fed premature infants should receive Fe-fortified formula from the onset of milk feeding.

Sodium and Potassium Premature infants generally need more Na per unit body weight than term infants.[123] This is attributable to immature renal Na conservation mechanisms. Na wasting is inversely related to gestational age. A comparison of Na intakes of 2.9 and 1.6 mEq (mmol)/kg/day in premature infants suggested that the former intake provided more appropriate serum Na concentrations.[170] Hyponatremia also may occur in premature infants primarily fed human milk because the Na content of preterm milk continues to decline through lactation.[170] The need for these electrolytes may increase during or after diuretic use.

Vitamins Fat-soluble vitamins, A, D, E, and K, are stored in the body, and large doses may result in toxicity. Water-soluble vitamins, thiamin, riboflavin, niacin, vitamin B_6, folate, vitamin B_{12}, pantothenic acid, biotin, and vitamin C, are not stored in the body, and excess intakes are excreted in the urine or bile (vitamin B_{12}). The intake of water-sol-

uble vitamins, therefore, should be at frequent intervals to avoid deficiency states. Vitamin A and riboflavin concentrations decline in human milk under conditions of light exposure and after passage through feeding tubes.[79] As a consequence of exposure to air, ascorbic acid concentrations are lower in pooled human milk.[171] Supplementary vitamins are provided in human milk fortifiers and in preterm formulas.[172] There is no indication for additional multivitamin supplements for infants receiving adequate intakes of fortified human milk, preterm formula, or enriched formula. Once the premature infant transitions to unfortified human milk or standard formula, a multivitamin supplement should be added. The supplemental vitamins should be continued until the infant is consuming 300 kcal/day or weighs more than 2.5 kg.

HUMAN MILK

The American Academy of Pediatrics acknowledges that human milk also is beneficial in the management of premature infants.[173] The beneficial effects generally relate to improvements in host defenses, digestion and absorption of nutrients, gastrointestinal function, neurodevelopment, and maternal psychological well-being. However, the special needs of the premature infant that arise as a result of metabolic and gastrointestinal immaturity, immunologic compromise, and associated medical conditions must be considered so that adequate nutrition can be provided to meet the needs for intrauterine rates of growth and nutrient accretion. Human milk is capable of satisfying most of the needs of premature infants if careful attention is given to nutritional status.

Benefits of Unfortified Human Milk

Clinical studies in nurseries throughout the world have suggested a decrease in the rate of a variety of infections, including sepsis, necrotizing enterocolitis, and urinary tract infection, in premature infants fed human milk compared with the feeding of formula.[174,175]

Necrotizing enterocolitis, the devastating acute intestinal inflammatory disease in premature infants, appears less frequently when the prior diet is human milk compared with formula. A large, nonrandomized study of hospitalized premature infants reported that the incidence of necrotizing enterocolitis was significantly lower in infants fed human milk, either exclusively or partially, compared with infants fed formula.[176] That study reported clinical cases as well as cases confirmed at surgery or autopsy, and in both circumstances, the incidence of necrotizing enterocolitis was significantly greater in premature infants solely fed formula. These data provide some encouragement for the potential prevention of necrotizing enterocolitis.

Specific factors such as secretory IgA, lactoferrin, lysozyme, oligosaccharides, cytokines (such as interleukin-10), enzymes (such as acetylhydrolase), growth factors (such as epidermal growth factor), and cellular components may affect the host defense of the premature infant. One of the major protective effects of human milk on the recipient infant operates through the enteromammary immune system. It is reasonable to expect that exposure of the mother to the environment of the neonatal nursery through skin-to-skin contact with her premature infant may be advantageous to the infant. In this manner, mothers potentially might be "induced" to make specific antibodies against the nosocomial pathogens in the nursery environment.

Limitations in the Use of Unfortified Human Milk

A major impediment in advocating human milk for premature infants is the difficulty many mothers experience in providing sufficient quantities of milk. Several explanations have been given for the low milk production, including biologic immaturity of the mammary gland, maternal stress and/or illness, and difficulty maintaining a supply without a suckling infant. Another reason of concern is that nutrient intake is limited by milk volume restrictions imposed on the premature infant because they cannot feed ad libitum and also because their medical condition warrants fluid restriction. The most compelling reason for concern is that nutrient intake is inadequate to meet the very great needs of the premature infant. Unfortified human milk may not supply sufficient quantities of nutrients for several reasons. Because of differences in the methods of milk expression and storage, the feeding of "spot" samples (individual samples of expressed milk from one or both breasts or milk partially expressed from one breast), the use of feeding tubes, and the differences in length of lactation, there is a large variation in the macronutrient composition of human milk used in feeding premature infants. Much of the variation in energy content, for example, is a result of differences in fat content of the unfortified milk (2.2 to 4.7 g/dL).

There also are significant declines in the contents of protein and sodium through lactation.[177] The content of other nutrients (Ca, P) is too low to meet the great needs of the premature infant. In addition, technical reasons associated with the collection, storage, and delivery of milk to the infant also result in a decreased quantity of available nutrients (fat, vitamin C, vitamin A, riboflavin). Given the reasons cited, it should not be a surprise that inadequacies of Ca, P, protein, Na, vitamins, and energy are observed in the premature infant fed unfortified human milk. Thus, the exclusive feeding of unfortified human milk in premature infants, generally infants with birth weights less than 1,500 g, has been associated with poorer rates of growth and nutritional deficits, during and beyond the period of hospitalization.[124,146,150,178,179]

Human Milk Fortification

Growth and nutrient deficits in the premature infant can be improved with the addition to human milk of multinutrient nutrient supplements, or fortifiers.[125,155,180,181] Mineral supplementation during hospitalization prevents a decrease in linear growth and increases bone mineralization during and beyond the neonatal period.[182] Supplementation with both Ca and P results in normalization of biochemical indices of mineral status: serum Ca, P, and alkaline phosphatase activity and urinary excretion of Ca

and P.[156] Na supplementation results in normalization of serum Na.[183] Protein and energy supplementation is associated with improved rates of weight gain and indices of protein nutritional status: blood urea nitrogen, serum albumin, and transthyretin.[124,125]

Current practice suggests the use of multinutrient fortification of human milk. Nutritional outcomes of feeding fortified human milk in the United States indicate that premature infants receive less volume but greater intakes of protein and minerals and experience greater gain in weight and increment in linear growth than infants fed unfortified human milk exclusively.[159,163,181,184] Balance study data indicate that the use of fortified human milk results in net nutrient retention that approaches or is greater than expected intrauterine rates of accretion. Fat absorption, however, with the use of some fortifiers has been lower than expected.[2,156] Fat absorption may be augmented by newer human milk fortifiers, which contain fat.[185]

Questions have been raised as to whether the addition of bovine-derived human milk fortifiers affects feeding tolerance in premature infants. Gastric residual volumes often are used to assess feeding tolerance. When compared throughout hospitalization, the use of fortified human milk was not associated with feeding intolerance, as manifest by abdominal distention, vomiting, changes in stool frequency, or volume of gastric aspirate when compared with control-supplemented human milk.[183] Comparisons with preterm formula also have been made, and no major differences in feeding tolerance have been attributed to human milk fortification.[163,186]

A major concern with human milk fortification is that the added nutrients may affect the complex system of host defense. The effects of nutrient fortification on some of the general host defense properties of the milk have been evaluated.[187] Fortification did not affect the concentration of IgA. Bacterial colony counts do not increase with 24 hours of refrigerator storage of fortified human milk.

The relationship between the feeding of fortified human milk and the incidence of illness (infection and necrotizing enterocolitis) in premature infants has been examined. Human milk–fed infants had a 26% incidence of documented infection compared with 49% in formula-fed infants.[188] The use of fortified human milk was not associated with either confirmed infection or necrotizing enterocolitis compared with control-supplemented human milk.[183] When the latter two events were combined, however, the group fed fortified human milk had more events than the control-supplement group. Although it is difficult to conclude that the use of fortifiers is harmful, these data indicate the need for continued surveillance of these events.[189]

In a comparison with preterm formula, premature infants fed exclusively fortified human milk had a significantly lower incidence of necrotizing enterocolitis and/or late-onset sepsis, fewer positive blood cultures, and less antibiotic use than those fed preterm formula.[163] Infants fed exclusively fortified human milk had more episodes of skin-to-skin contact with their mothers and a shorter duration of hospitalization. These data suggest that feeding premature infants fortified human milk had a marked effect on the cost of medical care. The data further suggest that skin-to-skin contact may promote an enteromammary response in the premature infant. It may well become the practice to encourage mothers to practice skin-to-skin contact to enhance their capacity to synthesize specific factors that counter the pathogens in the nursery environment.

Comparison of Human Milk Fortifiers

Human milk fortifiers are designed to be mixed with human milk. A variety of fortifiers are available globally, but no head-to-head comparison has been published. Most fortifiers are powdered nutrient preparations that contain protein, carbohydrate, Ca, P, Mg, and Na; the contents of Zn, Cu, and vitamins are variable (Table 28-20). Inherent in the design is the adequacy of mother's milk production to meet the needs of the infant. The use of pasteurized donor human milk has not been advocated routinely because of concerns with contamination, lack of sufficient supply, and cost. If there is an inadequate amount of mother's milk, two options currently are available: alter-

TABLE 28-20 Comparison of Selected Fortifiers for Human Milk*

No = no additional vitamins added.

nate the feeding of fortified human milk with preterm formula and mix mother's milk with preterm formula.

One study examined the nutrient adequacy of a liquid human milk fortifier mixing a preterm formula 1:1 with human milk.[190] Nitrogen, energy, Ca, and P retentions were below intrauterine rates of accretion. More beneficial outcomes may be observed if preterm formula is alternately fed with fortified mother's milk.

FEEDING TOLERANCE

The ability to tolerate enteral feedings is a major problem for premature infants. Moreover, the infants' tolerance of enteral feeding is a primary concern of neonatologists because it affects their decision to initiate, advance, and discontinue feedings. Because of these concerns, feeding intolerance may be a major factor affecting the duration of hospitalization. The fetus experiences swallowing of amniotic fluid from early gestation, but, postnatally, many premature neonates do not appear to share as "simple" a tolerance for enteral fluid, even dilute fluid mixtures. Several factors affect how feedings are tolerated: immature intestinal motility, digestive enzyme immaturity, medical complications, too great a volume intake, and hyperosmolar medications/feedings.

Despite its importance, there are no universally agreed on criteria to judge feeding tolerance in premature infants. Clinical criteria of feeding tolerance (Table 28-21) generally include physical examination findings of abdominal distention and abdominal tenderness, presence or absence and quality of bowel sounds, and signs of residual gastric fluid aspirated from the feeding tube just prior to the next feeding, emesis, and changes in stool output.[191] There are associated signs that occasionally suggest intolerance to a feeding. These associated signs include increased episodes of apnea and bradycardia, diminished oxygen saturation (desaturation events), and lethargy.

The gastric residual volume, usually measured prior to the next feeding, is an indication of milk remaining in the stomach several hours after a feeding.[192] The gastric residual volume indicates the rapidity of gastric emptying and appears to be a final common pathway, such that changes in the clinical examination may result in decreases in gastric emptying. The nonspecific nature of this assessment is that changes in the clinical examination may or may not be related to intestinal pathology. Gastric residual volume has been quantitated on the basis of body weight (eg, an abnormal sign being > 2 mL/kg per feeding) or on the volume of feeding (eg, > 50% of 3 hours of feeding).[108] Some premature infants have measurable gastric residual volumes before every feeding, whereas others never have any measurable volume. In the latter infants, therefore, any small change might indicate a change in the feeding tolerance. Furthermore, it would be expected that gastric residual volume would be difficult to interpret in infants receiving continuous gastric milk infusions. Such is not always true as these infants generally empty their stomachs rapidly and should still be evaluated every 2 to 4 hours in a similar manner as infants fed by the intermittent bolus technique.[108]

The quality of the gastric residual also has been discussed as a tool to determine feeding tolerance. Gastric residuals that are green, or bilious, could indicate intestinal obstruction but more often indicate overdistention of the stomach and retrograde reflux of bile into the stomach. A blood-tinged residual could indicate an inflammatory process but may indicate a slight mucosal irritation from the indwelling gastric tube.

Unfortunately, the aforementioned criteria have little prognostic significance. Infants having more gastric residuals and emesis episodes were just as likely to reach the milestone of full enteral tube feeding than infants not having any increases in these measurements.[186]

Most clinicians use the pattern of the above criteria, as opposed to a single measurement, as an aid to determine feeding status. Several instances will occur in which infants' feedings are withheld because of one or more of the above signs. Often a single feeding is discarded. Careful assessment and examination prior to the next feeding generally aid the decision to continue feedings. A withheld feeding, however, does not imply that further enteral feeding should be terminated. Too often, feedings are withheld for prolonged periods of time, which hastens the complications of parenteral nutrition and intestinal atrophy. The evaluation of the infant with a large gastric residual, for example, would include the following considerations: Has the medical condition worsened, such that gastric emptying is delayed owing to systemic disease? Is the infant's feeding tube in the correct location? If the feeding tube is high in the esophagus or too small a caliber, then swallowed air may not be evacuated. Large amounts of swallowed air may cause gastric overdistention and displace milk, resulting in emesis and/or large residuals. Body positioning also may play a role. Gastric emptying in some infants is improved by their being in the prone position or in the right lateral decubitus position compared with the supine position. At times, intolerance is corrected by lowering milk intake somewhat.

TABLE 28-21 Potential Indices Used to Assess Feeding Tolerance in Low Birth Weight Infants

Stool output
Increased frequency
Decreased frequency
Feeding withheld
Document reasons feedings withheld
Assess number of feedings held
Clinical condition
Any worsening in previous medical condition

FEEDING METHODS

Tube feeding is an essential tool in enteral nutrition because the premature infant may be unable to suck and/or coordinate suck-swallow-breathe. There are a variety of methods for tube feeding, continuous or intermittent bolus, and a number of approaches, orogastric, nasogastric, transpyloric, or gastrostomy. The selection of practice relates to the duration of the proposed therapy: premature infants eventually will suckle, so a temporary oro(naso)gastric tube is used; infants with major congenital anomalies may require a semipermanent gastrostomy.

The bolus feeding method mimics the normal adult feed-fast routine and has greater hormonal responses than continuous infusions.[193] The bolus technique does not require an infusion pump. Differences between continuous and intermittent bolus methods have been evaluated. Premature infants had more feeding intolerance and a slower rate of weight gain with continuous infusion compared with the bolus technique.[108] Neither method enhanced nutrient absorption.

Occasionally, intolerance is observed in the bolus-fed premature infant. In some instances, duodenal motility decreases following the bolus feeding.[194] A bolus feeding given over a longer time interval, such as 30 minutes to 120 minutes, results in a return of motility and improved tolerance. The continuous infusion technique has been associated with increased nutrient absorption in infants with gastrointestinal disease.[195] It seems prudent to use this method in infants who have had intestinal surgery and for infants receiving milk via a transpyloric tube. In some infants with persistent gastric residuals or emesis in absence of obvious intestinal pathology, the use of transpyloric feeding has been successful.

FEEDING ISSUES

Enteral feeding and concomitant use of an umbilical arterial catheter have been a subject of much concern. However, most infants had an indwelling umbilical arterial catheter in the recent studies of gastrointestinal priming, and no untoward events were reported.[104,108] Infants were no more likely to develop intolerance or necrotizing enterocolitis if they received enteral feedings while they had an umbilical arterial catheter in place than if they received enteral feeding 24 hours after the catheter was removed.[111] Moreover, fewer evaluations for sepsis and less use of central venous catheters were observed in the group receiving feeding while the catheter was in place. Thus, there appears to be no increased risk of enteral feeding while an umbilical arterial catheter is in place as long as the catheter is functioning optimally.

The use of diluted milks has been suggested for feeding premature infants. In one study, however, intestinal motility responses to feeding were initiated earlier and persisted longer following the use of full-strength formula compared with one-third and two-thirds dilutions of the formula.[196] The use of water for enteral feeding also has been shown not to affect intestinal motility compared with milk.[197] Thus, initiating feedings with full-strength milk appears to be tolerated and appropriate.

The advancement of daily feeding volumes also has been investigated, especially with respect to the development of necrotizing enterocolitis. When compared with matched case controls, infants with necrotizing enterocolitis were more likely to have received enteral nutrition with daily intakes > 20 mL/kg, averaging 46 mL/kg.[198] One study compared the morbidity of low birth weight infants whose daily increment in feeding volume was 15 or 35 mL/kg/day.[199] The infants whose feedings were advanced rapidly had a shorter duration of time to achieve full tube feeding and regain birth weight and no difference in morbidity than infants whose feedings were advanced slowly.

NUTRITION ASSESSMENT

Neonatal nutritional assessment is an emerging interest that requires a knowledge of both nutritional biochemistry and neonatal medical conditions. The nutritionist is a key person to provide input, on a daily basis, that is compatible with the medical condition of the infant.

The nutritional status of the premature infant is monitored by daily assessments of fluid and energy intake and evaluating the rate of growth in weight, length, and head circumference (Table 28-22). Growth parameters are plotted on graph paper or a specific chart for current premature infants' growth. The charts are helpful, but equally important is the computation of the weekly rate of growth (Table 28-23).[200] Once the infant reaches 2.5 kg, a daily weight gain of 20 to 30 g/day is appropriate.

The nutritional status of the premature infant also is monitored by serial evaluations of biochemical indices. These assessments include serum Ca, P, and alkaline phosphatase activity to assess bone mineral status and albumin

TABLE 28-22 Nutritional Assessment of the Enterally Fed Premature Infant

Length gain	0.7–1.0 cm/wk
Head circumference gain	0.7–1.0 cm/wk

and urea nitrogen to assess protein status. If more specific indices of protein status are needed, as in the case in which additional protein supplementation is used, the serum prealbumin (transthyretin) is measured before and 1 week after the supplementation. Serum Na, chloride, and bicarbonate are evaluated in infants receiving diuretics, those whose intakes are limited, or those with slow growth. The hemoglobin and reticulocyte count are monitored to assess anemia. Specific determinations of plasma Zn and Cur are not routinely useful, but Zn may be measured in infants with unusual losses, such as after gastrointestinal surgery and from enterostomies. The pattern of changes in biochemical indices may be more reflective of nutritional status than isolated values. Occasionally, renal ultrasonography to determine the presence of nephrocalcinosis and wrist radiography to identify rickets are warranted.

SUMMARY OF NUTRITION SUPPORT

A comprehensive nutrition pathway for LBW infants has been described. The approach is multifaceted, beginning with intravenous nutrition, transitioning via trophic feeding to enteral nutrition, and continuing to full enteral feeding and hospital discharge. This approach does not increase the risks already associated with LBW infants. Indeed, the use of an aggressive approach to nutritional support has resulted in improved growth, with fewer infants falling below the 10th percentile in standard growth charts.[201] Although improvements are found in growth, no increase in sepsis or necrotizing enterocolitis is associated with the more aggressive approach to nutritional support.[201]

GOALS OF INFANT FEEDING

The goals of infant feeding are to meet all nutritional needs, to aid mother–infant bonding, to aid the infant in making the transition from the predominantly liquid diet of the infant to the predominantly solid food diet of the child and adult, and to aid in establishing habits of eating in moderation. The goals can best be met by breast-feeding. However, in industrialized countries, feeding of commercially available infant formulas, although not ideal, is an acceptable substitute. Breast-feeding, besides meeting all nutritional needs, offers protection against infectious illnesses, may foster optimal neurocognitive development, and may offer some protection against conditions in adulthood such as obesity and atherosclerosis. Whether feeding practices during infancy can aid in establishing the goal of eating in moderation is unknown. Nevertheless, in various animal models, habits established during infancy have been difficult to extinguish later in life, and it therefore seems plausible that satiety signals can be reinforced if an infant is encouraged to discontinue nursing from the breast or bottle at the earliest sign of willingness to do so.

TRENDS IN INFANT FEEDING

Historically, in situations in which breast-feeding was not possible, survival of the infant was in jeopardy. The feeding of preparations based on various mammalian milks was associated with high morbidity and mortality. Success at formula feeding gradually improved from the end of the nineteenth century through the first half of the twentieth century. The objective was to make available safe and effective feedings for situations in which breast milk was not available. In the 1920s, the use of evaporated milk for formula preparation together with a number of improvements in formula preparation and storage contributed to successful formula feeding. By the 1950s, formulas reached a point at which they provided adequate nutrition and appeared to be reasonably safe. In the absence of convincing evidence of the inferiority of formula feeding, many parents and physicians adopted formula feeding, presumably because of the supposed greater convenience. The prevalence of formula feeding increased and the prevalence of breast-feeding decreased.

The decrease in the prevalence of breast-feeding was associated with earlier introduction into the infant's diet of beikost (foods other than milk or formula fed to infants) and cow's milk. By the end of the 1950s, feeding of beikost was common during the first month of life, and most infants were fed beikost before the end of the second month of life. Whole- or reduced-fat cow's milk commonly replaced formula by 4 to 6 months of age.[1]

A resurgence of breast-feeding began about 1971 (Figure 29-1).[2] The reasons for the initial increase in breast-feeding prevalence are poorly understood. But enthusiasm for breast-feeding was sustained, at least in part, by the ever-increasing number of reports on the demonstrated or assumed advantages of breast-feeding. As Figure 29-2 indicates, in 2001, about 70% of infants were breast-fed for at least some time.[3] The relatively quick decrease in breast-feeding prevalence with age is at least partially explained by mothers returning to work. Despite the pressures of work, the number of women who breast-feed for 6 months and longer has continued to increase.

In association with the increase in breast-feeding, infants were increasingly fed formula after cessation of breast-feeding (Figure 29-3).[4] Thus, formula feeding largely displaced feeding of cow's milk in older infants (Figure 29-4).[4] Also, beikost was less commonly fed during the early months of life, and it is now very uncommon to see beikost fed before 4 months of age.

TRENDS IN FORMULA COMPOSITION

The formulas fed in the United States in the late 1920s were generally prepared in the home with evaporated milk or fresh cow's milk and sugar. The protein content was considerably greater than that of current formulas, the fat was butterfat, the added carbohydrate was corn syrup or sucrose, and neither vitamins nor minerals were added. Prepared powdered formulas (to be diluted with water before use) were available, but their use was quite limited until the 1950s. With the introduction of concentrated liquid formulas (requiring only the addition of an equal volume of water before use), commercially prepared formulas gradually replaced home-prepared formulas. Over the years, formulas underwent a number of changes: the protein content was decreased, and whey proteins were included to result in a whey-to-casein ratio more like that of human milk; vegetable oils replaced butterfat; the added carbohydrate was lactose rather than corn syrup; and vita-

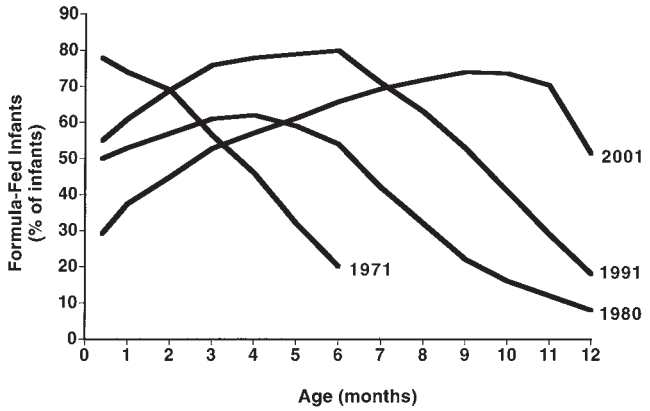

FIGURE 29-3 Formula-fed infants (including infants also breast-fed) as percentage of all infants in 1971, 1980, 1991, and 2001. Data for 1971 and 1980 from Martinez GA et al[4]; data for 1991 based on personal communication from Ross Mothers Survey (Greenbaum S, 1992, Ross Products Division, Columbus, OH); data for 2001 from Mead Johnson Nutritionals, Evansville, IN (J. A. Boettcher, personal communication, 2002).

mins and minerals were included. See below for detailed composition of currently available formulas.

NUTRIENT REQUIREMENTS

The approach to estimating nutrient requirements of the infant differs considerably from that for adults. The normal adult requires regular intake of energy and specific nutrients to maintain the size and composition of the body (ie, requirements for "maintenance"), whereas infants and young children need, in addition, energy and nutrients for growth. The ratio of need for growth to need for maintenance is greatest for the fetus, the rapidly growing preterm infant, and the term infant during the early months of life. Therefore, to obtain reasonable estimates of the requirements for energy and nutrients of the infant, it is desirable to have quantitative data on the increments in energy storage and the increments in specific nutrients needed for synthesis of new tissue. Defining the requirements of energy or nutrients for growth is much less important for children over the age of 2 years and for adolescents because, by then, the requirements for growth are quite small fractions of total requirements.

Thus, from a nutritional point of view, rapid growth is what differentiates infancy from all other ages. Nutrient requirements are exceedingly high primarily because of nutrients needed to support rapid growth. But growth is not only very rapid, it also changes dramatically in velocity as well as in composition. These dynamic changes are illustrated in Figure 29-5, which depicts rate as well as

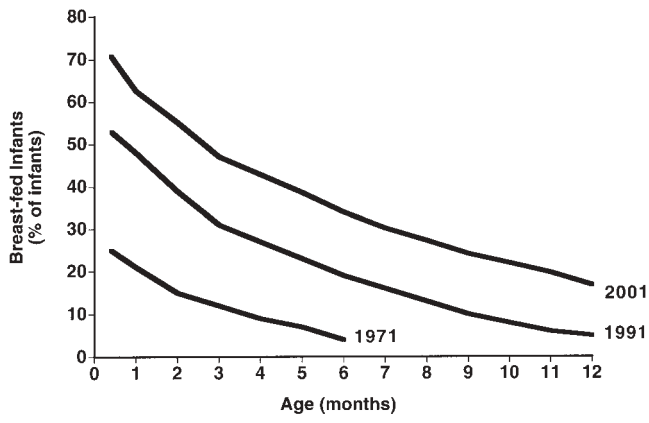

FIGURE 29-2 Exclusively and partially breast-fed infants as a percentage of all infants in 1971, 1991, and 2001. Data for 1971 from Martinez GA and Nalezienski JP[3] and for 1991 based on personal communication from Ross Mothers Survey (Greenbaum S, 1992, Ross Products Division, Columbus, OH); data for 2001 from Mead Johnson Nutritionals, Evansville, IN (J. A. Boettcher, personal communication, 2002).

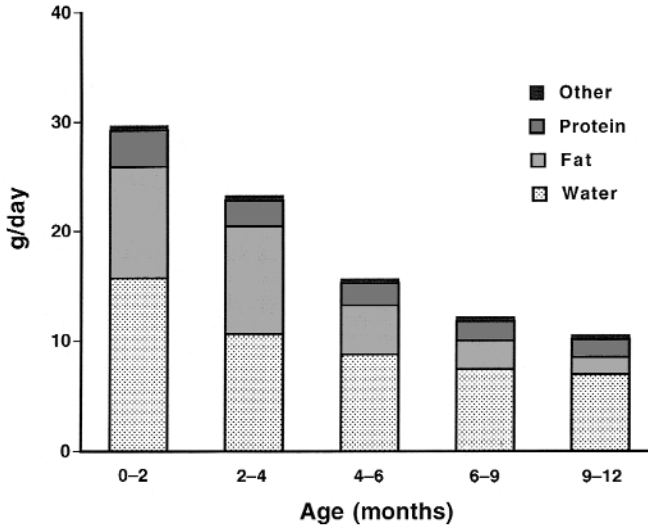

FIGURE 29-5 Gain in weight and in major body components of a "reference infant" (an infant with weight and length and body composition at the 50th percentile for age). Adapted from Fomon SJ and Nelson SE.[5]

composition of growth of a "reference infant."[5] The rapid decline in the rate of growth during the first year of life is readily appreciated. It is also evident that during the first 4 months of life, infants deposit large amounts of body fat. During that period, fat accounts for as much as 40% of weight gain, and the energy necessary for deposition of this fat accounts for about 20% of energy requirements. Toward the end of the first year of life, fat deposition slows down markedly, and so does the proportion of energy requirement explained by fat deposition. Although accretion of protein as a percentage of weight gain increases with age, absolute protein accretion is highest during the first 2 months of life.

Nutrient requirements of infants are obtained chiefly by two methods: the observational method and the factorial method. Each approach has its difficulties and limitations. The observational method relies on the model of the breast-fed infant. The main difficulty with this approach is the determination of representative concentrations of nutrients in breast milk. Concentrations of many nutrients change markedly with the duration of lactation and are in many cases influenced by maternal dietary intakes. Also, the breast-fed infant is not a reliable model in the case of certain nutrients, such as iron, that are not provided in breast milk in amounts that meet the infant's needs. The factorial method yields good estimates for certain nutrients, such as protein, for which estimates of rates of accretion by the infant are available. Nutrient requirements, largely because of the dynamic changes of the needs for growth, are strongly age dependent. Stating nutrient requirements in relation to energy requirements diminishes the age dependency of nutrient requirements somewhat but does not eliminate it completely.

Energy Requirement

Because the infant possesses the ability to self-regulate energy intake, it may be assumed that energy intakes observed in infants receiving feedings with normal energy density represent energy requirements. Table 29-1 presents energy intakes observed in breast-fed and formula-fed infants.[6] The data illustrate the markedly higher energy intakes during the early months of life compared with later infancy, a reflection of the deposition of large amounts of fat as energy stores. The data also show that formula-fed infants consume somewhat more energy than breast-fed infants, especially during the first 3 months of life. Therein may lie (part of) the reason for the somewhat more rapid growth of formula-fed infants. Gender-related differences in energy intake, although quite small, are nevertheless consistently present.

Protein Requirement

Table 29-2 presents estimates of requirements for protein by the factorial method as well as protein intakes observed in breast-fed infants.[7] The close agreement between the factorial estimate and observed intake is striking. During the first month of life, growth accounts for over 50% of protein requirement. But by the end of the first year of life, the proportion needed for growth is less than 20%.

THE BREAST-FED INFANT

Energy and Protein Intakes

The breast-fed infant receives water, energy, and specific nutrients in amounts that meet the needs of the infant at

9–12	92	92				

Adapted from Fomon SJ and Bell EF.[6]

all times, notwithstanding the fact that the needs change with the age of the infant. A prime example is protein. Through a combination of a sharp decrease in protein concentration and an increase in milk volume, a close match between intake of protein and protein requirement is achieved (see Table 29-2). In the case of energy, the content of which in breast milk does not change with the duration of lactation, the match between intake and need (see Table 29-1) is achieved solely through a decrease in volume of milk consumed per kilogram of body weight. Most other nutrients fall somewhere between protein and energy, that is, a match between intake and need is brought about through a combination of concentration changes and volume increase. Formulas, on the other hand, must be designed to meet the highest possible needs, that is, those of the youngest infants in the target age group. Consequently, as the infant grows, nutrient intakes from formulas exceed needs by an increasing margin.

Although it is well established that infants generally do not obtain all of the milk that is synthesized by the mammary gland,[8] the cause of the failure to consume all of the available milk is not known. One possible reason is infant fatigue because the process of obtaining milk from the breast requires considerable effort on the part of the infant. Whatever the mechanism may be, failure to consume all available milk may be one of the reasons why breast-fed infants consistently consume less energy than formula-fed infants, as shown in Table 29-1. It has been surmised that because the milk remaining in the breast is not visible to the mother, contrary to formula remaining in the bottle, she may be more prone to stop feeding at the earliest sign of satiety on the part of the infant than if the infant is fed by bottle.

Growth

Formula-fed infants grow more rapidly than breast-fed infants.[9,10] Differences in energy consumption may explain the difference in growth. However, inconsistent with this explanation is the fact that growth is similar during the first 6 weeks of life and only begins to differ significantly thereafter,[9] whereas the difference in energy consumption seems to be largest during the first 2 months of life. Therefore, there may be other explanations. When the average intake is close to the average requirement for a nutrient, there is the likelihood that for some individuals, intake falls short of requirement. That is the case for protein (see Table 29-2) and also for zinc,[11] a nutrient whose deficient intake can limit growth. Thus, it is possible that inadequate intakes of protein or zinc, or both, occur among breast-fed infants and explain the slower growth. But it must be stressed that the reason for the growth differential is not actually known. By the same token, it is not known whether there are any long-term consequences, beneficial or detrimental, owing to the slower growth of breast-fed infants or to the lower nutrient intake that may be causing it.

Flavor

Breast milk contains a variety of flavoring substances derived from the maternal diet, and there is clear evidence that the infant recognizes flavors and responds to them.[12] Thus, contrary to the formula-fed infant, the breast-fed infant is exposed to a variety of tastes from the earliest age. The nutritional significance of early exposure to flavor variety, perhaps even in the long term, is that it leads to greater acceptance and apparent enjoyment of novel flavors later on.[13,14]

Oligosaccharides

Breast milk contains substantial amounts (5 to 8 g/L) of oligosaccharides, a complex group of substances derived from lactose.[15,16] These oligosaccharides share similarities with epithelial cell surface carbohydrates and adhesion molecules. They exert a number of important functions, from blocking the adhesion of bacteria to intestinal cell surfaces[17] to being responsible for the predominance of the bifidus flora in the breast-fed infant. Consonant with these important functions is the fact that oligosaccharides are only minimally digested in the upper gastrointestinal tract and undergo fermentation in the colon, thereby accounting for much of the hydrogen gas that is exhaled by breast-fed infants.

Iron

Most infants are born with generous iron stores that render him/her independent of an exogenous supply of iron for the first 5 to 6 months of life. Breast milk provides a small amount of highly bioavailable iron that allows the infant to absorb about 0.15 mg each day. Beginning when iron stores are exhausted around 5 to 6 months of age, the infant needs to absorb approximately 0.75 mg each day to avoid iron deficiency. Because breast milk provides only about

0.15 mg/day of absorbed iron, the infant must absorb about 0.6 mg/day from other sources. Except for meat, which provides a highly bioavailable form of iron (heme iron), the natural iron content of most foods fed as beikost is low. Therefore, the breast-fed infant can obtain an adequate intake of iron, besides meat, only from iron-fortified foods such as infant cereals. Other options for securing an adequate iron intake include medicinal iron and iron-fortified formula. Although none of these options have ever been demonstrated to be effective in preventing iron deficiency during prolonged breast-feeding, prudence nevertheless dictates that attention be paid to ensuring an adequate intake of iron for breast-fed infants. Concerns that exogenous iron might exert adverse effects on the infant are theoretic in nature.

Some infants are born with diminished iron stores[18] and may become dependent on an exogenous iron supply sooner than infants born with more generous iron stores. Because these infants may be particularly prone to developing iron deficiency, it is advisable to start ensuring an adequate iron intake for all infants beginning at 4 months of age.

FORMULAS

Formulas provide macronutrients and micronutrients in amounts and proportions that permit infants to grow normally. Like breast milk, formulas provide energy in roughly equal amounts from carbohydrate and fat. Contrary to breast milk, the protein level is fixed and set at a level that meets the needs of the fastest-growing infants within the target age group. Formulas provide water in amounts that allow the infant to dispose of waste products with a satisfactory margin of safety. Owing to the higher potential renal solute load of formulas,[19] that margin is somewhat narrower than in the breast-fed infant, a difference that is not known to be of clinical consequence.

An enumeration of the myriad substances that are provided by breast milk but are absent from formulas is beyond the scope of this chapter (see Chapter 55 and Appendix 3). A number of substances, including macrominerals, trace minerals, and vitamins, are provided in formulas in greater concentration than in breast milk. Some substances that are believed to be biologically important for the infant are added to formulas in amounts similar to breast milk. Some formulas, notably the soy protein–based formulas, provide substances that are not provided by breast milk. Of considerable nutritional importance is the presence of phytate because of its potential to inhibit the absorption of macrominerals and, especially, trace minerals. A group of substances collectively referred to as phytoestrogens is provided by soy formulas.[20] These substances are not nutritionally important but are biologically active, exerting estrogenic as well as antiestrogenic activities. Phytoestrogens are readily absorbed by the infant[20] but produce no clinically or otherwise recognizable effects. When followed into young adulthood, women who had been exposed to soy formulas as infants had somewhat greater menstrual flow and experienced more discomfort with menstruation.[21] Although these effects are not clinically important, they are biologically significant because they demonstrate that relatively brief exposure during a susceptible period can have effects that last for decades.

Carbohydrates

Milk-based formulas contain lactose as the sole carbohydrate and lack the oligosaccharides that make up a substantial proportion of the carbohydrate of breast milk. Oligosaccharides are responsible in large part for the differences in colonic flora between breast-fed and formula-fed infants. Although it is essentially unabsorbable in the upper gastrointestinal tract, the colonic microflora is quite effective in fermenting the oligosaccharides. The fermentation products, acetate and butyrate, are absorbed from the colon.

Fat

The fat of formulas is made up of various combinations of plant oils, selected to provide major fatty acids in approximately the proportions found in breast milk. The absorbability of the fat of formulas is similar to that of breast milk fat. Sometimes formulas contain added polyunsaturated fatty acids (arachidonic acid [ARA] and docosahexaenoic acid [DHA]) from single-cell organisms.

Protein

Although formulas provide bulk casein and whey proteins in approximately the same proportions as breast milk, the individual whey proteins show little resemblance to those provided in breast milk. Manufacturers are able to selectively decrease and/or increase individual whey proteins and thereby alter the biologic quality and amino acid composition of the protein mix. The protein concentration of formulas is set to meet the highest needs, that is, those of the youngest infants in the target age group. Consequently, the older infants in the formula's target group, who have lower protein needs than the younger infants, receive protein intakes that exceed their needs by some margin. In contrast, breast-fed infants receive protein intakes that approximately match needs at all times.

Iron

Formulas fortified with quite large amounts of iron (1.8 mg/100 kcal) were introduced in 1959 and were shown to be effective in preventing iron deficiency. Although non–iron-fortified formulas continued to be used, the use of formulas providing iron at 1.8 mg/100 kcal gradually increased, as illustrated in Figure 29-6. In 1971, iron-fortified formulas accounted for less than 50% of formula sales in the United States, and in the year 2001, they accounted for about 95% of formula sales. At present, all formulas contain added iron. Only some of the routine formulas are available with an iron level of about 0.6 mg/100 kcal. These formulas are not labeled as iron fortified. All other formulas provide iron at 1.8 mg/100 kcal. Iron fortification is not associated with adverse effects on gastrointestinal function.[22]

Composition

The formulas for routine use are rather uniform in composition, as is evident from Table 29-3 (also see Appendix 3). One formula provides partially hydrolyzed whey proteins.

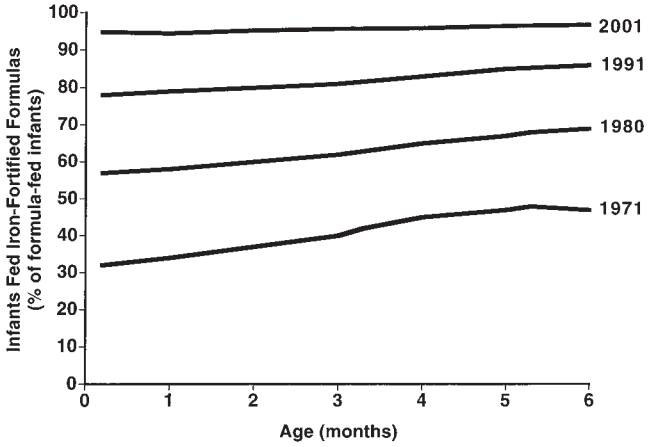

FIGURE 29-6 Infants fed iron-fortified formulas as a percentage of formula-fed infants in 1971, 1980, 1991, and 2001. Data for 1971 and 1980 from Martinez GA et al.[4] Data for 1991 from personal communication from Ross Mothers Survey (Greebaum S, 1992, Ross Products Division, Columbus, OH). Data for 2001 from Mead Johnson Nutritionals, Evansville, IN (J. A. Boettcher, personal communication, 2002).

The latter type of formula is sometimes referred to as "hypoallergenic."

The composition of lactose-free formulas is listed in Table 29-4 (also see Appendix 3). Whereas those based on soy protein isolate (with methionine supplementation) have been available for many years, those based on cow's milk have been introduced more recently. Although the scientific basis for the widespread use of these formulas is uncertain, it is fairly certain that these formulas provide all essential nutrients and support normal growth. The carbohydrates that are provided in lieu of lactose include sucrose and fractions of corn syrup. The protein concentration of soy-based formulas is generally higher than that of milk-based formulas, reflecting the (presumed) somewhat lesser quality (per unit of weight) of methionine-supplemented isolated soy protein. All lactose-free formulas contain iron at 1.8 mg/100 kcal. In the case of soy-based formulas, this includes a substantial amount of iron provided by the soy protein isolate. Little is known about the bioavailability of this iron.

Table 29-5 (also see Appendix 3) lists the extensively hydrolyzed formulas (also referred to as predigested) and one elemental formula. These formulas are characterized by the absence of intact protein as well as lactose. The source of nitrogen is hydrolyzed casein or, in the case of Neocate, free amino acids—hence its classification as elemental formula. Two of the formulas provide a sizable proportion of their fat in the form of medium-chain triglycerides.

Table 29-6 (also see Appendix 3) lists the composition of special formulas designed for specific indications. Enfamil AR is thicker than the usual consistency and is intended use in infants with severe gastroesophageal reflux. Isomil DF is intended for infants recovering from diarrhea. Portagen provides 85% of its fat in the form of medium-chain triglycerides. It is used in infants with chylothorax or chylous ascites. Similac PM 60/40 is low in sodium and phosphorus and is used in infants with renal failure.

Although the concept of age-specific formulas is not widely embraced in the United States, the feeding of unmodified cow's milk to older infants was practiced for many years. A number of formulas are now available for the older infant and toddler (Table 29-7; also see Appendix 3). The scientific rationale for the higher protein content compared with routine formulas is not clear because the protein requirement of the older infant is lower rather than higher than that of the young infant. It appears possible that the higher protein content is designed to ensure an adequate protein intake for those infants who otherwise consume a sizable amount of beikost, which tends to be low in protein content.

Substances Added to Formulas

Of the many bioactive substances that are present in human milk but are contained in cow's milk in lower concentration or are completely absent from cow's milk, some are added to formulas. Evidence that the addition ameliorates an otherwise existing deficiency is not always very convincing. However, it appears reasonable to add a substance when its presence in breast milk seems "intentional" and when its absence from the infant's diet is associated with deficits in serum or tissue concentrations relative to the breast-fed infant. A prerequisite for the addition of any substance is, of course, the availability of the technology necessary for making the addition feasible. The list of substances added to formulas now includes taurine, carnitine, nucleotides, and long-chain polyunsaturated fatty acids (LCPUFAs).

Taurine Taurine is an amino sulfonic acid found in high concentration in certain parts of the developing brain and in the retina. In infants, taurine also plays a role in the conjugation of bile acids and has osmoregulatory functions. Taurine is synthesized from cysteine, and the term infant (but perhaps not the preterm infant) appears to possess ample capacity to carry out the conversion. Breast milk contains appreciable quantities of taurine, whereas the taurine content of cow's milk and hence of cow's milk–based formulas is only a fraction of that of breast milk. However, except for low plasma taurine concentrations, adverse effects owing to low taurine intakes have not been demonstrated convincingly. Nevertheless, all formulas contain added taurine.

Carnitine Carnitine plays an essential role in the entry of fatty acids into the mitochondria and hence is necessary for fatty acid oxidation. Carnitine is derived from endogenous synthesis as well as the diet. Breast milk, cow's milk, and hence milk-based formulas, and meat provide ample amounts of carnitine. When carnitine is absent from the diet, plasma concentrations of infants are low, and certain biochemical abnormalities are observed, the clinical significance of which is uncertain. Carnitine is added to all nonmilk formulas.

Nucleotides Breast milk contains free ribonucleic acid (RNA) nucleosides (adenine, cytosine, guanine, and uridine) as well as their respective nucleotides (ie, nucleosides with one sugar moiety and one or more phosphate groups attached) and some polymeric RNA.[23, 24] For pur-

CHO = carbohydrate.

poses of quantification, they are collectively referred to as "total potentially available nucleosides."[23] The amount of available nucleosides in breast milk is considerably higher than in cow's milk. It is thought that during times of high demand, that is, during rapid growth, dietary nucleosides are useful and may be conditionally essential. Animal studies have shown nucleosides to enhance T-cell function and gastrointestinal maturation. Fortification of infant formula with the four main nucleotides found in human milk led to enhanced antibody responses to *Haemophilus influenzae* type b and diphtheria.[25]

Long-Chain Polyunsaturated Fatty Acids These fatty acids have received enormous attention in recent years. Although the consequences, especially those in the long term, of a lack of these fatty acids in the infant's diet remain controversial, formula manufacturers are now offering many formulas with and without added LCPUFAs. Formulas with added LCPUFAs are specially designated. The fatty acids in question are DHA and ARA. DHA is a $C_{22:6\ n-3}$ fatty acid with six double bonds. It is derived from dietary α-linolenic acid by a series of chain elongation and desaturation steps. ARA is a $C_{20:4\ n-6}$ fatty acid with four double bonds. It is derived from dietary linolenic acid. Breast milk contains preformed DHA (about 0.2% of fatty acids) and ARA (about 0.5% of fatty acids). The plant oils used in manufacturing formulas do not contain DHA and ARA, and formulas are devoid of DHA and ARA unless they are specifically added from other sources.

Infants, including premature infants, have the ability to synthesize DHA and ARA from their respective precursors, but the synthetic capacity appears to be insufficient to keep up with the high demands, especially for DHA. DHA is needed for incorporation into cortical gray matter and the retina. In infants who are fed formulas devoid of DHA, concentrations in gray matter and retina are substantially lower than in breast-fed infants.[26,27] The same is true for concentrations in plasma and erythrocyte membrane lipids.[28] Infants fed DHA-free formulas show evidence of impaired retinal function during the early months of life.[29] However, this effect seems to be transient and is no longer demonstrable in older infants. The presence of DHA and ARA in formulas is considered desirable because these fatty acids are present in breast milk and because their absence from the infant's diet produces abnormal concentrations in brain, retina, erythrocyte, and plasma lipids.

WEANING AND BEIKOST

Weaning is the withdrawal or displacement of breast-feeding (see Chapter 30). The weaning period begins with the first introduction of a food other than breast milk (water and vitamin-mineral supplements are not considered to be food) and extends until the complete discontinuation of breast-feeding. Beikost is the term for foods other than milk or formula fed to infants.[30] Although we do not apply the term weaning to the withdrawal of formula, beikost is also referred to as weaning food.

Age of Introduction of Beikost

Evidence that infants can tolerate beikost before the currently recommended age of its introduction into the diet was provided by the experience in the 1950s and 1960s, when various beikost items were fed to many infants even during the early weeks of life.[1] However, there is at least a theoretic objection to feeding beikost during the early months of life because, at this time, there is greater permeability of the gastrointestinal tract to macromolecules than later. But the major reason for deferring introduction of beikost until 4 to 6 months of age relates to establishment of eating habits.[31,32] By about 4 months of age, most infants can sit with support and have adequate neuromuscular control of the trunk and neck.[33] At this developmental stage, the caretaker can interact with the infant to permit the infant to discontinue eating at the earliest sign of willingness to do so. Weaning should generally begin within a month or 6 weeks after the infant is developmentally ready. In industrialized countries, there is no compelling argument for delaying introduction of beikost beyond 6 months of age.

Choices of Beikost

There is no evidence that the sequence of introduction of various beikost items is a matter of great importance. It is convenient to begin with cereal because a small amount of the dry powder can be mixed with human milk for the breast-fed infant or formula for the formula-fed infant at quite low expense. Initially, only a small amount, less than a teaspoonful, should be given at one time. Whether pureed fruits or vegetables are then introduced seems of little consequence. However, single foods, rather than combinations, should be offered. It is generally recommended that one food be fed for several days before introducing another. It is desirable to work toward acceptance of variations in tastes and textures.

The exclusively breast-fed infant consumes an adequate intake of protein, but once beikost begins to comprise a substantial portion of the total energy intake, it is important to include some high-protein foods. Deficiency of iron and zinc in breast-fed infants is not rare. Meats, especially red meats, are a good source of protein, zinc, and a highly bioavailable form of iron. We recommend for the breast-fed infant that soft-cooked meats be introduced within the first month or two of beikost feeding (by 5 or 6 months of age). We consider the risk of iron and zinc deficiency to be greater than the risk of sensitization to meat proteins.

With the exception of providing sources of iron and zinc of high bioavailability for the breast-fed infant, the goal of feeding beikost is to begin the transition from the infant's primarily liquid diet to the predominantly solid-food diet of the child. Therefore, as infancy progresses, the variety of flavors and textures offered to the infant should gradually be increased.

Fruit juices should be fed sparingly and only by cup. Fruit juices are associated with adverse reactions[34] and do not provide nutrients that are lacking in the diet of the breast-fed or formula-fed infant.

COW'S MILK

Feeding of cow's milk during the first year of life is undesirable because such feeding is associated with the development of iron deficiency. It is unclear which of the several mechanisms is mainly accountable for the iron deficiency. It has long been recognized that ingestion of large quantities of cow's milk may result in low intakes of other foods that contain more generous amounts of iron. In addition, there is considerable evidence that ingestion of cow's milk causes occult gastrointestinal blood loss.[35–37] Finally, the high intake provided by cow's milk of casein and calcium, potent inhibitors of iron absorption, may contribute to the development of iron deficiency.[38]

The potential renal solute load provided by cow's milk is undesirably high.[19] Feeding of whole cow's milk does not interfere with maintenance of water balance in normal infants under most circumstances. But in a hot environment or during febrile illness, especially if associated with decreased fluid intake, the infant is at greater risk of dehydration if fed cow's milk than if breast-fed or formula fed. The margin of safety is greater with breast-feeding or feeding of infant formulas than with feeding of cow's milk.[19]

CHAPTER 30

WEANING: PATHOPHYSIOLOGY, PRACTICE, AND POLICY

Kristy M. Hendricks, RD, DSc

DEFINITION

Infant feeding is frequently described by three overlapping periods: (1) exclusive breast-feeding, (2) weaning, which is a transitional period of continued breast-feeding with the introduction of complementary foods, and (3) a modified adult diet.[1,2] The word "wean" is derived from the Anglo-Saxon "wenian," meaning "to accustom (as a child) to take food otherwise than by nursing."[3] In a recent review, the World Health Organization (WHO) defined weaning as "the period during which any nutrient containing foods or liquids are provided along with breast milk."[4,5] In developed countries, weaning has referred to the transition from either breast milk or formula to complementary feedings that are solid foods.[1,2,6] This is the definition used for the purpose of this discussion.

Weaning is a time of life of considerable nutritional, physiologic, and developmental change, requiring transition from a complete liquid diet from a sole nutrient source to a varied diet of complex foods, the sum of which must provide nutritional adequacy. Potential health risks exist for the infant during this process, and these risks differ for infants in the developed versus developing world. Controversy exists as to the optimal timing of the introduction of complementary feeding, and progression through these phases is dependent on the infant's nutritional needs, physiologic maturation, and developmental readiness (Table 30-1). A 2001 WHO review on the optimal duration of exclusive breast-feeding recommends (for populations) exclusive breast-feeding for 6 months, with the introduction of complementary feeding at 6 months of age in conjunction with continued breast-feeding.[7] Despite broad cultural diversity, published recommendations for weaning are remarkably consistent worldwide.[1–6] In summary, they are:

- During the first 4 months of life, breast milk alone provides optimal nutrition for the rapidly growing infant.
- Between 4 and 6 months of age, breast milk alone becomes nutritionally inadequate and physical and developmental capacities mature. Complementary feedings are slowly introduced, and the composition and consistency of the diet advance so that by approximately 12 months of age, the infant is eating a variety of foods from a mixed diet.
- Dietary patterns continue to change rapidly throughout the second year of life as the transition to the family diet continues.

PATHOPHYSIOLOGY: FACTORS AFFECTING RECOMMENDATIONS

Nutritional Need

A primary goal is to meet the infant's nutritional needs during this period of very rapid growth. Human milk differs from the milk of other mammals and is uniquely suited to meet the needs of the growing infant. Nutrient recommendations for the first 6 months of life are derived primarily from the average amount consumed by healthy infants, growing at an optimal rate, exclusively breast-fed by healthy, well-nourished mothers.[8–10] Breast milk also contains components that assist in digestion, the absorption of certain nutrients, and the development of the gastrointestinal tract. In addition to providing optimal nutrition for the rapidly growing infant, breast-feeding promotes bonding between the nursing mother and her infant; breast milk also appears to provide protection against certain diseases such as diarrhea and allergy.[11–13] Because the volume of breast milk an infant consumes is determined by the amount that is needed to satisfy the infant, breast-feeding could play a role in the prevention of obesity.[14] The topics of breast milk and breast-feeding are more fully explored in Chapters 31, 32, and 33.

No specific time for the introduction of supplementary feeding has been universally shown to have positive short- or long-term effects on health.[1] Various investigators have calculated that between 3 and 4 months of age, exclusive breast-feeding becomes inadequate to meet the theoretic energy needs of the normal infant, whereas a more recent review indicates macronutrient but not micronutrient sufficiency.[7,10] Growth patterns and micronutrient intakes of infants exclusively breast-fed by well-nourished mothers indicate that subtle growth faltering, a possible precursor of more serious undernutrition, occurs at about 6 months.[1,8,9] Most of these studies have used growth charts based on predominantly bottle-fed infants, which

TABLE 30-1 Bases of Weaning Recommendations

	Breast-feeding	*Weaning*
Nutritional Need	Birth to 12 mo: appropriate calorie-to-protein ratio in infancy; high bioavailability (zinc, iron, vitamin A)	Four to 12 months: breast milk volume may become inadequate (700–970 mL/d) at 4–6 mo; nutrients of public health concern to emphasize in weaning foods are carbohydrate, fat (calories), protein, zinc, iron, and vitamins D, A, and E
Physiologic maturation		
Renal function capacity	Highly anabolic state, low renal solute load of breast milk; low concentrating and excretory capacity	Increased concentrating and excretory capacity
Gastrointestinal function	Immune factors (SIgA, lactoferrin, lysozyme); enzymes (breast milk amylase, lipase); omega-3 fatty acids; taurine; growth factors (peptides, nucleotides, IGF-I, cortisol, thyroxine, insulin)	Increased gastric capacity, higher-volume, less-frequent feeds; increased bile acid pool; increased pancreatic amylase; increased pepsin; bile-salt conjugation with glycine; matured microvillus membrane structure
Developmental readiness	Rooting; sucking; swallowing; extrusion reflex	Diminished extrusion reflex (4 mo); development of head, trunk, and gross and fine motor control (4–12 mo); development of exploratory behavior; manual dexterity (12–36 mo)

Adapted from Hendricks KM, et al. Weaning recommendations: the scientific basis. Nutr Rev 1992;50:125–33.
IGF = insulin-like growth factor; SIgA = secretory immunoglobulin A.

might be inappropriate. The growth faltering that occurs during weaning in many developing countries is a complex issue and is discussed below.

Mature human milk contains approximately 9 g protein per liter, of which approximately 70% is whey proteins. Protein quantity and quality affect both digestibility and the ability to support growth. The chemical properties of the casein in human milk promote the formation of a soft, flocculent curd, which is easier for human infants to digest than is the casein in other animals' milk. Additional proteins in human milk, such as the important immunologic factors secretory immunoglobulin A (SIgA), lactoferrin, and lysozyme, are active in the gastrointestinal tract but do not contribute nutritionally available protein. Their concentration has been estimated to be 3 g/L. Thus, nutritionally available protein could approximate 7 g/L. This would provide the normal infant consuming 180 mL/kg in the first months of life with approximately 1.3 g of protein per kilogram per day, a figure that agrees with theoretic calculations of protein requirements during early infancy but becomes inadequate to support growth during the second half of the first year of life.[1]

For the mother who cannot breast-feed or chooses not to, iron-fortified infant formula is appropriate for the first year of life.[2,15] The recommended guidelines for the composition of infant formulas have recently been extensively reviewed.[15] Although much progress has been made, certain nutrient issues remain controversial; formula does not provide the same components to the infant as breast milk does. Although all women should be encouraged to breast-feed, the final decision is the mother's. Coercion is inappropriate.[6]

Iron deficiency is the most common micronutrient deficiency in the world, and the weaning period is a particularly vulnerable time.[16] It is estimated that in the United States, 10% of infants and 9% of adolescent females have iron deficiency anemia. Worldwide, it affects 55% of infants and 50% of children. It appears that iron deficiency has both short- and long-term consequences, including lower scores on mental and motor development tests, with continued delayed development scores at age 2 to 3 years[17,18] and even into adolescence. In developed countries, at-risk infants are those born to mothers who are iron deficient because of lowered stores at birth, infants fed unfortified infant formula, and infants fed whole cow's milk early in life. Cow's milk is low in iron and vitamin E and high in protein, sodium, and potassium compared with human milk and infant formulas. In addition, gastrointestinal blood loss is well documented in infants receiving whole cow's milk. Guidelines for primary prevention and treatment of iron deficiency are outlined below.[16]

Milk and Infant Formulas

- Encourage breast-feeding of infants.
- Encourage exclusive breast-feeding of infants (without supplementary liquid, formula, or food) for 4 to 6 months after birth.
- When exclusive breast-feeding is stopped, encourage use of an additional source of iron (approximately 1 mg/kg/day), preferably from supplementary foods.
- For infants aged < 12 months who are not breast-fed or who are partially breast-fed, recommend only iron-fortified infant formulas as a substitute for breast milk.
- For breast-fed infants who receive insufficient iron from supplementary foods by age 6 months (ie, < 1 mg/kg/day), suggest 1 mg/kg/day of iron drops.
- For breast-fed infants who were preterm or had a low birth weight, recommend 2 to 4 mg/kg/day of iron drops (maximum of 15 mg/day) starting 1 month after birth and continuing until 12 months of age.
- Encourage use of only breast milk or iron-fortified infant formula for any milk-based part of the diet (eg, in infant cereal) and discourage use of low-iron milks (eg, cow's milk, goat's milk, soy milk) until age 12 months.

- Suggest that children aged 1 to 5 years consume no more than 700 mL of cow's milk, goat's milk, or soy milk each day.

Solid Foods

- At age 4 to 6 months or when the extrusion reflex disappears, recommend that infants be introduced to plain, iron-fortified infant cereal. Two or more servings per day of iron-fortified infant cereal can meet an infant's requirement for iron at this age.
- By approximately 6 months of age, encourage one feeding per day of foods rich in vitamin C (eg, fruits, vegetables, or juice) to improve iron absorption, preferably with meals.
- Suggest introducing plain, pureed meats after age 6 months or when the infant is developmentally ready to consume such food.

Guidelines for secondary prevention of iron deficiency through screening are outlined below.[16]

Universal Screening In populations of infants and preschool children at high risk for iron deficiency anemia (eg, children from low-income families; children eligible for the Special Supplemental Nutrition Program for Women, Infants, and Children; migrant children; or recently arrived refugee children), screen all children for anemia between ages 9 and 12 months, 6 months later, and annually from ages 2 to 5 years.

Selective Screening In populations of infants and preschool children not at high risk for iron deficiency anemia, screen only those children who have known risk factors for the condition, as follows: (1) consider anemia screening before age 6 months for preterm infants and low birth weight infants who are not fed iron-fortified infant formula; (2) annually assess children aged 2 to 5 years for risk factors for iron deficiency anemia (eg, a low-iron diet, limited access to food because of poverty or neglect, or special health care needs); screen these children if they have any of these risk factors; (3) at ages 9 to 12 months and 6 months later (at ages 15 to 18 months), assess infants and young children for risk factors for anemia. Screen the following children:

- Preterm or low birth weight infants
- Infants fed a diet of non-iron-fortified infant formula for more than 2 months
- Infants introduced to cow's milk before age 12 months
- Breast-fed infants who do not consume a diet adequate in iron after age 6 months (ie, who receive insufficient iron from supplementary foods)
- Children who consume more than 700 mL cow's milk daily
- Children who have special health care needs (eg, children who use medications that interfere with iron absorption or who have chronic infection, inflammatory disorders, restricted diets, or extensive blood loss from a wound, an accident, or surgery)

Physiologic Maturation

At birth, the renal system performs all of its normal functions, but with limited concentrating ability. Functional capacity of the kidneys increases rapidly, and by age 4 months, the ability to handle an increased solute load is adequate for the gradual addition of weaning foods. By 12 months, kidney size has almost doubled, and significant dietary variation is well tolerated. Between 6 weeks gestation and birth, the surface area of the intestine increases nearly 100,000-fold; the length of the small intestine at birth is approximately 2½ times the length of the infant.[19] Gastrointestinal motility increases with advancing fetal age and intestinal transit time at term averages 4½ to 7 hours. During the course of the first year of life, infants rapidly develop rhythm in their feeding patterns. As gastric capacity increases, most infants progress from consuming approximately 180 mL/kg per day at 2- to 3-hour intervals to less-frequent, higher-volume, and higher-density feedings by the end of the first year.[20]

Neurologic Development and Developmental Readiness

In newborns, the neurologic coordination of a rhythmic suck-swallow-breathe pattern is critical in successful feeding.[21] Breast-fed infants usually feed between 8 and 12 times every 24 hours during the first month of life and decrease to 6 to 8 times daily by age 4 to 6 months.[22] At approximately 3 to 6 months of age, the child's oral anatomy begins to change, and central nervous system control of swallowing increases. This allows for an increased range of movement of the oral structures, the development of internal stability, and greater lip control and closure. It also enables the infant to engage in oral-motor play and sensory-motor exploration.[23,24]

Infant motor development occurs at a rapid, sequential pace as part of the overall maturation process. Maturation is dependent partly on the growth of the infant, and physical developmental milestones are linked to the developmental readiness cues given by the infant regarding the introduction of complementary foods. Physical development milestones include a doubling of weight, physical control, sensory awareness, communication attempts, and improved mouth coordination.[24]

Continued refinement of oral-motor skills increases dexterity; cognitive development also prepares the 6-month-old child for more active participation in the feeding process. Development of trunk and shoulder control is a milestone at this stage because it provides the foundation for increased mobility and coordination of the oral structures during eating and playing.[24] By age 7 to 8 months, grasp becomes more refined and progresses from a palmar to a digital grasp; hand-to-hand transfer of objects develops. This facilitates finger feeding. Refinement of oral-motor skills continues and is enhanced through the introduction of spoon feeding (at 4 to 6 months), cup drinking, and self-feeding of finger foods. Characteristic of this developmental stage of feeding is the continued introduction of foods appropriate for biting and chewing. Reaching, grasping and releasing, and eye–hand coordination all improve from 6 to

12 months, allowing for the progression to self-feeding and emerging independence.

The 12-month-old infant is generally independent, mobile, and interactive, allowing for tremendous enthusiasm in the self-feeding process. Refined oral-motor skills lead to an increased ability to accept and manage a variety of food textures, shapes, and tastes. By 12 months, most infants can hold a cup with two hands and handle four or five consecutive swallows without choking. New flavors and textures coming from dietary variety continue throughout the weaning process and should be in forms compatible with developmental abilities.

The progression of feeding skills from 12 to 18 months of age is characterized by continued coordination of chewing, biting, and swallowing skills and by expansion of dietary variety. Important issues during this time are the child's opportunities for sensory-motor feeding experiences and the influence of parental expectations and attitudes about normal feeding and social-communicative experiences during feeding.[24] These factors contribute significantly both to the infant's developmental skills and to behaviors associated with eating. A critical component of the successful transition to complementary feedings is the individual infant's response to the feeding interaction. A positive mealtime and eating environment that leads to the establishment of a healthy attitude toward food and the development of normal eating habits is essential. Factors affecting this interaction include the infant's overall health and growth, the developmental readiness for weaning, the infant's ability to communicate that readiness, and the presence of a caregiver who understands and responds to the child's cues.

This communication between infant and caregiver is an essential component of the successful feeding relationship. Consistent awareness and accurate interpretation of, and appropriate response to, feeding cues strengthen the infant–feeder relationship and facilitate progression of feeding skills at an appropriate pace for the child. The ability of the caregiver to recognize and respond to the child's cues for feeding readiness and the ability of the parent to accept the infant's growing need for exploration and independence are essential to the development of the infant's feeding skills through the weaning period.

Much more is known about behavioral development during early infant feeding than during weaning. However, it is clear that pleasurable sensations associated with taste and ingestion promote exploratory behavior and tolerance for the unfamiliar once the weaning process has begun.[25–27] The original work of Clara Davis in 1928 documented the ability of newly weaned infants to self-select a nutritionally adequate diet when offered a wide variety of animal and vegetable foods that were thought to provide for all known nutrient needs.[25] These infants, who at the start of the study had little experience with the foods offered, showed strong preferences but selected a variety of foods rather than just the most preferred. This balancing of choices resulted in the consumption of nutritionally complete diets.

This confirmed that young children should be offered a variety of foods of high nutritional value and that a healthy young child's energy requirements are controlled by appetite. Research more closely evaluating the energy intakes of 15 children, aged 2 to 5 years, has confirmed this.[28] Food consumption patterns were highly variable from meal to meal, but daily energy intake was relatively constant because the children adjusted their caloric intake at successive meals. Additional research shows that children who have less exposure to variety in foods, who are more likely to be praised or rewarded for eating, and who are punished for not eating are more likely to develop problematic eating behavior.[29,30]

PRACTICE

Many of our recommendations about infant feeding come from observational studies, most of which were cross-sectional in design and used growth as the primary, and sometimes only, outcome. It is unclear whether this provides reliable data on which to base public health nutrition guidelines. More recent studies from developed countries have focused specifically on the weaning period and processes, following infants longitudinally during this period of rapid transition. In addition to reflecting current practice, together these studies provide new information on which to base policy.

Picciano and colleagues followed 55 healthy full-term infants from 12 to 18 months of age. Dietary intake and growth data were collected monthly.[31] Energy intake increased significantly between 12 and 16 months of age. The energy-yielding nutrients (carbohydrate, protein, and fat) increased in relation to increased energy intakes, whereas the percentage of calories supplied by each remained relatively stable, as did dietary diversity. The increase in dietary density from sucrose approached significance. Many children were consuming less than the recommended level of fat (< 30% of calories), despite the common nutrition message not to restrict fat intake until after age 2 years. Decreases in iron and vitamin E intake between 12 and 18 months of age resulted in intakes well below reference standards. No infant consuming less than 30% of calories from fat met the requirement for vitamin E intake at 12 months; only one child did at 18 months. Also, height was positively correlated with both total fat and energy intake at age 18 months. Although zinc intake increased over time, it was approximately half of the recommended intake at each age. Grains (enriched and fortified), whole-milk dairy products, and meats were identified as important sources of the problematic nutrients (iron, zinc, and vitamin E).

Hammer and colleagues followed 191 healthy, full-term infants monthly for up to 60 months.[32] More than 90% of the infants were exclusively breast-fed during the first month of life. This declined rapidly from 31% at 2 months to 14% at 6 months (plus 48% partially) and 7% at 1 year (plus 19% partially). Conversely, bottle-feeding increased from 64% at 2 months to 84% at 1 year. At 24 months, 41% of infants still received bottles; 16% received them at 36 months, 8% at 48 months, and 3% at 54 months. Formula use remained common at 12 to 15 months, after

which use of cow's milk was common. Interestingly, infants fed a combination of breast- and bottle feeds were fed more frequently than those either solely breast-or bottle-fed.

Complementary feeding was infrequent until 4 months of age. After that time, 35% of infants were receiving at least one complementary feeding per day, and by age 9 months, all infants were. The age of introducing complementary feedings was correlated with weaning from the breast but not with weaning from the bottle. Similarly, the mother's return to work was positively correlated with age of breast weaning but negatively with age of bottle weaning. Seventy-four percent of mothers had returned to work by the time their child was 24 months of age. Mothers who returned to work earlier bottle-fed longer and stopped breast-feeding sooner. There was a significant difference between breast weaning, but not bottle weaning, between mothers who worked full time, part time, or not at all. Maternal work status was not correlated with introduction or use of complementary feedings. Maternal age and education were positively correlated with age of introducing complementary feedings and duration of breast-feeding but not with age of bottle weaning. This study raises intriguing questions about the impact of prolonged bottle-feeding on growth and adiposity, which will hopefully be addressed in future research.

A study evaluating the effect of adding complementary feedings on infant growth from 12 to 24 months of age in 94 healthy, full-term infants found earlier-than-recommended introduction of complementary feedings.[33] Eighty-three percent of mothers initiated breast-feeding; 33% were still breast-feeding at 4 months and 18% at 6 months. The median age of introducing complementary feedings fit current guidelines, with cereal added at 4 months, juice at 4½ months, fruit at 5 months, and vegetables at 5½ months. However, two-thirds of all infants had been given complementary foods by 4 months of age (14% by 2 months, an additional 21% by 3 months, and another 29% by 4 months of age); another 9% were fed cereal via bottles. Although introduction of feeding was early, the types of foods initiated (cereal, fruit, then juice) were consistent with recommendations. The age of introducing complementary feeding was not associated with illness scores or growth of the infant.

Kattelmann and colleagues evaluated the impact of early (at 3 to 4 months of age) versus late (at 6 months) introduction of complementary feeding on iron and zinc status of healthy, full-term infants who were formula fed.[34] The infants, who were all fed commercial formulas, had mean iron intakes approximately equal to the Recommended Dietary Allowance (RDA) and mean zinc intakes slightly less than the RDA up to 12 months of age. Mean zinc intakes were 40 to 60% of the RDA between 12 and 36 months; there were no differences between groups. Serum zinc levels were normal, and there were no differences between groups. There were no differences in serum iron parameters at 12, 24, or 36 months between the two groups.

A large study conducted in Scotland of 671 infants, 455 of whom were followed to 24 months of age, reported interesting findings.[35,36] Complementary feeding before 12 weeks of age was associated with heavier infants at 4, 8, 13, and 26 weeks of age but not at 52 and 104 weeks. There was a significant increase in respiratory illness at 14 to 26 weeks and at 27 to 39 weeks in infants given complementary feedings early. The incidence of eczema was greater in these infants; gastrointestinal illness, wheezing, and diaper rash were unrelated to early complementary feeding. Longer-term follow-up (mean age, 7.3 years) of 545 of the initial 671 infants found that infants exclusively breast-fed for 15 weeks had a significant reduction in respiratory illness. Complementary feeding before 15 weeks was associated with increased probability of wheezing, as well as increased weight and percentage of body fat during childhood. Exclusive bottle-feeding was associated with higher systolic blood pressure in childhood. There was no association between timing of complementary feeding and blood pressure. Thus, exclusive breast-feeding and delaying complementary feeding until after 15 weeks of age could have a beneficial effect on childhood health and subsequent adult disease.

In a prospective randomized study, Simell and colleagues evaluated the impact of nutrition and lifestyle education in late infancy on dietary intake and serum lipid parameters and growth during the first 3 years of life.[37] At approximately 7 months of age, infants were randomized either to receive repeated individualized nutrition counseling (n = 540) or to the control group (n = 522), whose parents received a superficial discussion of nutrition. The nutritional intervention promoted a fat intake of approximately 30% and a 1:1:1 ratio of saturated, mono-, and polyunsaturated fatty acids. Results showed that the percentage of calories provided by fat intake was 29.5% for the counseled children at 8 months (29.4% for controls), 26.6% (28.5%) at 13 months, 30.5% (33.5%) at 24 months, and 31.5% (33.5%) at 36 months. Compared with the control children, those in the nutritional intervention group consistently consumed less saturated fat ($p < .0001$). Total cholesterol, high-density lipoprotein (HDL) cholesterol, and non-HDL cholesterol were 3 to 6% lower in the children who received nutritional counseling. The intervention had no effect on height, weight, or head circumference, and fat intake did not predict children's growth patterns. Thus, early childhood nutritional counseling aimed at reduced saturated fat and cholesterol intake did not have an impact on growth and appears safe in children more than 7 months and up to 3 years of age.

A longitudinal study of Swedish infants found that 43% had been introduced to complementary feeding before 4 months of age.[38] The transition to complementary feedings was a lengthy process, averaging approximately 1 month from the introduction of solids to consuming more than 10 mL per day and 1½ months to consuming more than 100 mL per day. The transition process was longer for those infants for whom weaning began at an earlier age. The authors postulate that this could be because of physical immaturity (requiring more time to master the art of eating solids) and to caregiver response to slow acceptance of foods.

Of 74 Caucasian mother–infant pairs in New Zealand, 88% initiated breast-feeding, 42% were exclusively breast-

feeding at 3 months, and 34% were partially breast-feeding at 12 months of age.[39] Longer duration of breast-feeding was seen with higher education of the mother, a finding similar to those in previous reports. Mothers who perceived insufficient breast milk or found breast-feeding in public embarrassing breast-fed for a shorter period. Overall, 95% of infants were given nonmilk feedings before 4 months of age and 69% were given unfortified cow's milk before 12 months of age.

Data from two nationwide, cross-sectional samples of children aged 1 to 2 years in the United States (the Nationwide Food Consumption Survey [NFCS], *N* = 1,045, and the Continuing Survey of Food Intakes, *N* = 1,039) and a longitudinal sample studied from ages 12 to 18 months (*N* = 55) evaluated secular trends in dietary intake.[40] Relationships among portion size, frequency of eating, dietary quality, and growth were evaluated. Portion size remained similar for most foods across decades with the exception of meat portions, which decreased in size in recent years. Portion size was longitudinally stable for most foods, except for milk, bread, cereal, juice, and peanut butter, which together contributed the daily share of children's energy intake. Body weight was positively related to energy intake and portion size but not to the number of times food was eaten daily or the foods consumed. Portion size appeared to be the means by which children self-regulated energy intake when foods offered and the number of meals eaten varied. Although energy intake and body weight were similar among groups, black children ate larger portions but fewer times daily than white children did. Similar results were found for the lowest versus the highest income categories. This study suggests that infants have the ability during the second year of life to consume larger portions if they are fed less frequently. The authors postulate that this behavior could affect energy intake and weight later in life and might in part explain the sociocultural trends in obesity seen on the United States.

Additional research supports the idea that in preschool children, environmental factors become increasingly important determinants of intake. Rolls and colleagues found that 3½-year-old children were not significantly affected by portion size; their intake varied across portion-size manipulation. However, amount of food offered influenced the intake of 5-year-old children, who ate greater amounts when presented with larger portions.[41] This indicated that as children develop, their food intake is increasingly influenced by social, cultural, and environmental factors. This is an important time for the development of dietary patterns related to obesity.

In summary, recent studies reinforce concerns about inappropriate timing of weaning and nutrient deficiency issues and have added new insight into how to optimize nutrition and health beginning in infancy. Although introduction of complementary feeding was frequently early, the types of foods initiated (cereal, fruit) were generally consistent with recommendations. Making the transition to complementary feedings was a lengthy process, and the transition was longer for infants weaned at an earlier age. This could be a result of physical immaturity (requiring more time to master the art of eating solids) and of caregiver response, the long-term impact of which is unknown. Infants fed commercial formulas had mean iron intakes approximately equal to the RDA and mean zinc intakes slightly less than the RDA up to 12 months of age. Zinc, iron, and vitamin E intakes were found to be well below the RDA in older infants. Grains, dairy products, and meats were identified as important sources of those problematic nutrients.

Researchers found a significant increase in respiratory illness at 14 to 26 weeks and at 27 to 39 weeks in infants given complementary feedings early; the incidence of eczema was also greater in these infants. Breast-feeding exclusively and delaying complementary feeding until after 15 weeks of age could have a beneficial effect on childhood health and subsequent adult disease. Despite the common nutritional message not to restrict fat intake until after age 2 years, many children were consuming less than the recommended level of fat (ie, < 30% of calories). This was associated with inadequate intake of vitamin E. Other findings relate to potential effects on long-term health. One study suggests that infants have the ability during the second year of life to consume larger portions if they are fed less frequently. The authors postulate that this behavior could affect energy intake and weight in later life. A well-designed intervention with early childhood nutritional counseling aimed at reducing saturated fat and cholesterol intake showed that counseling did not have an impact on growth but improved diet quality and appeared safe in infancy.

ADDITIONAL ISSUES

Juice: How Much and When?

Fluid that is rich in sugar can pool around the teeth, increasing the incidence of dental decay called nursing bottle syndrome.[42,43] In addition to this well-documented association with dental caries, case reports of high juice intake associated with failure to thrive in infants and short stature in young children have led to the recommendation to limit juice intake in children.[44] Current guidelines are[45]:

- Juice should not be introduced into the diet of infants before 6 months of age.
- Infants should not be given juice from bottles or easily transportable covered cups that allow them to consume juice easily throughout the day. Infants should not be given juice at bedtime.
- Intake of fruit juice should be limited to 125 to 180 mL/day for children aged 1 to 6 years. For children aged 7 to 18 years, juice intake should be limited to 250 to 360 mL, or two servings, per day.
- Children should be encouraged to eat whole fruits to meet their recommended daily fruit intake.
- Infants, children, and adolescents should not consume unpasteurized juice.
- In the evaluation of children with malnutrition (overnutrition or undernutrition), the health care provider should determine the amount of juice being consumed.
- In the evaluation of children with chronic diarrhea, excessive flatulence, abdominal pain, or bloating,

the health care provider should determine the amount of juice being consumed.
- In the evaluation of dental caries, the amount and means of juice consumption should be determined.
- Pediatricians should routinely discuss the use of fruit juice and fruit drinks and should educate parents about differences between the two.

More recent studies have questioned these recommendations. In a longitudinal study of juice intake and growth to 72 months of age in healthy, full-term infants, Skinner and Carruth found that 100% juice was not associated with overweight or short stature in young children.[46] Multiple food records from 37 boys and 35 girls looked at juice, milk, carbonated beverages, and other drinks over time. Overall mean daily beverage intake did not change significantly. However, 100% juice intake decreased, milk intake remained stable, and intakes of both carbonated and other less nutritious drinks more than doubled. Longitudinally, juice intake was not associated with either short stature or overweight. It is unclear whether previous studies specified 100% juice and most were case series or cross-sectional in design. It is likely that the etiologies of failure to thrive and obesity are multifactorial; these conditions are unlikely to be caused solely by a single dietary factor such as fruit juice consumption. Both nutritious foods and beverages are important for child nutrition.

Weaning the Allergic Infant

Weaning the allergic infant can be a slow and complex process. For infants with a family history of food allergy, exclusive breast-feeding is strongly recommended.[13,47,48]

A recent large cohort study examined the issue of whether breast-feeding truly protects against the development of allergy, and actually suggested the opposite; with increased duration of breast-feeding, the incidence of allergy and asthma at ages 13 to 21 years was higher.[49] As with many observational studies, other factors besides the decision to breast-feed could have influenced these results. A family propensity toward allergy might have prompted mothers to breast-feed longer, so reverse causality could have occurred in this study. In addition, most infants received a small amount of cow's milk formula in the neonatal period, raising questions about whether the definition of exclusive breast-feeding was accurate.[49] Recent data have also suggested that dietary supplementation of the nursing mother and infant with probiotics such as lactobacillus could reduce the occurrence of atopic disease.[50]

For the infant with a personal or family history of allergy, prudent recommendations are to delay the introduction of complementary feedings until 5 to 6 months of age. New foods should be added in small amounts, one at a time, ensuring that there are no (or limited) additives. Foods to begin during weaning at 5 to 9 months of age include rice and millet; cooked vegetables, including potato, yam, sweet potato, and squash; and fruits, such as banana, pear, and peach. Lamb and turkey are considered the least allergenic meats. From 9 to 12 months, additional grains such as oats and barley should be tried, one at a time and beginning with small amounts. Chicken, veal, and beef can be added, along with additional cooked vegetables and fruit. From 12 to 24 months of age, stronger vegetables, citrus fruits, berries, and melon are slowly added, as are other grains (specifically wheat). All of the protein-rich foods except shellfish, nuts, and seeds can be added slowly to the diet during the second year of life. The decision to begin dairy products of any kind is an individual one, but this can be done between 12 and 24 months or after 2 years of age, depending on the infant's clinical history.

Because it might be necessary to delay the addition of specific food groups to the weaning infant's diet, close attention should be paid to nutritional adequacy. Important nutrients in the common allergens egg, fish, nuts, and soy are protein, iron, vitamin B_{12}, zinc, and selenium. These nutrients should be met by intake of other rich food sources if possible or if necessary by supplementation.

Weaning Issues in Developing Countries

The importance of weaning is underscored when one considers the consequences of inappropriate weaning in deprived environments (Table 30-2). Too early initiation of weaning displaces breast milk, decreases the mother's milk production, and results in malnutrition, whereas weaning too late leads to growth faltering and depressed immune function.[27] Others have suggested that this association between growth failure and prolonged breast-feeding is not an etiologic one but is more related to poor quality of weaning foods in breast-fed infants, especially those of poor mothers.[51]

Growth faltering and diarrhea that occur at the time of weaning are significant public health problems. The recent WHO Global Database in Child Growth and Malnutrition reports that stunting affects 182 million children and wasting affects 150 million.[52] These growth deficits are associated with more than half of the 10 million annual deaths of children under the age of 5 years, primarily from infectious disease. Breast-feeding protects children from much of this disease burden while they are exclusively breast-fed; growth faltering, diarrheal disease, and progressive malnutrition begin about the time of weaning.[53] In societies where undernutrition, environmental contamination, and social deprivation are common, this has been termed the "weaning dilemma."[27] This occurs because either prolonged, exclusive breast milk intake or eating weaning foods that are contaminated or nutritionally inadequate will lead to the cycle of malnutrition, depressed immune function, and diarrhea. Potential interventions that can help in growth and reduction of morbidity by preventing infections, such as hygienically prepared commercial foods (which are expensive), heating and preparing fresh foods every time (which is expensive and impractical), or better storage with refrigeration, are not always feasible.[54]

There is no clear definition of growth faltering, but it is widely assumed to begin around the time of weaning in developing countries. A 2001 WHO review of the optimal duration of exclusive breast-feeding recommends (for populations) exclusive breast-feeding for 6 months, with the

TABLE 30-2 Weaning Consequences

Time of Weaning	*Consequences*
Too early	Increased diarrhea owing to intestinal immaturity; potential increased allergies in at-risk infants; potential risk of wheezing and respiratory illness; potential prolonged weaning; decreased breast milk production (displaced by weaning foods); malnutrition owing to diarrheal disease; potential risk of obesity
Ideal	Appropriately timed, starting at 4–6 mo; nutritionally adequate, emphasizing calories, protein, iron, zinc, and vitamins E, A, and D; hygienically prepared, cool, covered, clean, cooked; culturally appropriate, available, acceptable to the population
Too late	Growth failure: breast milk alone becomes calorically inadequate; depressed immunity owing to inadequate energy and protein intake; increased diarrheal disease owing to depressed immunity; malnutrition owing to inadequate calories and diarrheal disease; micronutrient deficiencies owing to inadequate dietary intake, increased needs with infection

Adapted from Hendricks KM, et al. Weaning recommendations: the scientific basis. Nutr Rev 1992;50:125–33.

introduction of complementary feedings at 6 months of age in conjunction with continued breast-feeding.[7] The authors also concluded that despite advantages, exclusive breast-feeding to 6 months can lead to iron deficiency and could put infants at risk for growth faltering and other micronutrient deficiencies. More recently, the WHO Multinational Study of Breastfeeding and Lactational Amenorrhea, a longitudinal, seven-country study, evaluated growth patterns and differing durations of breast-feeding and types and frequency of complementary feedings.[53] The infants were living in generally favorable environments. Growth was not sensitive to the differential timing of the introduction of complementary foods between 4 and 6 months or to types and frequencies of complementary feedings. These results do not provide compelling evidence of benefit or risk related to growth and the timing of introduction of complementary foods at a specific time between 4 and 6 months of age. Again, the application to populations living in poorer environments is unclear.

A recent analysis of the WHO Global Database on Child Growth and Malnutrition, containing 39 nationally representative data sets from recent growth monitoring programs in developing countries, attempted to address issues relating to the occurrence of growth faltering.[48] For children in the developing world at birth, in comparison with the National Center for Health Statistics (NCHS) Growth Charts, the average weight for age, length for age, and weight for length are quite close to reference values. Growth faltering then occurs, so that by 18 months, mean weight for age and mean length for age are between 1 and 2 standard deviations below the median reference values. The median weight for length is about –0.6 at 18 months, and the three primary growth parameters (WAZ, HAZ, WHZ) show different patterns. Mean weight starts to falter at about 3 months of age and declines rapidly until 12 months; between 12 and 19 months, this decline slows. Most wasting (WAZ) in children occurs in the period between 3 and 15 months of age. For length, although the mean birth values are close to the NCHS standards, faltering starts soon after birth and lasts well into the third year, and is not recovered thereafter. These processes appear to be independent of each other. The pattern was remarkably similar in many developing countries. It is clear from this new information that weaning is not the only—and might not be the primary—factor in this complex issue.

Prudent Weaning Recommendations

Weaning guidelines are similar for infants in deprived environments, but with several caveats. First, breast-feeding should be continued on infant demand to avoid displacement of breast milk. Variety is needed in complementary foods that are culturally appropriate but follow the basic recommendations summarized below. Special attention should be paid to changes in appetite, growth, or development, which could be indicators of or precursors to nutrient deficiencies or excess.

During the first 4 months of life, breast milk alone provides optimal nutrition for the rapidly growing infant. Between 4 and 6 months, breast milk alone becomes nutritionally inadequate as physical and developmental capacities mature. Complementary feedings are slowly introduced, and the composition and consistency of the diet advance so that by approximately 12 months of age, the infant is eating a variety of foods from a mixed diet. An infant feeding guide for the first year of life is detailed in Table 30-3. Deficiencies of iron, zinc, and possibly vitamin E are the most common micronutrient deficiencies observed during infancy in developed countries, plus vitamin A in developing countries. Examples of sources of these nutrients are listed in Table 30-4. Weaning recommendations have focused on prevention of deficiencies of these nutrients.

As the infant advances to an adult family diet, prevention of nutrient deficiencies can be achieved by eating foods from each of the basic food groups (dairy, grains, vegetables, fruits, and meats) daily. No one food group alone provides all of the essential nutrients, and each group makes an important contribution to a child's daily nutrient needs. A variety of foods from each group ensures an adequate intake of all nutrients. Exposure to many new foods during infancy expands a child's willingness to experiment with foods later, with the aim of achieving a base for long-term healthful eating habits. Current guidelines include the adoption of the American Heart Association Step 1 Diet in children over age 2 years, moderation in restricting fat, and an emphasis on overall dietary quality.

Approximately three to four servings per day of dairy products, such as whole milk, buttermilk, yogurt, cheese, ice cream, custard, or pudding, are appropriate for children ages 1 to 3 years. Dairy products are high in protein, cal-

TABLE 30-3 Infant Feeding Guide

Foods	*0–4 Months*	*4–6 Months*	*6–8 Months*	*8–10 Months*	*10–12 Months*
Breast milk	Short, frequent feedings 8 or more per day	Short, frequent feedings 5 or more per day	On demand 5 or more feedings per day	On demand	On demand
OR iron-fortified formula	500–950 mL, 5–10 feedings per day	700–1,180 mL, 4–7 feedings per day	700–950 mL, 3–4 feedings per day	500–950 mL, 3–4 feedings per day	500–700 mL, 3–4 feedings per day
Cereals and bread	None	Infant cereals, rice, oatmeal, or barley (spoonfed). Mix 10–15 mL with formula, water, or breast milk	Most varieties of boxed infant cereals, 15–60 mL twice a day	Infant cereals or other plain hot cereals, 120–180 mL/d Toast, bagel, or crackers	Hot or cold unsweetened cereals, 60–125 mL/day; bread, rice, noodles, or pasta (125 mL/d)
Fruit juices	None	Infant juice, adult apple juice, vitamin C fortified (avoid orange and tomato juice), 60–125 mL/d	Infant juice, adult apple juice (vitamin C fortified). Offer juice from a cup, 125 mL/d	All 100% juices (orange and tomato juice can be offered), 125 mL/d	All 100% juices from a cup, 125 mL/d
Vegetables	None	None	Strained or mashed dark yellow, orange, or green vegetables (avoid corn), ½–1 jar or 125 mL/d	Cooked, mashed fresh or frozen vegetables, 80–125 mL/d	Cooked vegetable pieces, 125 mL/d
Fruits	None	None	Fresh, cooked, mashed or strained fruits, ½–1 jar or 125 mL/d	Peeled, soft, mashed fruit or fruit wedges, 80–125 mL/d	All fresh fruits, peeled and seeded, 125 mL/d
Protein	None	None	Plain yogurt (can be mixed with soft fresh fruit or applesauce)	Lean meat, chicken, and fish (strained, chopped, or small tender pieces), 45–60 mL/d; egg yolk, yogurt, mild cheese, cooked dried beans	Small, tender pieces of meat, fish, or chicken, 60–75 mL/d; egg white, cheese, yogurt, cooked dried beans, peanut butter

Adapted from Infant feeding guidelines. Boston: Children's Hospital.

cium, vitamins A and D, and riboflavin, and whole milk is high in vitamin E. Low-fat and skim milk products are not recommended until a child is 2 years old.

Meat and meat substitutes include meat, fish, poultry, eggs, and legumes. These foods are generally good sources of protein, iron, zinc, copper, vitamins B_6 and B_{12}, and niacin. Two servings per day, each of approximately 1 to 2 ounces, is appropriate.

The bread and cereal group includes breads, muffins, cereals, rice, noodles, and pasta. Grains are high in thiamin, niacin, vitamin B_6, folate if enriched, and iron if fortified. If they are whole grains, they are generally rich in magnesium and zinc as well. Whole-grain breads and cereals contain significant amount of fiber, which is important in the diet because it aids in normal bowel function and could be important in the prevention of certain chronic intestinal disorders that can occur later in life.

The fruit and vegetable group includes fresh, frozen, canned, and dried fruits and vegetables. Fruits and vegetables are rich in B vitamins, folate, iron, and vitamins A and C. Unprocessed fruits and vegetables are also high in fiber. Between 8 and 10 months of age, as the infant begins to use a cup, juices can be introduced one at a time. Natural juices, particularly those with no added sugar, rather than fruit drinks, are best. It is important for an infant to drink juice from a cup rather than a bottle.

In addition to the type and amount of food offered to infants and children, it is clear that early infant feeding experiences have a profound effect on eating behaviors. Table 30-5 lists common caretaker behaviors that positively influence children's eating patterns and should be encouraged.

Tomatoes	Tomatoes		
Winter squash			

POLICY

Recommendations from developed countries for weaning infants, and for the addition of complementary feedings, have not varied significantly over the past 40 years.[55] In a recent review of the rationale for recommendations for feeding normal infants, Fomon[6] outlines them clearly:

- Every mother should be encouraged to breast-feed her infant but not coerced to do so.
- Every infant should be given an injection of vitamin K as soon as feasible after birth.
- While in hospital, every woman who breast-feeds her infant should be given instructions about breast-feeding.
- Follow-up approximately 48 hours after discharge from hospital should be arranged for women who breast-feed.
- Every breast-fed infant should receive a daily supplement of iron and vitamin D.
- Formula-fed infants should receive iron-fortified formulas.
- Actions of caregivers should be conducive to establishing habits of eating in moderation.
- Introduction of complementary feedings (ie, foods other than breast milk or formula) should be deferred until the infant reaches the stage of developmental readiness for such feedings.
- Complementary foods should be thoughtfully selected.
- Cow's milk should not be fed to children before the age of 1 year.

As the focus of public health in developed countries has moved to attaining optimal nutrition for long-term health, current research on infancy has begun to address the significant issues of prevention of diseases such as obesity and heart disease. Currently, data are inconclusive regarding further specific nutrition recommendations on these issues. Future research should focus on these important questions.

TABLE 30-5 Caregiver Behaviors and Children's Resulting Eating Patterns

Caregiver Behavior	*Child's Response*
Exposure	Familiarity increases food acceptance and willingness to try new foods
Modeling	Adults, siblings, and peers provide direct and indirect examples of eating behavior
Positive reinforcement	Happy, safe, relaxed feeding atmosphere; recognition, praise, and approval to reinforce appropriate behavior
Discipline	Consistent, appropriate limit setting; solid family organization in problem solving and guidance in feeding issues
Stimulation	Emotional support, encouragement, and affection around feeding
Caregiver responsiveness	Appropriate, sensitive responses to development readiness and emotional issues involved in feeding

CHAPTER 31

HUMAN MILK: NUTRITIONAL PROPERTIES

Jenifer R. Lightdale, MD, Jill C. Fulhan, MPH, RD, LD, IBCLC, Clifford W. Lo, MD, MPH, ScD

Breast milk has been the natural and traditional food of human infants for as long as they have existed. Today, it continues to be the optimal source of nutrition for almost all infants worldwide. Breast milk also affords unique immunologic protection and stands alone as a source of nutrition that adjusts to meet the needs of the growing infant.

The volume of breast milk available and its nutritional composition differ among individual mothers based on their infant's demand. Differences are also noted between stages of lactation (colostrum, transitional and mature milk, and weaning) and also within individual feedings (foremilk versus hindmilk).[1] Colostrum, produced from the first to the fifth day of lactation, is rich in many nutrients, particularly proteins. Transitional milk contains increasingly higher concentrations of fats and lactose, until stabilizing by about the fifteenth day as mature milk.[2] The breast milk of mothers who deliver their infants prematurely contains higher concentrations of fats and protein and lower concentrations of lactose than the milk of women who deliver at term (Table 31-1). During weaning, protein and fat concentrations increase as involution of the mammary gland occurs.[3] Although concentrations of proteins, lactose, and other water-soluble components tend to remain similar throughout a single feeding, fat concentrations increase during an individual feeding.[4] This chapter reviews the nutritional properties of breast milk.

Throughout most of human history, infant mortality rates have ranged from 15 to 25% as high as 90% in orphans lacking ready access to a wet nurse. As recently as a century ago, one-quarter of all infants born in the United States died before they reached their first birthday. Many of these deaths occurred because of malnutrition and infectious diarrheal diseases.[5] Breast-feeding was almost a life or death proposition for newborn infants until well into the 1900s. Attempts to simulate human milk by various alterations to cow's milk were the basis for early American pediatric theory and practice. The founding fathers of the field of pediatrics—such as Holt, Rotch, and Jacobi—devoted much of their careers to defining the nutritional needs of young infants and developing safe feedings for infants who were separated from their mother's milk.

Nevertheless, social, cultural, and economic influences have affected maternal decision making regarding breast-feeding, especially in the past century. Beginning in the early 1900s, the United States (and much of the industrialized world) saw a successive decline in breast-feeding initiation.[6] The decreasing trend in breast-feeding was partly attributed to increased advertising for and availability of artificial baby milk, an increased number of women in the workplace, and a newly found belief in science and technology.

Breast-feeding initiation rates reached a low of 22% in the United States in 1972[7] but began to reverse owing in part to changes in childbirth practices beginning in the 1960s. Unmedicated deliveries, infant-directed nursing, rooming-in, and immediate breast-feeding postpartum facilitated an increase in breast-feeding initiation.[8] Maternal education and social class, income level, race, attitude and behavioral intention regarding infant feeding, and social support network are some of the other factors affecting maternal decisions to breast-feed.[9]

Over the past decade, breast-feeding rates have continued to rise overall. As of 1998, the number of mothers initiating breast-feeding has risen to 64%, with 29% continuing breast-feeding at 6 months and 16% at 1 year.[10] These numbers, although improving, still fall far below the Healthy People 2010 target of 75% of mothers initiating breast-feeding, 50% continuing to 6 months, and 25% continuing until 1 year.[11] The Healthy People 2010 report recognizes that "education of new mothers and their partners; education of health providers; changes in routine maternity ward practices; social support, including support from employers; and greater media portrayal of breastfeeding as the normal method of infant feeding are needed to increase breastfeeding rates."[11]

A wealth of literature studying human milk and breast-feeding in the last few decades has highlighted many previously unappreciated differences between human milk and cow's milk–based formulas. Biochemical differences in proteins, vitamins, minerals, enzymes, and fats, along with the availability of anti-infective properties such as secretory immunoglobulin A, lactoferrin, lysozyme, and interferon, set breast milk above artificial baby milk for nutrition as well as immune protection. The 1997 American Academy of

Adapted from Riordan J.[1]

Pediatrics' (AAP) policy statement outlines the many "diverse and compelling advantages to infants, mothers, families and society from breastfeeding and the use of human milk for infant feeding."[12] The US Surgeon General, in the year 2000, released the *Health and Human Services Blueprint for Action on Breastfeeding*, outlining the action plan for increased breast-feeding education, training, awareness, support, and research in the United States.[13]

In 2001, a call for action for breast-feeding promotion from physicians, based on the advantages of human milk, was made to further advocate breast-feeding as the infant feeding of choice.[14] The AAP currently recommends exclusive breast-feeding for the first 6 months of life, at which point solid foods may be gradually introduced. Breast-feeding should then continue for at least 12 months "and thereafter for as long as mutually desired" between mother and infant.[12]

VOLUME AND COMPOSITION

The total volume of milk production and intake may vary considerably between individual feedings. Although the mean breast milk intake of babies in industrialized societies has often been quoted as high as 750 to 850 mL per day, values may range from 450 to 1,200 mL per day.[15] Milk output in extremely malnourished mothers may drop to as low as 100 to 200 mL per day. In this situation, the protein and lactose content remains surprisingly high, but fat content, total calories, and vitamins may be quite inadequate.

Milk production may not always be synonymous with milk intake. Infants regulate their own intake, which may vary from 360 to 1,000 g per day.[16] The most common method for measuring milk intake involves weighing infants before and after a feeding and estimating their insensible water loss.[17] It is also possible to determine 24-hour milk intakes of infants by weighing their mothers before and after breast-feeding and correcting for maternal insensible water loss.[17] If no correction for insensible water losses is made, then milk intake is subject to overestimation by as much as 15%. Another more technically complex way of measuring human milk production involves using a tungsten-halogen light source to analyze breast topography and calculate the changes in volume of the breast after feeding.[18] However, the biomechanics of such assessments are beyond the scope of most physicians and lactation consultants.

GROWTH

Babies who exclusively breast-feed have been found to grow faster initially than formula-fed infants.[19] However, after 3 to 6 months, breast-fed infants grow more slowly. By 2 years of age, weights of the two may be comparable[20]; by 6 years of age, formula-fed infants are on average slightly taller and heavier than their breast-fed counterparts.[21,22]

Although there has been much discussion about breast-feeding mitigating the risk of later obesity, this has been difficult to establish in good prospective trials that control adequately for socioeconomic, genetic, and cultural factors. In one recent study of 2,500 ethnically diverse children aged 3 to 5 years, investigators were able to compare participants' reports of the length of time children were exclusively breast-fed, age when breast-feeding was completely stopped, and age when solid foods were first introduced with direct measures of children's heights and weights.[23] In this study, the association of breast-feeding and reduced risk of being overweight was not found to be statistically significant. Nevertheless, longer breast-feeding patterns did appear to protect against the development of body mass indexes (BMIs) greater than the 85th percentile.

In a related study, a cohort of approximately 15,000 American children was analyzed to determine whether duration of breast-feeding, exclusivity of breast-feeding, and age at which solid foods were introduced affected later risk of becoming overweight.[24] The study children, aged 9 to 14 years, were asked to self-report their heights and weights, whereas their mothers reported infant feeding practices. The results of this study revealed a significant relationship between less breast-feeding and becoming overweight, even after investigators controlled for age, sex, sexual maturity, energy intake, time watching television, physical activity, maternal BMI, and other variables reflecting social, economic, and lifestyle factors. They also were consistent with a recent European study of 10,000 German children that found a reduced prevalence of obesity among children who were breast-fed.[25]

One of the most important parameters used to assess the nutritional adequacy of breast-feeding is an infant's weight gain. Some authors have noted that the growth rates of exclusively breast-fed infants fall behind rates of those fed formula after about 3 months of age. This has been interpreted as a need for supplemental feeding for some infants before the age of 6 months, but others claim that this "faltering" is actually physiologic and that different growth

standards should be used for breast-fed infants.[26] In 2000, the Centers for Disease Control and Prevention released updated growth charts that include breast-fed infants and are more nationally representative than the version released in 1977 by the National Center for Health Statistics.[27]

The AAP does not recommend giving fluid supplementation to breast-fed newborns without medical indication.[12] Yet there are many reported cases of significant weight loss, failure to thrive,[28,29] and even frank dehydration that have occurred in some breast-fed infants.[30] Recent studies have suggested that the era of short postpartum hospitalizations may increase the risk of neonatal dehydration, especially among first-born children of mothers planning to exclusively breast-feed.[31–33] Breast-feeding failure is still common in first-time mothers, probably more often owing to a lack of environmental stimuli and emotional support of the mother rather than physiologic inadequacy of lactation or biochemical deficiencies in the breast milk.[34]

Nevertheless, the perception of inadequate milk supply has been identified as the major reason that mothers introduce formula or other foods into their infants' diets.[35] Interestingly, although the introduction of formula into infants' diets leads to a rapid and abrupt weaning, the introduction of solids has been found to have essentially no effects on breast-feeding for at least several weeks.[36] The differences between formula and solids in their impact on breast-feeding may be attributed to volume. Whereas infants already have the oral and developmental skills to take in large amounts of formula, they must gradually learn to handle different textures of solids. Infants being introduced to solids will not take enough volume to be satiated and will still depend on the breast.

BIOCHEMICAL COMPOSITION

Breast milk is about 87.5% water. The other constituents of human milk are described in Table 31-2. There is no evidence to suggest that a healthy infant who is adequately breast-feeding needs extra water supplements, even in hot climates[37–39] or during breast milk jaundice.[40] Even among low birth weight infants in hot, relatively humid environments, breast milk alone should be sufficient to ensure adequate hydration status when consumed in quantities that maintain adequate growth.[41] The osmolarity of breast milk is around 286 mOsm per liter,[42] with common infant formulas ranging from 185 to 374 mOsm per liter.[43]

The specific gravity of breast milk is about 1.030, and total solids weigh 10 to 15 g per 100 mL. More than half of this (7 g/100 mL) is carbohydrate, primarily lactose. Another 4 g per 100 mL consists of fat, primarily triglycerides. About 1 g per 100 mL is protein, and 0.2 g per 100 mL is mineral ash. In comparison, cow's milk contains a similar amount of water, slightly less fat (3.7 g/100 mL) and lactose (4.7 g/100 mL), and much more protein (3.5 g/100 mL).

PROTEINS

The protein content of human milk was formerly considered to be somewhat higher, 1.1 to 1.3 g/100 mL, but this was calculated by multiplying Kjeldahl's analysis of total nitrogen by the usual conversion factor of 6.25. Nearly 25% of this nitrogen, however, is nonprotein nitrogen, including urea (27.4 mg/100 mL), creatinine (20.9 mg/100 mL), sugar amines (11 mg/100 mL), and free amino acids (30 mg/100 mL). These values are all at much higher levels than those found in cow's milk, in which only 5% of the nitrogen is nonprotein. Measurement of the protein content of human milk by amino acid analyzer gives the surprisingly low figure of 0.9%,[44] which is much lower than in most other mammalian milks.

The protein composition of human milk is different from that of cow's milk, containing relatively more whey and less casein. "Casein" is actually a group of glycoproteins that are characterized by precipitation at pH 4.6 and 20°C. There are four major families of casein proteins—alpha, beta, gamma, and kappa—each having many genetically determined polymorphic variants.[45] Caseins are rich in phosphorus and proline and low in cystine. They have a tendency to form loose "micelles," which allow them to be more easily digested by carboxypeptidase in the intestinal lumen. The protein content of human milk is only 30% casein (0.4 g/100 mL), primarily β-casein, compared with the much higher (80%) casein content of cow's milk, which is primarily α-casein.

In contrast to cow's milk and most other mammalian milks, the percentage of whey in human milk is an unusually high 70%. Whey is the fluid left after clotted milk contracts. It contains such important proteins as lactalbumin, lactoferrin, lysozyme, albumin, and immunoglobulins. Alpha-lactalbumin contains a component of the enzyme lactose synthetase, and high levels of this protein in human milk (2.6 mg/mL) correspond to the relatively high level of lactose. Although whey-predominant formulas are available, the major whey protein in cow's milk, β-lactoglobulin, is not present in human milk in any significant amount.

Because the estimated average protein intake of the breast-fed infant is only about 1.5 g/kg/day, compared with 2.7 g/kg/day in a formula-fed infant, the protein quality of human milk may be higher, reflecting differences in the amino acid profile. There are only slight differences in the relative amino acid compositions of human milk and cow's milk when expressed as a percentage of total protein. However, plasma and urine concentrations of all amino acids except taurine and cystine are higher after formula feeds than after breast-feeding.[46] This finding suggests that protein intake is in excess of requirements when formula is fed because excess dietary protein is excreted in the urine. This increased metabolic stress is reflected in increased blood urea nitrogen, blood ammonia, and urine osmolarity and may lead to metabolic acidosis, especially in low birth weight infants.[47]

On the other hand, the protein requirement for premature low birth weight infants is generally believed to be higher than that usually provided by mature breast milk.[48] This requirement is estimated to be between 1.8 and 3.0 g/kg/day, depending on whether the ideal growth rate is seen as that matching intrauterine growth accretion rates[49] and whether weight gain or length is

*All values are expressed per liter of milk, with the exception of lipids that are expressed as a percentage on the basis of milk volume or weight of total lipids.

[†]1 kJ = 0.2389 kcal.

[‡]The cholesterol content of human milk ranges from 100 to 200 mg/L in most samples of human milk after day 21 of lactation.

considered a better measure of growth.[50] Premature milk, like colostrum and transitional milk, contains more protein than mature milk, giving about 1.9 g/kg/day with adequate caloric intake, and breast milk expressed from their own mothers may be sufficient for adequate growth.[51]

Nonprotein Nitrogen

One of the most striking differences between the amino acid profiles of human milk and cow's milk is the relatively small amount of taurine present in the latter. Taurine is a free amino acid that is not incorporated into proteins. It is formed from the sulfur amino acids cystine and methionine. Taurocholate, not glycocholate, is the predominant bile salt conjugate in neonates.

Premature infants have a limited capacity to form taurine because of delayed maturation of the enzymes cystathionase and cystine sulfonic acid decarboxylase.[52] Taurine depletion leads to retinal degeneration in cats, although this effect on vision in humans has not been demonstrated. Nevertheless, taurine may play a role in brain development because its concentration is highest in the developing brain.[53] In preterm infants, taurine supplementation has been shown to result in lower cholesterol synthesis, higher bile acid excretion, and higher fatty acid absorption.[54,55] Therefore, taurine supplementation is recommended in preterm neonates who are not receiving human milk.

In addition to urea, free amino acids, and ammonia fractions, there are several other nonprotein nitrogen constituents of human milk, including nucleotides, nucleosides, and nucleobases, that play important roles in neonatal development. Generally speaking, concentrations of most of these constituents decrease gradually over time with advancing lactation period or nursing time.[56]

Nucleotides, particularly inosine monophosphate, may contribute to superior iron absorption in breast-fed infants and may act as growth factors.[57] Finally, there is growing evidence that nucleotides may have immunomodulating effects on host immune defenses by enhancing antibody responses in infants.[56] Human milk is particularly rich in cytidine nucleotides, whereas only small amounts of adenine nucleotides are found in cow's milk.[58] Polyamines

such as putrescine, spermine, and spermidine are known to be involved in cell proliferation and differentiation, may be present in highly variable amounts in both human milk and formula, and may be related to maternal atopy. Enterally administered polyamines have also been shown to influence intestinal maturation in a number of animal models.[59]

Enzymes and Hormones

Many enzymes are supplied in breast milk in far greater amounts than in cow's milk, including lipases, amylase, catalase, and proteases. Lysozyme has been previously mentioned. Amylase activity is 60 times greater in colostrum and 40 times greater in mature breast milk than in cow's milk, aiding in starch digestion.[60] Many other enzymes are also present in breast milk in higher levels than in cow's milk, including transaminase catalase, cholinesterase, lactate dehydrogenase, proteases, and lipases.

Many hormones, including estrogen, thyroid-stimulating hormone, and growth hormone, are also secreted in breast milk.[61] Additionally, leptin has been shown to be secreted in breast milk, although the physiologic significance of this is less certain.[62] Recent investigation into the bioactivity of phytoestrogens has suggested that soy formulas for infants have isoflavone concentrations that are four orders of magnitude higher than human breast milk.[63] These studies continue to support the notion that human milk may be safest for infants, who, as a group, are undergoing a critical period of growth, bone mineralization, and sexual determination that may be vulnerable to the estrogen-like effects of phytoestrogens.[64]

Growth Factors

Human milk contains gastrointestinal regulatory peptides such as gastric inhibitory peptide, bombesin, cholecystokinin, and neurotensin, which may be important for growth and maturation of the gastrointestinal tract in the neonate.[65] Growth factors such as growth hormone, insulin-like growth factor I, granulocyte-macrophage colony-stimulating factor, and tumor growth factor β have been shown to enhance intestinal function and mucosal defenses. There are also many other growth factors that stimulate DNA synthesis, such as epidermal growth factor and hepatocyte growth factor.[66,67] Tumor necrosis factor (cachectin) and other cytokines, such as interleukin (IL)-1, IL-6, IL-8, IL-10, and interferon, may be produced by stimulation of mononuclear cells in human milk.[68]

Fats

Fats provide the main energy source for newborn infants, supplying 40 to 50% of the total calories in human milk. There are numerous differences between the lipid profiles of human milk and infant formula. A bile salt–stimulated lipase in breast milk complements the immature pancreatic exocrine system of neonates to aid in fat digestion and absorption.

The essential fatty acids, linoleic and linolenic acid, also play a crucial role in brain development as a component of cell membranes. About 98% of the fat in human milk is in the form of triglycerides, consisting of glycerol and three fatty acid esters. Although 167 fatty acids have been identified in human milk (and 437 in cow's milk), the major fatty acids are palmitic (22%), stearic (7%), oleic (36%), and linoleic (9%).[69] Relatively few short-chain fatty acids (C_4 to C_8) are present in human milk (1 to 5%), as opposed to 6 to 9% in cow's milk.

Human milk also contains significant amounts of long-chain desaturation products of n-6 and n-3 fatty acids, including docosahexaenoic and arachidonic acids, that are essential for retinal and neural development.[70] Such long-chain polyunsaturated fatty acids (LCPUFAs) in human milk have been clearly demonstrated to directly impact the chemical composition of brain tissue,[71] as well as enhance retinal and cortical function.[72] The fatty acid composition of depot fat is also affected by dietary intake. It has long been suggested that supplementation of formula with LCPUFAs may be beneficial, especially in premature infants, even if it is not always directly indicated by increased circulating plasma lipid levels.[73,74] Recent studies have also suggested a benefit from LCPUFAs on visual acuity and stereoacuity of full-term healthy infants who are weaned from the breast at 6 weeks.[75]

Human milk has about equal amounts of unsaturated and saturated fats. As cow's milk has more saturated fats, most infant formulas are reconstituted with added vegetable unsaturated fat (corn oil, sunflower oil, or soy oil). Although the total lipid content is higher in hindmilk than in foremilk and higher in the morning than in the evening,[76] the fatty acid pattern has been shown to change little over at least 12 months of lactation.[77] However, the polyunsaturated-to-saturated ratio in breast milk may be influenced by changes in maternal diet (eg, margarine versus butter),[78] with the percentage of linoleic acid varying from 1 to 45%. Colostrum contains a lower amount of total lipids but a higher percentage of LCPUFAs.[79,80] Furthermore, the total lipid content of hindmilk rises more than threefold from colostrum up to the third month and then more slowly up to the twelfth month.[77]

The small amount of nonglyceride lipid in breast milk includes free fatty acids, mono- and diglycerides, phospholipids, sphingolipids, ether-esters, and cholesterol. These are synthesized in the mammary gland and are essential components of cell membranes.[81] The cholesterol content of human milk is greater than cow's milk but varies greatly between time of sampling, among individuals, and from day to day, from 3.1 to 28.8 mg per deciliter.[82]

The high percentage of fat in breast milk and formula is necessary to support rapid growth in infancy. Early infant feeding influences cholesterol metabolism, although breast-feeding has not been shown to reduce the risk of coronary disease in adult years.[64] The cholesterol content of human milk is much higher than in infant formulas, which may decrease endogenous cholesterol synthesis.[83] Increased dietary cholesterol and γ-linoleic acid may contribute to the maturation of high-density lipoprotein particles, which are present in higher levels in breast-fed infants.[84]

Lipases

Although fats provide a major energy source for infant growth, their ability to be absorbed is limited by the relative immaturity of pancreatic lipases and bile acid excretion in the newborn.[85,86] Neonates and infants normally excrete more than 5% of their fat intake in the stool, often up to 30%, which would be considered gross steatorrhea in the adult.[87,88] This is even more pronounced in low birth weight premature infants. Newborns, however, do have a number of compensatory mechanisms to enhance fat absorption, including lingual lipase and breast milk lipase.[89] Breast milk actually contains two lipases. Lipoprotein lipase plays a role in the uptake of plasma lipids by the mammary gland but has no role in digestion. Human milk also contains a bile salt–stimulated lipase that is complementary to pancreatic lipase and has been shown to improve the digestion and absorption of breast milk in vivo.[90] Thus, breast milk not only provides nutrients but also supplies the means to digest them. This enzyme is present in the milk of other primates but not in cow's milk. Adding human breast milk to cow's milk formulas has been shown to improve fat absorption in premature infants.[91]

Prostaglandins

Prostaglandins are derived from the essential fatty acids, linoleic and linnoleic acids. They affect many physiologic functions, including gastrointestinal secretion and absorption, smooth muscle contraction, local circulation, and cytoprotection.[92] Breast milk has been found to contain small amounts of prostaglandins E_2 and F_2, not present in cow's milk. These prostaglandins may play nutritional, immunologic, or hormonal roles in the newborn infant.

Carnitine

Carnitine (trimethylaminohydroxybutyrate) is a major constituent of the enzyme carnitine acyltransferase, which transfers long-chain fatty acids into the mitochondria for oxidation. The higher levels of carnitine (55 to 70 nmol/mL) present in breast milk during the first 3 weeks postpartum correspond to higher plasma levels found in breast-fed infants. This may indicate that ketogenesis and free fatty acid oxidation are major energy sources during early development.[93] The carnitine present in both breast milk and formulas may also aid in free fatty acid oxidation of the absorbed triglycerides.

Vitamins

Vitamin K Although breast milk is an ideal infant food, providing a nearly complete range of all required nutrients, it is recommended that certain vitamins and minerals be supplemented in breast-fed babies to prevent occasional catastrophic deficiency states.[94] This is particularly true of some of the fat-soluble vitamins. Vitamin K is normally produced in sufficient quantities by enteric bacteria, but neonates are susceptible to deficiency before bacterial colonization of their intestines augments their low stores of vitamin K at birth.

Studies have shown that average maternal vitamin K intakes correspond to less than 15% of the recommended infant dietary intake of 10 μg per day.[95] It has been noted for many years that breast-fed infants were particularly susceptible to hemorrhagic disease of the newborn. Breast milk contains less vitamin K activity than cow's milk (15 μg/100 mL versus 60 μg/100 mL), but another explanation may be that the *Lactobacillus*-predominant intestinal flora of breast-fed newborns produces less vitamin K than the *Escherichia coli*–predominant flora of formula-fed babies. Although episodes of severe bleeding are not common, levels of vitamin K in cord blood are very low,[96] and prothrombin levels in breast-fed newborns rise significantly after birth. This disease has essentially vanished since the establishment of routine postnatal administration of 1 mg vitamin K orally or intramuscularly, but cases continue to be reported, especially in breast-fed infants, when this practice is neglected.[97]

Vitamin D Human breast milk contains very little fat-soluble vitamin D. Sufficient amounts of vitamin D can, of course, be obtained by adequate exposure to sunlight, and in prospective studies, the majority of breast-fed infants show adequate growth and bone mineralization.[98,99] However, breast milk supplies much less than the recommended allowance of vitamin D or its active metabolites,[100] and cases of rickets continue to be reported among unsupplemented infants.[101] The AAP recommends that all breast-fed infants (and non breast-fed infants receiving less than 500 mL per day of Vitamin D–fortified formula) be supplemented with 200 IU per day of Vitamin D.[12]

Vitamin E Vitamin E plays an important part in preventing peroxide formation from polyunsaturated fats in the diet. This is particularly important in premature newborns in whom vitamin E deficiency may lead to red blood cell membrane fragility and hemolytic anemia. There has been a gradual but steady increased intake of polyunsaturated fatty acids in American maternal diets over the last 50 years, adding to potential oxidant stress.[102] Fortunately, the vitamin E content of human milk is also higher, particularly in colostrum and early transitional milk.[103] The major portion of vitamin E activity is provided by α-tocopherol, with a small amount of γ- and β-tocopherol.

Vitamin A Breast milk, particularly colostrum, is rich in vitamin A (200 IU/100 mL or 40 to 55 mg/100 mL retinol equivalents) and its dietary precursor, beta–carotene. This amount varies according to maternal diet; however, milk from underprivileged Ethiopian mothers has less vitamin A and retinol binding protein, as well as a lower percentage of retinyl ester, than that from European mothers.[104]

Water-Soluble Vitamins Most of the water-soluble vitamins are well provided in breast milk, but there may be great variation depending on maternal diet. For example, it is estimated that, globally, up to one-third of pregnant and lactating women have some degree of folate undernutrition.[105] Supplementation of water-soluble

vitamins to lactating women will raise levels in breast milk up to a plateau. Although supplementation may be beneficial in undernourished women, it may not be necessary in most well-nourished mothers.[106] Thiamin and riboflavin are usually not a problem,[107] but pyridoxine, vitamin B_{12}, and folate levels may be low in lower socioeconomic groups.[108] Because pyridoxine (vitamin B_6) is critical for early development of the central nervous system, it is of particular concern that breast milk concentrations on the lower end of the range, 100 to 300 μg per liter, may not meet the recommended allowance of 300 μg per day.[109] Pyridoxine supplementation of the maternal diet may adequately increase the concentration of pyridoxine in breast milk.[110] Because the major sources of vitamin B_{12} are foods of animal origin, a strict vegetarian maternal diet can lead to a vitamin B_{12} deficiency. This was reported in a breast-fed infant with severe hematologic, metabolic, and neurologic abnormalities, which recovered rapidly with vitamin B_{12} therapy.[111] Megaloblastic anemia may also occur in folate deficiency, but this is extremely rare in breast-fed infants.[112,113] Although levels of folate in cow's milk and human milk are similar, formula-fed infants are more susceptible to folate deficiency.[114] This may be attributable to the presence of a reducing agent (ascorbate), a regulating folate binding protein, or a greater proportion of the monoglutamate form in human milk.

Minerals

In contrast to vitamins, the mineral content of breast milk is less influenced by recent maternal dietary intake.[115] The mineral composition of breast milk at 1, 2, and 3 months is outlined in Table 31-3. Only small differences are noted over time, maternal age, or parity. Surprisingly, there are no significant effects of maternal nutrient status or dietary supplementation on milk mineral content. Socioeconomic status does affect the concentrations of some minerals in breast milk, but this does not seem to be related to maternal serum levels.[116] There is active regulation of uptake, transfer, retention, and excretion of many minerals. The bioavailability of minerals is generally higher in breast milk than in infant formulas, owing partly to the presence of binding ligands, which enhance absorption.[117] Regulation of certain minerals also occurs through urinary excretion, and simple measurement of dietary intake may not be as accurate as more complex calculations of net retention or tissue accretion.[118]

Calcium Calcium is a major nutrient of milk and contributes not only to skeletal growth but also to muscle contraction, nerve transmission, and blood clotting. Calcium homeostasis is affected by many other nutrients, particularly phosphorus, magnesium, vitamin D, and fats. Although the calcium content of human milk (20 to 34 mg/100 mL) is much lower than that of cow's milk (120 to 134 mg/100 mL), retention of calcium is much higher in the breast-fed infant (67% versus 25%).

Neonatal hypocalcemia and tetany are more often seen in formula-fed infants.[119] One reason may be that cow's milk contains a much higher concentration of phosphorus (93 mg/100 mL) with a calcium-to-phosphorus ratio of 1.2:1.0 (versus 2:1 in human milk). This leads to a decreased absorption and increased excretion of calcium.[120] Another reason may be the formation of nonabsorbable calcium palmitate soaps because of the different types of lipids in cow's milk. To this end, it has been suggested that changing the stereoisomeric structure of calcium palmitate in infant formulas might result in higher bone mineral content, reduced stool soap fatty acids, and softer stools more like those of breast-fed infants.[121] Nevertheless, calcium status in both formula- and breast-fed infants may be marginal, especially in very low birth weight infants. Also, short-term benefits of calcium supplementation to bone mineral density in preterm infants have been demonstrated, although long effects are less clear.[122] Calcium supplements should be routinely given to all premature infants to prevent rickets and hypocalcemic tetany.[123]

Iron Iron deficiency anemia is probably the most common nutritional disease among infants in both developed and developing countries. Both human milk and cow's milk contain low but variable amounts of iron (0.3 to 6.0 mg/100 mL). Breast-fed infants, however, are much less susceptible to iron deficiency. This is because iron absorption in exclusively breast-fed infants is much higher (20 to 50%) than in formula-fed infants (4 to 7%).[124] This may be owing to a number of characteristics of breast milk, including lower protein content, greater lactose, greater ascorbate, lower phosphorus, and different iron binding proteins.[125]

Interestingly, early introduction of solid foods impairs the efficiency of iron absorption in both formula-fed and breast-fed infants.[126] By 6 months of age, when the AAP recommends starting solid foods,[12] iron nutrition in both breast-fed and formula-fed infants may be marginal, and iron should be supplemented to provide the recommended allowance of 10 mg elemental iron per day in any infant with a hemoglobin level less than 11 g/dL.[127,128] Controversy about universal or prophylactic supplementation for all infants remains because excess iron supplements may increase susceptibility to gastrointestinal infections by

TABLE 31-3 Mean Mineral Contents of Human Milk Samples at Months 1, 2, and 3 of Lactation

	*Months**

†Significantly different from month 1 at $p < .05$.

saturating lactoferrin and transferrin, iron binding proteins that have a bacteriostatic effect in the intestine.[129] Also, it must be kept in mind that iron supplements may promote oxidant stress and vitamin E deficiency anemia in premature newborns and should not be empirically prescribed in the first few months of life.[130]

Zinc Zinc is an essential constituent of many metalloenzymes, including alkaline phosphatase, carbonic anhydrase, carboxypeptidase, superoxide dismutase, and DNA polymerase. An inherited form of zinc deficiency, acrodermatitis enteropathica, which is manifested by a rash, chronic diarrhea, irritability, and failure to thrive, was formerly treated with breast milk before specific zinc therapy was recognized.[131] The concentration of zinc in breast milk declines rapidly (60 to 22 mmol/L) over the first 3 months of lactation.[132] As in the case of iron, human milk contains less zinc than cow's milk, but its bioavailability is higher: 60% for breast milk, 43 to 50% for cow's milk, and only 27 to 32% for infant formulas.[133]

Plasma zinc and hair zinc levels are higher in breast-fed infants than in formula-fed infants, suggesting better zinc absorption and nutriture.[134] However, it has been recommended that preterm infants be supplemented with zinc as breast milk from mothers delivering preterm appears to be lower in zinc concentation and their babies appear to be zinc deficient.[135]

Other Minerals The copper content of breast milk varies widely (0.09 to 0.63 μg/mL)[136] and seems not to be affected by maternal supplementation. Selenium is usually higher in human milk (16.3 ng/mL) than in formula (8.6 ng/mL), which may be important because the daily requirement for this element in infants is higher owing to their rapid growth.[137] Much research remains to be done on other essential trace elements in milk, including iodine, manganese, molybdenum, fluoride, chromium, vanadium, nickel, and silicon.

STORAGE OF MILK

The many nutritional advantages of human milk explain the desirability of obtaining expressed breast milk for those infants who are unable to breast-feed. This is particularly true for low birth weight premature infants in critical care nurseries who are at risk for necrotizing enterocolitis and a host of other diseases that might be prevented by optimal nutrition with milk from the mother of the premature infant. Research has shown that human milk is remarkably resilient as long as good food-handling techniques are used.[138] In the storage of expressed breast milk, bacterial contamination by skin flora can present a major problem.[139] *Staphylococcus albus* and *Streptococcus viridans* are the most common organisms, but many samples contain pathogenic *Staphylococcus aureus* and *Enterobacter*,[140] and outbreaks of *Salmonella* have occurred in nurseries.[141] If breast milk is stored for more than 48 hours, it should be frozen or autoclaved.[142] Refrigeration, freezing, and pasteurization are all accompanied by some loss of cellular viability and host defense factors such as lactoferrin, IgA,[143] and vitamin C.[144] Although some studies have suggested that human milk stored in glass retains greater viability and immune function,[145] the bottom line is that these treatments do not markedly affect the nutritional quality of breast milk in terms of nitrogen, calcium, phosphorus, sodium, vitamin A, zinc, iron, or copper.[146,147] Fat absorption may be reduced by destruction of lipases, and several vitamins or their binding proteins may be denatured by heat treatment.

DRUGS AND ENVIRONMENTAL POLLUTANTS

Most medications taken by the mother are excreted into breast milk to some extent but are usually present in trace amounts and therefore not contraindicated in breast-feeding. Decisions regarding maternal medication use should be based on documented levels of medication transfer into human milk, bioavailability of the medication, potential effect to the infant, and effect on maternal milk supply.[148] Acceptable alternative medication for the mother should be considered if the initial medication choice is not preferred. It is important to realize the psychological and physiologic effect on mother and infant if weaning, especially abrupt weaning, is recommended. Telling a mother to arbitrarily stop breast-feeding without researching the medication is not in the best interest of the mother and baby.[149] Medication resources that include product inserts only should be avoided. Preferred are references that detail the medication's effects on breast-feeding.[150] The goal is to protect breast-feeding, not the liability of the clinician, while treating the mother.[151] Although most medications are compatible with breast-feeding, the effect of some to nursing infants is unknown but may be of concern, require temporary cessation of breast-feeding (Table 31-4), or are absolutely contraindicated.[152]

In terms of those drugs that definitively contraindicate breast-feeding, cytotoxic drugs including cyclophosphamide, cyclosporine, doxorubicin, and methotrexate may interfere with the cellular metabolism of the infant via immune suppression, growth, association with carcinogenesis, or neutropenia.[12] Illicit drugs, including amphetamines, cocaine, heroin, marijuana, and phencyclidine, should not be ingested by the mother because of their adverse effects on the infant, as well as the mother's ability to take care of the infant. In comparison, although strict avoidance of nicotine is highly recommended, mothers who continue to smoke should be encouraged to breast-feed. Indeed, breast milk has been shown to offer a protective effect in decreasing acute respiratory illnesses in children whose mothers smoke.[153]

Environmental pollutants are found worldwide in human milk, as well as in cow's milk, milk-based formula, and food. Mothers may not know of their exposure to pollutants, including pesticides (DDT [dichlorophenyltrichloroethane], dichlorodiphenyldichloroethylene [DDE], and heptachlor), polychlorinated biphenyls (PCBs), dioxin, lead, and methylmercury.[154] Maternal occupation, diet, and location of residence may affect exposure to a number of pollutants identified in human milk. Most lactating women are at minimal risk, however, and there is little evidence of consequent illness in their

nursing infants. Therefore, in the absence of known poisonings, breast-feeding is recommended despite the presence of chemical residues.[155]

CONCLUSIONS

As discussed in this chapter, human milk is the ideal nourishment for almost all infants, including those born prematurely. As the volume of research on the nutritional composition and immunologic properties of breast milk grows, so do efforts regarding the support and promotion of breast-feeding within the medical community. Breast-feeding initiation and continuation rates have continued to rise over the last quarter century but remain far below the Healthy People 2010 goals. However, the message in today's industrialized society is clear: breast milk should no longer be regarded as an equal option for infant feeding but as the norm with which artificial baby milks are compared.

Only human milk has the unique ability to change in volume and composition to meet the needs of the growing human infant. Growth patterns of breast-fed infants may demonstrate physiologic growth against which non-breast-fed infants should be assessed. Breast-feeding may also protect against later obesity. Evaluating the success of breast-feeding via careful monitoring of hydration and weight gain in newborns in the first days and weeks of life may prevent unnecessary cases of dehydration and failure to thrive. Should problems occur, enlisting the help of an international board-certified lactation consultant[156] to assess mother and infant will allow for modifications in feeding to improve milk transfer to the infant.

Breast milk is nearly 90% water, providing adequate hydration for an infant who takes sufficient volumes to grow. Fat, which comprises approximately half of the calories in breast milk, also provides essential fatty acids and LCPUFAs. Combined with bile salt–stimulated lipase in the breast milk, fat complements the immature pancreatic exocrine system to aid in fat digestion and absorption. Whey proteins provide not only nutrition but also a host of immune defense factors as well. Hormones, growth factors, and enzymes continue to be discovered and studied for their crucial role in infant growth and development.

Infants who are separated from their mothers, for reasons including hospitalization and mother's return to work, benefit from expressed milk. Proper expression techniques and storage guidelines help ensure that expressed milk is safe for the baby. Maternal medications, if any, should be reviewed to rule out rare contraindications.

Current recommendations in favor of universal breast-feeding by a number of national and international organizations have mirrored a global return of mothers providing ideal infant nutrition and immunologic protection to their babies. Understanding of lactation physiology and breast-feeding practice is warranted to facilitate breast-feeding success.

TABLE 31-4 Radioactive Compounds That Require Temporary Cessation of Breast-feeding*

Compound	*Recommended Time for Cessation of Breastfeeding**
Copper 64	Radioactivity in milk present at 50 h
Gallium 67	Radioactivity in milk present for 2 wk
Indium 111	Very small amount present at 20 h
Iodine 123	Radioactivity in milk up to 36 h
Iodine 125	Radioactivity in milk present for 12 d
Iodine 131	Radioactivity in milk present 2–14 d, depending on study
Iodine 131	If used for treatment of thyroid cancer, high radioactivity may prolong exposure to infant
Radioactive sodium	Radioactivity in milk present 96 h
Technetium 99m (^{99m}Tc), ^{99m}Tc macroaggregates, ^{99m}Tc O_4	Radioactivity in milk present 15 h to 3 d

Consult nuclear medicine physician before performing diagnostic study so that radionuclide that has the shortest excretion time in breast milk can be used. Before study, the mother should pump her breast and store enough milk in the freezer for feeding the infant; after study, the mother should pump her breast to maintain milk production but discard all milk pumped for the required time that radioactivity is present in milk. Milk samples can be screened by radiology departments for radioactivity before resumption of nursing.

CHAPTER 32

PROTECTIVE PROPERTIES OF HUMAN MILK

Armond S. Goldman, MD, Randall M. Goldblum, MD, Frank C. Schmalstieg Jr, MD, PhD

Shortly after cow's milk was introduced commercially as a substitute for breast-feeding in the early twentieth century, it was reported that morbidity and mortality were much lower in breast-fed than in cow's milk–fed infants.[1–3] In the mid-twentieth century and thereafter, these findings were confirmed and extended by epidemiologic investigations in developing and industrialized countries.[4–14] Particularly in developing countries, the incidence of diarrheal diseases and deaths was remarkably higher in non-breast-fed infants, and the protection owing to breast-feeding lasted until weaning was complete. However, it was unclear from those observations whether the observed differences were attributable to an increased number of microbial pathogens contaminating non–human milk feedings or to protective factors in human milk. In that respect, studies in Central America strongly suggested that the protection afforded by breast-feeding was not attributable solely to differences in the degree of exposure to microbial pathogens.[4–6] These investigators found that the frequency of intestinal colonization and diarrhea owing to bacterial enteric pathogens was lower in breast-fed infants, despite the prevalence of carriers of these organisms in the community and the presence of bacterial enteropathogens on the nipples and areola and in maternal milk.

The protective effects of breast-feeding have been more difficult to demonstrate in industrialized countries,[12,13] where advances in sanitation, immunizations, maternal nutrition, and other health care measures led to a decline in morbidity and mortality owing to infectious diseases. In addition, it has been difficult to design studies in which potential confounding demographic variables are controlled.[12,13] Nevertheless, the results in most current carefully designed studies, including one in which breast-feeding education was randomized among several hospitals in one country,[14] suggest that breast-feeding protects against common viral and bacterial enteric infections[4–9,12–14] and possibly against respiratory infections,[10–13] certain allergic disorders such as atopic dermatitis,[13–16] and urinary tract infections during infancy.[17] Further, breast-feeding may have long-term protective effects against certain disorders that have an immunologic, inflammatory, or oncogenic basis.[18–21] These epidemiologic studies provided the impetus to investigate the nature of the immune system in human milk and the effects of the components of that system on the recipient infant.

MAJOR DIVISIONS OF THE IMMUNOLOGIC SYSTEM IN HUMAN MILK

The immune system in human milk consists of three overlapping groups of bioactive compounds. They are direct-acting antimicrobial (Tables 32-1 and 32-2), anti-inflammatory (Table 32-3), and immunomodulating agents (Tables 32-4 and 32-5). Many of these factors in human milk share the following features: (1) they are common to external secretions; (2) they are adapted to protect mucosal surfaces; (3) they often display more than one function; (4) they often act synergistically; (5) they protect by noninflammatory mechanisms; (6) their concentrations in human milk usually decline as lactation proceeds[22,23]; and (7) the patterns of their production are often inversely related to the production of those same factors by the recipient infant (Table 32-6).

Thus, it seems likely that the system evolved in part to augment mucosal immunity of the infant until the defenses of the recipient were fully developed. That proposition has been borne out by a number of observations, including many studies that demonstrate developmental delays in the production of immune factors by the recipient infant (see Table 32–6).[13,24–34] Also in that respect, the immune system in human milk has been found to be different from analogous systems in milks from other species used to feed human infants.

DIRECT-ACTING ANTIMICROBIAL FACTORS

The direct-acting antimicrobial factors in human milk include (1) growth promoters of protective enteric bacteria; (2) factors that interfere with bacterial metabolism; (3) enzymes that lyse bacterial cell walls; (4) antibodies adapted to mucosal sites; (5) certain antimicrobial mucins, oligosaccharides, and lipids; and (6) living leukocytes. A brief description of these agents (see Table 32-1) follows.

Table 32-1 Functions of Antimicrobial Agents in Human Milk.

Agents	*Antimicrobial Functions*
Proteins	
Lactoferrin	Bacteriostasis owing to Fe+++ chelation Bacterial killing owing to lactoferricin
Lysozyme	Lyses bacterial cell walls by degrading peptidoglycans
Secretory IgA	Binds bacterial adherence sites, toxins, and virulence factors
MUC1	Inhibits binding of S-fimbriated *Escherichia coli* to epithelial cells
Lactadhedrin	Binds rotavirus and thus prevents its contact with epithelium
Oligosaccharides and glycoconjugates	Receptor analogues inhibit binding of enteric/respiratory pathogens and their toxins to epithelial cells
Monoglycerides and fatty acids from lipid digestion	Disrupt enveloped viruses, kill certain bacteria, defend against *Giardia lambdia and Entamoeba histolytica*

Growth Factors for Enteric Commensal Bacteria

Human milk, but not cow's milk, promotes the in vitro growth of *Bifidobacterium bifidum var. Pennsylvanicus*.[35] The growth promoters are oligosaccharides, casein and its derivatives,[35,36] and the prebiotic lactoferrin-derived peptide I generated by partial proteolysis of lactoferrin or soluble secretory component.[37] It appears that these components are responsible at least in part for the proliferation of *B. bifidum* and lactobacilli in the lower intestinal tract of breast-fed infants.[38,39] Organic acids produced by those organisms are largely responsible for high hydrogen ion concentrations in stools of breast-fed infants.[40] That acidic environment retards the growth of enteric pathogens such as yeast, *Escherichia coli,* and *Shigella* sp. In addition, these commensal bacteria augment the production of low-molecular-weight, antibacterial peptides by epithelial cells.[41]

Table 32-2 Secretory IgA Antibodies in Human Milk Directed against Pathogens

Bacteria: Toxins Virulence Factors	*Viruses*	*Fungi*	*Parasites*
Escherichia coli	Adenovirus	*Candida* sp	*Giardia lamblia*
Campylobacter sp	Cytomegalovirus		
Clostridium botulinum	Enteroviruses		
Clostridium difficile	Human immunodeficiency virus (HIV)		
Haemophilus influenzae	Influenza virus		
Helicobacter pylori	Respiratory syncytial virus		
Klebsiella pneumoniae	Rotavirus		
Streptococcus pneumoniae			
Vibrio cholerae			
Salmonella sp			
Shigella sp			

Table 32-3 Anti-inflammatory Factors in Human Milk

Categories	*Components*
Cytoprotectives	Prostaglandins E_2, $F_{2\alpha}$
Epithelial growth factors	Epidermal growth factor, lactoferrin, polyamines
Maturational factors	Cortisol
Enzymes that degrade mediators	PAF-AH
Binders of enzymes	α_1-Antichymotrypsin
Binders of substrates of enzymes	Lysozyme to elastin
Modulators of leukocytes	Interleukin-10
Antioxidants	Uric acid, α-tocopherol, betacarotene, ascorbate

PAF-AH = platelet activating factor acetylhydrolase.

Inhibitors of Bacterial Metabolism

Lactoferrin, a ferric iron binding protein common to many external secretions, is largely unsaturated (apo-lactoferrin)[42] and is present in high concentrations in human milk throughout lactation.[21,22] Apo-lactoferrin inhibits the growth of organisms such as *E. coli* by competing with bacterial enterochellin for ferric iron. The chelation is enhanced by bicarbonate, the principal buffer in human milk.[43]

Besides the bacteriostatic effects owing to the chelation of ferric iron, lactoferrin kills certain bacteria such as *Streptococcus mutans* and *Vibrio cholerae* by a chelation-independent mechanism[44] that is attributable to the N-terminal peptide of the molecule lactoferricin.[45] Lactoferricin kills by disrupting cell walls of susceptible pathogens.

Also, there is recent evidence that lactoferrin protects against certain viruses.[46–48] Thus, lactoferrin is a prime example of the multiple functions of certain defense agents in human milk. Moreover, lactoferrin often enhances antimicrobial effects of other agents in human milk.

Lactoferrin is not readily digested by proteolytic enzymes from the gastrointestinal tract.[49] Indeed, a substantial proportion of ingested lactoferrin from human milk remains intact throughout the gastrointestinal tract,[50,51] and some whole lactoferrin molecules and proteolytic fragments of them are absorbed and excreted into the urine of the recipient,[51] where they may protect against urinary tract infections.[17]

Another inhibitor of bacterial metabolism, vitamin B_{12} binding protein, is also found in human milk.[49] Unlike lactoferrin, this protein is readily degraded by proteolytic enzymes.[49] It seems improbable that this binding protein would survive the small intestine, but a role for this agent in the upper portion of the alimentary tract, where proteases are lacking, has not been ruled out.

Lysozyme and α-Lactalbumin

Lysozyme, an enzyme that cleaves peptidoglycans in cell walls of susceptible bacteria,[52] is present in exceptionally high concentrations in human milk throughout lactation.[21,22] In contrast, the quantity of this enzyme is low in other mammalian milks used to feed human infants. Longitudinal changes in the concentrations of lysozyme during

Table 32-4 Types of Immunomodulating Agents in Human Milk

Agents	*Functions*
β-Casomorphin	Activates macrophages
Prolactin	Enhances T-cell development
Anti-idiotypic antibodies	Immunizing agents
α-Tocopherol	Augments cell-mediated immunity
Nucleotides	Enhance natural killer cell, macrophage, T helper activities and antibody formation to certain immunogens
Cytokines	See Table 32-5

lactation are unlike most other immunologic components in human milk. After an initial fall to a nadir at 2 to 4 weeks of lactation, the concentration rises by 6 months to levels three times higher than those found in colostrum. The necessity of these high lysozyme levels in human milk may be related to the low production of the protein by mucosal cells during infancy. The synthesis of this enzyme by cultured epithelial cells from the tracheobronchial tree is lowest during early infancy.[28] It is likely that the attainment of normal intraluminal concentrations of lysozyme in the tracheobronchial tree of infants depends on breast-feeding. This is supported by higher lysozyme activities in stools of breast-fed than in those of non-breast-fed infants.[50]

An evolutionary descendent of lysozyme, α-lactalbumin, enhances the activity of lactose synthase that is found only in the mammary gland. The expression of the protein is essential for lactation.[53] It has also been reported that three domains of α-lactalbumin are antibacterial[54] and that a partially unfolded form of the protein with a specific fatty acid ($C_{18:1}$) increases apoptosis of cultured neoplastic cells.[55] The partial unfolding of the protein and the liberation of the fatty acid from milk lipid may occur in the stomach.[55]

Table 32-5 Potential Functions of Certain Cytokines in Human Milk

Cytokines	*Possible Functions*
Interferon-γ	T helper 1 cytokine. Activates macrophages
IL-1b	Activates T cells and macrophages
IL-6	Enhances IgA production
IL-8	Chemotaxin for neutrophils and $CD8^+$ T cells
IL-10	T helper 2 cytokine
	Inhibits production of many proinflammatory cytokines
IL-12	T helper 1 cytokine. Enhances production of interferon-γ
TNF-α	Enhances production of polymeric Ig receptors
TGF-β	Enhances isotype switching to IgA^+ B cells
G-CSF	Increases granulocyte (neutrophil) production
M-CSF	Increases monocyte production

G-CSF = granulocyte colony-stimulating factor; M-CSF = monocyte colony-stimulating factor; TGF-β = transforming growth factor-β; TNF-α = tumor necrosis factor-α.

ANTIBODIES

Four classes of immunoglobulins are found in human milk (IgA, IgM, IgG, and IgD).[21,22,56] The dominant immunoglobulin in human milk throughout lactation is secretory IgA.[21,22,56] Although the levels of this immunoglobulin decrease during the first few months of lactation, substantial concentrations persist during the first 2 years of lactation.[21,22,56]

There is a wide spectrum of secretory IgA antibodies in human milk directed against enteric and respiratory pathogens (see Table 32-2).[56–63] The heavy, light, and J chains of the immunoglobulin part of the molecules are produced by plasma cells in the mammary gland, which originate from B cells from the small intestines (the enteromammary pathway)[64–66] and the bronchial tree (the bronchomammary pathway).[67] The entrance of these immunologically precommitted mucosal B cells into the pathways is triggered by specific antigens that bind to antibodies on the surface of those cells. As a consequence of the antigenic stimulation and the influence of local T helper (Th) 2 cytokines, B cells in those sites undergo an isotype switch from IgM to IgA.[68,69] The stimulated, antigen-specific B cells migrate first to efferent lymphatics and then enter the systemic circulation through the superior vena cava. In mice, and presumably in humans, lactogenic hormones influence those B cells to home to the mammary gland, where they undergo terminal differentiation to plasma cells that predominantly produce dimeric IgA.[66] This process may be controlled by the mucosal cell adhesion system, for example, mucosal cell adhesion molecule 1 and its counterstructure, α4-β7.[70,71] However, in mice, that has not been found to be the case.[72]

Secretory IgA molecules are assembled as J chain–containing IgA dimers bind to the first domain of polymeric immunoglobulin receptors on the basolateral membranes of mammary epithelial cells.[73–76] The endoplasmic part of the receptor is cleaved from the complex. The ectoplasmic part of the receptor that remains bound to the IgA dimer or trimer is termed the secretory component. The receptor-dimeric IgA complex is transported across the

Table 32-6 Representative Immune Factors in Human Milk Whose Production Is Delayed in Infancy

Agents	*Time of Maturation*
Secretory IgA	~ 4–12 mo

Memory T cells	~ 2 yr
Lysozyme	~ 1–2 yr
Lactoferrin	?
Interferon-γ	?
IL-6	?
IL-8	?
IL-10	?
TNF-α	?
PAF acetylhydrolase	?

Ig = immunoglobulin; IL = interleukin; PAF = platelet activating factor; TNF-α = tumor necrosis factor-α.

epithelial cell.[75,76] After fusion with the apical membrane, the endoplasmic part of the receptor is cleaved away. The remainder of the assembled molecule, secretory IgA, is subsequently secreted into the milk.

The secretory IgA antibodies derived from the enteromammary and bronchomammary pathways protect the recipient infant against infectious agents in the maternal environment. This mechanism is important in early infancy, when there is little production of secretory IgA.[25–27] During that period, about 0.5 to 1.0 g of secretory IgA is transferred daily to the mature infant by breast-feeding.[77]

The ability of secretory IgA antibodies to successfully survive in the gastrointestinal tract of the recipient infant is evidenced by several different lines of investigation: (1) secretory IgA is more resistant than other immunoglobulins to in vitro degradation by trypsin or chymotrypsin[78]; (2) the IgA subclass that is more resistant to bacterial IgA proteases, IgA_2, is more prominent in human milk than in blood[56]; (3) furthermore, secretory IgA antibodies against bacterial IgA proteases are often found in human milk.[79] Thus, the dominant immunoglobulin in human milk is well adapted to persist in environments such as the intestinal tract, where those enzymes are found. In keeping with these findings, concentrations of secretory IgA antibodies in the stools are much higher in infants fed human milk than in those fed cow's milk formulas.[50] Based on in vitro experiments and animal model studies, it is postulated that these maternal secretory IgA antibodies protect by agglutinating and thus immobilizing pathogens, by neutralizing their toxins or virulence factors, or by preventing their adherence to mucous membrane surfaces.

Antibacterial Oligosaccharides and Glycoconjugates

An array of oligosaccharides in human milk is produced by glycosyltransferases in the mammary gland. Many of them act as receptor analogs that inhibit the binding of certain enteric or respiratory bacterial pathogens or their toxins to epithelial cells.[80–87]

The chemistry of these carbohydrates dictates the specificity of their binding to adherence structures of bacterial pathogens or their toxins. In that respect, GM_1 gangliosides are receptor analogues for toxins produced by *V. cholerae* and *E. coli*,[83] whereas the globotriaosylceramide Gb3 binds to the B subunits of Shiga toxin.[84] A fucosyloligosaccharide inhibits the stable toxin of *E. coli*,[85] whereas a different one inhibits *Campylobacter jejuni*.[86] Other oligosaccharides in human milk such as G1cNAc (1–3) Gal-disaccharide subunits interfere with the attachment of *Haemophilus influenzae* and *Streptococcus pneumoniae* to respiratory epithelium.[87]

Certain glycosylated proteins also interfere with bacterial or viral adherence. The prime examples are the high-molecular-weight, heavily glycosylated milk mucins.[88] About two-thirds of the mucin in human milk is membrane bound. The concentration of mucin in human milk is about 50 to 90 mg/mL.

The most prominent mucin in human milk, MUC1, is primarily found bound to membranes of milk fat globules.[88] In that respect, human milk fat globules and mucin from their membranes inhibit the binding of S-fimbriated *E. coli* to human epithelial cells.[89]

Antiviral Factors

In addition to secretory IgA antibodies, other types of antiviral agents have been identified in human milk or are produced by digestion of substrates in human milk. They include human milk fat globules[90] and free fatty acids and monoglycerides generated by the enzymatic digestion of triglycerides in human milk that disrupt enveloped viruses.[91,92] These fatty acids and monoglycerides are also antibacterial[91,92] and kill *Giardia lamblia*,[93] a common intestinal parasite in humans.

Human milk fat globules protect against rotavirus infections in mice[90] and presumably do so in the human infant. The antirotavirus component of the human milk fat globule membrane complex is lactadhedrin, a 49 kDa glycoprotein.[94] Lactadhedrin is thus an important constituent of human milk because rotavirus is the most common cause of infectious enteritis in human infants.[95]

Leukocytes

Living cells are found in human milk.[96–98] In contrast to B cells, which transform into plasma cells that remain sessile in the mammary gland, other types of leukocytes attracted to the site traverse the mammary epithelium and enter milk secretions. The highest concentrations of leukocytes in human milk occur in the first few days of lactation ($1–3 \pm 10^6$/mL). They include neutrophils (40 to 65%), macrophages (35 to 55%), and lymphocytes (5 to 10%).

Human milk lymphocytes are predominantly T cells. Both $CD4^+$ (helper) and $CD8^+$ (cytotoxic/suppressor) T cells are present in human milk.[99,100] In comparison with human blood T cells, there is an increased proportion of $CD8^+$ T cells in human milk.[100] This pattern is similar to that found in other mucosal sites. Virtually all $CD4^+$ (helper) T cells and $CD8^+$ T cells in human milk bear the CD45 isoform CD45RO,[99,100] associated with T-cell activation and immunologic memory.[101,102] In addition, an increased proportion of the T cells display other phenotypic markers of activation.[100]

The ability of leukocytes from human milk to produce certain cytokines has been investigated in in vitro studies. Interferon is produced by virus-infected or phytohemagglutinin-stimulated human milk lymphocytes.[99,103–105] The antiviral agent produced by these mitogen-stimulated cells is interferon-γ,[99] which is consistent with their CD45RO phenotype.[99,100] Other cytokines, such as macrophage migration inhibitor factor and monocyte chemotactic factors, are also produced and secreted by stimulated milk T cells.[105] Additional cytokines are produced by human milk leukocytes,[106] but the extent of their production and secretion is not determined.

In other mammals such as sheep, it has been demonstrated that mononuclear leukocytes from milk enter into the tissues of the recipient's intestinal tract and mesenteric lymph nodes.[107] However, passage of milk leukocytes into the intestinal or lymphoid tissues of the recipient infant has not been demonstrated in humans.[98] There are, however,

observations that suggest that cellular immunity to tuberculosis is transferred from mother to infant during breast-feeding.[108] It is unclear whether that is attributable to the transfer of sensitized T cells or to other immunomodulating mechanisms.

Neutrophils and macrophages in human milk are lipid laden because of the ingestion of milk fat globules and therefore are difficult to distinguish by conventional staining methods. They can be identified, however, by appropriate cytochemical and immunochemical procedures. These cells are phagocytic, and there is some evidence that phagocytosis induces a respiratory burst in milk macrophages.[99,109]

The motility of the neutrophils is decreased,[110] whereas the motility of macrophages in human milk is increased compared with their counterparts in blood.[111] These features are attributable to cellular activation. Indeed, neutrophils and macrophages in human milk display phenotypic markers of activation, including an increased expression of CD18/CD11b and a decreased expression of CD62 (L-selectin).[110] The in vivo fate and role of these activated leukocytes in host defense of the infant are undetermined.

ANTI-INFLAMMATORY PROPERTIES

Human milk protects without clinical manifestations of injury to the recipient infant.[5,6,112] There is evidence that this may be owing to a paucity of many of the initiators and mediators of inflammation and the presence of anti-inflammatory agents in human milk[113,114] More recent in vitro and in vivo animal experiments support the concept that human milk is anti-inflammatory. The in vitro oxidative injury produced by neutrophils is decreased by human milk,[115] and human milk decreases carrageenan-induced inflammation and a chemical-induced colitis in rats.[116,117]

Paucity of Inflammatory Agents

Many of the known inducers or mediators of inflammation are either absent or poorly represented in human milk.[113,114] These include (1) the coagulation system; (2) the kallikrein-kininogen system; (3) major components of the complement system; (4) IgE; (5) basophils, mast cells, and eosinophils; and (6) natural killer cells.

Anti-inflammatory Agents

The anti-inflammatory agents in human milk are (1) antioxidants; (2) protease inhibitors, particularly a_1-antichymotrypsin and α_1-antitrypsin; (3) enzymes that bind to substrates such as lysozyme to elastin[118]; (4) anti-inflammatory cytokines including interleukin (IL)-10[119] and transforming growth factor (TGF)-β[120,121]; (5) soluble receptors that bind to proinflammatory cytokines such as tumor necrosis factor (TNF)-α[122]; (6) enzymes that degrade mediators of inflammation; (7) epithelial growth factors; and (8) cytoprotective agents (see Table 32-3).

The antioxidants include an ascorbate-like compound,[115] uric acid,[115] α-tocopherol,[123,124] and betacarotene.[123,124] In that regard, blood levels of α-tocopherol and betacarotene are higher in breast-fed infants than in artificially fed infants who are not supplemented with those nutrients.[123,124]

The human milk growth factors for epithelium include epithelial growth factor,[125] lactoferrin,[126] cortisol,[127] and polyamines.[128,129] Other hormones and growth factors in human milk[130] may also affect the growth, differentiation, and turnover of epithelial cells and thus limit the penetration of free antigens and pathogenic microorganisms and affect other barrier functions of the intestinal tract. In that respect, there are significant differences between the biophysical/biochemical organization and function of the mucosal barrier system in adults and neonates,[131,132] and the maturation of those functions may be accelerated by human milk.[133–135] In addition, the permeability of the intestinal tract of human infants is decreased in early infancy as a result of human milk feedings.[136–138]

Protection against Necrotizing Enterocolitis

Because human milk appears to protect against necrotizing enterocolitis (NEC) in early infancy,[139] a search has been made to identify the possible agents in human milk that might inhibit intestinal inflammation. Platelet activating factor (PAF) acetylhydrolase, an enzyme that degrades PAF, is a prime candidate. In that respect, PAF plays a role in an endotoxin- and hypoxia-induced intestinal injury in rats that mimics human NEC.[140] Furthermore, PAF acetylhydrolase is present in human milk,[141] and the production of human PAF acetylhydrolase is developmentally delayed.[32]

A role for IL-10 in preventing human NEC is suggested from mice that have been rendered deficient in IL-10 by a targeted gene deletion.[142,143] The mice are asymptomatic until after weaning. Afterward, they develop a fatal enterocolitis that resembles NEC in human premature infants. In keeping with the results of that animal model, stimulated blood monocytes and T cells from human newborn infants produce very little IL-10,[34] whereas high levels of IL-10 are found in milk in the majority of women who deliver at term[119,144] and those who deliver prematurely.[144] Furthermore, it is of interest that high and low producers of IL-10 in human milk have been found,[144] and in the most recent study, very low to undetectable concentrations of IL-10 in human milk were found in most women whose premature infants developed NEC despite receiving maternal milk.[144]

Human Milk and Allergic Diseases

The effects of human milk on the development of allergic diseases have been examined by many investigators, but there is no agreement about the protective effect of breast-feeding,[145] except for two types of allergic disorders. The first is atopic dermatitis,[14–16,145] and the second is diseases such as celiac disease that are provoked by food allergens that are avoided by complete breast-feeding.[146] Much of the discrepancy in the results of the investigations may be owing to confounding variables such as variations in the genetic predisposition to atopic disorders, the sufficiency of breast-feeding, dietary exposures not appreciated by parents, and concomitant exposures to inhalant allergens or irritants that produce respiratory symptoms. Furthermore, there is some evidence that high exposures to certain

infectious agents facilitate Th1 responses and hence the development of cellular immunity, whereas lower exposures engender Th2 responses that lead to antibody formation and possibly to IgE-mediated hypersensitivity.[147] Thus, the effect of breast-feeding on the risk of atopic diseases may well depend on a multiplicity of factors that are not equally represented in all investigated populations.

Moreover, foreign food antigens in human milk are transmitted to the breast-fed infant,[148] and allergic reactions to those antigens may be triggered in some of the recipient infants by this route of exposure.[149] However, only a small subpopulation of breast-fed infants develops atopic diseases. To establish whether a breast-fed infant reacts to a foreign food antigen in human milk, trials of dietary elimination and oral challenge with the food in question should be conducted in the breast-feeding mother.[13,149,150] If those trials suggest that the infant reacts to a foreign food antigen transmitted by breast-feeding, then the problem may be avoided by eliminating the food allergen from the maternal diet.[13,149,150] If the food allergen is a basic food such as cow's milk, the woman must have a diet that supplies the correct types and quantities of nutrients needed during lactation.[13,150] If long-term elimination is impractical, then breast-feeding may be stopped and the infant tried on a hypoallergenic formula.

In addition, the development of allergic disease in breast-fed infants may also be attributable to alterations in the types of fatty acids found in milks produced by mothers of the allergic infants.[13,151,152] The proposition is that some fatty acids that are anti-inflammatory may be reduced, whereas others that are proinflammatory may be increased in those milks.[152]

IMMUNOMODULATING AGENTS

Immunomodulating agents in human milk have only recently been recognized. Certain seemingly unrelated observations provided the basis of this idea:

1. Although the evidence is not completely conclusive, epidemiologic investigations suggested that breast-fed infants may be at less risk for developing type 1 diabetes mellitus,[17] lymphoma,[18] acute lymphocytic leukemia,[20] or inflammatory bowel disease, particularly Crohn's disease,[21] later in childhood. The prevention or lessening of the effects of infections by antimicrobial agents and anti-inflammatory agents in human milk or the avoidance of early introduction of foreign food antigens into the diet may have long-term consequences. However, it also seems tenable that the observed delayed effects may be attributable to agents in human milk that influence the long-term development of the child's immune system.
2. Increased levels of certain immune factors in the infant, levels that could not be accounted for by passive transfer of those substances from human milk, also suggested that human milk is immunomodulating. Breast-feeding primes the infant to produce higher blood levels of interferon-α in response to respiratory syncytial virus infection.[153] Also, the increments in blood levels of fibronectin achieved by breast-feeding are not owing to the amounts of that protein in human milk.[154] In addition, human milk feedings lead to a more rapid development in systemic antibody responses[155] and the appearance of secretory IgA in external secretions,[156–158] including urine, which are far removed from the route of ingestion.[157,158] Therefore, it does not seem likely that the increments were attributable to those same factors in human milk.
3. The third line of evidence developed from the discoveries that all types of leukocytes in human milk are activated (see previous section on the leukocytes in human milk). Further in vitro investigations revealed that human milk enhanced the movement of blood monocytes and that much of that increased motility was abrogated by antibodies to TNF-α.[159] Subsequently, the presence of TNF-α in human milk was verified immunochemically.[160]

CYTOKINES

In addition to TNF-α, many other cytokines have been discovered in human milk, including some that are proinflammatory (IL-1b,[161] IL-6,[162,163] IL-8[164]), anti-inflammatory (TGF-β[164-166], IL-10[119]), growth promoters for hematopoietic cells (erythropoietin,[167] granulocyte colony-stimulating factor,[168] macrophage colony-stimulating factor[169]), chemokines (IL-8,[164] RANTES, [170] eotaxin[170]), Th1 agents (interferon-γ,[171] IL-12,[172] IL-18[173]), and Th2 cytokines (IL-10[119]). Some potential effects of those agents in human milk in the recipient infant have been suggested from in vitro studies (see Table 32-5), but the in vivo sites of action and the extent of their effects on the recipient infant are not determined.

OTHER IMMUNOMODULATING AGENTS

Several other immunomodulating agents have been found in human milk (see Table 32-4), including β-casomorphins from the digestion of β-casein,[174] prolactin,[130,175] anti-idiotypic antibodies,[176] and nutrients including α-tocopherol[123,124] and a host of nucleotides[177,178] that enhance natural killer cell,[179] macrophage,[179] Th cell activities,[180] and antibody formation to certain immunogens.[181]

HUMAN MILK AND TH1 AND TH2 RESPONSES

It is of interest that Th1 and Th2 cytokines are present in human milk and that Th1 and Th2 cells are found in alimentary tract tissues of the recipient infant.[182] The effects of human milk cytokines on the expression of Th1 and Th2 activities in the gastrointestinal tract of human infants are unknown. Furthermore, the types and, in some cases, the intensity of infections dictate the mix of Th1 and Th2 cytokines produced by the host and hence whether cellular immunity characterized by activated T cells, cytotoxicity, and activated macrophages or the production of immmunoglobulins will occur.[147] Antimicrobial agents in human milk often reduce the load of microbial pathogens by killing them, interfering with their replication, preventing their adherence to mucosal sites, or neutralizing their toxins or virulence factors. Thus, it seems plausible that

these agents as well as cytokines in human milk may influence the recipient's T cell helper responses.

Immunologic Tolerance

Another immunomodulating effect of human milk is the induction of immunologic tolerance to maternal human leukocyte antigens. Children breast-fed during infancy have been found to be more tolerant of maternal renal transplants than those who were not breast-fed.[183–185] Furthermore, blood T cells from such children are less likely to react against maternal blood lymphocytes in culture than those from children who were not breast-fed during infancy.[186] The tolerance may be induced by major histocompatibility complex (MHC) class II antigens found on milk fat globules.[187,188] Macrophages and some of the activated T cells in human milk may possibly contribute additional MHC class II antigens[100,110] for the induction of tolerance to those maternal antigens. The natural effects of this tolerance to MHC class II are unknown, but one possibility may be that it may help to establish and maintain residency of maternal human milk T cells or macrophages in the tissues of the alimentary tract or respiratory system of the recipient infant. It is also unclear whether tolerance to other antigens such as foreign food proteins in human milk is induced by breast-feeding.

SUMMARY

There are seven evolutionary outcomes concerning the relationship between the immunologic status of the infant and the immunologic agents produced by the mammary gland:

1. Certain postnatal developmental delays in the infant's immune system are replaced by those same agents in human milk (see Table 32-6).
2. Other postnatal delays in the infant's immune system are offset by dissimilar agents in human milk.
3. Agents in human milk initiate or augment functions that are otherwise poorly expressed in the infant.
4. Agents in human milk alter the physiologic/biochemical state of the alimentary tract from one suited for fetal life to one that is appropriate for extrauterine life.
5. Defense agents in human milk protect without provoking inflammation and by providing some agents that inhibit inflammation (see Table 32-3).
6. Defense agents in human milk have an enhanced survival in the gastrointestinal tract of the recipient infant compared with most foreign dietary proteins.
7. Growth factors in human milk augment the proliferation of a commensal enteric bacterial flora.

Much has been learned about the in vitro activities of the protective factors in human milk, but little is known about how those bioactive agents produce the in vivo effects that are attributed to breast-feeding. The problem is compounded by the interactions between the defense agents in human milk, the many functions of some of the agents, and the dynamic changes in the immune systems of the infant and of the maternal mammary gland during the postnatal period and lactation. Also, the spectrum of bioactive agents such as the cytokines in human milk and the extent of developmental delays in the immune system are not completely known.[189] Furthermore, some consequences of the immunomodulating factors in human milk may not be evident until long after breast-feeding is over. Thus, many investigations will be required to elucidate the immunologic aspects of these maternal–infant interactions. Nevertheless, the uniqueness of the immune system in human milk and its known health benefits are important reasons to encourage breast-feeding.

CHAPTER 33

APPROACH TO BREAST-FEEDING

Ruth Lawrence, MD, Robert M. Lawrence, MD

The health goals of our nation include a statement regarding breast-feeding. By the year 2010, 75% of women will leave the hospital breast-feeding, at least 50% will continue to breast-feed for at least 6 months, and at 12 months, at least 25% will still be breast-feeding. The goal particularly addresses high-risk women, those from minority, low-income, and undereducated groups.[1]

The Institute of Medicine issued a report on nutrition during lactation as part of a review of nutrition in the perinatal period that stated that breast-feeding was ideal for all infants under ordinary circumstances.[2] It further stated that even women without perfect diets could produce good milk and nourish their young well.[2] Professional medical associations such as the American Academy of Pediatrics,[3] the American College of Obstetrics and Gynecology, and the Academy of Family Practice have developed policies encouraging universal breast-feeding. The World Health Organization and United Nations International Children's Emergency Fund (UNICEF) have taken very strong positions in support of worldwide breast-feeding, including the development of the Baby Friendly Hospital Initiative.[4,5]

Human milk is specifically designed for the needs of the human infant. Its nutritional advantages have been noted to be especially important for brain growth.[6–8] In the first year of life, the brain of the human infant doubles in size.[9] The myelinization of nerves is equally as important and occurs extensively in the first year of life. Taurine, cholesterol, and omega fatty acids are essential to brain growth and are uniquely present in human milk.[10]

The presence of dozens of active enzymes, immunologic properties, infection protection properties, and allergy protection are some of the compelling reasons breast-feeding is superior for human infants.[11–14]

The number of women who elect to breast-feed has continued to increase, and the renaissance of breast-feeding is well established.[15,16] It is important for the clinician to be knowledgeable about the value of human milk, the advantages of breast-feeding, the clinical management of lactation, and the diagnosis and treatment of problems.[17] The current scientific literature provides a large resource of information on these topics, which will be summarized here.

ANATOMY AND PHYSIOLOGY

Lactation is the completion of the normal reproductive cycle. It is a physiologic process triggered by the termination of pregnancy but anticipated both anatomically and physiologically from early development.[10]

The breast bud is present at birth in both sexes but remains dormant until early pubescence, when growth is stimulated by the increase in estrogen and progesterone in the female.[18,19] The ductal system proliferates and the breast matures. This maturation continues with stimulus from each menstrual cycle until age 25. When growth stabilizes, further proliferation does not occur until pregnancy intervenes (Figure 33-1).

Changes in circulating hormones result in profound changes in the ductular-lobular-alveolar growth during pregnancy.[20] There is a marked increase in ductular sprouting, branching, and lobular formation evoked by luteal and placental hormones (Figure 33-2). Placental lactogen, prolactin, and chorionic gonadotropin have been identified as contributors to the accelerated growth.

From the third month of gestation, secretory material resembling colostrum appears in the alveoli. By the second trimester, placental lactogen begins to stimulate the production of colostrum so that a woman delivering immaturely as early as 16 weeks may secrete colostrum, although her baby is not viable. Until delivery, the production of milk is suppressed by prolactin-inhibiting hormone, produced by the placenta. Progesterone produced by the placenta has been recognized as important in blocking milk production in pregnancy. At delivery, the withdrawal of placental and luteal sex hormones and the infant's sucking result in the loss of the inhibiting hormones and the stimulation of prolactin-releasing factors.[21]

The initiation of milk secretion at delivery and the continued production of milk occur because the breast has developed extensively throughout pregnancy.[10] The ductal system has arborized to form an extended network of collecting ducts. The alveoli are richly lined with epithelial cells varying from flat to low columnar in shape, all capable of producing milk. Some cells protrude into the lumen of the alveoli; others are short and smooth. The lumen of the alveolus is crowded with fine granular material and lipid droplets (Figure 33-3). The division and differentiation of the mammary epithelial cells and presecretory alveolar cells into secretory milk-releasing alveolar cells complete the preparation for milk production. The biosynthesis of milk involves this cellular site, where the metabolic processes occur. There are stem cells and highly differentiated secretory alveolar cells at the terminal ducts. The stem cells are stimulated by

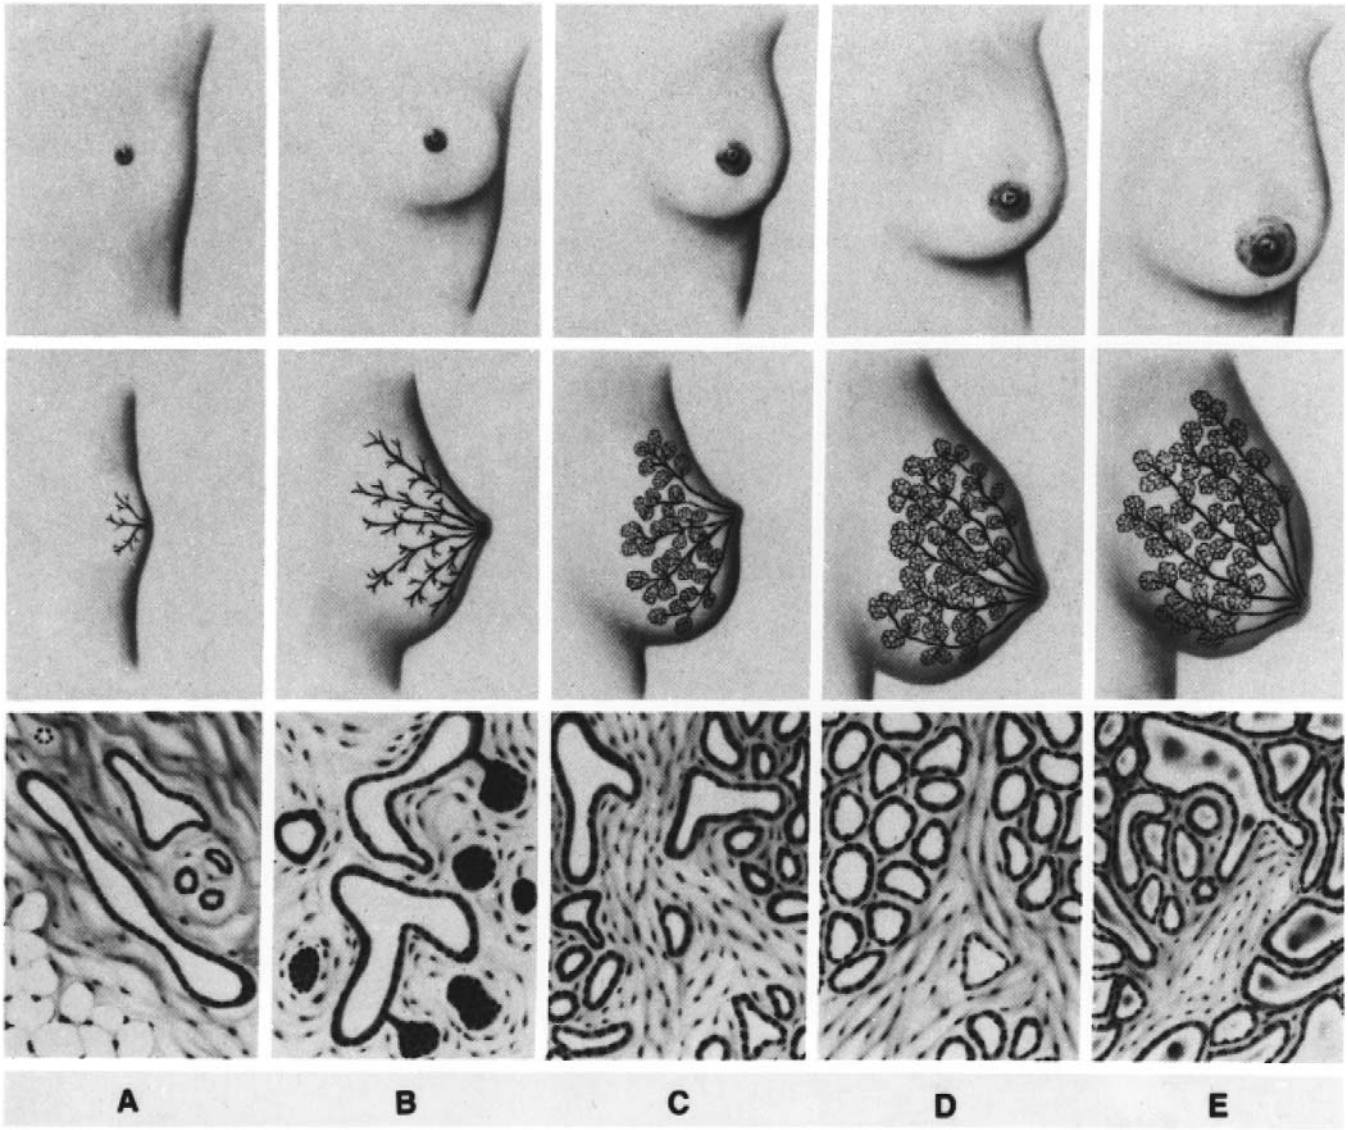

FIGURE 33-1 Female breast from infancy to lactation with corresponding cross-section and duct structure. *A, B, C,* Gradual development of well-differentiated ductular and peripheral lobular-alveolar system. *D,* Ductular sprouting and intensified peripheral lobular-alveolar development in pregnancy. Glandular luminal cells begin actively synthesizing milk fat and proteins near term. Only small amounts are released into lumen. *E,* With postpartum withdrawal of luteal and placental sex steroids and placental lactogen, prolactin is able to induce full secretory activity of alveolar cells and release of milk into alveoli and smaller ducts. Reproduced with permission from Lawrence RA and Lawrence RM.[10]

growth hormone and insulin, which is synergized by prolactin to stimulate the cells to secretory activity. The breast acts in response to the interactions of the pituitary, thyroid, pancreatic, adrenal, and ovarian hormones (Figure 33-4).

The process of milk synthesis involves apocrine secretion for the de novo production of fat and protein and the merocrine secretion of lactose synthesized from glucose.[18] Ions diffuse across the membrane and, in some cases, are actively transported. The primary alveolar milk is then diluted within the lumen to be isotonic with plasma by water that diffuses from extracellular fluid.[22] The pathways for milk synthesis and secretion into the mammary alveolus include (1) exocytosis of protein and lactose, (2) formation of the milk fat globule, (3) secretion of ions and water, (4) pinocytosis-exocytosis of immunoglobulins, and (5) the paracellular pathway (Figure 33-5).

Because lactation is anticipated, the body prepares the breast during pregnancy and also develops additional nutritional maternal stores that will be needed during lactation, in the form of 6 to 8 pounds of body weight apart from the uterus and its contents. When lactation begins, there is a redistribution of blood supply from the uterus to the breast, where there is an increased demand for nutrients and an increased metabolic rate to accommodate the demands of milk production. The mammary gland may have to produce milk at the expense of other organs if stores are inadequate. There are cardiovascular adjustments as mammary blood flow increases. The mammary blood flow, cardiac output, and milk secretion are suckling dependent. In addition, suckling induces the release of anterior pituitary hormones, prolactin and oxytocin, which act directly on the breast tissue and on the uterus.[21]

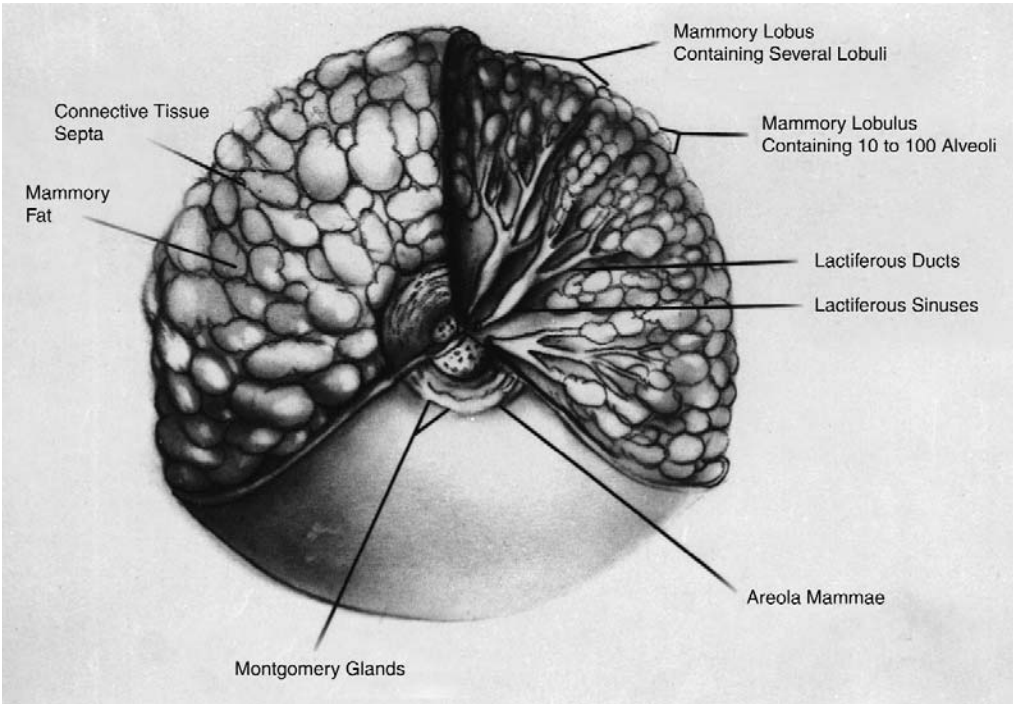

FIGURE 33-2 Morphology of mature breast with dissection to reveal mammary fat and duct system. Reproduced with permission from Lawrence RA and Lawrence RM.[10]

In addition to glandular preparation, the nipple and areola are also preparing for lactation. There is an increase in vascularization. The Montgomery glands, which are sebaceous glands on the areola circling the nipple, become enlarged and begin to secrete a substance that lubricates and protects the areola and nipple during pregnancy and lactation. There are 15 to 25 milk ducts opening in the nipple. Each tubuloalveolar gland arborization, called a lobe, opens separately in the nipple. The collecting duct or lactiferous sinus of the system lies beneath the areola, which is why the infant must have most of the areola in the mouth to "milk" the collecting ductules. The nipple has many sensory nerve fibers, but the areola does not, an important fact in terms of comfort for the mother while nursing. The response to tactile sensation of the nipple increases dramatically at delivery as an adaptation for lactation that enhances the nervous response to suckling by the infant (Figure 33-6).

INITIATION OF MILK SECRETION

Withdrawal of placental and luteal sex hormones and stimulation of prolactin-releasing factor result in the increased prolactin synthesis by the adenohypophysis, which stimulates milk synthesis in the mammary alveoli. The release of milk from the alveolar collecting ductules or lactiferous sinuses depends on the ejection or let-down reflex (see Figure 33-6). The let-down reflex is a simple arc that is initiated by the suckling of the infant. This suckling stimulates the mechanoreceptors in the nipple and areola that send stimuli along nerve pathways to the hypothalamus, which stimulates the posterior pituitary to release oxytocin. Oxytocin is carried via the bloodstream to the breast and uterus.[23] Oxytocin stimulates the myoepithelial cells, which envelop the secretory alveoli and the collecting ductules in the breast, to contract, ejecting milk through the ductule. The oxytocin also stimulates the myoepithelial cells in the uterus to contract, causing the "after pains" a mother associates with lactation. Physiologically, this uterine contraction enhances the uterine postpartum involution so that the uterus of the lactating woman returns to normal more quickly postpartum. Oxytocin release can also be stimulated by seeing or hearing the infant; thus, a woman notices that her milk begins to drip when she sees her infant. Prolactin, however, is released only when the breast is stimulated by suckling or pumping.

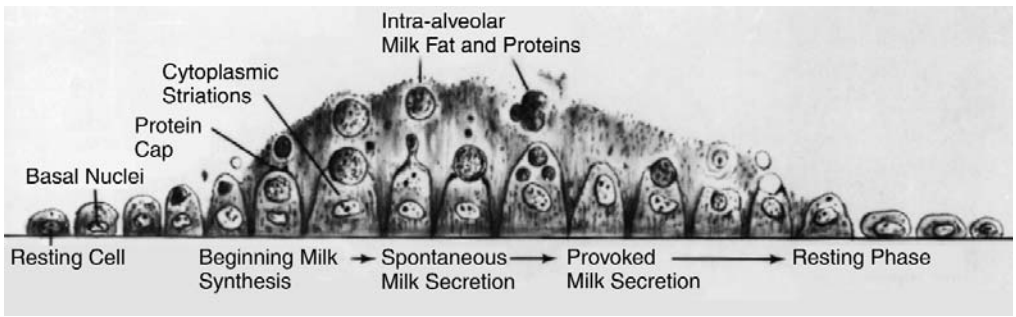

FIGURE 33-3 Cycle of secretory cells from resting stage to secretion and return to resting stage. Reproduced with permission from Lawrence RA and Lawrence RM.[10]

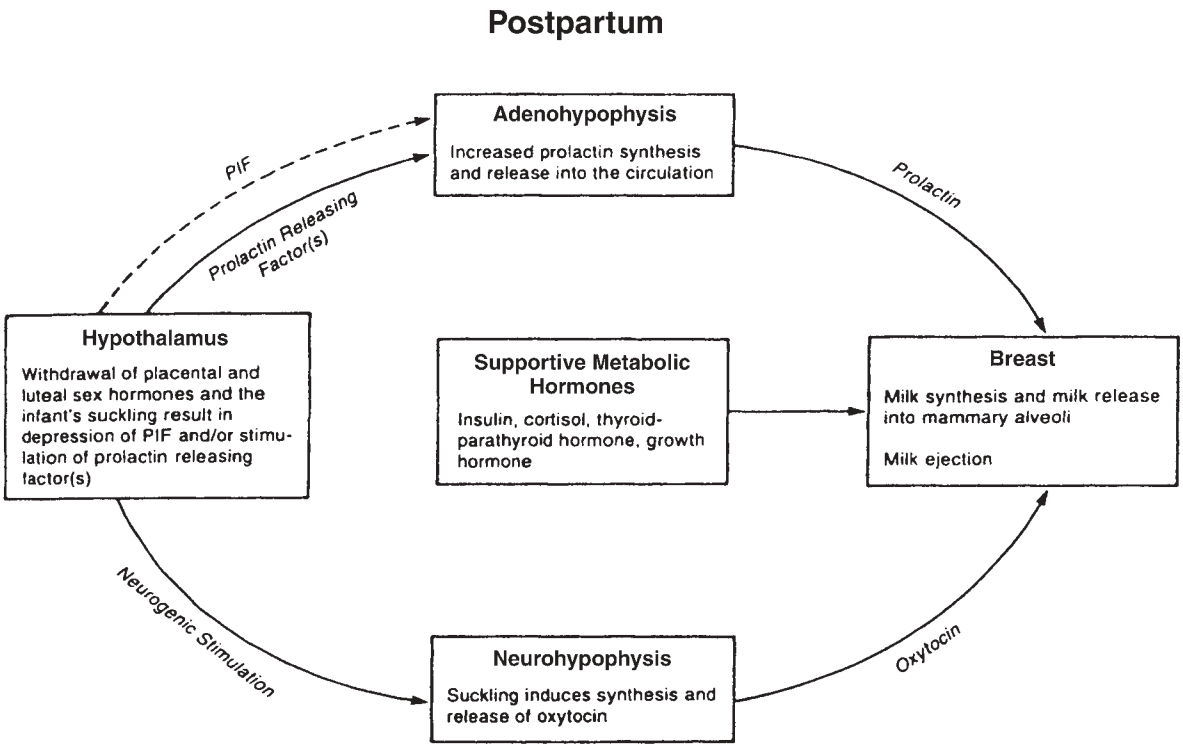

FIGURE 33-4 Hormonal preparation of breast postpartum for lactation. Reproduced with permission from Lawrence RA and Lawrence RM.[10]

Prolactin, which is also released from the hypothalamus during sucking, stimulates the production of milk. Prolactin levels during early lactation are increased 10 to 20 times greater than normal. The technology required to obtain prolactin levels has been available for clinical investigation, but the role of prolactin in the volume of milk produced is still not clearly defined. It is clear, however, that the surge in prolactin to about twice baseline levels is critical to the successful production of an adequate supply of milk. When evaluating prolactin during lactation, a sample of blood is drawn at baseline and then a second sample is drawn after 10 minutes of breast-feeding or pumping with an electric pump.[10]

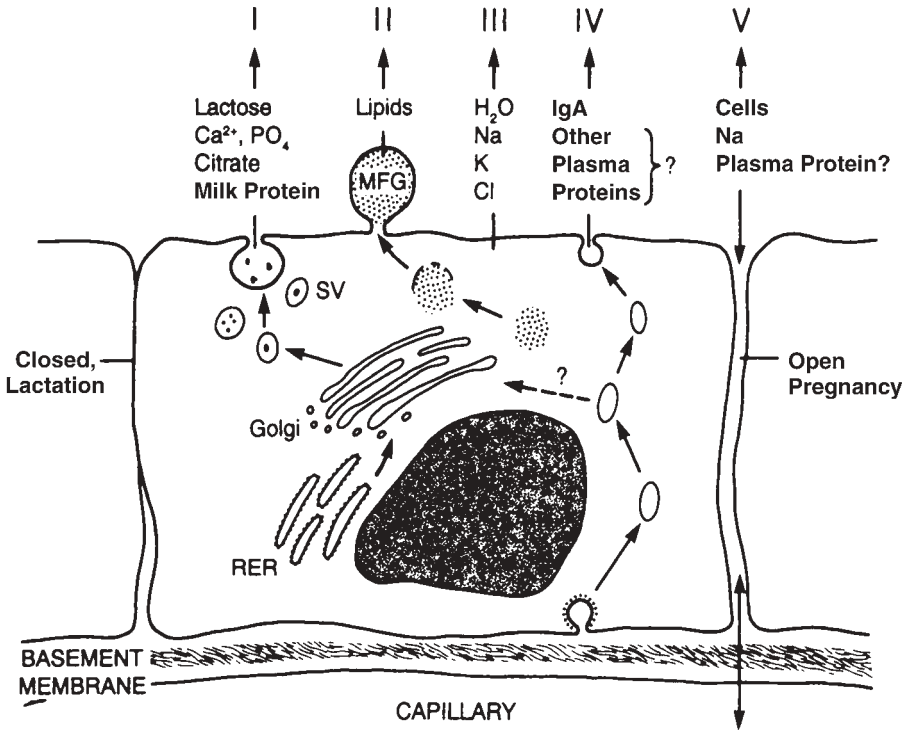

FIGURE 33-5 The pathways for milk synthesis and secretion in the mammary alveolus. (II) Exocytosis of milk protein and lactose in Golgi-derived secretory vesicles. (III) Secretion of ions and water across the apical membrane. (IV) Pinocytosis-exocytosis of immunoglobulins. (V) The paracellular pathway of plasma components and leukocytes. MFG = milk fat globule; RER = rough endoplasmic reticulum; SV = secretory vesicle. Adapted from Neville MC.[18] Reproduced with permission from Lawrence RA and Lawrence RM.[10]

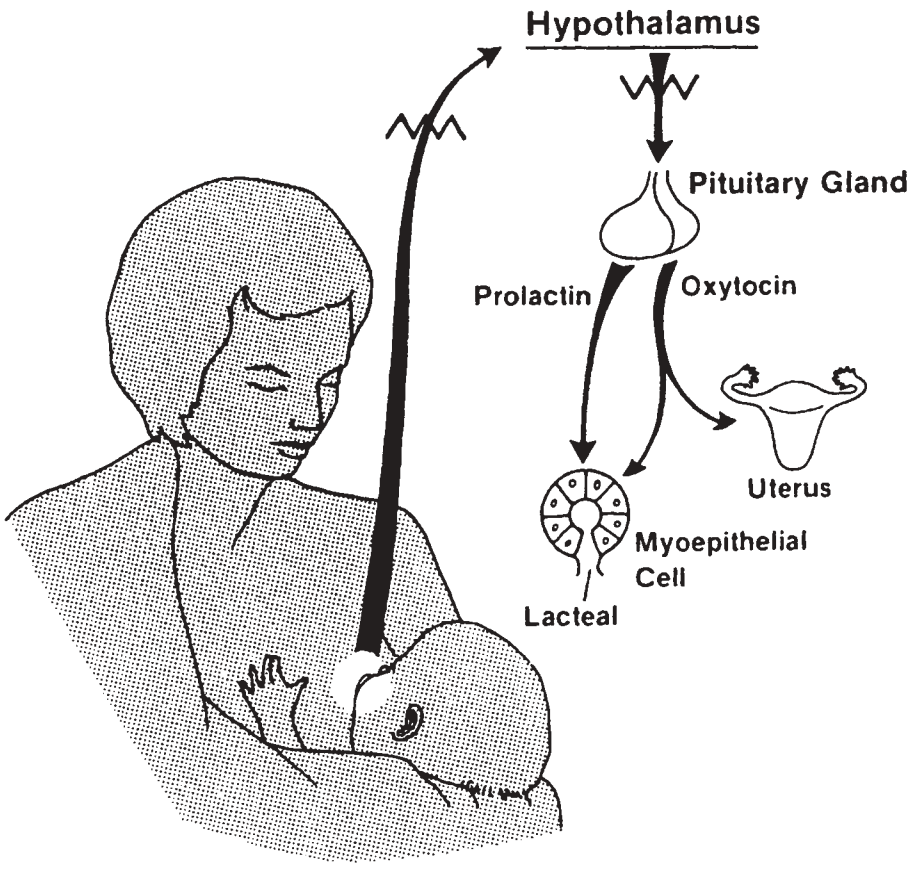

FIGURE 33-6 Ejection reflex arc. When suckling the breast, the infant stimulates mechanoreceptors in the nipple and areola that send a stimulus along nerve pathways to the hypothalamus, which stimulates the posterior pituitary to release oxytocin. It is carried via the bloodstream to the breast and uterus. Oxytocin stimulates myoepithelial cells in the breast to contract and eject milk from the alveolus. It is secreted by the anterior pituitary gland in response to suckling. Stress such as pain and anxiety can inhibit the let-down reflex. The sight or cry of an infant can stimulate it. Reproduced with permission from Lawrence RA and Lawrence RM.[10]

PRENATAL CONSIDERATIONS

Although the breast prepares for lactation independent of the mother's decision to breast-feed, it is important to introduce the question of feeding the infant as soon as possible during pregnancy so that the mother can make an informed choice on behalf of her baby. Although it has been suggested that well-educated mothers have made up their minds about how they will feed their infants long before conception occurs, there are many women who need to be informed about breast-feeding and need to receive reinforcement from their physician.[24] Many women, especially primiparas, will need considerable assistance to lactate successfully. The significant benefits of human milk to the human infant have already been reviewed in previous chapters. The psychological benefits are equally as important to both mother and child.[25]

The nutritional benefits of human milk, although legion, can in part be substituted with a modern prepared formula, but the infection protection, immunologic properties, and psychological benefits of human milk cannot be duplicated.[13,14] In the mid-twentieth century, when bottle feeding was rampant, the single, clear, unchallenged advantage to breast-feeding that was articulated was the special interrelationship between the mother and her baby.[25] The key elements of attachment are said to include early contact, closeness, eye-to-eye contact, and body warmth. Breast-feeding includes these naturally. A woman has a surge of oxytocin and prolactin during each feeding, which has been demonstrated biologically to stimulate mothering behavior.[26,27]

When a mother wishes to be free of the responsibility of breast-feeding, it is often so that she will not be tied down, will not always have to be available, and can have others feed the infant, thus depriving the infant of this special frequent closeness with the mother.

Preparation of the Breasts

Nature prepares the breasts. It is not necessary to manipulate the breasts and nipples prenatally in preparation in the normal woman. Part of the prenatal physical examination should include the breasts with respect to lactation so that any anatomic variations that may interfere with lactation can be discussed.[24] The size of the breast is not related to lactation success and is not a measure of glandular potential. Women who have had benign cysts removed can still nurse successfully. Augmentation mammoplasty does not interfere with lactation if the nipple and duct system have been left intact, that is, the nipple has not been realigned and the implant is placed under the breast tissue on the chest wall. Unless the implant has ruptured and has caused scarring, lactation should be successful. When breast size has been surgically diminished by reduction mammoplasty, the duct system may have been interrupted if the nipple was completely removed and replaced central to the remaining tissue. This may make lactation improbable, and this issue should be discussed with the operating surgeon. If the procedure was done leaving the nipple and areola on

a pedicle, lactation may be successful. Women who have had one breast removed surgically can successfully breast-feed, although when the mastectomy is for malignant disease, it may not be recommended because of the potential effect of continued high levels of sex steroids in the system if pregnancy occurs within 5 years of treatment. It should be discussed with the oncologist. Women who are in the process of treatment for breast cancer during lactation may pump and discard their milk for a few days after chemotherapy and then resume feeding until the next treatment. Length of time for discarding varies with the drug employed. The time for complete clearance can be calculated as five times the half-life of the drug involved.[10]

Inverted nipples are the most common anatomic problem identified (Figure 33-7). Although there are stretching exercises that can be done to pull the nipple out, exercises require time, considerable dedication, and a commitment on the part of the mother to this daily manipulation. Some mothers find nipple exercises distasteful. Nipple stimulus prenatally may trigger uterine contractions and premature labor. Another method of treatment for inverted nipples is wearing specially designed plastic shells (Figure 33-8) inside the normal brassiere daily during the last 6 weeks of pregnancy, beginning with a few minutes a day and increasing time worn to 8 to 10 hours after about 2 weeks. The continued gentle pressure on the areola, stretching the fibrous tissue, will evert the nipple through the central hole. After delivery, these shells can be worn between feedings (but not during) until the eversion is firmly established postpartum and the nipple is easily grasped by the infant. A controlled study by Alexander and colleagues found that neither technique was very effective, and it often discouraged some women from even initiating breast-feeding.[28] Inverted or small nipples may best be everted by using a good hand pump or an electric pump just prior to putting the infant in position to latch on for a feeding in the first few days postpartum. Usually, the nipple will remain erect without pumping in less than a week of these efforts. In subsequent pregnancies, the nipples are more everted, probably owing to the stretching of the fibers that were tying the nipple down.

Only gentle face soap and clear water are needed for breast care. No ointments or lotions are advised prophylactically as they irritate the skin and plug the natural pores, inhibiting the natural secretions. The sebaceous secretions of the glands of Montgomery on the areola are intended to lubricate the areola and nipple. Buffing the tissues briskly with a turkish towel or a toothbrush is neither necessary nor recommended. In a very dry climate, where skin dryness is a problem, a bland ointment such as A and D ointment or purified lanolin might be prescribed in some cases.

Removing colostrum in the last few weeks of pregnancy by manual expression is not recommended as it may irritate the tissues and cause an early mastitis. Because the colostrum is discarded, it wastes a very valuable commodity, which should be left for the infant. Such manipulation of the breast may also stimulate premature contractions of the uterus. Prior to delivery, the mother should purchase and bring to the hospital a well-constructed nursing brassiere to support the breasts, especially as the milk first comes in. This will alleviate the feeling of heaviness and engorgement. Many women wear a nursing brassiere night and day, especially in the first few weeks postpartum.

A new mother may find it helpful to attend breast-feeding classes prenatally and actually see an infant at the breast before she delivers if she is totally unfamiliar with breast-feeding.[29] Many childbirth classes include breast-feeding in the curriculum. If not, the physician may wish to have the office staff provide that educational service or

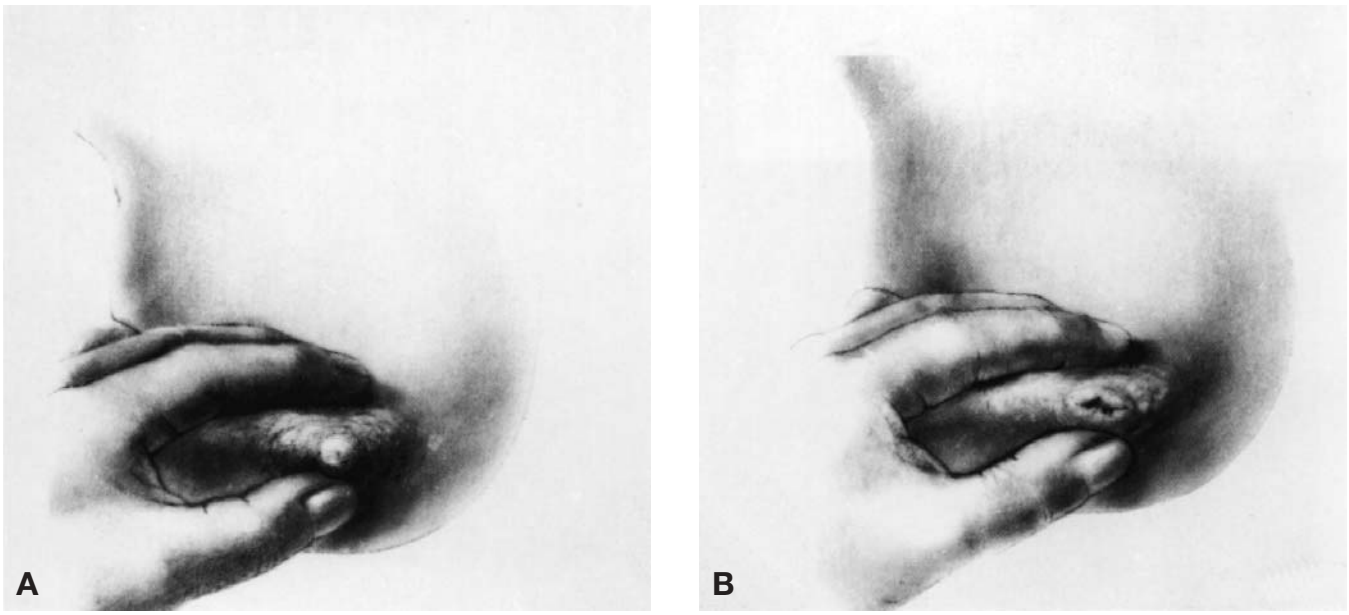

FIGURE 33-7 *A,* Normal nipple everts with gentle pressure. *B,* Inverted or tied nipple inverts with gentle pressure. Reproduced with permission from Lawrence RA and Lawrence RM.[10]

refer the patient to a community breast-feeding support group, such as La Leche League.

Initiating Lactation: The First Feed

As soon after birth as possible, the infant should be breast-fed.[4,5] Once the infant is stable, with the airway clear and respirations established, he can be offered the breast with the mother lying on her side facing the infant, who is also lying on his side. The infant should be held close to the breast. The areola will be soft and compressible. If the mother strokes the infant's lower lip with the nipple, he will quickly root, open the mouth wide, grasp the nipple and areola, and begin to suckle. The nipple and areola elongate to form a teat as they are drawn into the mouth. The infant should grasp well beyond the nipple to compress the areola and stroke the ampullae of the collecting ductules, which lie under the areola (Figures 33-9 and 33-10). Because nipple size and areola size vary, the infant may not be able to get the entire areola into the mouth. Even at the first feeding, the infant will receive colostrum. The mother should be further instructed in the art of positioning herself comfortably and supporting her breast with her hand. Changing her position at different feedings allows the infant to grasp from different angles.[29,30] This will rotate the point of greatest suckling pressure and will evenly distribute the suckling pressure over the entire areola. A mother may lie down or sit up as she chooses. If the nipple is tender, the baby can be held on the right breast as if he were nursing on the left side, that is, facing the mother's right side with feet to her right (or the reverse on the left breast, with the infant facing the mother's left side). The key to correct positioning is having the infant face the breast. The infant can be brought close by moving the mother's arm that is holding the infant and not by pushing the infant's head toward the breast. Pushing the head toward the breast causes the infant to arch back away from the breast, which is the arching reflex. This results when the back of the head is held. This appears to the mother as if the infant is rejecting the breast.

Initially, a mother may offer both breasts at each feeding to stimulate each breast as often as possible during the first weeks. The infant, however, should nurse long

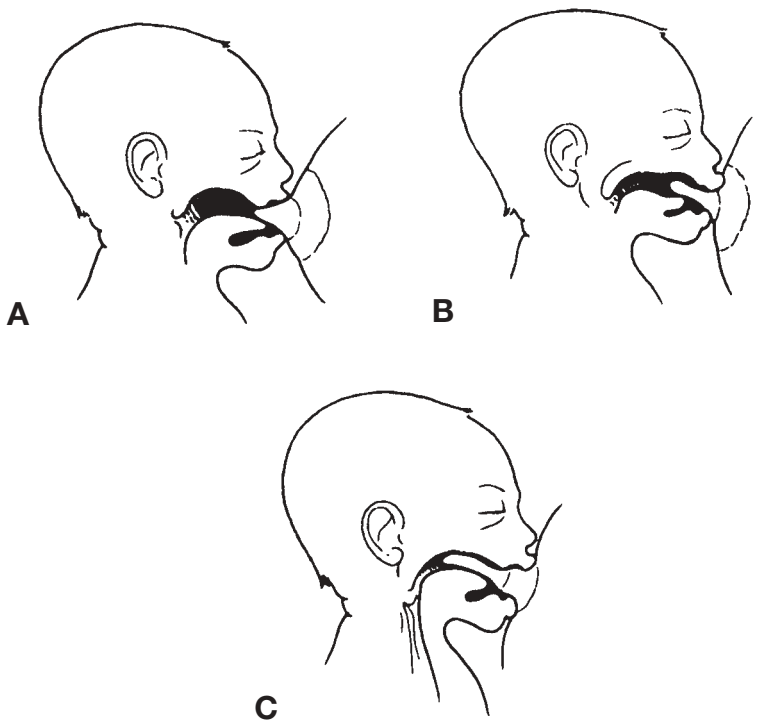

FIGURE 33-9 *A*, As the infant grasps the breast, the tongue moves forward to draw the nipple in. *B*, The nipple and the areola move toward the palate as the glottis still permits breathing. *C*, The tongue moves along the nipple, pressing it against the hard palate and creating pressure. Ductules under the areola are milked and flow begins as a result of peristaltic movement of the tongue. The glottis closes. Swallow follows. enough on the first side to receive the hindmilk, that is, over 5 minutes. In reality, he may drift off to sleep before being switched to the second side. At the next feeding, he should be offered the other breast first. This will balance the stimulus and, thus, milk production. The infant should nurse every time he awakens and is alert and hungry, which may be as frequently as every 2 hours. Intervals between feedings should not be greater than 4 to 5 hours in the beginning, when frequent stimulus is critical to establishing a good milk supply. If the infant sleeps 6 hours, he should be awakened in the first few weeks. Having the mother and baby cared for in close proximity as in rooming-in or by mother-baby nursing staff assignments will facilitate frequent appropriate feeding and will enhance milk production. In programs in which infants are fed more than 6 times daily (average 10 to 12 times), the length of each feeding tends to be shorter. With frequent feeding, there is better milk production, less weight loss, earlier regain of birth weight, and less neonatal jaundice.[31–35] This increase in feeding frequency has not been associated with an increase in sore nipples. Sore nipples are associated with inappropriate positioning at the breast. Care should be taken not to overwhelm the mother with many suggestions for different positions, alternate hand grips, and other angles for the infant. She should find a simple way that works before leaving the hospital. If there is a problem, then different approaches can be suggested. The infant should feed when hungry with no rules for timing or intervals.

Healthy mothers and their infants are being discharged in 48 hours or less in sharp contrast to the 4- to 5-day stay of the past. Mothers with cesarean sections may leave in 36 hours. Having a helpless newborn totally dependent on a mother is an awesome, frightening, and sometimes discouraging responsibility. The mother is no longer an independent person. This responsibility may be overwhelming unless care is taken to "mother the mother" because our culture does not automatically provide maternal support. In fact, our culture programs a superwoman concept in which the new mother must return to her other household chores unless the health professional intervenes. Adequate rest should be prescribed. Discussing the joint responsibilities of parenthood with both parents may facilitate a smoother transition from the sheltered hospital environment to home. Early discharge home also places a responsibility on the physician to see the breast-fed infant in the first week of life at home. Provision for weight checks and assessment of jaundice should involve a home visit or an office visit within 2 days of discharge.[3,34] Many offices have a nurse practitioner skilled in newborn care and breast-feeding who provides this service.

Nourishment for the lactating woman should make sense, but nurturance while providing these nutrients is equally important. Raphael has expressed it as the need for a *doula,* which is taken from the Greek language to mean "a helpful friend from across the street."[36] It means that someone must care for the mother, support her efforts to breast-feed, and make her confident in her ability to mother her infant.

Supplementation with Milk or Water

Careful study of weight loss in breast-fed and formula-fed infants in the first days of life indicates that the breast-fed baby does not lose more weight than the formula-fed baby when breast-feeding is adequately assisted. Furthermore, infants who are fed frequently at the breast in the first few days begin to gain weight as promptly as the formula-fed infants or at least by the fourth day. Studies correlating the method of feeding with the level of bilirubin show no significant difference between breast-feeding and formula feeding.[33,37] Studies comparing the frequency of feeding in the breast-feeding group show that infants who are fed seven or more times per day have significantly lower bilirubins than those fed six or less times per day. Findings were independent of the total number of minutes per day spent nursing.[32,33] In terms of lactation physiology, the breast produces milk in response to suckling and the removal of milk by suckling or pumping. The greatest volume of milk is obtained in the first 5 to 10 minutes at each breast. If the infant feeds more frequently, he receives more milk, and the breast produces more in response. Animal studies by Gartner and Herschel suggest a relationship between elevated bilirubin levels and starvation.[34] Weight loss of greater than 5% requires evaluation of the breast-feeding, as does unexplained hyperbilirubinemia.[3,31]

If, on the other hand, the influence of giving water or milk supplements to babies who are breast-fed is scrutinized, it is noted that supplementation, especially with water, is associated with increased weight loss and increased bilirubin levels in the first few days of life.[32–38] If the influence of water or milk supplements on babies who are breast-fed is investigated from the standpoint of successful establishment of lactation, length of breast-feeding, and reasons for early weaning, it is also noted to be negative. Mothers who add supplements have more difficulty establishing a good milk supply, are more apt to wean early,

and give "insufficient milk" as a reason for weaning. Supplements interfere with successful lactation.[39]

In the first few weeks of lactation, it is important to encourage a feeding program that meets the infant's needs, that is, providing feeding when the infant is awake and hungry (so-called demand or on-request feeding). This may be 12 to 16 times per day. Most babies have a period of a few hours when they want to nurse every hour and that is appropriate for several feedings. There is a relationship between the fatigue and stamina of the mother that has to be balanced against the true needs of the infant. A fussy breast-fed infant who has been well fed may need to be comforted by someone else. This is an important role for the father. Lactating women may not be able to comfort their own infants without offering the breast because the infant smells the milk and will root even though he is well fed. This sometimes leads to incessant non-nutritive suckling, which may be a drain on the mother's energy resources and traumatic to the nipple. Non-nutritive comforting is a significant need of most infants and can be provided by the father.

An additional side effect of supplementation is the use of a bottle and a rubber nipple, which may lead to nipple confusion on the part of the newborn.[40] The sucking mechanism used at the breast is the sucking reflex present at birth. The infant will have much of the areola in the mouth, compressing it against the hard palate as it elongates into a teat, maintaining the seal with the gum and lips. The tongue undulates with a peristaltic motion that also triggers the swallow and initiates peristalsis in the esophagus and the stomach. The nipple is a passive passageway for the milk to exit. When a bottle is used, the infant's jaws do little but hold the nipple in place. There is little undulating of the tongue, and milk flows easily, with a little suction created by the seal. The tongue may even be thrust upward to control the flow from the unyielding rubber nipple. Because this is a different position and action, some babies are confused by switching back and forth between breast and bottle, especially in the first few weeks or when the infant is slightly premature. When the tongue thrusting of bottle feeding is used with the breast, it pushes the human nipple out of the mouth.

The position a mother assumes while nursing should be comfortable and relaxing for her. A rocking chair is often the best for the sitting position. It is recommended that a mother may increase her comfort if she varies the hold and orientation of the baby to the breast. This includes not only lying down and sitting up but also holding the baby under the arm in a football hold or across her body so he is held by the left arm at the right breast or the reverse.[10,30,41] The infant should always be facing the breast directly regardless of the position of the rest of the body, and the back of the head should not be handled.

Management at Home

Adjustments at home for a new baby are often amplified when the mother is breast-feeding because any problem such as fussiness, colic, wakefulness, or night feedings are assumed by the mother to be owing to a problem with breast-feeding. Instilling confidence in the mother's ability to care for and nourish her infant is important. Closer surveillance by the physician in the first few days, however, is necessary to be certain that the new, inexperienced mother does not interpret long sleeping periods with little feeding as adequate for proper growth. Successful breast-feeding results in fewer problems and illnesses later. Review of weight status, number of wet diapers (at least six per day), stool pattern (at least three per day in the first month), and feeding pattern is a further check on successful lactation. When a breast-fed infant does not stop losing weight by 5 days, does not produce a stool every day, does not void adequately, or does not regain birth weight by 14 days, aggressive intervention is indicated. The physician needs to evaluate the infant and the breast-feeding.[41]

Maternal Nutrition

The nursing mother should have a nutrition check to confirm her appropriate food intake. A lactating woman should have 500 extra calories over the prepregnancy baseline, 20 extra grams of protein, and a balanced diet. Mothers who are concerned about losing weight should be counseled to consume no less than 1,800 kcal per day and to consume adequate vitamins and minerals.[2,42] Weight loss after the initial drop should not exceed 1 to 1.5 kg per month in the first 6 months of lactation. The most important dietary increase is calcium and phosphorus, to a total of 1,200 mg per day.[43] The neonatal calcium-phosphorus requirement exceeds that of the fetus in the last trimester of pregnancy. Dairy products are the best source, but if these products are not tolerated by the mother, she needs to seek out additional sources in dark green vegetables, nuts, legumes, and certain dried fruits. Dark green leafy vegetables such as kale, cabbage, collards, and turnip greens contain readily available calcium, whereas the calcium in spinach, swiss chard, and beet greens is bound to oxalic acid and is unabsorbable.[2,42] The amount of calcium in the diet will not influence the amount in the milk, but a deficiency will lead to leaching from maternal bone and significant osteoporosis. A lactating woman does not need added iron for milk but will need to replace stores lost in pregnancy and parturition. A balanced diet should provide all other nutrients. The quality of the milk day by day is balanced by intake and stores (Figure 33-11). The strict vegetarian is in jeopardy, however, of causing vitamin B_{12} deficiency in her offspring unless she takes supplements because vitamin B_{12} is not found in nature except in animal protein.

The lactating woman does have increased needs for fluids and thus increased thirst. If a woman selects beverages that contain caffeine or other active pharmacologic principles, it could affect the infant. Beverages that either contain no caffeine or have been decaffeinated are appropriate. With the increasing interest in herbal teas, attention should be given to the content of such teas.[44] A partial list of products is shown in Table 33-1. Many teas contain very potent glucosides that have pharmacologic properties; others are benign and a few even nutritious, such as rose hips, which contain vitamin C.

Documenting the consumption of herbal teas by the mother or given to the infant directly should be part of the

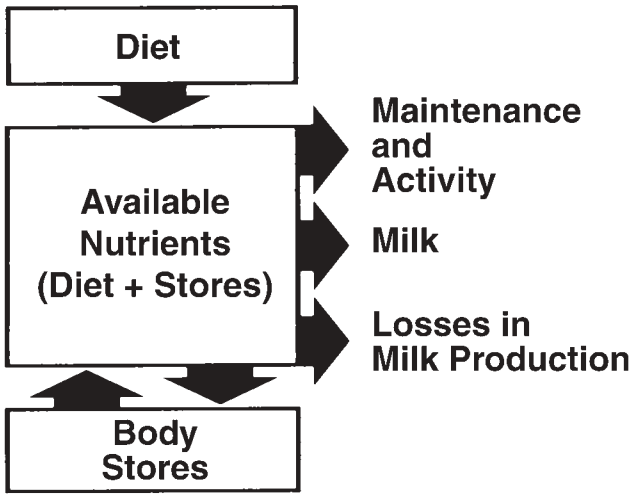

FIGURE 33-11 Energy use in lactation, showing availability of body stores and dietary sources. Reproduced with permission from Lawrence RA and Lawrence RM.[10]

medical history. Some herbs, such as fenugreek, are reputed to enhance lactation. The required dose is large, and soon the milk, all secretions, and the infant smell like maple syrup. It helps some women but not all. There can be a cross-allergy to peanuts and chickpeas that may cause colic in the infant. Comfrey has been widely used in midwifery and in lactation but is banned in many countries. The US Food and Drug Administration has also issued a warning as its use can cause veno-occlusive disease and even be fatal, especially in infants.[45]

STAGES OF BREAST-FEEDING

ADAPTATION

Initially, there is a period of adjustment and adaptation as the mother and baby settle into a reciprocal relationship of supply and demand. The infant can be exclusively nourished at the breast for the first 6 months of life. During that time, there may be gradual changes in the feeding pattern as the infant matures and sleeps longer between feedings and also spends more time awake and socializing. Periods of stress or illness in the infant may be marked with tem-

TABLE 33-1 Herbal Teas

Ingredient	*Botanical Source*	*Pharmacologic Principle*	*Use*	*Effects*
African yohimbe bark, yohimbe	*Corynanthe yohimbe*	Yohimbine	Smoke or drink as stimulant	Mild hallucinogen
Catnip	*Nepeta cataria*	Nepetalactone	Smoke or drink as marijuana substitute	Mild hallucinogen
Gordolobo yerbal	*Senecio douglassi*	Pyrrolizidine alkaloids	Drink	Sore throat therapy, ? tranquilizer
Hops	*Humulus lupulus*	Lupuline	Smoke or drink as sedative and marijuana substitute	? None
Kavakava	*Piper methysticum*	Yangonin, pyrones	Smoke or drink as marijuana substitute	Mild hallucinogen
Kola nut	*Cola* spp	Caffeine, theobromine, kolanin	Smoke, drink, or take as capsules as stimulant	Stimulant
Lobelia	*Lobelia inflata*	Lobeline	Smoke or drink as marijuana substitute	Mild euphoriant
Mandrake	*Mandragora officinarum*	Scopolamine, hyoscyamine	Drink as hallucinogen	Hallucinogen
Mate	*Ilex paraguayensis*	Caffeine	Drink as stimulant	Stimulant
Mormon tea	*Ephedra nevadensis*	Ephedrine	Drink as stimulant	Stimulant
Nutmeg	*Myristica fragrans*	Myristicin	Drink as hallucinogen	Hallucinogen
Passion flower	*Passiflora incarnata*	Harmine alkaloids	Smoke, drink, or take as capsules as marijuana substitute	Mild stimulant
Periwinkle	*Catharanthus roseus*	Indole alkaloids	Smoke or drink as euphoriant	Hallucinogen
Snakeroot	*Rauwolfia serpentina*	Reserpine	Smoke or drink as tobacco substitute	Tranquilizer
Thorn apple	*Datura stramonium*	Atropine, scopolamine	Smoke or drink as tobacco substitute or hallucinogen	Strong hallucinogen
Valerian	*Valeriana officinalis*	Chatinine, velerine alkaloids	Drink or take as capsules as tranquilizer	Tranquilizer
Wormwood	*Artemisia absinthium*	Absinthe	Smoke or drink as relaxant	Narcotic-analgesic

Adapted from Siegel RK. Herbal intoxication.[44]

porarily increased suckling, especially non-nutritive suckling for comfort. Human milk meets all of the nutrient needs of the infant for the first 6 months, except for women who live in cold climates with little sunshine, have dark pigmented skin, wear occlusive clothing, or use sunscreen frequently who may be vitamin D deficient.[46] Recommendations from the Centers for Disease Control and Prevention suggest supplementing the infants beginning at 2 months with 200 U vitamin D daily by mouth.[47] Very low birth weight infants may need iron. Healthy exclusively breast-fed infants do not need iron for the first 6 months of life. When weaning foods are added in the second 6 months, they should be iron containing such as iron-supplemented cereal.[48]

Adding Solid Foods

The single nutrient needed to add to solid foods in an exclusively breast-fed infant is additional dietary iron; thus, introduction of iron-fortified weaning foods at around 6 months is recommended, although the exact age is poorly defined.[48] At about 6 months of age, it is appropriate to begin the addition of solid foods to the infant's diet for nutritional reasons (see Chapter 28, "The Low Birth Weight Infant"). Learning to take solid foods is also an important developmental milestone that involves a new use of tongue, jaw, and lips—a use that differs from suckling. Beginning to take fluids from a cup is also a developmental task that should be learned around 7 months of age. The infant who is exclusively breast-fed to this point needs to explore these activities and develop these skills just as a bottle-fed infant would. The fluids can be water, juice, or pumped breast milk. It is probably significant that the composition of human milk gradually changes during this time to provide a lower protein content than previously. If a mother continues to provide her milk, there is no need to introduce formula. Cow's milk when the infant is under 1 year of age is not recommended.

Weaning

To wean is "to transfer the young of any animal from dependence on its mother's milk to another form of nourishment" or "to estrange from former habits or associations," according to the dictionary.[49] The weaning process takes many forms, depending on the mother's schedule and beliefs and the needs of the infant. Some women plan to breast-feed for only a few months "to give the baby a good start"; other mothers wean as soon as solid foods can be started, and some continue to offer the breast for several years, even during a subsequent pregnancy and while feeding a new baby. The appropriate time for weaning should be based on nutritional and psychological needs and developmental milestones. Feeding is an important social as well as nutritional encounter, and eating solids and drinking from a cup are important social accomplishments. This does not mean that the infant is taken completely off the breast. In practice, the mother is usually the instigator of weaning. The process ideally is gradual, replacing one feeding at a time with solids and the introduction of a bottle or cup, depending on the infant's age and stage of development. After the adjustment has been made to substitute one feeding, a second feeding is replaced, usually at the opposite time of day. The process is continued until there is only one nursing at night and one in the morning. These two feedings may be maintained for many months or gradually discontinued over weeks. A mother may be able to express milk from the breast for weeks after the final feeding. An infant who has not weaned by 18 to 24 months usually does not spontaneously wean until 4 or 5 years of age.[10]

Emergency weaning because of a crisis such as illness or separation may be stormy for the dyad. The infant may reject the bottle and refuse all nourishment at first. The mother who abruptly weans may experience severe engorgement, pain, and systemic symptoms attributed to the resorption of milk and referred to as "milk fever." Emergency weaning is facilitated by the assistance of another adult who can initiate the new feeding method and is patient and understanding with the child. Cup feeding with a small medicine cup may be a helpful alternative.

Breast-feeding and the Return to Work

Returning to work has been cited by epidemiologists as a major hurdle in the initiation and duration of breast-feeding.[50,51] Because they need to return to work or to school, women often think it is best not to start. Before the industrial revolution, all women worked on the farm or in a cottage industry, keeping their children with them. In developing countries today, women carry their infants with them to feed them whenever necessary while working. It was the industrial revolution that separated home and work and made parenting a separate role for women.

More women are employed today outside the home than ever before.[52] Women with children under 6 years of age were the fastest-growing segment of the female workforce in 2000 (64.4% of women with a child under 6 years old). Even more startling are the number of working mothers with children under 3 years of age (60.7%).[53] Of the women who work during pregnancy, over 50% plan to return to work by 3 months postpartum. These dramatic statistics make it clear that the decision about infant feeding is an important part of this issue.[51] Child care also presents another consideration for the woman who may well have to choose day care or some form of child care that means that her infant will be in close contact with other children. In modern pediatrics, "day care syndrome" is real. It is the increase in the number of infections, especially diarrhea, respiratory illness, and otitis media, experienced by young infants in day care.

The data are clear that breast-feeding impacts these figures. These illnesses are seen predominantly in bottle-fed infants. A quantitative study has shown that extending breast-feeding from 4 to 6 months of age decreases the risk of respiratory infection, including pneumonia and otitis media, even further.[11] The protective properties in human milk (see Chapters 31 and 32) are even more important for the child exposed to other children early in life while the mother works or attends school. A comparison of mothers' absenteeism showed that those who were breast-feeding had reduced absenteeism.[54] Looking at the illness rates of chil-

dren whose mothers work, 75% of children who were bottle fed were ill and only 25% of those breast-fed had any illness.

The feeding pattern for mothers who work is as follows: Ideally, the mother does not return to work for at least 6 weeks, so she is able to establish her milk supply before having to add work to her schedule. She will have to decide how she will cope.[55] If her job permits her to visit her child several times a day, then she can feed the infant at the usual times. An employer who has a daycare center on the premises makes such an arrangement possible. Professional women who control their own schedules (lawyers, doctors, consultants) may be able to keep the infant on the premises under the care of a baby attendant and feed on demand. For most women, however, their jobs are more rigid, and they may have to settle for an opportunity to pump their milk every 3 or 4 hours on lunch or coffee breaks and store the milk in a cooler to take home for the next day's feedings. Most women practice pumping at home several weeks ahead of time and store up a supply of milk in the freezer so that they do not run out.

Employers such as hospitals, health departments, and family-friendly industries like Amoco, Chicago; Dow Chemical of Midland, Michigan; and the Los Angeles Department of Water and Power, to name a few, have been recognized for their support of "Healthy Mothers and Healthy Babies" and their accommodations for nursing mothers. They provide a room to pump, electric pumps, refrigerators, and, in some cases, lactation consultants to assist with any breast-feeding issues. This support improves the incidence and duration of breast-feeding for the working woman.[56]

Pumping and Storing Milk

If the employer does not provide pumps, a mother should obtain a pump by either renting or purchasing it several weeks in advance of the return to work. All pumps are not equal.[57,58] There are, however, several brands of good portable electric pumps that provide disposable attachments for those parts that contact the breast and the milk. Attachments that allow pumping both sides simultaneously save time and for some women stimulate more milk release. Other women find double pumping overwhelming and choose to do one side at a time. Hand (manual) pumps are good for stimulating milk release and relieving engorgement but not for large-volume pumping for most women. Many hospitals have lactation consultants on staff and a shop or service that rents pumps and sells other breast-feeding devices, such as breast pads and storage bottles. Information about local resources should be available on the postpartum floor. If not, a mother can call La Leche League International (800-LALECHE [800-525-3243]) for a local contact person. After each pumping session, the disposable flanges, tubing, and bottles used for pumping should be rinsed with cool water first and then washed in warm soapy water and thoroughly rinsed and air dried. After rinsing with cold water to remove the milk, the equipment may also be washed in an electric dishwasher.

The pumped milk should be placed in a glass bottle or a firm plastic polypropylene nursing bottle that can be capped with an airtight seal without a nipple and then used to feed the infant later. Polyethylene bags are adequate for term baby use. Storage temperatures and times have been carefully studied.[57] The container, which should be labeled with the name, date, and time, should be placed in a refrigerator immediately or in a cooling bag or container with freezer packs if at work or school where there is no refrigerator. It is safe in a cooler bag as long as the packs remain cold (24 hours). On arrival home, the bottles should be placed in the refrigerator if the milk will be used within 3 days or in the freezer if stored for later use. When milk is pumped at home, it can be placed in the refrigerator (4°C) immediately and kept for 5 days. Actually, when there is no alternative or a bottle has been inadvertently left out, milk can be kept in a sterile container at room temperature for 8 hours and then used immediately or refrigerated for a day.

If milk is placed in the freezer of the refrigerator that has a separate door, it can be stored for 3 months if it is placed in the back to avoid thawing and freezing when the door is opened. If milk is placed in a deep freeze (–20°C), it can be kept for 6 months, or if at –70°C, it is good for a year or longer.[52,56,58] The nutritional impact of freezing on the milk is minimal, destroying only the cells and their function. The effect of refrigeration is also minimal, decreasing the cells and some of their function. Nutrients are unchanged. Storing mother's milk for her own infant does not require pasteurization. Providing donor milk to another infant does require pasteurization by regulation owing to the increase in risk of infection in the present environment. Pasteurization does affect some properties, destroying cells and decreasing lipase activity and some other enzymes (Table 33-2).[52,59]

Day Care for the Breast-feeding Infant

In choosing a daycare service, care should be taken to ensure that breast-feeding and breast milk are welcome. When taking an infant to day care, a mother may wish to nurse the infant just before she leaves her child or she may wish to nurse the infant at day care when she has a break from work. Further, she may wish to feed the child before she sets out for home with the infant in the afternoon. There needs to be a place to sit quietly with the infant out of the mainstream of activity. The staff should be prepared to make these accommodations and delay a feeding if the mother is going to arrive shortly.

The mother will probably wish to provide her stored breast milk for her infant to receive during the day. It is not necessary for the caretaker to wear gloves to handle the milk or feed the infant. It is, however, appropriate to wear gloves to change any babies' diaper. If the milk was frozen, it can be thawed in the refrigerator at day care or thawed by swirling in a container of warm water. It should not be warmed in the microwave because of possible hot spots and scalding the infant. Microwaving interferes with the anti-infective properties as well as decreases the vitamin C content. If the infant does not empty the container, it can be refrigerated and fed later unless it has been microwaved.[10] This is not true of formula, but the protective factors in human milk will keep the bacterial count down. The daycare attendants should save the containers

Table 33-2 Storage and Use of Pumped Milk for Healthy Term Infants

Place	*Length of Time*
Refrigerator (4°C)	5 d at home, 3 d in day care
Freezer section (separate door) refrigerator (–20°C)	3 mo
Deep freeze (manual defrost) (–20°C)	6 mo
Commercial deep freeze (–70°C)	1 yr
Sterile container at room temperature (23°C) (not ideal but milk need not be discarded)	8 h
Stored in cooler bag with frozen packs (as long as packs are still cold)	Less than 24 h
Thawed previously frozen in refrigerator	24 h

for reuse by the mother. Thawed breast milk can be maintained in the refrigerator for 24 hours.

The milk containers should be carefully labeled with the name and date of collection. The attendant should carefully confirm the name on the container before feeding. Mishaps of giving the wrong milk to the wrong infant do occur. It should be reported to both families and the daycare's medical consultant with an incident report. There are no reported cases of injury following such an event.

FAILURE TO THRIVE WHILE BREAST-FEEDING

Paralleling the increasing incidence of breast-feeding, there has been an increase in the number of clinical reports, including one in the *Wall Street Journal*, each describing a few cases of failure to thrive while breast-feeding.[38,60–62] The *New York Times* followed the dramatic story of a teenage mother prosecuted for the death of her 8-week-old breast-fed son from starvation. The event followed a series of misadventures and refusal to see the child at a Medicaid clinic.[63] The majority of these cases have reflected a lack of clinical knowledge on the part of the professionals regarding the basic physiology of lactation and a general failure of the health care system to provide an appropriate safety net for new and inexperienced mothers following the current early postpartum discharge practices (hospital stay ≤ 2 days). As cost drives the health care system to earlier and earlier discharge, the risk of infant problems increases because lactation will not be well established prior to discharge. The American Academy of Pediatrics has recommended that infants be seen by the pediatrician within a week of discharge but in 2 days if breast-fed.[3]

Failure to thrive in children has been thoroughly reviewed, however, there are some critical differential factors when the infant is breast-fed (see Chapter 52, "Failure to Thrive: Malnutrition in the Pediatric Outpatient Setting"). Most cases of significant failure to thrive in the breast-fed infant manifest themselves in the first few weeks or months of life. There is also an important distinction between failure to thrive and the slow-gaining breast-fed infant.[39,64] The weight curve of an adequately nourished breast-fed infant from birth may well include a weight loss of 6 to 8% and the regain of birth weight at 10 to 14 days, in contrast to the formula-fed infant, who may lose only 3 to 4% of birth weight and quickly regain birth weight by 5 to 7 days.

The critical clinical distinctions between failure to thrive and slow gaining are enumerated in Table 33-3. The salient points include the slow increase in weight compared with the erratic gaining and losing pattern in failure to thrive. The slow-gaining infant is alert and active, with good skin turgor and muscle tone. He feeds frequently night and day, wets many diapers with pale dilute urine, and has a normal stool pattern. The infant looks scrawny but well.[64]

Because he sleeps long periods between feeds, the infant who fails to thrive may be mistakenly considered satisfied when actually he has starvation inanition. The infant often fed poorly in the first few days or for various other reasons does not stimulate good milk production. Because breast milk production depends on the supply-and-demand phenomenon, when the infant sucks weakly, he receives little milk and thus remains weak from some degree of starvation. This infant also has few wet diapers; the urine is concentrated and described as "strong" by the mother. There are few and small stools, which are often the color of the green mucus of starvation. The tone and turgor are poor, the cry is weak and infrequent, and the infant looks sick. This may well be a medical emergency requiring hospitalization. The feeding pattern should be evaluated, especially focusing on the length of time spent at the first breast during a feeding to be sure that it is long enough to allow the high-fat hindmilk to be obtained. Sometimes the pattern of slow gaining can be reversed by limiting a feeding to a single breast to ensure high-fat, high-calorie feeds.[65] Switching back and forth between breasts several times during a feeding does not increase milk supply and can reduce the amount of high-calorie fat provided.

The diagnostic workup of these phenomena requires the same clinical assessment that is appropriate when the infant is not breast-fed, and for this, the reader is referred to Chapter 48. Because the breast-feeding infant is part of a synchronous dyad, there are additional considerations in the differential diagnosis.[10] A suggested schema for identifying the cause of the problem is presented in Figure 33-

TABLE 33-3 Differential Diagnosis in Poor Weight Gain

Slow Gainer	*Failure to Thrive*
Alert, healthy appearance	Apathetic or crying
Good muscle tone	Poor tone
Good skin turgor	Poor turgor
At least 6 wet diapers daily	Few wet diapers
Pale unconcentrated urine	"Strong" urine
Stools frequent and seedy (or, if infrequent, large and soft)	Stools infrequent and scanty
8 or more nursings daily lasting 15–20 min	Fewer than 8 feedings, often brief
Well-established let-down reflex	No signs of functioning let-down reflex
Weight gain consistent but slow	Weight erratic (loss may occur)

Reproduced with permission from Lawrence RA and Lawrence RM.[10]

12. The clinician should take a history oriented to the process of lactation. This history should include additional parameters that affect the success of the breast-feeding dyad, such as the mother's perinatal history, general health, diet, habits, psychosocial state, social support system, and the attitudes of the father and family about breast-feeding. Parameters unique to the breast-fed infant include any anatomic or physiologic conditions that would interfere with sucking, which is a critical link in the milk production process.

Difficulties with sucking include anatomic abnormalities that result in mechanical interference with sucking such as cleft lip, cleft palate, hypoplasia of the jaw, macroglossia, ankyloglossia (tongue "tie"), and tumors or cysts of the oropharynx. These abnormalities can be identified by physical examination, which includes observation of the infant's suck. There may be neurologic interference, resulting in a diminished or absent suck. Events at birth, such as maternal anesthesia or analgesia and fetal anoxia or hypoxia, may contribute to poor suckling in the immediate neonatal period and failure to provide adequate stimulus to the breast to initiate lactation. The ensuing lack of nutrition for the infant leads to hypometabolism and continued lack of vigor. Congenital cardiac anomalies may present in this manner. Other causes of neurologic deficit in sucking include trisomy 13 to 15, trisomy 21, and neuromuscular diseases such as Werdnig-Hoffmann, neonatal myasthenia gravis, and congenital muscular dystrophy. Hypothyroidism, prematurity, and congenital intrauterine viral infections contribute to poor suck and lack of vigor. The greatest number of infants, however, are entirely normal but have not had sufficient assistance in establishing the proper grasp of the breast and possibly have been further confused by being given a bottle supplement, which continues to confound their learning experience.[40] In addition to examining the infant and the maternal breast, the clinician should observe the feeding dynamics.

All physicians who counsel breast-feeding mothers should be knowledgeable about normal sucking at the breast so that observation of lactation in a diagnostic situation can be constructive. The style with which the mother approaches a feeding, her body language, may be a clue. If she is relaxed, confident, loving, and gentle with her infant, it suggests that it is not maternal inexperience at fault. Her verbal interaction can be revealing. A baby suckling at the breast brings reflexive eye-to-eye contact, stroking, and verbal nuances that a seasoned lactating woman utters without consideration for the environment. The insecure, inexperienced mother will sit tensely, offering the breast gingerly, with little or no verbal communication to the infant. If the process is mechanical or punctuated by unrealistic commands to the infant, it may suggest an inability to help the infant root, grasp, and suckle properly. Rigidly timed feedings that are scheduled by the clock may result in poor milk production. The treatment rests with frequent on-request feedings that fit the infant's biologic rhythms. A quiet room, a rocking chair, soft music, or a relaxing beverage for the mother may all improve the situation.

The behavior of the infant when offered the breast may indicate an infant with a suckling disorder, not associated with any other neurologic symptom or long-range problem. Sucking inadequately at the breast can be altered so the infant learns the technique. The infant is identified when it is noted that the infant cannot maintain the breast in the mouth unless his mother holds it there. In other words, when she takes her hand away, the breast falls away. A normal infant sucks without help from his mother's hands if the grip is proper and the seal is adequate. When the infant does begin to suck when the breast is held in position, the suck may be a flutter or ineffective

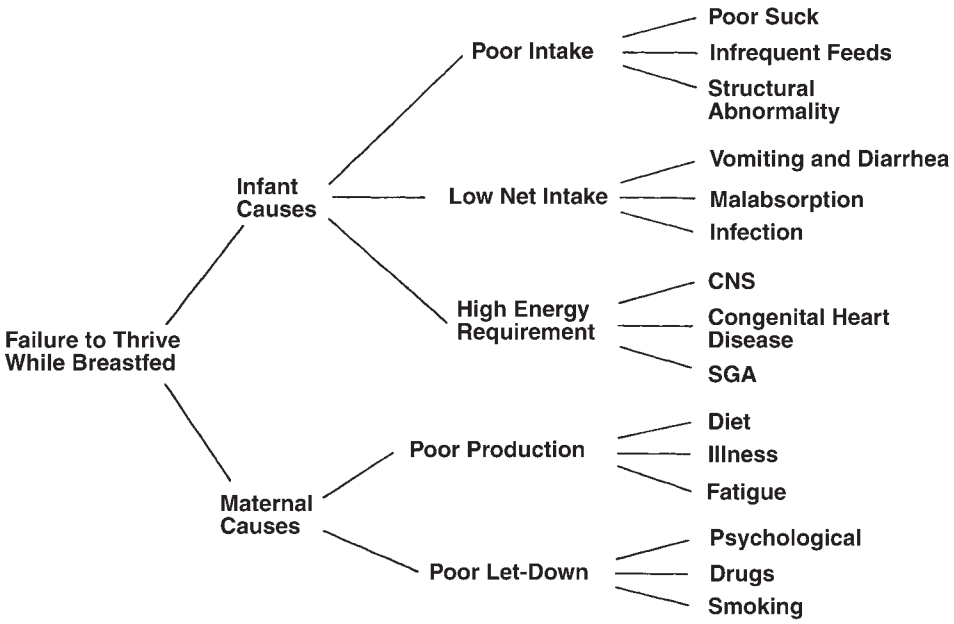

FIGURE 33-12 Diagnostic flow chart for failure to thrive. Reproduced with permission from Lawrence RA and Lawrence RM.[10] CNS = central nervous system; SGA = small for gestational age.

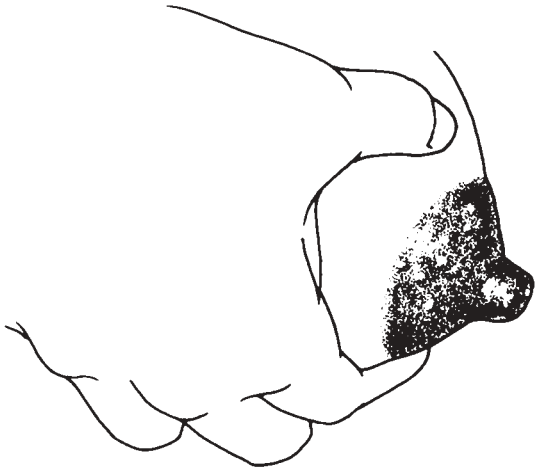

FIGURE 33-13 Palmar grasp (C-hold). When the palm and fingers cup the breast with support and the thumb rests lightly above the areola, the nipple projects straight ahead or slightly downward (correct). Reproduced with permission from Lawrence RA and Lawrence RM.[10]

tongue actions. This may be improved by having the mother hold the breast between thumb and index finger, with fingers under the breast (palmar hold) (Figure 33-13) rather than with the areola compressed between the middle and index finger (scissor hold) (Figure 33-14). The infant's position should be adjusted so his body is turned toward the mother's body (instead of just turning his head). Thus, the breast is centered toward the infant, and this position will improve the effectiveness of the infant's efforts. The mother may have to continue to hold the breast in place for weeks until the infant perfects his technique. The mother may also have to pull his lower lip down to keep the infant from drawing the lip into the mouth and moving it along the lower surface of the breast. The lip should be held as part of the seal holding the breast in place and permitting development of some negative sucking pressure. If the mother stimulates the rooting reflex by stroking the center of the lower lip, the infant will open wide and draw the nipple and areola into the mouth to form a teat.

While the infant is learning to suckle properly, it is urgent to avoid introduction of a rubber nipple on a bottle or a pacifier. This poses a problem if adequate nutrition is critical and the mother's supply needs to be stimulated to be adequate. A trial of frequent feeds, waking the infant every 2 hours, may suffice. Extra calories may be offered by medicine cup or Haberman feeder. When the failure to thrive has reached critical starvation, a more aggressive approach is mandatory. If hospitalization is necessary, intravenous therapy to treat dehydration may also be necessary. Hypernatremia and hypochloremia have been described, and a complete workup, including pH, electrolytes, blood urea nitrogen, and creatinine, are essential.[22,38,41,66,67] While the infant receives intravenous therapy, the mother should be assisted to pump frequently to develop and increase her milk supply. When it is safe to begin oral feedings, the infant should be exclusively breast-fed as far as sucking is concerned, and additional nourishment should be provided by intravenous line, gastric tube, or medicine cup. Thus, the infant avoids the introduction of a bottle. When the crisis has abated and full breast-feeding is appropriate, but the milk production is still inadequate, the use of a nursing supplementer (Lact-Aid) may be useful. This device permits the uninterrupted nursing at the breast while supplementary nourishment is provided via a fine capillary tube that runs along the breast into the infant's mouth (Figure 33-15). The tube brings the supplementary fluid from a reservoir plastic bag that hangs around the mother's neck. The system is carefully engineered. It provides fluid only when the baby sucks; thus, it coordinates with the infant's swallowing mechanism. It is not a siphon or a pump. When used to help establish or increase milk production, as with a premature infant first going to breast, the infant is usually weaned from the supplementer within 1 or 2 weeks by providing smaller and smaller volumes of supplement as maternal production increases. The supplementing device may make the critical difference when the degree of starvation is great and lactation is being preserved. It is important to point out that all too often the infant is quickly weaned to a bottle without any effort to solve the underlying lactation problem, which is unfortunate (see Figures 34-15 and 34-16).

In rare cases of failure to thrive while breast-feeding, the underlying cause is actually metabolic, and the infant does even less well on formula prepared from cow's milk or soy protein. In that case, it is quite possible to have the mother relactate. It is an art practiced in most cultures over the centuries and resorted to when the biologic mother became ill or died and another female (often the grandmother) had to assume the nourishment of the baby. In the case of premature weaning, there has already been the biologic stimulus of pregnancy and early lactation, so reinstituting the milk supply occurs more easily. The lactation

supplementer may be of great value in this situation as the infant can return to the breast and be nourished with donor human milk while the mother builds up her own supply (see Figure 33-16).

Maternal Causes of Failure to Thrive

Poor milk production may be the cause of the failure to thrive. This is usually characterized by an alert, active infant who cries hungrily and is very demanding but never satisfied. This baby demands attention and is usually seen by the physician because of his dissatisfaction. The quiet, sleepy, starved baby gets into serious trouble before he is discovered because his sleeping is interpreted as satiation. It is rare in the United States that diet is the true cause of insufficient milk, although it is appropriate to evaluate the mother's diet and make recommendations for increases or adjustments where needed (see Figure 33-11).[68] An additional 600 kcal or a minimum of 1,800 kcal per day, a balance of foods with 20 g extra protein and 400 mg extra calcium, is minimal for every mother. "Mothering the mother" by caring about her diet may have a positive effect. However, the major factor in poor production is fatigue. It is the single most important element in milk production. The present-day "supermom" model that has been developed by women may be the actual destructive element. A postpartum woman needs rest to recover whether she nurses or not. When she is also nourishing an infant, she needs more rest. This is often neglected when the infant needs care every 3 to 4 hours around the clock and only the mother is involved in the feeding of the infant. When her physician suggests that the mother needs to reorder her priorities and schedule naps for herself, it may be the necessary official approval she needs to do so. A mother may need to be told it is not only okay, but it is also necessary for her to take care of herself to provide for her baby. The physician may need to prescribe rest as well as nourishment.

A small number of women are unable to make sufficient milk. Some of these women have inadequate glandular tissue. Markedly asymmetric breasts, conically shaped breasts, and extremely small ones may be in this category. Even extremely large breasts are occasionally nonfunctional. Failure of the breasts to change and enlarge during pregnancy and/or failure of the breasts to become engorged immediately postpartum are signs of inadequately functioning tissue. These signs prenatally should alert the medical team to extra vigilance as lactation is initiated.

Failure to Let Down Milk

A woman may make milk abundantly but be unable to release it. As the practitioner observes the lactation process, evidence of successful let-down should be sought. If the sucking is interrupted by breaking the suction by putting a finger in the corner of the infant's mouth, milk should continue to flow in a steady drip if not a stream. Although many women describe a tingling and turgescence when the milk lets down, it is possible to have an effective ejection reflex without these sensations. As indicated in Figure 33-6, it is possible for pain or stress to interfere with let-down. If the mother has sore nipples or

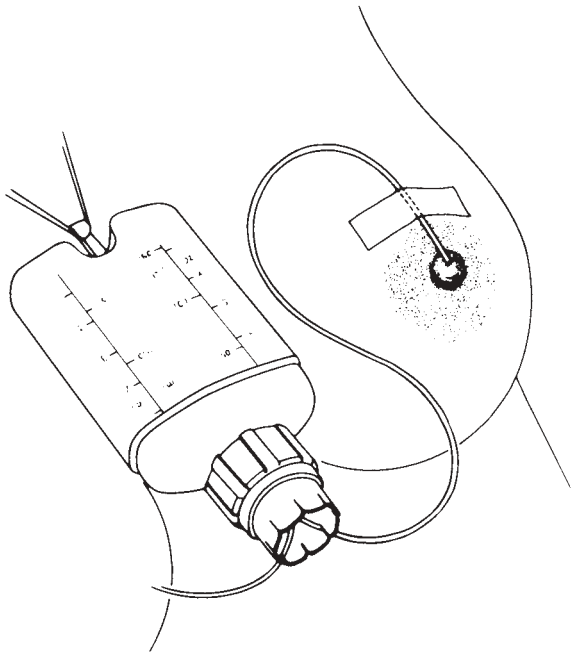

FIGURE 33-16 Lactation Supplementer by Medela, which provides additional nourishment to the infant while it suckles at the underproducing breast. Reproduced with permission from Lawrence RA and Lawrence RM.[10]

the infant has an improper grasp at the breast, the pain may interfere with let-down.[23] If the adjustments and remedial actions to avoid stress and enhance confidence do not result in a change in the release of milk, it may be necessary to temporarily provide the oxytocin needed for the let-down arc.[10] Synthetic oxytocin can be prepared by the pharmacist as a nasal spray for home use using the injectable oxytocin. It is packaged in 5 to 10 mL nasal dropper bottles. It contains 10 USP IU per milliliter of oxytocin, a polypeptide hormone of the posterior pituitary gland. A prescription is required. It is destroyed in the gastrointestinal tract; therefore, it must be used nasally on the mucous membranes, where it is rapidly absorbed. Four to six drops into one nostril followed by having the infant suckle within 2 to 3 minutes is sufficient. This is repeated using the second nares if the infant is switched to the second breast. This may also be used when using a breast pump and collecting for an infant who cannot nurse directly, as in the case of a premature baby. Usually, it is only necessary to use the medication for a few days as the natural process will take over.

A rare finding in lactation failure is the lack of a prolactin surge when the breast is stimulated by the suckling or pumping. The prolactin level should double over baseline on suckling. If prolactin levels are obtained, the samples should be carefully timed so that the baseline sample is drawn from a heparin lock after the mother has recovered from the needle stick. Then she should feed the infant or pump her breasts for 10 minutes, and a second sample should be drawn. The percentage increase in prolactin over baseline should approach 50%. The baseline should be above normal for the laboratory. Replacement prolactin is not clinically available, although prolactin stimulation with fenugreek or metoclopromide or other galactogues may work.[10]

Knowing When to Discontinue Breast-feeding

Although breast-feeding provides species-specific nourishment, infection protection, immunologic protection, and psychological benefits for both mother and baby, there are times when it should be discontinued. The role of the physician is a delicate one, one in which true support of breast-feeding is necessary for credibility. On the other hand, the physician must recognize when other alternatives are medically preferable. The mother will need help in accepting this. Having to wean prematurely or before the planned date is not to be construed as maternal failure. It is still possible to nurture the infant, to be a good mother, and to have a good mother-infant relationship, even though the mother may no longer be able to breast-feed.

The contraindictions to breast-feeding are rare but include severe illness in the mother, severe galactosemia in the infant, and a few maternal drugs such as therapeutic doses of radioactive pharmaceuticals.[69]

CHAPTER 34

DEVELOPMENTAL DISABILITIES

Babette S. Zemel, PhD, Virginia A. Stallings, MD

Children with moderate to severe disabilities have a markedly increased risk for malnutrition. Neurologic abnormalities—resulting in altered physical activity (voluntary and involuntary), fine motor patterns, and oral-motor patterns—will often significantly affect food intake and nutrient requirements. Chronic undernutrition, characterized by growth failure and reductions in fat stores and lean body mass, is the most common form of malnutrition, but overweight and obesity also occur. Despite these clinical observations, only limited research-based information on the nutrient needs and nutritional status of children with severe disabilities is available. Consequently, recommended nutrient intakes and growth pattern expectations for this group of patients are poorly defined and must be approached on an individual basis.

Nutritional status assessment is essential for identifying the undernourished or overnourished child, estimating the optimum energy intake to promote growth and well-being, and monitoring treatment. In children with moderate to severe disabilities, nutritional assessment is complicated by the interaction of the primary disease process (eg, muscle atrophy, contractures, central nervous system pathology, or movement disorders) and both chronic and acute malnutrition. Cerebral palsy (CP), a common disability with significant risk for malnutrition, will be used as a model to describe the nutritional needs and nutritional status of children with severe disabilities.

The scope of problems relating to feeding difficulties and malnutrition is now being described through community or registry surveys. Studies have revealed that close to 90% of children with neurologic impairment require at least some assistance with feeding or have oral-motor dysfunction.[1,2] A large, multicenter, community-based study in North America reported that 30 to 40% of children with CP had severe feeding difficulties.[3] A recent population-based cohort study in the United Kingdom demonstrated that feeding difficulty at 4 weeks and 6 months of age was associated with subsequent impairment and poor weight gain and developmental outcomes later in childhood.[4] The association of feeding difficulties and nutritional status has been demonstrated in every population studied.[1–7] Nevertheless, a pattern of inadequate food intake, growth failure, and disease-specific nutritional concerns is still evident.

Several important nutritional issues were recognized in these studies. Assistance with feeding, prolonged feeding times, and choking significantly affect food intake.[1,2] In addition, gastrointestinal problems, such as reflux, vomiting, and constipation, and some medications, such as those used to treat seizures, contribute to alterations in both nutritional intake and requirements.[1,8] Food intake low in energy density is of particular concern because of the marked linear growth failure, delayed skeletal[9,10] and sexual maturation,[11] poor weight gain, and reduced energy reserves seen in patients with CP.[12] Abnormal body composition, with reductions in muscle and fat stores, and a high prevalence of undernutrition (failure to thrive, marasmus) and less frequently overnutrition (overweight, obesity) have also been noted.[12–14] Some specific nutrients are also at risk, particularly vitamins C, A, and D; iron; and calcium. Recently, poor bone mineralization,[14–16] associated with degree of immobilization, hypovitaminosis D, feeding difficulties, and lower triceps skinfold measurements in children with CP, also has been reported.

For children with CP, the drug–nutrient interactions of anticonvulsant medications and vitamin D were demonstrated by several investigators in the 1970s. Vitamin D deficiency continues to be a concern in the nutritional care of these children.[17,18] Some classes of anticonvulsants,

through the action of the hepatic microsomal enzymes, cause increased vitamin D catabolism. In a survey of 125 heterogeneous noninstitutionalized children with CP in the United States, nearly 20% had low serum 25-hydroxy-vitamin D levels. However, low vitamin D status was not associated with severity of CP, growth failure, or use of anticonvulsants.[18] Another study of institutionalized children in South Africa found that anticonvulsant therapy was associated with long-bone fracture, and that 3 months of vitamin D and calcium supplementation resulted in marked improvement in serum calcium and phosphate and reduced alkaline phosphatase and fracture rate.[19] Another vitamin D and calcium supplementation study demonstrated improved bone mineral density.[17] Thus, in addition to anticonvulsants, low dietary intake of vitamin D and calcium, limited physical activity, and low sunlight exposure also contribute to rickets, osteopenia, and pathologic fractures in children with CP.[20–23]

Nutritional assessment of children with severe disabilities has several components, including evaluation of dietary intake, growth status, body composition, energy expenditure, and laboratory data in the context of the nutritional risk factors related to the medical history, physical examination, diagnosis, and current therapy. The need for interdisciplinary evaluation and treatment of nutrition and feeding abnormalities for children and adults with CP has been addressed by numerous investigators and position papers.[24–28] Inadequate caloric intake is a primary concern. Children with CP have abnormal growth and body composition. Therefore, conventional methods for estimating caloric requirements based on the Recommended Dietary Allowance (RDA)[29] for age and gender group, or prediction equations that use body weight or surface area, are inappropriate for nonambulatory children with CP.[30,31] The importance of determining energy requirements and meeting those requirements in children with CP is underscored by several nutrition intervention trials in which caloric supplementation by gastrostomy or nasogastric feeding tube resulted in improvements in various components of nutritional status.[32–36]

Another approach to determining energy needs in children with severe CP has been to determine the extent of growth failure and poor nutritional status and their relationship to nutritional and disease-related factors and energy expenditure. In one study, a large group (N = 142) of children ages 2 to 18 years with spastic quadriplegic cerebral palsy (SQCP) participated in a survey of growth and nutritional status.[6,7] Linear growth, assessed by upper-arm and lower-leg lengths, was significantly reduced (z-scores, –1.57 to –2.38) relative to healthy children.[37] Weight and triceps skinfold thickness were, on average, about 65% of age- and sex-specific medians for children in the United States; subscapular skinfold thickness was 81% of the median. Poor nutritional status was evident in children as young as 2 to 4 years of age. Linear growth retardation in upper-arm and lower-leg length was significantly associated with poor nutritional status (arm muscle area, percent body fat), after adjusting for disease severity (diagnosis, cognitive ability, oral-motor function, ambulatory status, gastrostomy feeding, and dyskinetic component) and nondisease variables (age, gender, race, pubertal status, and midparental height). This analysis demonstrated that the effect of poor nutritional status on linear growth was independent of, and additive to, the effects of the severity of the CP and nondisease factors.

Energy expenditure and dietary intake were measured in a subsample of these children with SQCP. Resting energy expenditure (REE), expressed as the percentage of the predicted value from World Health Organization (WHO) prediction equations, was considerably lower than in normal children (91% predicted in CP versus 105% in controls). REE was lowest (88% predicted) among the majority group of poorly nourished children with CP.[38] Total energy expenditure, measured by the doubly labeled water method, was also lower than in control children, in keeping with reduced physical activity in children with severe SQCP. The physical activity factor, or ratio of total to resting energy expenditure, was 1.23 for children with CP as opposed to 1.57 for controls. This is similar to the patterns of resting and total energy expenditure observed in adults[39] with CP. Thus, in children with SQCP, energy requirements are lower than in normal children. However, determination of energy intake proved to be far more difficult. The ratio of total caloric intake, measured by a 3-day weighed food intake diary, to total energy expenditure indicated a large—about 50%—overestimation of food intake by the caregivers of these children with poor oral-motor function.

These findings illustrate the complexity of assessing energy requirements in disabled children. Although total energy requirements are lower in children with severe CP, dietary intake is likely to be grossly overestimated in the clinical setting. The prevalence of chronic undernutrition and growth failure in many children with SQCP indicates that energy needs are not being met. The next sections outline an approach to determining energy requirements in children with CP or other severe disabilities. The first step is the assessment of growth and nutritional status to identify those children whose energy needs are not being met and the degree of past or current undernutrition. Methods for estimating energy requirements based on nutritional status and related factors are reviewed.

NUTRITION STATUS ASSESSMENT

Inadequate energy intake appears to be a major cause of nutrition-related growth failure in children with cerebral palsy. Thus, two clinical management needs arise: (1) methods to assess nutritional and growth status to identify patients who are undernourished or overnourished and (2) methods to determine the caloric requirement of the individual patient. The elements of complete nutritional assessment are based on the standard pediatric medical evaluation and are presented in more detail in Chapter 2 and 3.

The medical history includes assessment of acute and chronic medical problems and medications. In addition, a nutritional history, including review of a "typical" day's

food intake; dietary history; use of caloric, vitamin, mineral, herbal, or other nutritional supplements; and unusual food practices by the child or family are obtained. The past growth patterns, including pubertal history and growth charts, are reviewed. The history includes a review of systems, with emphasis on dental and oral-motor function and on the gastrointestinal tract (emesis, gastroesophageal reflux, diarrhea, constipation).

The physical examination includes current pubertal status[40]; weight; height, length, or alternative linear growth measures; head circumference; midarm circumference; and skinfold measurements. Details of the recommended methods, equipment, and reference standards for the anthropometric measurements are in the following section. (For an overview of some of the physical findings associated with nutritional deficiencies, see Appendix, Table A–12.)

The laboratory evaluation is focused by recognizing the risk factors identified from the history and physical examination for each individual patient. The primary nutritional problem is usually inadequate caloric intake, and laboratory assessment of this pattern of malnutrition is of limited use. Both serum albumin and prealbumin can be indicators of the adequacy of calorie and protein intake, with albumin reflecting the past month (half-life, approximately 18 to 20 days) and prealbumin reflecting the past week (half-life, approximately 2 to 3 days) of nutrient intake. However, these are often in the normal range with the chronic undernutrition associated with CP. Iron deficiency anemia is seen in groups of patients who have limited caloric intake or who have monotonous food intake with few iron-rich foods. Iron status evaluation includes a complete blood count (hemoglobin, hematocrit, and red cell indices) as a screen, followed by other iron studies (serum iron, total iron-binding capacity, transferrin, ferritin) as indicated. Response to iron therapy is monitored by changes in the components of the complete blood count and a reticulocyte count. A summary of common drug–nutrient interactions is given in Table 34-1.

Laboratory tests are selected depending on the patient's history and physical examination and could include serum values for vitamin D, calcium, phosphorus, and alkaline phosphatase and radiologic examination of long bones to diagnose rickets. Clinically significant osteopenia often occurs without rachitic changes and can be diagnosed by determining bone mineral content or bone density (dual-energy x-ray absorptiometry). Bone density of the distal femur has been proposed as a measure for children with CP and contractures who are difficult to position for standard measurement sites.[41] Skeletal age determination is useful for diagnosing nutritional dwarfism in children with a delay of 2 or more years in bone age and for determining the potential for catch-up growth. Blood values for selected vitamins and minerals are available when indicated.

ANTHROPOMETRY

Anthropometric evaluation of growth and nutritional status is an essential component of nutritional care. It is a rapid, inexpensive, noninvasive means of determining both short- and long-term nutritional status. A well-trained anthropometrist is required in order to ensure accurate, reproducible measurements. Numerous anthropometric measures are used in the assessment of nutritional status. Each measure offers different information, and no single measure is sufficient for characterization of nutritional status. Proper equipment should be used, and it should be calibrated regularly to ensure accurate measurements. When accurate measurements are obtained and compared to appropriate reference standards, the clinician obtains a current classification of nutritional status and an opportunity to see changes in status over time. Guidelines for anthropometric measurement techniques are available[42,43] and are summarized below with consideration of the child with developmental disabilities.

Measurement of Growth

Weight, stature or length, and head circumference should be measured at routine office visits and every hospital admission. Current status and increments in growth between visits are very informative, especially for tracking progress in the individual patient. For children with severe disabilities, alternative measures of linear growth—upper-arm length and lower-leg length—are described below for assessment when a length or stature measurement is not possible.

Weight

Because growth retardation is common in children with severe disabilities, it is of extra importance that both weight and linear growth are measured at the same time. Because excess weight can be attributable to excess fat, excess water caused by edema, or organomegaly, other anthropometric measures, such as arm circumference and skinfold thicknesses, are important complements to interpreting a weight measurement.

Equipment, Measurement Technique, and Reference Standards Weight should be measured on a digital electronic or beam balance scale. The scale should be checked weekly with known calibration weights. The measurement should be taken to the nearest 0.1 kg in older children and to the nearest 0.01 kg in infants.

The scale should be reset to zero prior to placing a child on it. Children should be weighed wearing little or no outer clothing and without shoes. Infants should be measured without diapers. Wheelchair-accessible scales are available for older children who cannot stand unattended on a scale. The measured weight of the wheelchair alone is deducted from the weight of the child (with little or no clothing) in the wheelchair.

For reference standards for weight, see the Centers for Disease Control and Prevention (CDC) 2000 growth charts.[44]

Length or Stature

Linear growth is a measure of a child's nutritional history and genetic potential and helps to distinguish between short- and long-term nutritional problems. Length or

Table 34-1 Selected Drug–Nutrient Interactions

Drug	*Nutrient*	*Mechanism*
Antacids	Iron	Decreased absorption
Aluminum hydroxide		
Aluminum phosphate	Thiamin	Unstable in alkaline pH
Calcium carbonate		
Cimetidine	Folate, vitamin B_{12}	Decreased absorption
Magnesium carbonate	Phosphorus	Decreased absorption
Magnesium hydroxide		
Magnesium oxide		
Magnesium trisilicate		
Sodium bicarbonate		
Ranitidine	Vitamin B_{12}	Decreased absorption when administered chronically
Anticonvulsants		
Ethosuximide	Vitamin D	Unknown
Phenobarbital	Folate; vitamins B_{12}, B_6, K, C; calcium	Decreased intestinal absorption, altered vitamin D metabolism, increased renal excretion
Phenytoin	Folate; vitamins B_{12}, B_6, D; calcium	Altered vitamin D metabolism, others unknown
Primidone	Vitamins D, K	Altered vitamin D metabolism
Valproic acid	Carnitine	Unknown; possible causes include decreased synthesis, decreased absorption, or urinary loss
Anti-inflammatory drugs		
Acetylsalicylic acid	Folic acid	Competitive absorption at carrier site
	Vitamin C	Increased excretion
	Iron	Chronic blood loss
Corticosteroids	Protein	Decreased glucose tolerance
	Fat	Increased protein catabolism
	Zinc, sodium, potassium, calcium	Increased excretion/decreased absorption
Antimicrobials		
Clindamycin	Potassium	Unknown
Cycloserine	Vitamin B_6, calcium, magnesium,	Vitamin B_6 antagonist Decreased intestinal absorption
	Vitamin B_{12}, folate	Decreased serum levels
Gentamicin	Potassium, magnesium	Increased urinary excretion
Isoniazid	Vitamin B_6, niacin	Increased urinary excretion of vitamin B_6, necessary for conversion of tryptophan to niacin
Neomycin	Fat; vitamins A, D, K, B_{12}; sodium; potassium; calcium; magnesium; lactose; sucrose	Bile salt precipitation
Penicillin	Potassium	Increased urinary losses
Pyrimethamine	Folic acid	Folic acid antagonist
Sulfonamides	Folate, iron	Decreased intestinal absorption
Tetracycline	Zinc, iron, calcium, protein	Decreased intestinal absorption, increased nitrogen balance
Trimethoprim	Folic acid	Folic acid antagonist
Cardiovascular drugs		
Cholestyramine	Vitamins A, D, K, B_{12}; folate; fat; calcium	Bile salt depletion, increased renal excretion, decreased absorption
Digitalis	Magnesium, potassium, calcium	Competitive inhibition of dehydrofolate reductase
Enalapril maleate	Calcium	Unknown
Hydralazine	Vitamin B_6 depletion (?) trace elements	Vitamin inactivation, possible chelation of trace minerals
Cathartics		
Calomel	Phosphorus	Decreased absorption
Mineral oil	Vitamins A, D, E, K; carotene; calcium	Decreased absorption; solvent interference with micelle formation
Phenolphthalein	Vitamin D, calcium, potassium, riboflavin	Increased transit time
Diuretics		
Furosemide	Zinc	Increased renal losses
General	Thiamin, pyridoxine, magnesium, potassium	Increased renal excretion
Thiazides	Zinc	Increased renal losses
Electrolyte repletion		
Potassium chloride	Vitamin B_{12}	Decreased absorption secondary to decreased ileum pH
Heavy metal antagonists		
Penicillamine	Pyridoxine, copper, zinc	Increased renal excretion
Immune suppressants		
Cyclosporin	Lipids	Absorption altered by dietary lipids

For a complete list, see Allen AM. Powers and Moore's food medication interactions. Tempe (AZ): Ann Moore Allen; 1994.

stature measurements are appropriate for children who can be properly positioned, as described below. For children less than 2 years of age or children older than 2 who are not able to stand erect unsupported, a supine length measurement is taken. Standing height, or stature, is measured at age 2 and older. In older children with developmental disabilities, a length measurement is often required past 2 years of age. When comparing a supine length measurement to a growth chart for stature, the length should be decreased by approximately 2 cm[45] to adjust for the known difference between length and stature measurements.

Equipment, Measurement Technique, and Reference Standards To measure supine length, an infantometer or an inflexible length board with a fixed headboard and a movable footboard should be used. Length is measured to the nearest 0.1 cm. Infantometers and stadiometers with digital counters should be calibrated daily with a calibration bar of fixed length.

Measurement of supine length requires two people to position and hold the child. The head should be placed at the top of the board, with the Frankfort plane perpendicular to the floor. The Frankfort plane extends from the lower margin of the orbit to the upper margin of the auditory meatus (Figure 34-1). An assistant is needed to hold the head firmly in this position. The knees should be flattened to fully extend the legs. The feet should be together and flexed to a 90° angle by the footboard with the infant fully stretched.

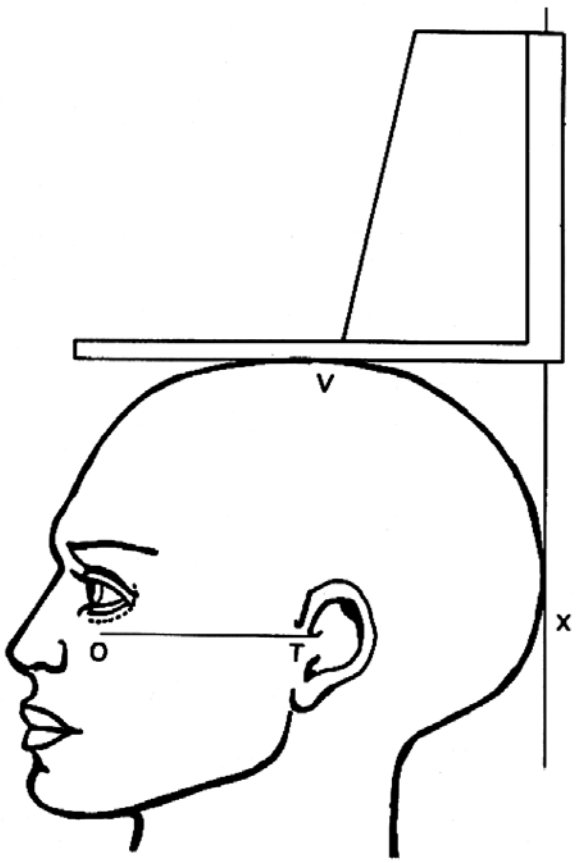

Figure 34-1 The Frankfort plane extends from the auditory meatus to the lower border of the orbit. This plane should be parallel to the paddle or headboard when measuring stature or length. Reproduced from Ross W et al.[61]

To measure stature, the child should stand with the heels, buttocks, and back of the head against the stadiometer. The arms should be down and relaxed and the heels together. The position of the head should be adjusted so that the Frankfort plane is parallel to the floor. Stature should be measured using a stadiometer with a head paddle that glides smoothly but is firmly perpendicular to the back of the stadiometer. Alternatively, a tape measure permanently fixed to a wall or doorframe can be used provided that a head paddle is available that will fit at a 90° angle to the wall. Both length and stature measurements should be accurate to 0.1 cm.

Length and stature measures are inappropriate for children with spinal curvature, contractures, or other conditions that prevent proper positioning for the measurement. Upper-arm length and lower-leg length are alternatives under these conditions (see below).

For both length and stature, measurements should be taken in triplicate, with the measurements in agreement within 0.5 cm, and the mean recorded. Whenever possible, the statures of both biological parents should be obtained and midparental stature computed (the average stature of the mother and father). Adjustment of stature or length measurements using midparental stature charts is a technique that recognizes and corrects for differences in the genetic potential for linear growth.[46]

For reference standards for length and stature, see the CDC 2000 growth charts.[44] Related information is found in Guo and colleagues,[47] Roche and Himes,[48] Himes and colleagues,[46] Berkey and colleagues,[49] and Tanner and Davis.[50]

Weight-for-Height Indices

Weight-for-length and weight-for-height indices are important in the assessment of nutritional status to ensure energy reserves adequate for maintaining growth and overall health. In infants and young children, weight-for-height charts are available[44] to assess nutritional status. For children more than 2 years of age, the body mass index (BMI) can be used. BMI is calculated as weight in kilograms divided by height in meters squared (wt/ht^2). BMI percentile charts are available for children from age 2 to 20 years.[44] Use of these charts is essential for interpretation of BMI in the pediatric range.

Head Circumference

Brain growth is most rapid in the first 3 years of life. Head circumference is a good indicator of brain growth and therefore should be included in the assessment of growth and nutritional status. Because of the high risk of growth failure in children with developmental disabilities, it is important to measure head circumference until age 3, or longer in some children, to determine whether growth of the brain and head is also compromised. However, head circumference is of limited use in nutritional status assessment of patients with central nervous system damage and micro- or megalocephaly of non-nutritional etiology.

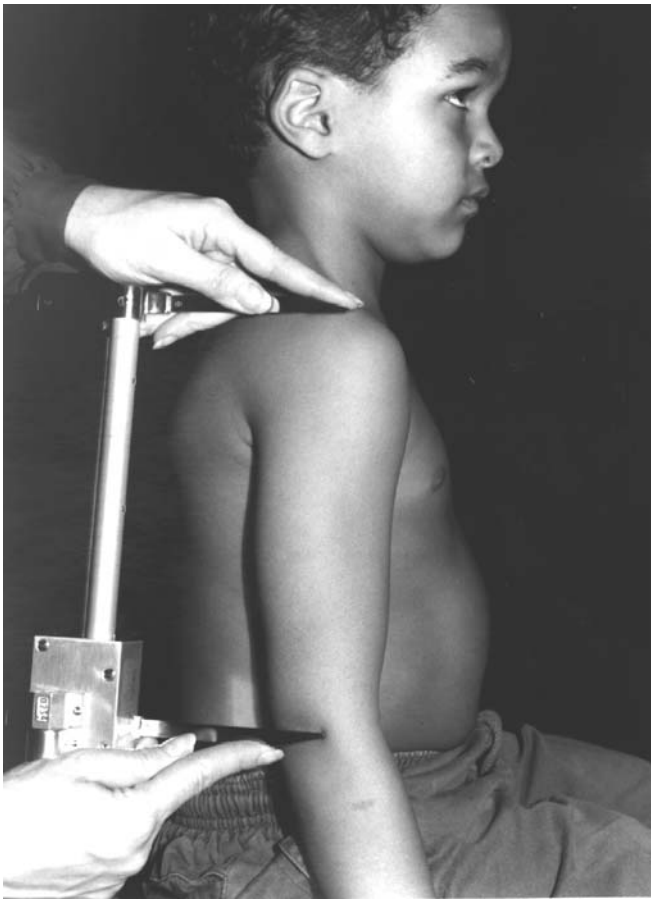

Figure 34-2 Upper-arm length measurement technique.

Equipment, Measurement Technique, and Reference Standards A flexible metal or nonstretch plastic-coated measuring tape scaled to 0.1 cm should be used. The tape is placed over the supraorbital ridge and around the occiput so that a maximum circumference is obtained. Care should be taken that the tape is evenly placed on all sides and is flat against the skull. Three measurements should be obtained and the mean recorded.

For reference standards for head circumference, see the CDC 2000 growth charts.[44,48,51]

Upper-Arm and Lower-Leg Length

Upper-arm length and lower-leg length are alternative measures of linear growth when length or stature measurements are not possible. This commonly occurs in children with developmental disabilities. Both upper-arm and lower-leg length should be measured because they provide measures of upper- and lower-body long-bone growth. Frequently, lower-leg length is more compromised than upper-arm length in children who are nonambulatory.

Equipment, Measurement Technique, and Reference Standards For young infants, sliding calipers (0 to 200 mm) are used. For older infants and children, an anthropometer (50 to 570 mm) is used. All measurements should be taken in triplicate to the nearest 0.1 cm and repeated every 3 months. For infants and young children up to 24 months of age, upper-arm length is measured as shoulder-to-elbow length. With the arm flexed at a 90° angle, the upper arm is measured from the superior lateral surface of the acromion to the inferior surface of the elbow. In children 2 to 18 years of age, upper-arm length is measured from the superior lateral surface of the acromion to the radiale (head of the radius) with the arm relaxed, as shown in Figure 34-2.

For infants and young children, lower-leg length is measured as a knee-to-heel length. With the infant lying supine—with the leg flexed to 90° at the hip, the knee, and the ankle—the lower-leg length is measured from the heel to the superior surface of the knee. For children 2 to 18 years of age, the lower-leg length measure is taken from the lower border of the medial malleolus (sphyrion) to the medial tip of the tibia while the patient is sitting in a relaxed position, as shown in Figure 34-3. The right side should be measured unless there is unilateral involvement affecting the right side. The least-affected side should be measured and thus noted on the growth chart so that repeat measures are always taken on the same limb. Reference percentiles for upper-arm length and lower-leg length for infants are given in Figures 34-4 and 34-5 and for older children (3 to 18 years) in Figures 34-6 through 34-9.

Nutritional Status

Anthropometric indicators of nutritional status consist of measurements of lean and fat tissues at sites known to be sensitive indicators of nutrition and health. Upper-arm anthropometry, the measurement of arm circumference and skinfold thickness, is particularly useful because excellent reference data are available for clinical interpretation. An additional measure of subcutaneous fat on the trunk, the subscapular skinfold thickness measure, is also important because reference data are available and it provides more information for understanding total body fat stores.

Mid-Upper-Arm Circumference

Mid-upper-arm circumference is a composite measure of muscle, fat, and bone in the arm. It is sensitive to current nutritional status and can be used in combination with the triceps skinfold thickness measure to estimate upper-arm muscle area and upper-arm fat area.

Equipment, Measurement Technique, and Reference Standards A nonstretch flexible tape measure is used. All measurements should be taken in triplicate to the nearest 0.1 cm. The midpoint of the upper arm is located by measuring the length of the upper arm (from the acromion to the olecranon with the arm flexed at 90°) and marking the midpoint with a washable ink pen. The midarm circumference is taken with the arm down and in a fully relaxed position. Gently shaking the arm usually ensures that it is relaxed. The tape is placed over the midpoint perpendicular to the long axis of the arm. Care should be taken so that there is no pinching or gaping of the tape as it encircles the arm. This process improves the accuracy and reproducibility of the measure.

For reference standards for mid-upper-arm circumference, see Frisancho.[53]

Skinfold Thickness

Skinfold thickness measures assess subcutaneous fat at specified sites. The triceps and subscapular skinfold measures are indicators of total body fat stores and are sensitive to changes in nutrient intake and nutritional status. Depletion of fat stores at the triceps site is common in children with CP and in other chronically undernourished groups, whereas fatness at the subscapular site is not affected as severely.[6,7,54] Reference data for the sum of these two skinfold measures are available[55] and are used in the research setting as a characterization of total body fat.

Equipment, Measurement Technique, and Reference Standards Holtain skinfold calipers are preferred because they are scaled to 0.2 mm. Lange calipers can be used, but with some loss of accuracy as they are scaled to the nearest 0.5 mm. Calipers that are not spring-loaded and therefore do not provide a constant tension are not recommended.

The triceps skinfold thickness is measured over the triceps muscle, along the back of the arm. The measurement is taken at the same level at which the mid-upper-arm circumference is measured. The patient should be upright with the arm down and fully relaxed for the measurement. The fold of fat and skin is lifted away from the underlying muscle and held throughout the measurement. The calipers are placed on the skin next to the fingers lifting up the skinfold; the skinfold is held in position while the thickness is measured with calipers, and the reading should be taken 3 to 4 seconds after releasing the caliper's handles.

For the subscapular skinfold, the patient should be upright with the arm and shoulder down and fully relaxed. The skinfold is lifted 1 cm below the tip of the scapula at a 45° angle following the natural contour of the body. The fold is held in place, and the calipers are placed next to the fingers holding the fold. The reading should be taken 3 to 4 seconds after releasing the caliper's handles.

For reference standards for skinfold thickness, see Frisancho,[53, 55] Cronk and Roche,[56] and Johnson and colleagues.[57]

Table 34-2 Anthropometric Equations for Prediction of Percent Fat (Ages 8–18 Years)

White males	
Prepubescent:	1.21 (triceps + subscapular) – 0.008 (triceps + subscapular)^2 – 1.7
Pubescent:	1.21 (triceps + subscapular) – 0.008 (triceps + subscapular)^2 – 3.4
Postpubescent:	1.21 (triceps + subscapular) – 0.008 (triceps + subscapular)^2 – 5.5
Black males	
Prepubescent:	1.21 (triceps + subscapular) – 0.008 (triceps + subscapular)^2 – 3.2
Pubescent:	1.21 (triceps + subscapular) – 0.008 (triceps + subscapular)^2 – 5.2
Postpubescent:	1.21 (triceps + subscapular) – 0.008 (triceps + subscapular)^2 – 6.8
All females:	1.33 (triceps + subscapular) – 0.013 (triceps + subscapular)^2 – 2.5
If (triceps + subscapular) greater than 35 mm:	
Males:	0.783 (triceps + subscapular) + 1.6
Females:	0.546 (triceps + subscapular) + 9.7

Adapted from Slaughter MH et al.[58]

Body Composition

Body composition assessment, the measurement of fat and lean body mass stores, is an essential component of nutritional assessment of the disabled child. Whereas linear growth reflects the longer-term nutritional history and genetic potential and is often compromised in children with disabilities, fat and lean body mass stores reflect short-term nutritional adequacy. Body composition can be estimated using the prediction equations of Slaughter and colleagues[58] in children ages 8 to 20 years. These equations use the triceps and subscapular skinfold thickness measures shown in Table 34-2. Specific equations are given based on race, gender, and pubertal status groups.

Body composition values estimated from these anthropometric prediction equations have been compared with measures determined from total body water[59] in children with severe SQCP. Fat mass measured by these two methods is significantly correlated (r = .69), indicating that the anthropometric prediction equations can be used as a clinical, noninvasive method to estimate total body fat in children with CP.[58] Other methods, such as bioelectrical impedance analysis (BIA), total body electrical conductivity (TOBEC), and dual-energy x-ray absorptiometry (DXA), are possible. However, motion artifact and inability to properly position the patient could increase the measurement error and give inconsistent results in children with moderate to severe disabilities. In addition, both TOBEC and BIA require a height measurement. For children whose height can be estimated only from long-bone measures, the measurement error is greatly increased so that these methods become less effective measures of body composition.

ENERGY INTAKE RECOMMENDATIONS

Assessment of energy intake compared to requirement is an essential component of the nutritional care of children with significant disabilities. Undernutrition and overnutrition are the common nutritional pathologies and are the result of energy imbalance. True energy intake is difficult to determine accurately in children with poor oral-motor function and other gastrointestinal problems. Food loss during feeding and regurgitation contribute to the inaccurate estimation of energy intake, even when weighed food diaries recorded over several days are obtained.[38] Daily energy expenditure and its components can be measured in individuals in a research setting (doubly labeled water, 24-hour indirect room calorimetry, REE, thermic effect of food, physical activity). Only REE by indirect calorimetry, a measurement of basal metabolic needs, is available as a clinical evaluation and can be used with estimates of physical activity to predict total caloric needs.

The use of population standards for energy recommendation, such as the RDA from the United States,[29] is not helpful for individual patients with developmental disabilities with atypical body size, body composition, and physical activity. The formulas for energy requirement from WHO[60] are more useful and allow for a more individualized prediction of REE based on gender, age, and body weight, as shown in Table 34-3. Whenever possible, REE should be measured by indirect calorimetry in the early morning with the child fully at rest and in a fasting state. Under these conditions, measurements obtained over 30 to 60 minutes of inactivity can provide an excellent estimate of resting energy needs. The value for REE, whether from indirect calorimetry or a prediction equation, is adjusted by an activity factor to determine total energy expenditure and daily energy requirements. In normally active healthy children and in adults with light or moderate activity, the activity factors range between 1.50 and 1.89 times the REE. Recent work[38] suggests that the physical activity factor for well-nourished children with spastic quadriplegia is much lower, about 1.3 times the REE, and about 1.5 in malnourished children with CP.

Two other methods for estimating caloric requirements have been published. Culley and Middleton developed a

Table 34-3 Equations for Predicting Resting Energy Expenditure from Body Weight (w)

Age, yr	*Male*	*Female*
0–3	60.9 W – 54	61.0 W – 51
3–10	22.7 W + 495	22.5 W + 499
10–18	17.5 W + 651	12.2 W + 746
18–30	15.3 W + 679	14.7 W + 496
30–60	11.6 W + 879	8.7 W + 829
> 60	13.5 W + 487	10.5 W + 596

Adapted from World Health Organization.[60]

method for disabled children that takes level of motor function into account.[59] The caloric consumption based on motor function status was 14.7 kcal/cm of height and 77 kcal/kg for children without motor dysfunction, 13.9 kcal/cm and 75 kcal/kg for ambulatory children with some motor dysfunction, and 11.1 kcal/cm and 64 kcal/kg for nonambulatory children with motor dysfunction. In addition, Krick and Murphy reported a factorial method approach to determining caloric needs in children with CP.[30] This method accounts for caloric intake based on estimated REE needs, muscle-tone alterations, normal growth needs, and catch-up growth or nutritional repletion in malnourished children. The formula is summarized as

kcal/d = resting energy needs × tone factor + growth factor(s).

SUMMARY

Monitoring nutrition and growth status in children and adults with CP and other severe types of developmental disabilities is an essential component of care. This chapter summarizes the previous work in the area and outlines clinical approaches to determining nutritional status and estimating caloric needs. Although data are not available to provide precise definitions of the levels of severity of malnutrition and growth failure and their effect on long-term outcome, it is clear that many patients with moderate to severe cerebral palsy or other disabilities have malnutrition and growth failure as the result of inadequate caloric intake. Nutritional status assessment every 3 to 6 months will enable the clinical care team to identify malnutrition and growth failure and will provide an objective means of following the response to nutritional intervention.

CHAPTER 35

INBORN ERRORS OF FASTING ADAPTATION

Jon Oden, MD, William R. Treem, MD

A number of inborn errors of metabolism compromise the child's normal response to fasting. Depending on the enzyme and metabolic pathway affected, the individual will tolerate fasting for a brief or more prolonged period of time. The abnormal enzymatic pathway will also determine which potentially toxic intermediates accumulate, which substrates are consumed, and which products fail to be produced. In general, these derangements in fuel conservation and energy production are characterized biochemically by hypoglycemia and acidosis and by either an abundance or a paucity of ketone bodies. They are characterized histologically by effects on the tissues most involved in fuel metabolism and substrate production during fasting, such as the liver, and those most dependent on the maintenance of adequate substrate for sustained energy requirements during fasting, such as the heart and skeletal muscles. Brain function is intimately linked to an adequate glucose supply and is vulnerable to the accumulation of metabolic toxins. Thus, it is easy to understand why patients with these disorders often present with symptoms of stupor, coma, or even seizures; hypotonia, rhabdomyolysis, or cardiomyopathy; and an enlarged liver filled with fat or glycogen. Accumulation of toxins in the liver, particularly within the mitochondria, can also lead to generalized mitochondrial failure, lactic acidosis, and fulminant hepatic failure.

Normal infants are more likely to develop hypoglycemia and manifest hyperketonemia earlier during a fast than their adult counterparts. This is probably the result of several factors, including decreased hepatic glycogen stores, decreased muscle mass with reduced mobilization of amino acid substrates for gluconeogenesis, and a larger brain mass to body size. This latter factor is important because glucose is the main fuel for the brain. In the rest of the body, free fatty acids (FFAs) replace glucose as the major fuel, but the brain remains the major consumer of glucose during fasting.[1,2] Fasting provocation occurs at several periods during infancy, including the time of placental separation, the time when the infant first sleeps through the night, the time of weaning from the breast, and the time of the first intercurrent illness with fever, vomiting, and catabolic stress. It is at these critical junctures that symptoms and signs of inborn errors in fasting adaptation may present.

This chapter reviews the normal physiology of adaptation to the immediate and prolonged fasting state in infants and children. It then explores specific hormonal and enzymatic abnormalities that disrupt this adaptive process. These include derangements in glycogenolysis, gluconeogenesis, fatty acid oxidation, ketogenesis, or ketolysis. With this background, the nutritional management of these problems is reviewed. Inborn errors of metabolism that are provoked by feeding and the ingestion of substrates that cannot be adequately metabolized are not covered. For a review of these feeding-induced disorders (ie, galactosemia, hereditary fructose intolerance, urea cycle defects, and disorders of amino acid metabolism), the reader is referred to several excellent texts.[3–6]

NORMAL PHYSIOLOGY OF FASTING

In a 24-hour period, a normal man who consumes 1,800 calories per day burns about 75 g of protein, primarily from muscle, and 160 g of adipose tissue triglyceride. Hepatic output of glucose approximates 180 g, of which 144 g is used by nerve tissue (mainly brain) and is completely oxidized to CO_2 and water.[1] Other glycolytic tissues, such as erythrocytes, renal medulla, and normal muscle, metabolize glucose but convert it primarily to lactate and pyruvate. These metabolites are recycled by entering the bloodstream and being converted back into glucose by the liver and kidney (Cori cycle). About 36 g (20%) of the glucose used daily is broken down by anaerobic glycolysis and then remade into glucose. The remainder of the tissues (heart, skeletal muscle, renal cortex) metabolizes either fatty acids released directly into the circulation or ketone bodies derived from fatty acid oxidation by the liver (Figure 35-1).

As shown in Table 35-1, fatty acids stored as adipose tissue triglyceride comprise by far the largest reserve of fuel in the body. Because liver glycogen stores are depleted within only a few hours of a meal, fatty acids then become the predominant substrate for energy production via oxidation in the liver, cardiac muscle, and skeletal muscle. In an adult man, fatty acids provide 80% of caloric requirements after a 24-hour period of fasting.[7] In the muscle, the metabolic end product of fatty acid oxidation is acetyl coenzyme A (CoA), which is further metabolized to CO_2

Table 35-1 Body Fuel Stores and the Potential Length of Time They Could Supply Energy in a 30kg Child Utilizing 1200 cal/day

	Fuel Stores (kg)	*Time*
Tissues		
Fat (adipose tissue)	4.5	34 d
Protein (mainly muscle)	1.5	5 d
Glycogen (muscle)	.09	8.0 h
Glycogen (liver)	.045	3.5 h
Circulating fuels		
Glucose (extracellular fluid)	.010	50 min
Triglyceride (plasma)	.0015	20 min
Free fatty acids (plasma)	.00015	1 min

Adapted from Cahill GF.[1]

via the tricarboxylic acid (TCA) cycle, yielding adenosine triphosphate (ATP) for the energy needs of the cell. In the liver, the primary metabolic product of fatty acid oxidation is β-hydroxybutyrate, a ketone body, synthesized from acetyl CoA and subsequently exported to peripheral tissues as a glucose-sparing fuel.

The predominant hormones controlling hepatic and peripheral glucose metabolism include insulin, glucagon, cortisol, growth hormone (GH), insulin-like growth factors (IGFs), and the catecholamines. Insulin is the primary hormone responsible for lowering blood glucose and protecting the individual from hyperglycemia. A detailed description of insulin release is beyond the scope of this summary; however, a brief overview would be appropriate. The initial response to increased serum glucose is its uptake and metabolism in the beta cell. The rate-limiting step in this reaction involves the catalyst glucokinase. The catabolism of glucose results in an increased ATP-to-adenosine diphosphate (ADP) ratio sensed by the sulfonylurea type 1 (SUR1) receptor. This leads to the closure of the K^+_{ATP} channels and depolarization of the cell membrane. Depolarization leads to the opening of calcium channels and, finally, release of stored insulin.[8] Inappropriate beta cell regulation owing to mutations in critical enzymes and receptors results in uncontrolled insulin secretion and subsequent hypoglycemia. Several groups have published data on specific genetic and receptor defects responsible for congenital hyperinsulinism.[9,10]

During fasting, insulin levels decline and the effects of glucagon produced by the pancreatic alpha cell become predominant (Table 35-2). The primary stimulus for the release of glucagon is a lowering of the blood glucose concentration, although other factors, particularly increased sympathetic neuronal activity, also play a role. Increased glucagon concentrations and changes in the molar ratio of insulin to glucagon have far-reaching effects. These hormonal changes provoke glycogenolysis, gluconeogenesis, fatty acid oxidation, and ketogenesis in the liver; increase lipolysis in peripheral adipose tissue; and stimulate the release of lactate and amino acids from skeletal muscle. These adaptive mechanisms are designed to maintain plasma glucose concentrations, enhance glucose production via gluconeogenesis, allow the consumption of alternative fuels by the bulk of tissues in the body, and preserve glucose for brain metabolism.

GH, catecholamines, and cortisol are other counterregulatory hormones that raise blood sugar in periods of increased demand such as fasting or stress. In the newborn period, deficiency of GH can result in acute hypoglycemia in 20% of cases. Likewise, defects in the GH receptor

Table 35-2 Hormonal Control of Glucose Homeostasis

Substrate	*Enzymes*	*Effects*	
Insulin	Glycogen	↑ Glucokinase ↑ Glycogen synthase ↓ Glucose-6-phosphatase ↓ Glycogen phosphorylase	Stimulates entry of glucose into cells; stimulates storage of glucose as glycogen and inhibits its breakdown
	Glucose	↑ Phosphofructokinase ↑ Pyruvate kinase ↓ Fructose-1,6-diphosphatase ↓ PEP-carboxykinase ↓ Pyruvate carboxylase	Stimulates complete utilization of glucose to CO_2 and H_2O through the TCA cycle; inhibits gluconeogenesis from glycerol, lactate, and alanine
	Fat	↑ Acetyl-CoA carboxylase ↓ Lipase ↓ CPT-I	Stimulates fatty acid synthesis and increases glycerol production for TG synthesis; inhibits FAO and ketogenesis
*Glucagon**	Glycogen	↑ Glucose-6-phosphatase ↑ Glycogen phosphorylase ↓ Glycogen synthase	Increases degradation of glycogen and release of glucose from cells; inhibits glycogen synthesis
	Glucose	↑ Fructose-1,6-diphosphatase ↑ PEP-carboxykinase ↑ Pyruvate carboxylase ↓ Phosphofructokinase ↓ Pryuvate kinase	Promotes gluconeogenesis from recycled lactate and alanine and from glycerol; inhibits glycolysis
	Fat	↑ Lipase ↑ CPT-I ↓ Acetyl-CoA carboxylase	Stimulates lipolysis of TG, FFA release, FAO, and ketogenesis; inhibits fatty acid and TG synthesis

*Other counterregulatory hormones such as epinephrine, cortisol, and growth hormone also act in concert with glucagon on certain enzymes.
CoA = coenzyme A; CPT-I = carnitine palmitoyl transferase I; FAO = fatty acid oxidation; FFA = free fatty acid; PEP = phospho*enol*pyruvate; TCA = tricarboxylic acid; TG = triglyceride.

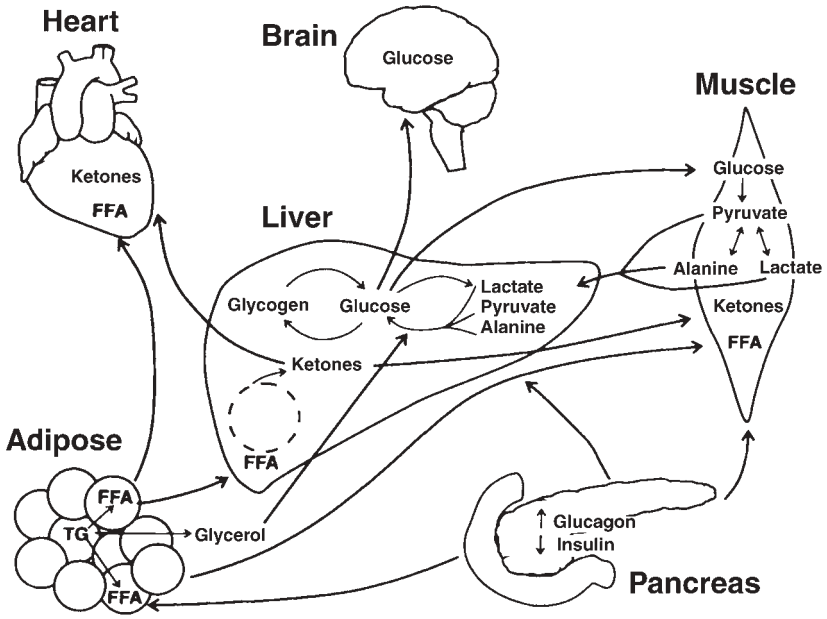

FIGURE 35-1 Organ and substrate interactions illustrating the normal adaptation to fasting. Under the influence of an increased circulating molar ratio of glucagon to insulin, enzymes are activated in the target organs to maintain glucose production, provide alternative fuels in tissues that can use them, and conserve glucose for brain metabolism. Glycogen is degraded to glucose in the liver. Glucose is resynthesized from recycled pyruvate, lactate, and alanine liberated from muscle catabolism and also newly synthesized from glycerol produced by lipolysis of triglycerides (TG) stored in adipose tissue. Free fatty acids (FFA) are mobilized from adipose tissue and exported directly to heart and skeletal muscle for complete oxidation to CO_2. The liver becomes a ketogenic organ and oxidizes FFAs to ketones. Ketones are exported to heart and skeletal muscle for catabolism in lieu of glucose. Glucose is conserved for the metabolic needs of the brain.

(Laron syndrome) may present with hypoglycemia owing to decreased or absent production of IGF-I. Patients with Laron syndrome may present with more profound hypoglycemia when compared with GH-deficient individuals.[11] Glucagon and cortisol play a more crucial role in gluconeogenesis and glucose regulation. Hypoglycemia can occur in the setting of decreased cortisol production or adrenocorticotropic hormone (ACTH) secretion owing to a lack of a counterregulatory response to hypoglycemia.

Glycogen Degradation

Most glucose production during fasting arises from the liver, and this is usually sufficient to provide for the brain's needs. Three elements account for this glucose output: glucose from glycogen, gluconeogenesis from protein and fat, and glucose resynthesized from the products of glycolysis. Hepatic glycogenolysis is the main provider of the body's glucose requirements in the early stages of fasting. In children aged 3 to 5 years, the administration of glucagon or epinephrine injections after 12 to 15 hours of fasting still results in a significant increase in plasma glucose, suggesting that adequate glycogen stores are maintained for at least this period of time.[12] By 24 hours, this effect is no longer seen in fasting infants and children.[13] Glycogen comprises up to 5% of the wet weight of the liver,[14] and approximately one-third of the body's production of glucose is derived from hepatic glycogenolysis during the first few hours of a fast. Although muscle glycogen accounts for a larger tissue reserve than that found in liver, muscle glycogen is depleted slowly over several days and is used primarily for local needs when the external carbohydrate supply is limited. Because the muscle lacks glucose-6-phosphatase, it is also unable to release free glucose into the blood in any significant amount.

In the early fasting state, insulin is decreased, and increased epinephrine and glucagon secretion stimulate glycogenolysis and inhibit glycogen synthesis. These hormones increase the synthesis of cyclic adenosine monophosphate (cAMP) intracellularly, thereby increasing the activity of a cAMP-mediated protein kinase that activates the degradative enzyme glycogen phosphorylase and inhibits glycogen synthetase (Figure 32-2). The phosphorylase reaction cleaves 1,4 straight-chain glucose linkages, producing glucose-1-phosphate, which is subsequently converted to glucose-6-phosphate. Another debrancher enzyme (amylo-1, 6-glucosidase) cleaves the 1,6-glucose linkages found at the branch points of the glycogen molecule, allowing for the continued action of the phosphorylase on the remaining straight chains of glucose polymers. Sequential degradation of glycogen results in the production of approximately 8 to 12% free glucose and 90% glucose-6-phosphate. Further glucose is released through the hydrolysis of glucose-6-phosphate by a reaction catalyzed by the enzyme glucose-6-phosphatase. This complex enzyme is composed of at least five different polypeptides situated in the lumen of the endoplasmic reticulum and is found only in the liver, kidney, and intestinal mucosa.[15]

Gluconeogenesis and Recycling of Glycolytic Metabolites

Gluconeogenesis is the synthesis of new glucose from other noncarbohydrate metabolites such as protein or fat and thus adds to the total body pool of glucose. A quantitatively more important factor in maintaining glucose homeostasis is the conservation of glucose by the recycling of three-carbon fragments generated by glycolysis in the muscle: pyruvate, lactate, and transaminated pyruvate in the form of alanine.[16]

When liver glycogen is depleted, adipose tissue triglyceride (triacylglycerol) is cleaved by a lipase that is inhibited by insulin and activated by epinephrine and glucagon, with the permissive effects of GH and cortisol. This results in the release of large amounts of FFAs and glycerol into the blood, the former serving as substrate for hepatic

ketone production and the latter for gluconeogenesis. Simultaneously, lactate, pyruvate, and alanine liberated from muscle catabolism (glycolysis and proteolysis) are recycled back into glucose synthesis in the liver. Alanine is probably produced by the myocyte because it is released from skeletal muscle in quantities that exceed the amounts stored in these tissues.[17] Transamination of pyruvate to alanine allows muscle to rid itself of ammonia. These recycling processes of alanine (alanine cycle), pyruvate, and lactate (Cori cycle) are responsible for more than half of the glucose produced during prolonged fasting. The energy for conversion of these three-carbon fragments back to glucose is derived from hepatic and muscle fatty acid oxidation. The net effect is that energy derived from fatty acid oxidation is used to spare glucose use in the muscle and regenerate glucose in liver.

The key enzymes responsible for the complete oxidation of glucose during the fed state are phosphofructokinase (PFK), pyruvate kinase, and pyruvate dehydrogenase (see Figure 35-2). PFK activity is increased by insulin and catalyzes a key step in glucose use, the conversion of fructose-6-phosphate to fructose-1,6-diphosphate. Pyruvate kinase is also stimulated by insulin and catalyzes the formation of pyruvate from phospho*enol*pyruvate (PEP). Pyruvate dehydrogenase promotes the entry of pyruvate into the TCA cycle by conversion of pyruvate to acetyl CoA and is stimulated by the availability of pyruvate and free CoA. In the fasting state, stimulated by a decrease in insulin relative to glucagon and by cortisol and epinephrine, pyruvate is preferentially converted to oxaloacetate rather than to acetyl CoA through the action of intramitochondrial pyruvate carboxylase. Oxaloacetate is then converted to malate, and malate is shuttled out of the mitochondria into the cytosol, where it is reconverted to oxaloacetate and metabolized to PEP through the action of PEP carboxykinase (PEPCK). PEP is then ultimately converted to glucose-6-phosphate, which is then hydrolyzed to the free glucose that is released into the blood.

Fatty Acid Oxidation

In the fed state, insulin simultaneously inhibits the enzymes that catalyze triglyceride breakdown, enhances glycerol production via glycolysis, allows for increased esterification of fatty acids as triglycerides, and promotes glucose use by driving conversion of pyruvate to acetyl CoA and eventually to malonyl CoA (see Table 35–2). The accumulation of malonyl CoA inhibits the activity of carnitine palmitoyltransferase I (CPT-I). CPT-I is one of the enzymes responsible for the transesterification of fatty acid ester to carnitine and the transport of the acylcarnitine ester across the inner mitochondrial membrane (Figure 35-3). CPT-I is a major site of regulation that determines whether fatty acids are directed toward intramitochondrial β-oxidation or to resynthesis as triglycerides.[18] The activity, immunoreactive protein, ribonucleic acid (RNA), and transcription rate of CPT-I are increased in high-fat feeding, starvation, and

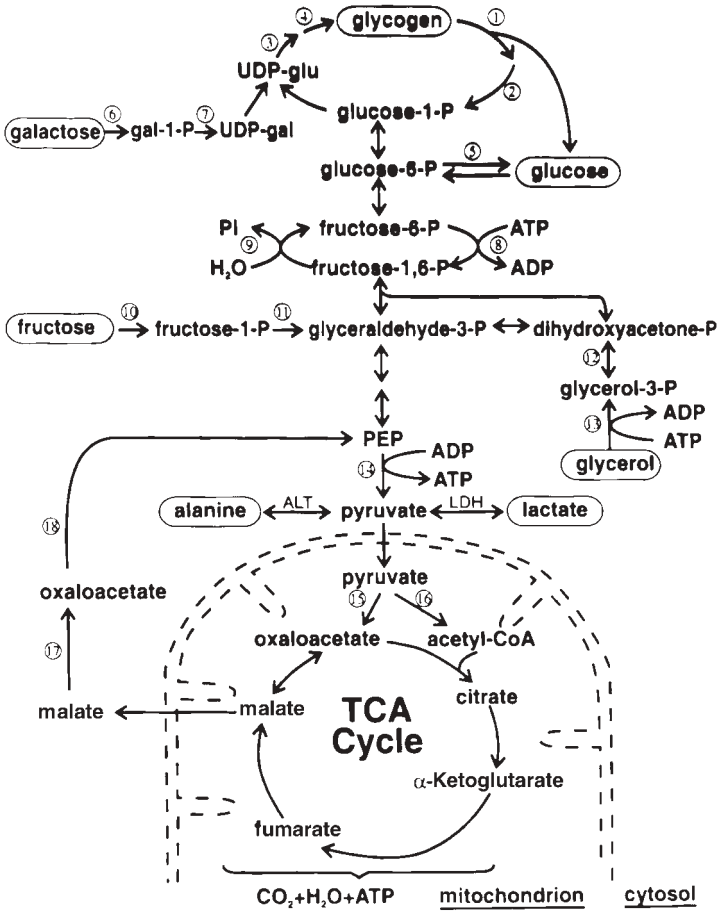

FIGURE 35-2 Pathways of carbohydrate metabolism in the liver including glycogenolysis and glycogen synthesis, glycolysis and gluconeogenesis, and the metabolism of pyruvate. Substrates for gluconeogenesis are circled. Numbers identify major enzymes in the pathways: (1) debrancher, (2) phosphorylase, (3) glycogen synthetase, (4) brancher, (5) glucose-6-phosphatase, (6) galactokinase, (7) galactose-1-phosphate uridyl transferase, (8) phosphofructokinase, (9) fructose-1,6-diphosphatase, (10) fructokinase, (11) fructose-1-phosphate aldolase, (12) glycerol-3-phosphate dehydrogenase, (13) glycerol kinase, (14) pyruvate kinase, (15) pyruvate carboxylase, (16) pyruvate dehydrogenase, (17) malate dehydrogenase, (18) phospho*enol*pyruvate carboxykinase. ADP = adenosine diphosphate; ALT = alanine aminotransferase; ATP = adenosine triphosphate; CoA = coenzyme A; LDH = lactate dehydrogenase; P = phosphate; PEP = phospho*enol*pyruvate; Pi = inorganic phosphate; TCA = tricarboxylic acid.

diabetes and by glucagon, cAMP, aspirin, hypolipidemic drugs, and cytokines.[19] Enhanced glucagon levels during fasting inhibit acetyl-CoA carboxylase, which catalyzes the conversion of acetyl CoA to malonyl CoA. Reduced tissue levels of malonyl-CoA allow increased activity of CPT-I and promote entry of fatty acids into mitochondria for β-oxidation. In the fasting state, ratios of glucagon to insulin are high, lipogenesis is repressed, fatty acid oxidation is enhanced, and the liver becomes a ketogenic organ.

To traverse the inner mitochondrial membrane, long-chain fatty acid esters (long-chain acyl CoAs) must first be transesterified to carnitine to form a fatty acylcarnitine and then transported by a membrane-bound transporter and subsequently reconverted back to long-chain fatty acyl CoAs at the interface of the inner mitochondrial membrane with the mitochondrial matrix (see Figure 35-3).[20] In contrast to long-chain fatty acids such as palmitate and oleate, short- and medium-chain fatty acids can traverse the mitochondrial membrane as free acids without the need for esterification to carnitine. Once inside the mitochondria, the long-chain acyl CoA enters the β-oxidation spiral. Figure 35-3 shows the four enzymes responsible for each turn of the cycle, which results in the shortening of the fatty acyl CoA by two carbons. This cycle results in the production of acetyl CoA, the generation of ATP to support gluconeogenesis and other energy-requiring reactions, and the transfer of two electrons to electron transfer flavoprotein. These electrons ultimately pass to the electron transport chain, resulting in further ATP production via oxidative phosphorylation. Adequate generation of mitochondrial acetyl CoA is crucial to the efficiency of gluconeogenesis because acetyl CoA is the primary activator of pyruvate carboxylase, which converts pyruvate to oxaloacetate.

Ketogenesis and Ketolysis

During times of carbohydrate insufficiency, the body's needs for energy may be partially met by use of ketones derived from hepatic fatty acid oxidation. The liver has a remarkable capacity to oxidize fatty acids and produce the ketones acetoacetate and β-hydroxybutyrate. In one day, the liver can synthesize about half its weight in ketone bodies (about 900 g/day).[21] Although the liver is the major organ for production of ketones, it does not itself oxidize nonthiolated acetoacetate. It exports ketones to many peripheral tissues, including heart, skeletal muscle, kidney, and intestine, where acetoacetate may be oxidized and glucose conserved. Fatty acids and ketones generated during prolonged fasting spare the oxidation of glucose in part by impairing its entry into muscles and by inhibiting the important glycolytic enzymes PFK and pyruvate carboxylase. During more prolonged periods of fasting and starvation, the brain adapts to the use of ketones as a major fuel and derives over half of its energy by the oxidation of ketones.[2] This adaptation results in a marked decrease in the demand for de novo glucose synthesis from alanine and consequently permits the organism to conserve its vital protein stores.

In liver mitochondria, the end product of fatty acid oxidation, acetyl CoA, has the option of entering the TCA cycle by condensing with oxaloacetate to form citrate or, alternatively, of forming 3-methylglutaryl CoA, which can be cleaved to form the ketone bodies acetoacetate and reduced 3-hydroxybutyrate. Thus, the concentration of oxaloacetate at this fork helps to determine the path taken by acetyl CoA. Glucagon and cAMP (through which glucagon exerts its effects) cause a marked diminution of mitochondrial oxaloacetate. This is coincident with decreased synthesis of fatty acids, increased oxidation of fatty acids, and increased ketogenesis.

SPECIAL FEATURES OF THE NEWBORN PERIOD

Glycogenolysis and Gluconeogenesis

As outlined above, maintenance of the plasma glucose concentration in a normal fasted individual depends on (1) a normal endocrine system for modulating substrate mobilization and use; (2) intact enzyme pathways for glycogenolysis, gluconeogenesis, fatty acid oxidation, and ketogenesis; and (3) an adequate supply of endogenous fat, glycogen, and gluconeogenic substrates. In newborns, particularly premature infants subjected to stress, a number of factors combine to render the fasting newborn more susceptible to hypoglycemia (Table 35-3). The adult human is capable of maintaining a normal blood glucose concentration even when totally deprived of calories for weeks. In contrast, the normal neonate and infant exhibit a progressive fall in blood glucose to hypoglycemic levels when fasted for even short periods of 24 to 48 hours.[22–24]

Immediately after birth, the newborn must withstand a brief period of starvation before receiving a new source of nutrients from milk. During this period, the large liver glycogen stores and endogenous fat stores that have accumulated during late fetal life must sustain the infant. In spite of intrahepatic concentrations comparable with those seen in children with glycogen storage disease (GSD), liver glycogen stores in normal newborns are usually exhausted within 12 hours of delivery.[25] At the time of separation of the newborn from the maternal blood supply, there is a relative surge in glucagon secretion. However, the administration of glucagon to neonates has been shown to have little effect on plasma glucose concentrations, implying that the normal glycogenolytic response to endogenous glucagon may be blunted.[26] Marked increases in sympathetic nervous system tone and epinephrine secretion owing to the stress of birth play an important role in initiating glycogenolysis and lipolysis by stimulating glucagon and inhibiting insulin secretion. Prolonged fetal distress, cold stress, or infection accentuates epinephrine secretion and results in a rapid depletion of both fat and glycogen stores, greatly limiting the substrates for subsequent glucose and ketone production.

Although the timing of the induction of the hepatic gluconeogenic enzymes in humans remains to be established, gluconeogenesis is either absent or markedly depressed in the fetus of various experimental animals.[22,27] This activity does not increase until the perinatal period and reaches adult levels only after several hours to days of extrauterine life. Small-for-gestational-age (SGA) infants exhibit a relative functional delay in gluco-

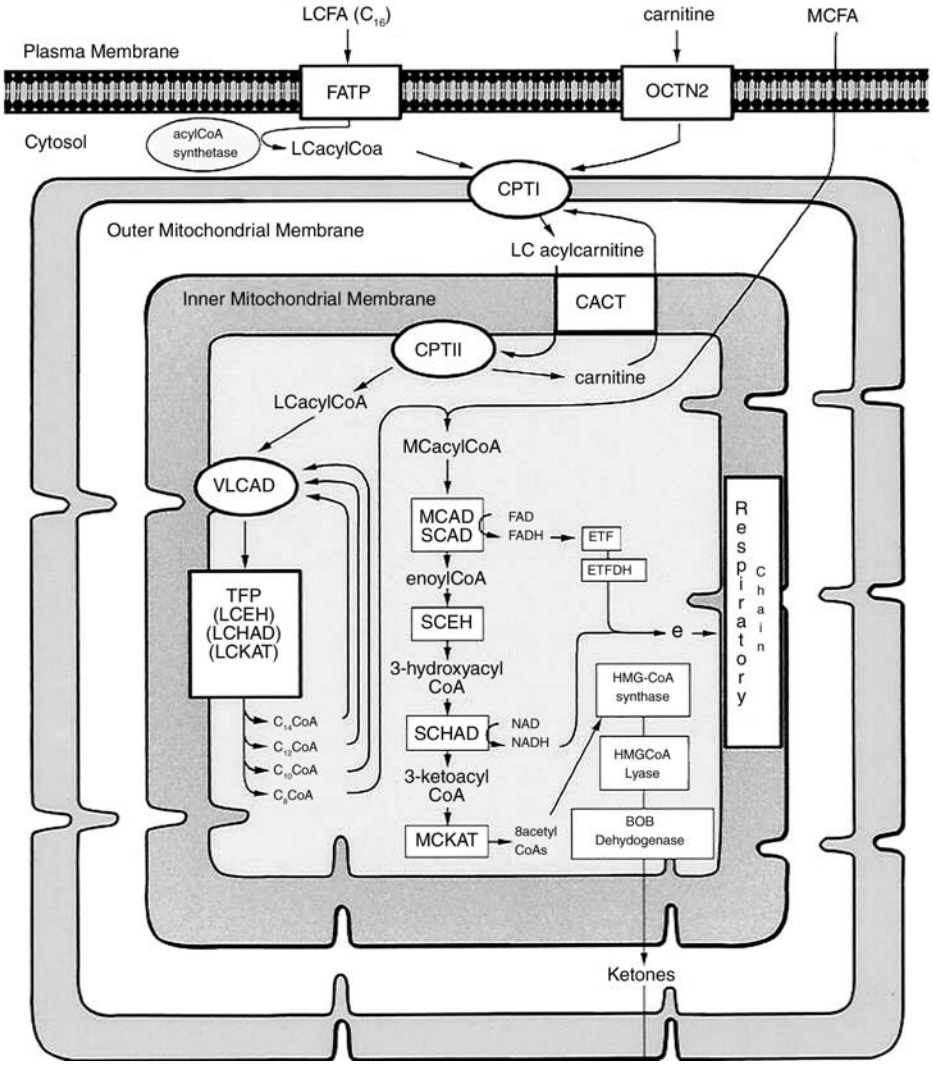

FIGURE 35-3 Pathway of hepatic mitochondrial fatty acid oxidation and ketogenesis. Shown are the steps for the oxidation of palmitate, a 16-carbon (C_{16}) long-chain fatty acid (LCFA). Note that eight-carbon medium-chain fatty acids enter the mitochondria independent of the carnitine cycle. LCFAs are transported across the plasma membrane by a liver-specific LCFA-transporting polypeptide. Carnitine is supplied by a plasma membrane sodium-dependent carnitine transporter (OCTN2). On the outer mitochondrial membrane, carnitine palmityl transferase I (CPT-I) is a major site of regulation that determines whether LCFAs are directed toward β-oxidation to ketones or to the resynthesis of triglycerides. LCFA-coenzyme A (CoA) in the cytosol must first be transesterified to long-chain acylcarnities by CPT-I and then enter the carnitine cycle to be shuttled across the inner mitochondrial membrane. Once across the membrane, the acylcarnitine is re-esterified to an LCacylCoA and enters the β-oxidation cycle. All of the relevant enzymes for LCacylCoAs are bound to the inner mitochondrial membrane (very-long-chain acyl-CoA dehydrogenase, trifunctional protein). At the completion of the four reactions of the β-oxidation cycle, the LCFA has been shortened by two carbons; one molecule of acetyl CoA has been generated for ketone body synthesis, and electrons have been transported to the respiratory chain via flavin adenine dinucleotide and nicotinamide adenine dinucleotide. As the LCFA is shortened, β-oxidation proceeds via enzymes located in the mitochondrial matrix (medium-chain acyl-CoA dehydrogenase [MCAD], short-chain acyl-CoA dehydrogenase [SCAD], short-chain 3-hydroxyacyl-CoA dehydrogenase [SCHAD], medium-chain ketothiolase). Enzymes and transporters are circled. AcAc = acetoacetate; BOB = β-hydroxybutyrate; ETF = electron transport flavoprotein; ETFDH = electron transport flavoprotein dehydrogenase; HMG = 3-hydroxy-3-methylglutaryl; LCEH = long-chain enoyl-CoA hydratase; LCHAD = long-chain 3-hydroxyacyl-CoA dehydrogenase; LCKAT = long-chain ketothiolase; SCEH = short-chain enoyl-CoA dehydrogenase; SCKAT = short-chain ketothiolase.

neogenic activity and have significantly higher blood lactate, pyruvate, and plasma alanine levels than full-term neonates.[28,29] This pattern is already seen in cord blood and is maintained for the first 24 hours of life despite the institution of feeding at the time hypoglycemia is documented. SGA infants do not respond with stimulated hepatic glucose output to the provision of the gluconeogenic substrate alanine as do their appropriate-for-gestational age (AGA) counterparts.[30] These findings suggest a maturational delay in the function of intrahepatic enzymes of gluconeogenesis.

Cytosolic PEPCK is considered to be the rate-limiting enzyme in the gluconeogenesis, with a substantially reduced activity (0 to 25% of adult activity) in the near-term fetus.[31] The rate of PEPCK synthesis increases rapidly after birth, reaching adult values within 24 to 48 hours. Injections of glucagon and cAMP or insulin deficiency caused by streptozocin administration both cause a

marked induction of messenger RNA for PEPCK,[32] suggesting that it is the fall in the plasma insulin-to-glucagon molar ratio that occurs spontaneously after birth that triggers the induction of liver PEPCK. Neonates also exhibit a relative insensitivity of the islet cells to changes in blood glucose, making them more likely to develop hypoglycemia owing to a lack of adequate glucagon secretion in response to falling blood sugar.

Fatty Acid Oxidation and Ketogenesis

The capacity for long-chain fatty acid oxidation and ketone production is low in the fetal liver and markedly increases during the first 24 hours following birth.[33,34] These changes are accompanied by an increase in the activity of key enzymes and substrates in fatty acid oxidation and ketogenesis including CPT-I, hydroxymethylglutaryl CoA synthase, and intramitochondrial free CoA. The shift in the insulin-to-glucagon molar ratio is probably important here as well because both glucagon and cAMP induce fatty acid oxidation in cultured hepatocytes from near-term animals and decrease lipogenesis and intracellular malonyl CoA concentration, leading to increased activity of CPT-I.

The rapid increase in the capacity for intramitochondrial fatty acid oxidation and ketogenesis is of crucial importance within 6 to 12 hours after birth, when glycogen stores are depleted and gluconeogenesis must sustain glucose homeostasis. When the activities of all gluconeogenic enzymes have reached adult levels in the liver soon after birth, gluconeogenesis is mainly controlled by the supply of gluconeogenic precursors—lactate, amino acids, and glycerol—and by the availability of FFAs. The normal baby has a high body fat content (approximately 16% of body weight) and can mobilize FFAs from the periphery, leading to increased gluconeogenic substrate availability in the form of glycerol. In contrast, the SGA infant has a low body fat content at birth and develops hypoglycemia after a short fast. In spite of hypoglycemia, blood β-hydroxybutyrate and acetoacetate levels in SGA babies remain lower than in normal-weight neonates, suggesting inadequate fatty acid stores or a defect in mobilization or oxidation of fatty acids. A deficiency of protein- and fat-derived gluconeogenic substrates also has been implicated as the main factor in the pathogenesis of hypoglycemia associated with severe diarrhea in children.[35]

Table 35-3 Features That Compromise Normal Adaptation to Fasting in the Newborn Period and Predispose to Hypoglycemia

↓ Glycogenolysis in response to glucagon
↓ Gluconeogenesis
↑ Epinephrine (birth stress)
↓ PEP-carboxykinase
↓ α-Butyrobetaine hydroxylase
↓ Carnitine
↓ Fat and glycogen stores (especially in SGA infants)
↑ Brain to body mass ratio
↓ Muscle mass

PEP = phospho*enol*pyruvate; SGA = small for gestational age.

The importance of fatty acid oxidation to the maintenance of the gluconeogenic pathway is further illustrated by experiments in fasting animals and human neonates in whom medium-chain triglyceride (MCT) feeding is associated with an increase in glucose production and the conversion of labeled lactate to glucose.[36,37] Also, inhibitors of long-chain fatty acid oxidation administered to suckling neonatal rats cause an 80% reduction in gluconeogenesis and induce a dramatic fall in blood glucose levels. The administration of MCT to these animals (thereby providing substrate that can bypass the block in long chain fatty acid oxidation) restores a normal blood glucose and a normal rate of gluconeogenesis. In addition to generating substrates and cofactors for gluconeogenesis, enhanced fatty acid oxidation and ketogenesis lead to inhibition of pyruvate oxidation in the peripheral tissues and increased release of recyclable substrates for gluconeogenesis into the blood, namely lactate, pyruvate, and alanine.

Carnitine may be an essential nutrient during the neonatal period owing to a substantially decreased activity of the key enzyme in the synthetic pathway, γ-butyrobetaine hydroxylase.[38] Without an exogenous source of carnitine, such as breast milk or carnitine-supplemented infant formula, neonates who are maintained on carnitine-free total parenteral nutrition develop low plasma and tissue carnitine levels.[39,40] Excessive urinary loss of free carnitine may also contribute to low plasma carnitine levels in premature, stressed, and sick neonates.[41] Exogenous carnitine appears to stimulate fatty acid oxidation and ketogenesis in neonates who are receiving infusions of triglycerides.[42] In some neonates, plasma and tissue levels of carnitine may be reduced sufficiently to inhibit the entry of long-chain fatty acids into mitochondria, thus compromising fatty acid oxidation.

Glucose Use and Brain-to-Body Mass Ratio

Whether expressed on the basis of weight or body surface area, the rate of glucose flux (production and use) is nearly three times higher in infants than in adults, both in the postabsorptive period (4 to 14 hours after eating) and following a more prolonged 30- to 40-hour fast.[43] However, when the data are expressed on the basis of estimated brain weight, the glucose flux is similar in children and adults. The brain of the adult takes up approximately 100 g of glucose per 24 hours. This quantity is disproportionately large because the mass of the adult brain is only 2% of the total body mass, yet it consumes approximately one-fifth of the total calories. The child's brain is larger in relation to body size and must use an even greater proportion of the total calories, predominantly in the form of glucose. This observation supports the hypothesis that the relatively high proportion of brain mass to body size (13% in the newborn versus 2% in the adult) places infants and children at higher risk of hypoglycemia.[44] The ratio of brain to body mass is greatest in premature infants who have an increased glucose flux compared with term infants.[45]

Decreased muscle mass and the subsequent reduction in the provision of substrate for both de novo gluconeogenesis and recycling of three-carbon fragments into glu-

cose are also likely to contribute to the greater susceptibility of the infant and young child to hypoglycemia after glycogen stores are depleted and gluconeogenesis becomes the primary source of endogenous plasma glucose. Several studies have demonstrated an age-related increase in the fasting value of blood glucose and alanine in children and a decrease in fasting blood ketone and FFA levels with increasing age, which is independent of glucose concentrations.[23,46] Comparative studies in normal men, women, and children have determined that after a 30-hour fast, children have the lowest glucose and alanine and the highest β-hydroxybutyrate concentrations.[24] When fasted for 36 hours, children aged 2 to 8 years have lower plasma glucose levels, lower alanine, higher FFAs, and higher β-hydroxybutyrate than older children aged 10 to 18 years whose fasting metabolic profile mimics that of adults.[47] In infants aged 1 to 2 years, the rate and magnitude of substrate changes associated with fasting are even greater.[48] Thus, a combination of more rapid depletion of glycogen stores and decreased availability of substrates for gluconeogenesis results in earlier mobilization of fat in infants and younger children. Their dependency on fatty acid oxidation and ketogenesis during a fast, to maintain glucose homeostasis, is greater and occurs earlier than in older children and adults.[49]

INBORN ERRORS OF METABOLISM LEADING TO FASTING MALADAPTATION

The biochemical hallmark of inborn errors in metabolism that lead to fasting maladaptation is hypoglycemia. Most clinicians define hypoglycemia as a plasma glucose concentration of less than 40 mg/dL (< 2.2 mmol) in infancy (5 days to 1 month) and less than 50 mg/dL (2.8 mmol) in older infants and children.[50] In premature infants, 30 mg/dL is the lower limit of normal. It is important to remember, however, that some normal infants can have low plasma glucose levels and be asymptomatic, and certain infants with inborn errors of metabolism, particularly fatty acid oxidation defects, may manifest symptoms of vomiting, lethargy, or even coma before their blood sugar falls below these levels.[51] The occurrence of hypoglycemia in relation to the duration of the fasting period can give the physician a clue to the metabolic derangement present. The age of the patient will influence the duration of these periods. In infants and younger children, the duration of these periods will be compressed. This classification of inherited metabolic defects leading to fasting maladaptation is not meant to be rigid, and there are numerous patients who will be exceptions to these rules. However, this type of categorization should reinforce in the reader's mind the previous discussion of the sequential steps in the normal adaptation to fasting (Table 35-4).

Hypoglycemia within 0 to 8 Hours of Fasting

Hyperinsulinemia (Increased Glucose Use) Conditions characterized by endogenous insulin excess are probably the most common cause of persistent hypoglycemia in infants, especially in the first year of life. Congenital hyperinsulinism is the predominant cause of persistent hypoglycemia in the neonatal age group, occurring in 1 in 30,000 to 50,000 live births in the general population.[52] Consanguinity increases the incidence to roughly 1 in 2,500. Three subgroups exist based on age of diagnosis. The neonatal form (diagnosed within the first 3 days of life) accounts for 60% of congenital hyperinsulinism, the infantile form for 35% (diagnosed within the first year of life), and the childhood form for 5% (diagnosed after 1 year of age). Other "hyperinsulinemic" states include Beckwith-Wiedemann syndrome, infants of diabetic mothers, infants with erythroblastosis fetalis, and asphyxiated infants.[53] These latter forms are considered transient in nature.

Often these infants are large for gestational age, which suggests that the insulin excess began in utero. An increase in hepatic glycogen synthesis accompanying hyperinsulinism may lead to mild hepatic enlargement; however, hepatomegaly is much less conspicuous than in infants with metabolic defects affecting glycogenolysis, gluconeogenesis, or fatty acid oxidation. Younger patients can present with such nonspecific signs and symptoms as hypotonia, cyanosis, poor feeding, irritability, or hypothermia. Unfortunately, most symptoms are not initially recognized as evidence of hypoglycemia.[10] In addition, 20% will be asymptomatic.[8] The childhood form can present with more specific autonomic symptoms such as perspiration, anxiety, weakness, and reports of palpitations. On the other hand, there are several common features for most patients with hyperinsulinism, including macrosomia at birth and a high risk of hypoglycemic seizure as the presenting event (50% of patients across subtypes).[10] Interestingly, some patients with the childhood form of hyperinsulinism may tolerate hypoglycemia, perhaps owing to decreased central nervous system glucose requirements,[54] and require only increased calories initially for stabilization of blood sugars. These children also respond favorably to medication, principally owing to genetic mutations not affecting the normal expression of critical receptors (SUR1) in this age group.[11] Conversely, neonatal disease is much more difficult to manage.

Excessive insulin promotes increased glucose use, resulting in removal of glucose from the blood. Lipolysis and fatty acid oxidation are inhibited, thus decreasing the availability of FFAs and ketones as alternate fuels. Because of the constant presence of excessive endogenous insulin and resulting inhibition of gluconeogenesis, lipolysis, and ketogenesis, the hypoglycemia that accompanies insulin excess occurs early in the fasting period, is profound, and often requires high rates of glucose infusion for correction.[55] Most patients require a glucose infusion rate greater than the 8 mg/kg/minute generally accepted as the normal newborn requirement to maintain a plasma glucose concentration > 2.6 mmol during fasting, and some even exceed 10 mg/kg/minute, which is considered the maximum amount of glucose needed to maintain an adequate blood glucose concentration in a premature infant or stressed SGA infant.[56] In one study of 12 patients with hyperinsulinemia, the mean glucose requirement was 14.5 mg/kg/minute and the range was 7.1 to 28 mg/kg/minute.[50]

Table 35-4 Inborn Errors of Metabolism Leading to Fasting Maladaptation and Hypoglycemia

Within 0–6 hours of fasting
Hyperinsulinemia: nesidioblastosis, insulinoma

GSD-I; glucose-6-phosphatase deficiency
(↓ glycogenolysis, ↓gluconeogenesis)
6–12 hours postfasting
GSD-III; debrancher enzyme deficiency
(↓ glycogenolysis)
12–18 hours postfasting
Fructose-1,6-diphosphatase deficiency
(↓ gluconeogenesis)
With prolonged fasting
Fatty acid oxidation disorders
(↓ ketogenesis, ↑glucose utilization)
Ketolysis defects
(↓ peripheral utilization of ketones)

GSD = glycogen storage disease.

Most patients with hyperinsulinemia develop hypoglycemia less than 8 hours after beginning a fast. In one study, 11 patients became hypoglycemic in a mean interval of 2.1 hours, and in another, the mean time of fasting to hypoglycemia was 6.4 hours.[50,57] This contrasts to a mean time of 24.7 hours in children with ketotic hypoglycemia. The diagnosis of hyperinsulinism in both infants and children is made by an inappropriately elevated serum insulin concentration during a period of hypoglycemia (blood glucose < 45 mg/dL). The excessive insulin secretion usually reduces the glucose-to-insulin ratio in the blood to < 4.0. This relative ratio may be used to establish the diagnosis of hyperinsulinism even in the absence of an absolute elevation of serum insulin concentration. A plasma insulin concentration > 10 U/mL with a simultaneous glucose concentration of < 50 mg/dL (2.8 mM) at any time has been accepted as diagnostic of hyperinsulinemia by some authors.[58]

At the time of hypoglycemia, it is imperative to obtain several critical laboratory studies (Table 35-5). Diagnostic clues to hyperinsulinism during a hypoglycemic episode include suppressed ketone formation and low levels of FFAs and IGF binding protein I. However, children under the age of 3 months may lack the apparatus to generate ketones, underlining the importance of serum insulin levels in these children.

Paradoxically, decreased concentrations of ketones and FFAs are often found at the time of hypoglycemia. Thus, patients with hyperinsulinemia present with hypoketotic or nonketotic hypoglycemia. Plasma levels of β-hydroxybutyrate at the time of hypoglycemia may be the best indicator of hyperinsulinemia. In a study by Stanley and Baker, fasted normal control infants and children with ketotic hypoglycemia who developed a plasma glucose < 40 mg/dL had an expected mean level of β-hydroxybutyrate of 2.9 mM with a lower limit (mean 2 SD) of 1.1 mM.[55] However, 10 of the 11 determinations of β-hydroxybutyrate in patients with hyperinsulinemia and plasma glucose < 40 mg/dL were more than 2 SD below the expected level of 2.9 mM. Concentrations of FFAs at the time of hypoglycemia are also a good discriminator of hyperinsulinemia, with a level below 0.46 mM separating these patients from normal infants or children with ketotic hypoglycemia. Cortisol and GH levels are usually elevated; thyroid hormone levels are normal.

Owing to excessive glycogen stores in patients with hyperinsulinemia, the administration of glucagon (1 mg intramuscularly) stimulates hepatic glycogenolysis and results in a marked increase in serum glucose values, exceeding increments of 30 mg/dL.[50] This test differentiates patients with hyperinsulinemia from those with disorders of glycogen synthesis and breakdown, with the exception of glycogen synthase deficiency. This finding is also contrary to what is seen in patients with most other metabolic causes of hypoketotic hypoglycemia, such as fatty acid oxidation disorders. In these patients, the hypoglycemia occurs later in the fasting period when glycogen stores are already exhausted, and there is a blunted or absent glucose response to parenteral glucagon.

Recently, several groups have published data concerning the histologic heterogeneity of congenital hyperinsulism. Histologically, the neonatal and infantile groups are composed of two categories based on the morphology of the affected beta cells. These are the focal adenomatous and the diffuse forms.[10] Focal areas of beta cell hyperplasia, responsible for 25 to 50% of cases, are associated with large islet cell clusters around connective tissue, whereas diffuse disease appears as islets with prominent, enlarged beta cell nuclei.[8] However, the childhood form is predominantly caused by focal adenomas (insulinomas). Most insulinomas are sporadically inherited, whereas some are associated with multiple endocrine neoplasia syndrome. Rarely, children have true islet cell adenomas of the pancreas.[59] When the diagnosis of an islet cell adenoma is made in a child, a search for hyperparathyroidism, hypergastrinemia, and pituitary tumors must be undertaken to exclude multiple endocrine neoplasia syndrome, type I.

Sustained hyperinsulinemia in infants is usually the result of nesidioblastosis, which is defined by diffusely increased numbers of beta islet cells in the pancreas. These cells appear to arise by budding from the exocrine pancreatic ducts and resemble the histologic pattern of early fetal pancreas. The histologic subtypes common to both neonatal and infantile disease are associated with specific genetic mutations of beta cell receptors, which have implications for the patient's ability to respond to current therapy. Most

Give glucagon (usually 0.5 mg intramuscularly) after serum samples are obtained and measure serum glucose response every 10 minutes over the next half hour.

mutations discovered to date are found in the neonatal-onset form of hyperinsulinism. Focal lesions are linked to the loss of the maternal 11p15 allele and an alteration in homozygosity of either paternally derived K^+_{ATP} channel subunits, the SUR1 or the inward-rectifying potassium channel KIR6.2.[10] Unfortunately, most patients respond poorly to medical treatment because diazoxide targets the SUR1 receptor. This precludes its use in children with mutations of this receptor and of receptors associated with it (KIR6.2). Diffuse beta cell hyperplasia results from either a mutation in the SUR1 or the *KIR6.2* gene.[10] Dominantly inherited patterns of diffuse hyperinsulinism may likewise have mutations of the glucokinase (GCK) or the glutamate dehydrogenase (GDH) gene.[9] Overactivity of these genes causes an increase in the ATP-to-ADP ratio and subsequent insulin release. In GDH mutations, hyperammonemia is a concurrent finding that rarely causes symptoms or requires therapy.[6] The accumulation of serum ammonium is attributable to decreased levels of *N*-acetylglutamate, an enzyme critical for ammonium catabolism.[9] Lesions owing to GDH or GCK mutations typically present later and respond well to medical therapy.

Transient hypoglycemia associated with hyperinsulinism has been documented in children with Beckwith-Wiedemann syndrome, infants of diabetic mothers, infants with erythroblastosis fetalis, and infants subjected to perinatal asphyxia.[53] Beckwith-Wiedemann syndrome is characterized by macroglossia, macrosomia, omphalocele, and a prominent earlobe fissure.[60] Hypoglycemia typically resolves within the first few months of life but is difficult to control and frequently requires medical intervention. Beta cell hyperplasia has been noted at autopsy. The cause of transient hyperinsulinism in children born to mothers with diabetes has been well defined. These infants are subjected to high serum glucose concentrations in utero, which is amplified during poor diabetes control. This increased serum glucose stimulates pancreatic insulin secretion and beta cell hyperplasia.[61,62] Consequently, the fetus stores large amounts of protein, fat, and glycogen, resulting in the typical phenotype of a large, plethoric infant. In mothers who are able to establish tight metabolic control (mean glucose concentration of 86 mg/dL), the opposite is true: 20% of resulting newborns are SGA. Hypoglycemia in infants of diabetic mothers is the result of postnatal dysregulated insulin secretion and suppressed glucagon release. This classic hormonal profile inhibits the breakdown of stored glucose during periods of fasting (immediate postnatal period). Therefore, these infants may require large amounts of intravenous glucose to stabilize blood sugar, which may normalize within several days. It is, however, not unusual for infants to depend on supplemental glucose for long periods. Hyperplasia of pancreatic islet cells also occurs in infants with erythroblastosis fetalis, which is a hemolytic process in the newborn resulting from the transplacental passage of maternal antibodies to the baby's red blood cells.[63] The cause is uncertain but may be linked to elevated levels of reduced glutathione resulting from hemolysis, which may stimulate insulin release.[64] Infants born SGA and asphyxiated infants are of particular concern during the first few weeks of life. The etiology of the hypersecretion of insulin is unknown; however, these patients may require diazoxide as well as large amounts of glucose to maintain euglycemia (20 mg/kg/minute or more). Although transient in nature, these infants are at increased risk for neurodevelopmental delays from hypoglycemia, as well as their underlying disease.

Glycogen Storage Disease (Impaired Production of Glucose from Glycogen) As opposed to the increased glucose use seen in patients with hypoglycemia owing to hyperinsulinemia, a second major category of conditions causing hypoglycemia is characterized by a deficiency of glucose production during fasting (see Table 35-4). Deficiencies of glycogen synthesis or glycogen degradation can lead to hypoglycemia relatively early during the fasting period. Severe hypoglycemia may be observed in newborns with glycogen synthetase deficiency (type 0 GSD).[65] Other patients have presented later, after nighttime feedings were stopped, with hypoglycemia but without hepatomegaly.[66] Hypoglycemia appears 6 to 10 hours after meals and is accompanied by markedly elevated plasma ketones. The liver biopsy may show little besides a relatively low glycogen content. In contrast, hypoglycemia in response to fasting is distinctly uncommon in another disorder affecting glycogen synthesis, brancher enzyme deficiency (type IV, Andersen's disease, amylopectinosis).[67] Most of these patients present late in the first year or in the second year of life with hepatosplenomegaly, abdominal distention, and failure to thrive. Later, progressive liver dysfunction and cirrhosis dominate the clinical picture. This enzyme defect causes the formation of glycogen with long outer branches that resemble amylopectin, a form of plant starch. The abnormally structured glycogen may act as a foreign body, stimulating a chronic inflammatory reaction in the liver.

The onset of fasting-induced hypoglycemia occurs more slowly (4 to 12 hours into a fast) in some patients with debrancher enzyme deficiency (type III GSD, Cori disease, limit dextrinosis). This is probably owing to the fact that this defect is rarely complete and hepatic gluconeogenesis remains intact. Debrancher enzyme deficiency results in an inability to degrade the 1,6-glucosyl linkages, which form the branch points in glycogen, and in the presence of glycogen with short outer chains.[68] Growth failure and hepatomegaly are prominent early in life.[69] Hepatic fibrosis may lead to the development of splenomegaly in some children by the time they are 4 to 6 years of age. Cardiomyopathy and muscle weakness frequently develop during the second and third decades of life. Moderate elevations in serum triglycerides are common, and liver transaminases are often increased to 200 to 400 U/L. Early on, the liver biopsy may show increased glycogen and fat and varying degrees of fibrosis. Several clinical findings are helpful in diagnosing debrancher deficiency and distinguishing it from the more common glucose-6-phosphatase deficiency (type I GSD [see below]). The rise in plasma glucose following administration of glucagon is usually normal 2 to 3 hours after a meal, when the terminal branches of glycogen are still full of available 1,4-glucosyl linkages. However, 6 to 12 hours

after a meal, there is no response to glucagon because glycogen has already been degraded to its 1,6-glycosyl linkage branch points. Blood lactate levels are normal or low during fasting because there is no defect in gluconeogenesis. Plasma lactate increases abnormally to 4 to 6 mEq/L following an oral glucose load, perhaps owing to an abundance of glycogen stores and disposal of glucose via glycolysis to pyruvate and lactate. Phosphorylase deficiency (type VI GSD) resembles a mild form of debrancher deficiency, with fewer problems with hypoglycemia and growth failure and without the late development of cirrhosis and myopathy.

Deficiency of glucose-6-phosphatase (type Ia GSD) is the most common of the GSDs and is associated with profound hypoglycemia, growth failure, and massive hepatomegaly.[70] Liver biopsy shows markedly increased fat and glycogen, with glycogen levels of 6 to 10 g per 100 g of tissue. A less common form of this disorder is attributable to a defect in the microsomal transport of glucose-6-phosphate (type Ib GSD) and is associated with impaired neutrophil function, neutropenia, recurrent infections, and occasionally inflammatory bowel disease.[71] Because this enzymatic defect is not truly in the glycogenolysis pathway but in the hydrolysis of glucose-6-phosphatase to glucose, this disorder is usually considered with other disorders of gluconeogenesis. Hydrolysis of glucose-6-phosphate is the final common enzymatic event in the hepatic release of glucose from both the gluconeogenic and glycogenolytic pathways. Therefore, deficiency of glucose-6-phosphatase typically results in severe hypoglycemia occurring 3 to 6 hours after a meal and is associated with ketosis and lactic acidosis in early infancy. The mechanism for glycogen accumulation in this disorder is not clear because insulin concentrations are low, glucagon concentrations are elevated, and the in vitro activities of the enzymes responsible for glycogenolysis are normal. Recent studies suggest that accumulating glucose-6-phosphate itself may activate glycogen synthesis and inhibit glycogen degradation via inhibition of the phosphorylase enzyme.[72]

Other metabolic abnormalities encountered in patients with GSD type I are understandable as consequences of a block in gluconeogenesis. Chronic hypoglycemia not only provokes increased secretion of various insulin counterregulatory hormones (catecholamine, glucagon, and cortisol), it also suppresses insulin secretion, resulting in increased glycogenolysis, lipolysis, and muscle catabolism. The lactate generated from increased anaerobic glycolytic processes in muscle and from red blood cell metabolism would normally be removed and reconverted to glucose via the hepatic gluconeogenic pathway. This avenue is blocked, resulting in levels of blood lactate generally 4 to 8 times normal. High levels of lactate can serve as an alternative fuel for the brain, and this is thought to be the explanation for the lack of seizures or other central nervous system manifestations of hypoglycemia in some patients with this disorder. In contrast to type III GSD (debrancher enzyme deficiency [see above]), the administration of intramuscular glucagon does not result in any significant rise in blood glucose but does result in a dramatic increase in blood lactate levels. Ketosis is associated with exaggerated lipolysis and low basal insulin levels. However, the degree of ketonemia observed in these patients is less than that observed in children fasted for 24 to 30 hours, suggesting a defect in ketogenesis.[73] Excessive lipolysis and a relative impairment in ketogenesis may account for the hypertriglyceridemia that is characteristic of this disorder. Hypophosphatemia and hyperuricemia are also common in older patients and result from the sequestration of intracellular phosphate as glucose-6-phosphate and the subsequent reduction in intracellular ATP levels. The decrease in intracellular phosphate levels results in the deinhibition of AMP deaminase and the overproduction of uric acid from AMP.

Hypoglycemia within 8 to 16 Hours of Fasting

Defects in Gluconeogenesis: Impaired Conversion of Gluconeogenic Precursors into Glucose In disorders of gluconeogenesis, fasting hypoglycemia is generally more pronounced the closer the enzyme defect is located to the final common pathway for glucose release via glucose-6-phosphate (see Figure 35-2). Thus, in pyruvate carboxylase deficiency, a disorder of intramitochondrial pyruvate oxidation to oxaloacetate, hypoglycemia is not an obligatory symptom; however, in glucose-6-phosphatase deficiency (GSD type Ia), it is invariably a severe component of the disease. All of these disorders are characterized by elevated plasma levels of substrates at the origin of gluconeogenesis such as lactate, pyruvate, and alanine. In some of these disorders (pyruvate carboxylase deficiency and PEPCK deficiency), the urea cycle may be secondarily compromised, resulting in an increase in plasma levels of ammonia, citrulline, and lysine.

Hepatic fructose-1,6-diphosphatase deficiency results in a defect in the conversion of fructose-1,6-diphosphate to fructose-6-phosphate, which is then converted to glucose-6-phosphate. Patients with this rare enzyme defect usually present during the first year with life-threatening episodes of hypoglycemia provoked by fasting or catabolic stress (eg, infections, burns) and other signs, symptoms, and laboratory findings similar to those of GSD type I. However, in contrast to GSD type I, the timing of the hypoglycemia after 12 to 16 hours of fasting is later, and excessive hepatic glycogen accumulation does not occur because the glycogenolytic pathway is intact. The mild to moderate hepatomegaly is secondary to hepatic steatosis, and liver enzymes are either normal or only mildly disturbed. Between crises of hypoglycemia and metabolic acidosis, the most frequent findings are hyperventilation, mild lactic acidosis, and muscle weakness.

Because glycogenolysis is intact, glucagon administration produces a hyperglycemic response in the immediate postprandial period.[74] Glucose, galactose (lactose), and maltose can be metabolized normally and stored as glycogen. Because fructose (sucrose), glycerol, and alanine enter the gluconeogenic pathway below the level of the defective

enzyme, these substances cannot be converted to glucose. The ingestion of these precursors will result in the accumulation of lactate and may actually precipitate a fall in plasma glucose concentration. However, unlike the more common defect in fructose metabolism, hereditary fructose intolerance (fructose-1-phosphate aldolase deficiency), crises of hypoglycemia, lethargy, coma, acidosis, hypophosphatemia, and hyperuricemia are not solely dependent on the ingestion of fructose.

Two other enzymes are responsible for the recycling of pyruvate and other three-carbon precursors (lactate, alanine) into the gluconeogenic pathway (see Figure 35-2). The mitochondrial biotin-dependent enzyme pyruvate carboxylase catalyzes the conversion of pyruvate to oxaloacetate, which is then converted to malate and shuttled out of the mitochondria to be reconverted back to oxaloacetate. PEPCK then catalyzes the metabolism of oxaloacetate to PEP. Hypoglycemia is an inconsistent finding in patients with pyruvate carboxylase deficiency in whom congenital lactic acidosis, progressive neurologic deterioration, and elevated levels of pyruvate, alanine, and ketones are almost invariably observed. The presentation is more or less severe, depending on whether some enzyme protein is present or there is a complete lack of messenger RNA for pyruvate carboxylase and no residual activity of the enzyme.[75] PEPCK deficiency has only been reported in a few patients and is characterized by hypoketotic hypoglycemia, hypotonia, lactic acidosis, hepatomegaly, and hepatic and muscle steatosis in the first few months of life. Both cytosolic and mitochondrial forms of this enzyme defect have been described.[76]

Hormone Deficiences

Hypoglycemia is also caused by isolated compensatory hormone deficiencies. The presentation of children with panhypopituitarism may be subtle. However, there can be evidence of anatomic abnormalities including midline defects, which provide valuable clues to the diagnosis. Midline defects include structural central nervous system abnormalities (absent corpus collosum, ectopic pituitary), microphallus, cleft palate, and central incisor. One of the most common causes of congenital panhypopituitarism is septo-optic dysplasia, which presents in early childhood with nystagmus (optic nerve hypoplasia), seizures, and developmental delay. These children can develop progressive pituitary dysfunction and may present with hypoglycemia owing to a lack of ACTH and GH. The signs and symptoms of hypoglycemia are similar to those found in children with hyperinsulinism. With this in mind, these children may be ketotic and usually have suppressed serum insulin levels at the time of hypoglycemia. In addition, there is a lack of response to glucagon. Therapy is tailored to provide the missing hormone(s).

Persistent hypoglycemia is a relatively common sign of isolated deficiencies in GH or cortisol, occurring in 11 to 27% of affected newborns. The pathogenesis of hypoglycemia in these children is the inability to stimulate gluconeogenesis (cortisol), a lack of substrate mobilization (cortisol and GH), and increased insulin sensitivity. The most common cause of isolated GH deficiency is the idiopathic form. However, each child should be carefully screened for other hormonal deficiencies and should undergo radiologic studies to ensure an intact hypothalamic-pituitary unit and a lack of mass lesion. One cause of cortisol deficiency in infants is a family of enzymatic defects known as congenital adrenal hyperplasia (CAH). The most common form of CAH is the classic 21-hydroxylase deficiency, which results in electrolyte disturbances (hyponatremia and hyperkalemia), genital ambiguity in female infants, and hypotension. However, hypoglycemia is not the typical presenting sign. Other causes of hypocortisolemia include adrenal hypoplasia, Addison's disease (usually acquired in older children), and ACTH receptor defects. Again, therapy consists of supplementing with the deficient hormone.

Hypoglycemia Occurring with Prolonged Fasting

Fatty Acid Oxidation Disorders There are now at least 24 inherited disorders in this growing family of recently described metabolic defects in the transport and intramitochondrial oxidation of fatty acids. There are three main reasons why these disorders have escaped recognition until recently. First, fatty acid oxidation does not play a major role in energy production until late in fasting, and afflicted individuals may remain asymptomatic until fasting continues long beyond the usual overnight period of 12 hours. Second, the important clue of a paucity of urinary and plasma ketones at the time of hypoglycemia may be overlooked. Third, methods of detecting abnormal fatty acid metabolites in the urine or plasma have only been routinely available for the last decade.

In general, the disorders that affect the most proximal steps in long-chain fatty acid oxidation will result in more profound reductions in ketogenesis, more severe hypoglycemia, and a more precipitous presentation after a shorter period of fasting. Thus, defects affecting the transport of long-chain fatty acids across the mitochondrial membrane (ie, carnitine palmityl transferase deficiency, carnitine transport deficiency) and those affecting the oxidation of long-chain fatty acids (ie, very-long-chain acyl-CoA dehydrogenase deficiency and long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency) are most likely to present in the first year of life with potentially life-threatening episodes of hypoketotic, hypoglycemic coma. Patients with defects that allow several turns of the β-oxidation cycle of long-chain fatty acids before encountering the enzymatic block will generate some acetyl CoA, ketones, and ATP from intramitochondrial fatty acid oxidation. Patients with these disorders (ie, medium-chain acyl-CoA dehydrogenase deficiency, short-chain acyl-CoA dehydrogenase deficiency) are likely to tolerate longer periods of fasting and may present later with hypoketotic hypoglycemia, hypotonia, rhabdomyolysis, and failure to thrive.

The hypoglycemia characteristic of these disorders can be explained by two major mechanisms: (1) an increase in

peripheral glucose use owing to the deficient production of ketones, normally the preferred fuel for myocardium and skeletal muscle during prolonged fasting, and (2) the limitation of acetyl-CoA synthesis, which is ordinarily a stimulator of the important gluconeogenic enzyme pyruvate carboxylase. Defective energy production in the skeletal muscle and heart owing to the inability to metabolize long-chain fatty acids leads to fatty deposition, cardiomyopathy, muscle weakness, and rhabdomyolysis, especially during periods of prolonged fasting or catabolic stress brought on by infection, vomiting, dehydration, or other factors. The inability to oxidize fatty acids in the liver results in their diversion into triacylglycerol synthesis and marked hepatic steatosis.

The accumulation of toxic metabolites may be responsible for some of the other metabolic findings in these disorders. Because free CoA does not exchange between the intramitochondrial and cytosolic compartments, blocked fatty acid oxidation leads to intramitochondrial accumulation of acyl-CoA intermediates at the expense of the production of acetyl CoA and the maintenance of the free CoA pool. Hyperammonemia has been attributed to the direct inhibition of key intramitochondrial urea cycle enzymes by accumulating short- and medium-chain acyl-CoA compounds.[77,78] Low intramitochondrial acetyl-CoA levels could also contribute to the hyperammonemia through an inhibition of the production of *N*-acetylglutamate, the allosteric activator of carbamyl-phosphate synthetase, which is the first enzyme in the urea cycle. In an effort to meet the increased demands for gluconeogenesis during episodes of fasting stress and illness, there is accelerated proteolysis and tissue catabolism, which also is likely to contribute to the elevated ammonia, urea, and uric acid characteristically found in these patients.

Alterations in mental status may precede hypoglycemia in some patients with defects in fatty acid oxidation. Accumulating medium- and long-chain fatty acids and dicarboxylic acids are metabolic toxins and have been shown to precipitate mitochondrial damage, uncouple oxidative phosphorylation, cause electroencephalographic changes, and result in increased intracranial pressure in animal models.[79] Long-chain acylcarnitines, another metabolic by-product of inhibited long-chain fatty acid oxidation, have been shown to precipitate myocardial dysfunction, arrhythmias, and cardiac arrest in animals.[80–82] Cardiomyopathy can be a prominent feature in patients with CPT-II deficiency, carnitine transport deficiency, long-chain acyl-CoA dehydrogenase deficiency, and long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency.

Although originally characterized as having nonketotic hypoglycemia, most patients with disorders of the fatty acid oxidation continue to produce some ketones even at the time of severe metabolic decompensation. In patients with defects in medium- or short-chain fatty acid oxidation, ketones can be generated from partial β-oxidation of long-chain acyl CoAs to medium-chain intermediates and by continued oxidation of branched-chain amino acids. Even in patients deficient in enzymes of long-chain fatty acid transport or oxidation, peroxisomal oxidation may generate medium-chain intermediates, which can then enter the mitochondria below the block and be further oxidized to ketones.

What is important is that the degree of ketogenesis is inadequate for the degree of fasting, hypoglycemia, and circulating FFAs (Figure 35-4). This dissociation between high plasma levels of FFAs and low plasma levels of ketone bodies can be used as a screening method for diagnosing patients with disorders of fatty acid oxidation or transport. In normal infants, ages 1 to 12 months, the FFA-to-ketone body ratio ranges from 0.3 to 0.7 after a 24-hour fast.[84] When normal children are fasting and blood glucose is less than 3.0 mM (56 mg/dL), plasma ketones are always greater than 1.8 mM. In contrast, in patients with defective fatty acid oxidation, plasma ketones rarely exceed 1.0 mM during fasting, and the ratio of FFA to ketones in the blood always exceeds 1.0 and is often greater than 2.0 when the patient is hypoglycemic. Thus, determination of simultaneous plasma concentrations of glucose, ketones, and FFAs at the time of an acute metabolic decompensation before resuscitation with intravenous glucose can be helpful in making a diagnosis.

Defects in Ketogenesis and Ketolysis Oxidation of fatty acids yields acetyl CoA, the building block for the synthesis of ketones. After condensation of two molecules of acetyl CoA to form acetoacetyl CoA, deacylation is achieved by incorporation of a third acetyl-CoA molecule to form 3-hydroxy-3-methylglutaryl CoA. Cleavage of this molecule by the enzyme hydroxymethylglutaryl-CoA lyase (HMG-CoA lyase) liberates acetoacetate. HMG-CoA lyase also catalyzes the terminal step of the catabolism of leucine to acetyl CoA and acetoacetate. HMG-CoA lyase deficiency has been identified in patients who usually present in the first or second year of life with severe, sometimes fatal, episodes of hypoketotic hypoglycemia, coma, hyperammonemia, elevated aminotransferases, coagulopathy, and marked hepatic steatosis mimicking Reye's syndrome.[85,86] They also manifest severe acidosis from the accumulated intermediates of leucine catabolism (3-hydroxy-3-methylglutaric, 3-methylglutaconic, 3-hydroxyisovaleric, 3-methylglutaric acids). Administration of 3-hydroxybutyrate to a fasting subject with HMG-CoA lyase deficiency resulted in the maintenance of plasma glucose levels. This supports the hypothesis that the hypoglycemia seen in these patients during fasting and catabolic stress is a direct result of the lack of ketone body synthesis.

A functional impairment in the peripheral use of ketones would be expected to mimic a deficiency of ketones and result in increased glucose use during fasting. A few patients have been described with a deficiency of the mitochondrial enzyme acetoacetyl-CoA thiolase (β-ketothiolase), which is responsible for cleavage of acetoacetyl CoA to form acetyl CoA in extrahepatic tissues.[87–89] These patients present in the first or second year of life with episodes of fasting or stress-induced hypoglycemia, often precipitated by a febrile illness or viral gastroenteritis. They are markedly acidotic and ketotic and may accumulate 2-methylacetoacetate, a

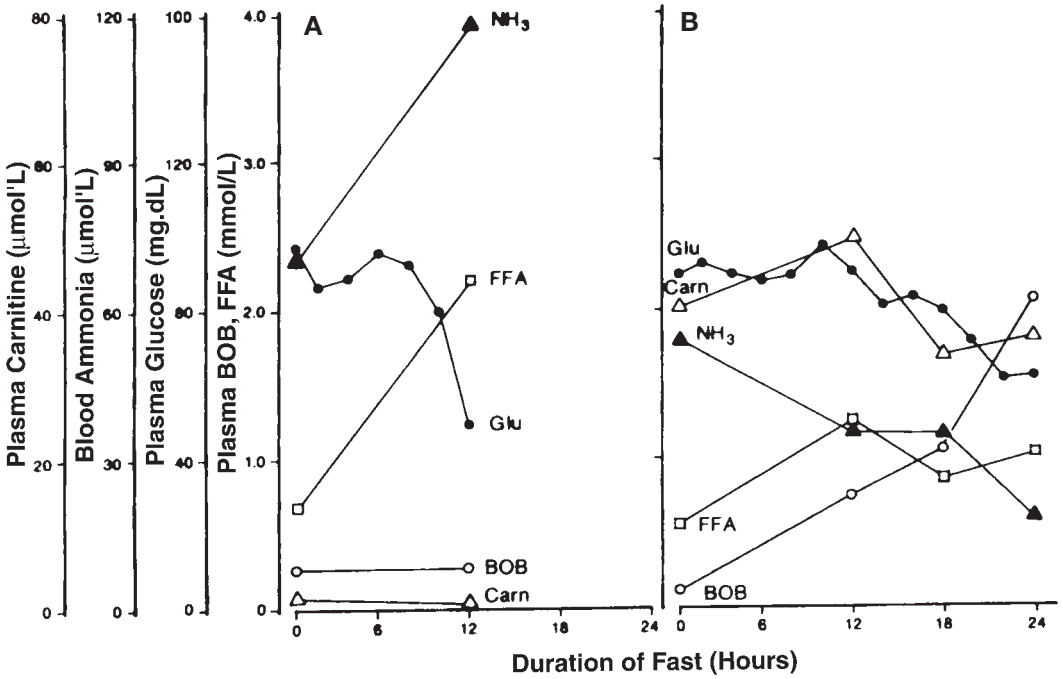

FIGURE 35-4 Metabolic response to fasting in a patient with the carnitine transport defect before (*A*) and after (*B*) long-term oral therapy with L-carnitine. Shown are plasma levels of glucose (Glu), β-hydroxybutyrate (BOB), free fatty acids (FFA), carnitine (carn), and ammonia (NH_3). *A*, The patient's response to fasting before L-carnitine therapy represented clear evidence that hepatic fatty acid oxidation was impaired. Note the falling glucose after a 12-hour fast and the high ratio of FFA to BOB. After L-carnitine therapy (*B*), the defect in ketogenesis was corrected, and a normal capacity for hepatic fatty acid oxidation was restored. Reproduced with permission from Treem WR et al.[83]

metabolite of isoleucine degradation. Several other patients with similar presentations have been reported with a deficiency in succinyl CoA-3-oxoacid CoA transferase activity in extrahepatic tissues. This enzyme is responsible for conversion of acetoacetate to acetoacetyl CoA, which is then cleaved to acetyl CoA by β-ketothiolase.[90] A hallmark of these defects is hyperketosis during fasting owing to the impaired peripheral use of ketones. Fasting studies lasting 20 to 24 hours in these patients result in high levels of ketones in the blood (≥ 4.8 mmol) and very low ratios of FFAs to ketones (≤ 0.3).[84] The product of the plasma ketone body concentration and plasma glucose level (expressed in mM) may also be helpful in separating patients with ketolysis defects from normal infants. Although normal infants and children reach values between 6 and 13 after 20 to 24 hours of fasting, two patients with ketolysis defects achieved markedly elevated levels of 21 and 31.[84]

Typically presenting between 18 months and 5 years, ketotic hypoglycemia is the most common form of low blood sugar, excluding causes related to the treatment of diabetes, during childhood. Being a diagnosis of exclusion, most children presenting with a history of hypoglycemia who are ketotic are evaluated thoroughly for evidence of a metabolic disorder. Initially believed to be secondary to inadequate epinephrine release during times of stress or fasting, there have now been several other hypotheses to explain the pathophysiology. The usual picture is of an acutely ill child who has had poor oral intake. Healthy children are able to withstand 36 hours of fasting before exhibiting signs of hypoglycemia, whereas children with ketotic hypoglycemia are able to tolerate fasting for less than 12 to 24 hours. Blood sugars can be below 20 mg/dL, and hypoglycemic seizures have been reported. Insulin levels are appropriately suppressed, and the counterregulatory hormones (ie, GH and cortisol) are elevated. Alanine levels, on the other hand, are low, indicating a possible defect in protein catabolism or substrate supply. Patients are treated with supplemental intravenous glucose until they are again able to tolerate enteral feeds. Most patients require frequent feedings, and cornstarch supplements at bedtime may be helpful. Parents are advised to monitor urine ketones during illness or fasting as this typically heralds hypoglycemia. This generally benign condition resolves by 9 years of age, suggesting immaturity of the autonomic nervous system and/or of pathways controlling protein catabolism.

DIETARY AND MEDICAL TREATMENT

Because hypoglycemia is a medical emergency, treatment should commence immediately with adequate infusions of intravenous dextrose to prevent seizures and permanent neurologic sequelae. A rate of glucose infusion of 8 to 10 mg/kg/minute or greater in infants should be sufficient to correct the hypoglycemia even in the sickest patients, with the exception of those with hyperinsulinemia, for whom much higher infusion rates may be

needed. The plasma glucose concentration should be maintained above 70 mg/dL (> 4.0 mM). The importance of obtaining plasma and urine samples at the time of hypoglycemia cannot be overemphasized. These samples can be frozen and used for later analysis of insulin, cortisol, GH, thyroid hormone, FFAs, ketone bodies, lactate, pyruvate, ammonia, triglycerides, uric acid, total and free carnitine, acylcarnitines, amino acids, and organic acids.

Once stabilized, the mainstay of therapy for many of these disorders is avoidance of fasting and the provision of adequate amounts of dextrose during periods of catabolic stress. In infants with GSD type I and those with defects in long-chain fatty acid oxidation or transport, this often means continuous overnight intragastric feedings via a gastrostomy or nasogastric tube. In other patients, a late-night feeding with a nutrient that can bypass the metabolic block will be sufficient.

Treatment of Specific Causes of Hypoglycemia

Hyperinsulinemia Medical management of hyperinsulinemia has generally been divided into three strategies: (1) treatments that suppress insulin secretion such as diazoxide[91] and somatostatin analogues[92]; (2) medications that antagonize the effects of insulin on tissues such as glucocorticoids, epinephrine, and glucagon; and (3) therapies that destroy islet cells such as streptozotocin. No single method of treatment has been uniformly successful, and many of them give rise to unacceptable side effects. Specific dietary manipulations in infants have consisted of frequent feedings and a low-protein (low-leucine) diet. Leucine, in addition to a number of other amino acids, has been found to be an insulin secretagogue,[93] and some patients with hyperinsulinemia demonstrate an exaggerated fall in plasma glucose concentration accompanied by a rise in insulin in response to leucine. Most infants (90%) with the onset of symptoms before 1 month of age must undergo subtotal pancreatectomy to control intractable hypoglycemia.[94] These patients often require intravenous glucose infusion rates of 15 to 20 mg/kg/minute along with continuous enteral feeding prior to surgery. If an older infant or child cannot tolerate at least an overnight fast while receiving medical treatment, surgery to remove 85 to 90% of the pancreas is indicated. Even those children who do tolerate such a fast remain at risk for recurrent hypoglycemia during periods of illness and decreased food intake.

Surgical therapy is the only definitive therapy for islet cell hyperplasia. Current computed tomography and magnetic resonance imaging technology rarely allows for the identification of lesions such as islet cell hyperplasia (focal and diffuse) and adenomas. Several centers are now using pancreatic venous catheterization to define the extent of hyperplastic lesions and facilitate surgery, which is currently the only definitive approach. Because diffuse lesions are more common in the neonatal form, a 95% pancreatic resection is often necessary. This increases the risk of developing diabetes later in life. Pancreatectomy, however, is postponed up to 4 weeks in the newborn to exclude transient forms of hyperinsulinism. Therapy should not be delayed; permanent brain damage can be found in 20% of patients with persistent, profound hypoglycemia.

Glycogen Storage Diseases A cessation of the episodes of hypoglycemia and improvement in the metabolic derangements of hyperlipidemia, hyperuricemia, lactic acidosis, and ketoacidosis have been observed in infants and children with GSD type I who were treated with continuous nocturnal intragastric infusion of glucose or glucose polymer–containing solutions.[95] The rate of glucose infused should exceed the normal infant hepatic glucose production rate of 0.25 to 0.5 g/kg per hour (8 mg/kg/minute). This therapy is often continued through adolescence. This is combined with frequent daytime feedings of a high-carbohydrate diet (65 to 70% of calories) containing abundant starch, maltose, and glucose.[96] Most infants will require feedings every 2 to 3 hours. Breast milk may be used, but a formula with glucose polymers and low lactose is preferable if breast milk is unavailable. In patients above the age of 2 to 3 years, feedings of 1 to 2 g/kg of uncooked cornstarch suspensions every 6 hours have been effective as a slowly absorbed form of carbohydrate, allowing greater stability in blood glucose concentrations and a longer interval between feedings.[97,98] Lactose (galactose) and sucrose (fructose) are avoided because galactose and fructose cannot be converted to glucose when glucose-6-phosphate is deficient. Although the liver remains enlarged, many children treated with this aggressive dietary intervention exhibit a sustained increase in growth velocity. Most patients require allopurinol to prevent the formation of renal uric acid stones, and in spite of treatment, many develop focal segmental glomerulosclerosis, nephrotic syndrome, and renal failure in the third to fourth decades of life.[99] They are also at increased risk of developing hepatic adenomas and even hepatocellular carcinoma later in life.[100]

Treatment of type III GSD (debrancher enzyme deficiency) is modified to reflect the intact gluconeogenic pathway. To promote gluconeogenesis from amino acids, frequent feedings of a high-protein, low-carbohydrate diet, together with continuous overnight intragastric infusions of glucose plus protein, are given. Protein intake is increased to approximately twice the normal intake for age. The use of high-protein rather than high-carbohydrate feedings blunts the tendency toward postprandial hypoglycemia. The emphasis on the use of cooked and uncooked starch is similar to that for GSD type I. Fructose and galactose are not excluded from the diet (see Appendix: Table A–24).

Defects in Gluconeogenesis Treatment of patients presenting with fructose-1,6-diphosphatase deficiency early in life consists of frequent feedings to avoid prolonged periods of fasting beyond 8 to 12 hours and the elimination of fructose, sucrose, and sorbitol from the diet. A diet containing 60 to 65% usable carbohydrate (glucose, maltose, and lactose), 10 to 15% protein, and 20 to 25% fat is effective in controlling the chronic lactic acidosis and hypoglycemia. On this diet, patients demonstrate normal

growth. However, at times of infection or other catabolic stress, these patients can develop severe lactic acidosis, ketoacidosis, and hypoglycemia and require parenteral glucose administration. Treatment of patients with pyruvate decarboxylase deficiency has generally been disappointing. It has included dietary supplementation with L-glutamine and aspartate to increase the availability of oxaloacetate and promote gluconeogenesis.[101] Cofactors such as lipoic acid, thiamin, and biotin have been used, especially in patients with some enzyme protein present.[102]

Defects in Fatty Acid Oxidation Infants with defects in fatty acid oxidation or transport may require aggressive nutritional management, particularly if they are hypotonic or have developed cardiomyopathy and do not take adequate oral calories. They will benefit from continuous overnight high-carbohydrate, low-fat formulas administered via nasogastric or gastrostomy tubes. During the day, frequent oral or gastrostomy tube boluses are given. The choice of formula depends on the defect. In patients with long-chain fatty acid oxidation or transport defect, formulas high in MCT are recommended. The advantages of medium-chain fatty acids in this setting include passage into the mitochondria without the need for the formation of an acylcarnitine intermediate and continued availability for oxidation to acetyl CoA by intact intramitochondrial β-oxidation enzymes with substrate specificity for medium-chain substrates.[103,104] In addition, recent work implicating long-chain acylcarnitines and long-chain dicarboxylic acids in disrupting the normal metabolism of cardiac and skeletal muscle myocytes raises the specter of development of cardiomyopathy, muscle weakness, or rhabdomyolysis over time if the provision of long-chain fat is not curtailed. Beyond the age of 2 years, a prebedtime high-carbohydrate snack or a late night feeding of uncooked cornstarch may be substituted for overnight feedings. We continue to recommend a high-carbohydrate, low-fat diet (approximately 20% of calories), supplemented with MCT oil, even for older children.

Patients with medium-chain acyl-CoA dehydrogenase deficiency and other enzyme deficiencies affecting the oxidation of medium- and short-chain fatty acids do not require a special formula, and there is no clear evidence that restricting long-chain fats is necessary. MCT oil is contraindicated in patients with medium- and short-chain fatty acid oxidation defects. Drugs that inhibit intramitochondrial fatty acid oxidation should be avoided in all patients with fatty acid oxidation disorders. These include valproic acid, salicylates, ibuprofen, and amiodarone.

L-Carnitine supplementation at a dose of 100 mg/kg/day is essential in patients with the carnitine transport defect in whom it will maintain plasma carnitine levels in the normal range, restore hepatic carnitine to near-normal levels, correct the defect in fatty acid oxidation in the liver, and increase skeletal muscle and cardiac muscle carnitine levels sufficiently to reverse myopathy and cardiomyopathy in these patients (see Figure 35-4).[83] In other fatty acid oxidation disorders, the benefits of exogenous L-carnitine are not as clear. The administration of large doses of oral L-carnitine to patients with medium-chain acyl-CoA dehydrogenase deficiency results in increased urinary excretion of the medium-chain fatty acid metabolite octanoylcarnitine with restoration of normal plasma levels of total and free carnitine.[105] Some investigators believe that this mimics the situation inside the mitochondria and indicates detoxification of accumulating metabolites, excretion of these metabolites as acylcarnitine esters, and restoration of a normal intramitochondrial free CoA pool. This is the same justification for the use of L-carnitine as that used in the treatment of propionic and isovaleric acidemia.[106,107] Currently, most patients with long-chain fatty acid oxidation defects are supplemented with modest doses of L-carnitine (20 to 50 mg/kg/day) to normalize their plasma carnitine concentrations.

CHAPTER 36

PERSISTENT RENAL FAILURE

Rita D. Swinford, MD, Ewa Elenberg, MD, Julie R. Ingelfinger, MD

This chapter outlines principles for the management of nutritional disturbances related to acute and chronic kidney diseases. The relationship between blood composition and nutritional balance is dependent in many ways on the regulatory action of the kidney. The presence of adequate urine volume, although reassuring, does not necessarily indicate the presence of adequate filtering capacity or glomerular filtration rate (GFR). Furthermore, the concentrating and diluting capacity of the kidney depends on a complex set of physiologic factors, which are variably affected by renal disease. Thus, dysfunction of either GFR or urinary concentrating and diluting capacity can affect urine volume.

Understanding the effects of dietary modification on renal function, as well as on renal growth and development, could permit implementation of nutritional therapy that improves prognosis in patients with progressive renal insufficiency. The effects of modifying diet on the progression of chronic renal disease have been examined principally in adult patients; thus, pediatric data are limited. It should be noted that Recommended Dietary Allowances (RDAs) have been developed from observations in normal children and in adults. Because the RDA is generated from normal individuals, it should be used only as a starting point in children in chronic renal disease. Some components of the diet might need to be provided in amounts that seem excessive, whereas others are required in amounts that might seem too small.[1]

We first discuss renal development and function, because both have relevance to nutritional issues. We then discuss the general nutritional needs of children requiring intensive care unit monitoring because such patients often have concomitant renal and nutritional problems. We then consider nutrition in children with various degrees of renal insufficiency and discuss nutritional issues in acute renal failure, followed by chronic renal insufficiency, dialysis, and transplantation. Finally, we include a section that considers specific renal dysfunctions—of glomerulus, proximal tubule, and collecting duct—and describe nutritional adjustments tailored for such patients.

NUTRITIONAL ASPECTS OF RENAL GROWTH AND FUNCTIONAL MATURATION

During gestation, the fetal kidney plays little direct role in metabolic balance, even though fetal urine appears by the third month.[2,3] The placenta regulates fluid and electrolyte balance, even when there is bilateral renal agenesis. Indeed, in the case of unilateral renal agenesis, compensatory hypertrophy occurs following birth, when renal function takes over its regulatory role in metabolic balance, but not before.[4,5] Renal development is influenced by many factors, both genetic and environmental. One important factor is maternal nutrition. Recent data suggest that maternal diet could influence nephrogenesis, with the result that individuals whose mothers have low protein intakes during gestation could have a relatively lower total complement of nephrons at birth.[6] Several large population studies suggest that birth weight is inversely related to hypertension later in life, possibly as a result of nephron endowment, in that fewer nephrons could lead to increased work per nephron, eventual hyperfiltration, and then scarring.[7–9]

Renal function is relatively low at birth and increases during the first months of life.[10] Low birth weight infants have a relatively rapid increase in GFR compared with full-term infants. However, in general, postnatal renal function increases more rapidly than does renal weight, basal metabolic weight, or surface area. An infant's nutritional intake is a major stimulus to both postnatal renal growth and renal functional maturation. A full-term infant exposed to human milk, which has a low renal solute load (25 mOsm/L urine), has a relatively low GFR and a low rate of renal metabolic energy expenditure. In early infancy, protein or amino acid intake can influence renal growth. When premature infants receive a relatively high-protein diet, GFR increases more rapidly than in those who do not.[11] However, a diet too high in protein has been reported to be associated with metabolic acidosis, failure to thrive, and even evidence of renal injury.[12]

GLOMERULAR FILTRATION RATE

Creatinine clearance varies with age and gender secondary both to differences in creatinine production (a function of muscle mass) and actual clearance of creatinine. Serum creatinine can be used to estimate creatinine clearance in children by using an equation that multiplies the child's length or height by a proportionality constant and divides this by the serum creatinine (Table 36-1).[13] A formal endogenous creatinine clearance can overestimate the percentage of residual function because tubular secretion and filtration of creatinine occur and the latter becomes a larger fraction of total urine creatinine as glomerular filtration decreases.

Loss of muscle mass or clearance of creatinine by nonrenal routes also contributes to inaccuracy of serum creatinine and creatinine clearance in predicting residual function. Nevertheless, creatinine clearance assessment remains in common use because of its ease of performance and low cost. The GFR is assessed by measuring total plasma clearance of a substance (eg, creatinine [endogenous], inulin [exogenous]) that is excreted only in the urine and using a timed collection of urine and a serum sample.[14] The formula for calculating GFR is:

$$GFR = U_x \times V/P_x$$

where U_x is the concentration of a substance in the urine (eg, creatinine in mg/dL), V is measured in mL/min, and P_x is the concentration of a substance in plasma (eg, plasma creatinine in mg/dL). GFR is measured in milliliters per minute. This value is corrected to a specified surface area, most often 1.73 m^2 (or 1.0 m^2) to account for differences in body size.

The gold standard for measurement of GFR is inulin, a polyfructosan thought to be freely filtered at the glomerulus; other markers for GFR include ^{125}I-iothalamate, cold or nonradioactive sodium iothalamate, ^{51}Cr-ethylenediaminetetraacetic acid (EDTA), and Tc 99m-diethylenetriamine pentaacetic acid (DTPA). These markers can be used to measure GFR by either standard urine or serum sampling or by the constant-infusion or decay-curve methods. Estimation of GFR from plasma creatinine without a urine sample can be made by using a constant K, which varies with age—preterm infants, full-term infants, children, and adolescents—along with body length or height. The Schwartz formula is:

$$\text{Creatinine clearance} = K \times L/P_{Cr}$$

where L is height in centimeters and P_{Cr} is plasma creatinine in mg/dL. Creatinine clearance is measured in mL/min/1.73m^2. It has also been suggested that GFR be referenced until age 12 to weight and age rather than to surface area (see Table 36-1).[14]

TABLE 36-1 Estimation of Glomerular Filtration Rate

Creatinine clearance may be estimated as $C_{Cr} = kL/S_{Cr}$

C = clearance
k = proportionality constant
L = length (cm)
S_{Cr} = serum creatinine

k values	
Low birth weight babies during year 1 of life	= 0.33
Full-term babies (appropriate for gestational age) during year 1 of life	= 0.45
Children and adolescent girls	= 0.55
Adolescent boys	= 0.79

Note: If a patient's body habitus differs markedly from normal, more standard methods of creatinine clearance should be used.

Adapted from Schwartz GJ, Brain LP, Spitzer A. The use of plasma creatinine concentration for estimating glomerular filtration rate in infants, children and adolescents. Pediatr Clin North Am 1987;34:571.

The slope of 1/serum creatinine ($1/S_{Cr}$) plotted against time can be used to predict time to end-stage renal disease or need for dialysis.[15] When $1/S_{Cr}$ is less than 0.1, end-stage renal disease care is usually needed,[16] but prediction by this technique can be prone to substantial error.

Renal concentration and dilution are crucial to homeostasis. The kidney is able to achieve a maximum concentration of 1,400 mOsm/L and a minimum of about 50 mOsm/L.[17] However, in renal dysfunction, urine is often isosmotic—300 mOsm/L—with the result that a liter of water must be excreted for each 300 mOsm of renal solute. Thus, solute per 1,000 calories becomes important. Special renal formulas that provide lower mOsm/1,000 calories are preferable in many forms of renal dysfunction.[1]

UNDERNUTRITION AND RENAL FUNCTION

Undernutrition can complicate renal injury from any cause, and this must be kept in mind in the nutritional management of renal disorders. Alterations in renal function have parallels to diverse forms of undernutrition, for example, primary protein-energy malnutrition, iatrogenic malnutrition, or anorexia nervosa. Changes in renal function include decreases in GFR, a decrease in renal plasma flow, poor urinary concentrating ability, decreased ability to excrete sodium, and impaired acid excretion. Significant reductions in GFR are not necessarily accompanied by renal structural damage and are not always explained by hypoproteinemia or edema, which can occur in such states.[18–22]

Protein intake influences both GFR and renal plasma flow.[23] In fact, protein loading can be used to determine renal functional reserve, which is the increase in GFR seen with a challenge to glomerular filtration.[24] Increased intrarenal angiotensin II could play a role both in GFR changes and in lack of urinary concentrating ability.

A number of trace elements are elevated in chronic renal insufficiency,[25,26] including copper, lead, strontium, tin, aluminum, chromium, and silicon, whereas others, such as zinc, can be low. In the 1970s and early 1980s, aluminum phosphate binders were commonly used, with resultant aluminum overload.[27] In polyuric children, water-soluble vitamins can be depleted; this is certainly the case in children on dialysis. Special vitamin preparations are helpful. These include Nephrocaps (Fleming, Fenton, MO), Nephrovite (R and D Laboratories, Marina del Rey, CA), Iberet (Abbott Laboratories, Chicago, IL), and Berocca (Roche, Nutley, NJ). Levels of vitamin A and other fat-soluble vitamins are high in patients with renal insufficiency and do not require supplementation.[28,29] It has been suggested that vitamin C be given very judiciously to avoid elevating serum oxalate levels.[30]

NUTRITIONAL SUPPORT FOR THE CHILD IN INTENSIVE CARE

In addition to treating renal failure per se, any pediatric patient in the intensive care setting with renal concerns requires nutritional support both to minimize the catabolic effects of hypermetabolism, which can follow an acute

injury, and to maintain the positive nitrogen balance necessary for growth and repair. Additionally, prolonged immobilization can alter the fine balance of calcium-phosphorus, vitamin D, and parathyroid hormone (PTH), further emphasizing the need for optimal long-term nutritional planning. Early intervention with protein, calories, and vitamin support can prevent the shifts seen in growth percentiles after an acute stress and, more importantly, can prevent the development of multisystem organ failure. However, no data presently exist that definitively show that nutritional support shortens the need for intensive care or reduces patient morbidity or mortality.

NUTRITIONAL SUPPORT OF THE STRESSED PATIENT

The hypermetabolic response to acute injury results in increased oxygen consumption and significant negative nitrogen balance, depending on the type of stress. Along with the specific injury, renal factors need to be considered in such circumstances. Major burns, sepsis, and skeletal trauma all lead to significant increases in resting energy expenditure and nitrogen excretion as early as the first day of such stress.[31–34] Initially, glycogen and carbohydrate stores can be used for energy production; later, gluconeogenesis and ketone body production, along with consumption of stored fat and protein, provide fuel for the hypermetabolic state. Observations regarding the type of energy source used in critically ill children indicate that more than half the expended calories are derived from fat sources, roughly a third from carbohydrates, and about a tenth from protein sources.[31,35]

Ideally, a nutritional assessment should be made at the time of admission to the intensive care unit. Although influenced by several factors, serum protein levels can provide a quick estimate of the preillness nutritional state. Influencing factors include intravenous (IV) hydration, tissue edema, and metabolic rate.[31] Additionally, and importantly, serum proteins, and albumin in particular, are negative acute-phase reactants. In a stressed and septic patient, a low albumin level (< 2.5 mg/dL) is not uncommon and reflects a compromised overall nutritional status. Planning nutritional care should consider both ongoing needs and preexisting deficits so that calories can be provided with an adequate balance of carbohydrate, fat, and protein sources, along with essential minerals and vitamins. A simple method for estimating such requirements is to multiply the calculated caloric requirements by a ratio of ideal to actual weight. Caloric requirements can also be estimated by weight and type of stress.

Assessing ongoing needs in intensive care patients can be difficult because some patients could have preexisting diseases or specific organ injuries that might prevent adequate use of calories. For instance, a patient with poor liver function might not be able to tolerate lactate or acetate-based parenteral nutrition for acid-base control. Diets for patients with antecedant renal disease or with acute renal dysfunction require further planning.[36–38]

In addition to the number of calories to be provided, the mode of supplementation must be addressed early. Substantial evidence supports enteral over parenteral feeding, if possible. Thus, tube feeding (with gastric or jejunal tube, depending on gastric emptying) should be used whenever possible, depending on the gastrointestinal ability to absorb nutrients.[39–41] Parenteral nutrition is appropriate in conditions such as short-gut syndrome, ileus, severe dysmotility, inflammatory bowel disease, necrotizing enterocolitis, hemolytic uremic syndrome, or Henoch-Schönlein purpura. Other factors that can limit the effective use of enteral feedings include the need for narcotics, benzodiazepines, or high-osmolality formula.

When fluid intake must be limited—for example, during acute renal failure or during interdialytic periods—higher-calorie formula can be useful. Most children will tolerate 24 kcal/oz formula. When further increases in caloric density are needed, the child should be monitored for possible intolerance and need for prokinetic agents. Increasing calories by 3 kcal/oz every 3 to 4 days is usually tolerated.[31] In an acutely ill patient, carbohydrate absorption might be limited, and stool should be checked for reducing substances. Predigested (elemental) formulas might be more easily absorbed than other formulas in patients who are critically ill. The use of medium-chain rather than long-chain triglycerides can also augment absorption.

With parenteral nutrition (whether through central or peripheral venous catheter), care should be taken to provide an optimal mixture of lipid, glucose, and protein. Glucose concentrations above 12.5% should be given centrally, and even so can increase ventilatory requirements or cause hepatic steatosis. Ideally, 1.0 g/kg/day of fat can be given initially and then increased by 1.0 to 1.5 g/kg/day, until 30 to 50% of the calories are derived from fat. Serum triglycerides, cholesterol, liver function (glutamic-oxaloacetic transaminase, glutamate pyruvate transaminase, and bilirubin), and alkaline phosphatase levels should be monitored weekly. Protein should provide 15 to 20% of the calories, calculated on the basis of half the amino acids and half the infused protein products as total protein calories.[31]

Total parenteral nutrition (TPN) solution for patients with renal disease can be modified as needed for individual patients if the concentrations of calcium, magnesium, phosphorus, and potassium need to be altered (often decreased). Branched-chain amino acids, when available, have been used in pediatric patients with chronic liver and acute renal disease with varied success. Patients on dialysis might be helped by receiving a 15% solution of amino acids (0.5 to 1.0 g/kg/day) to maintain adequate nutrition,[42,43] despite fluid restriction.

CALCIUM, MAGNESIUM, AND PHOSPHATE BALANCE

Several aspects of intensive care illness (eg, immobilization, overhydration, or renal tubular damage) can cause several perturbations in the balance of bone formation and bone resorption, especially in pediatric patients because of their relatively high bone turnover rate.[44] Hypercalcemia or hypocalcemia can be found in this setting, along with derangements in phosphate and a low or

high PTH level. Factors that can contribute to these derangements include volume contraction, hypomagnesemia, and malnutrition. Table 36-2 lists sources of calcium, magnesium, and phosphate.

Magnesium is an ion frequently overlooked in the intensive care setting,[45,46] but its importance as an essential nutrient in health and disease should be emphasized. Magnesium deficiency is rarely seen in normal individuals eating a regular diet (containing green vegetables, nuts, grains, seafoods, and meats); however, certain pathologic conditions and medications can lead to disturbances in magnesium balance. Factors that increase renal excretion include extracellular volume expansion, loop diuretic administration, acidemia, proximal tubule dysfunction, and medications such as cisplatin, cyclosporine, and amphotericin B. Factors that decrease intestinal absorption include inadequate intake or prolonged IV therapy, malabsorption, severe diarrhea or inflammatory bowel disease, prolonged nasogastric suction, PTH deficiency, vitamin D deficiency, and acute pancreatitis. Both diabetes mellitus and parathyroid disorders can affect magnesium levels.

Found predominantly intracellularly, magnesium has an essential role there in energy production and use. The availability of magnesium is linked to the gastrointestinal tract, kidney, and bone; regulation is not well understood. Serum levels tend to predict total body stores poorly. Magnesium, like calcium, is highly bound to serum proteins and therefore is affected by hypoalbuminemia and serum pH level. Magnesium and potassium levels tend to change together proportionately. As a result, recalcitrant hypokalemia tends to be aggravated if associated with hypomagnesemia. Concurrent replacement facilitates normalization of both potassium and magnesium.

In the intensive care setting, values for calcium (total and ionized), phosphate, and magnesium should be obtained early, and prompt supplementation can avoid significant depletion. In patients with preexisting low magnesium levels, slow and gradual replacement is preferred unless a patient is symptomatic; in symptomatic patients, IV or intramuscular replacement can be given over 10 to 15 minutes.

Phosphate levels are not invariably monitored, yet phosphate levels are affected by stress. Furthermore, deranged phosphate levels are associated with adverse effects. Factors such as volume expansion, hyperglycemia, mild hypercalcemia, and use of diuretics (especially metolazone) can increase phosphate excretion. Hypophosphatemia (serum levels of 1.0 to 2.5 mg/dL) can indicate phosphorus depletion. Phosphate levels follow a circadian rhythm, peaking at 1 am and ebbing at noon. Simple dietary restriction is unlikely to cause hypophosphatemia, particularly in light of renal phosphate reabsorption and mobilization from bone and soft tissues.

Factors that contribute to moderate phosphate loss include decreased gastrointestinal absorption (because of insulin administration, vitamin D deficiency, malabsorption, or draining fistulas), maldistribution of phosphorus from the blood into bones and cells, and renal tubular loss from various causes (hypokalemia, hypomagnesemia, pharmacotherapy, intrinsic tubular defects, or the diuretic phase of acute tubular necrosis). Excessive use of phosphate binders, diabetic ketoacidosis, parenteral nutrition, catecholamine excess, and respiratory alkalosis can also alter phosphate level, sometimes profoundly. Additionally,

TABLE 36-2 Calcium, Magnesium, and Phosphate Supplementation for Pediatric Patients

Calcium		
Calcium Availability of Calcium Salts		
Calcium acetate	25%	
Calcium carbonate	40%	
Calcium chloride	36%	
Calcium citrate	17%	
Calcium gluconate	8%	
Calcium lactate	12%	
Calcium Supplements	*Product Tablet Size*	*Elemental Calcium Supplied*
Calcium Carbonate	650 mg	260 mg
Calci-Chew	1,250 mg	500 mg
Calci-Mix	1,250 mg	500 mg
Oscal 500	1,250 mg	500 mg
Tums	500 mg	200 mg
TumsES	750 mg	300 mg
Calcium Acetate		
Phos-Lo	667 mg	169 mg
Calcium Citrate		
Citracal	950 mg	200 mg
Magnesium		
Oral Magnesium		
Children: 3–6 mg/kg of elemental magnesium (eMg) divided tid or qid		
Adults: 200–400 mg eMg divided tid or qid		
Magnesium gluconate		
Magonate 500	27 mg eMg per tab	
Magonate Susp	54 mg eMg per 5 cc	
Magnesium oxide		
MgOx 400	241 mg eMg per tab	
UroMag	140 mg eMg per tab	
Magnesium chloride	60 mg eMg per 5 cc	
Antacids		
Maalox Suspension	83 mg eMg per 5 cc	
Laxatives		
Milk of Magnesia	500 mg eMg per 15 cc	
Parenteral Magnesium		
25–30 mg/kg/dose q 4–6 h, maximum 1 g/h		
Magnesium sulfate	24 mg eMg/mL	
	48 mg eMg/mL	
Phosphate		
Oral Phosphate		
Begin with 30–90 mg/kg day.		
Milk (skim, nonfat, dried)	255 mg/230 mL*	
Neutra-Phos†		
Sodium phosphate	250 mg/pkt	
Potassium phosphate	250 mg/pkt	7 mEq K^+/pkt
Fleets Enema	31 mg/mL	14 mEq K^+/mL
Fleets Phosphosoda	125 mg/mL	6 mEq K^+/mL
KPhos	114 mg/tab	3.7 mEq K^+/tab
KPhos-Neutral	250 mg/tab	2.0 mEq K+/tab

*If supplementing with calcium, make sure these are not given together as they can neutralize each other.

†Milk contains calcium, so phosphate availability is lower; however, the palatability of milk is much better, particularly when mixed with chocolate. The taste of phosphate products is reminiscent of soap.

many of these factors can be additive. For example, a severely burned patient 4 or 5 days post trauma could have elevated levels of catecholamines, respiratory alkalosis, and elevated cortisol secretion and could be receiving parenteral nutrition, all of which lead to hypophosphatemia.[44]

Hypophosphatemia in the stressed patient should be treated; however, it is somewhat difficult to predict the response.[31] Attention should be directed to signs and symptoms of hypophosphatemia (eg, proximal muscle weakness or pain, difficulty in weaning from respiratory support, anorexia, hypoglycemia, hypercalciuria, hypermagnesuria, or bicarbonaturia). The type of phosphate support should be gauged by the duration of IV support and timing of resumption of oral intake. For serum phosphate levels of less than 1 mg/dL, treatment should commence immediately with slow administration of parenteral neutral phosphate (5 to 10 mg/kg/dose or 15 to 45 mg/kg/day IV; for adults, 1.5 to 2 g/day) because as IV administration can produce weakness, bradycardia, and dyspnea.

Additionally, hyperkalemia can occur because phosphate is typically delivered with potassium. If the serum phosphate is greater that 2 mg/dL, parenteral treatment should be initiated if a prolonged course is expected. If enteral supplementation is possible, it is the preferred route. When phosphate is administered, it is important to consider the potential effects on other electrolytes, particularly calcium, because IV phosphate can decrease serum calcium as a result of calcium-phosphate complexing. In a hypocalcemic patient, this phenomenon can lead to tetany. Finally, attention should be given to situations that predispose to significant phosphate binding (eg, concomitant antacid treatment).

Conversely, hyperphosphatemia can be seen in the intensive care setting in stressed patients with either acute or chronic kidney disease and in those with increased phosphate loads (caused by laxative ingestion, excessive vitamin D intake, hyperpyrexia, burns, neoplasms, hemolysis, or respiratory acidosis). In hyperphosphatemia, calcium-phosphate salts can precipitate into soft tissues such as kidney, muscle, or vessels. This can occur acutely but is an even greater risk with chronicity. Monitoring the calcium-phosphate product can be useful as precipitation begins typically with a calcium × phosphate product greater than 70. Treatment of hyperphosphatemia includes the use of gastrointestinal phosphate binders, reduction in oral and parenteral phosphate intake, and, in extreme instances, hemodialysis.

Calcium is a predominantly intracellular cation found mainly in bone (99%).[30] Plasma calcium exists in two phases, one bound to albumin (40%) and the other free and ionized (60%). At least three biologic processes regulate calcium homeostasis: gastrointestinal absorption of calcium, bone turnover, and renal calcium reabsorption in conjunction with the actions of PTH and vitamin D. Hypocalcemia is seen more often than hypercalcemia in the intensive care setting. In a symptomatic child with tetany, especially a child with seizures, calcium should be provided at a dose of 10 mg/kg (0.5 mEq/kg) as elemental calcium over 10 to 20 minutes via slow, steady IV infusion (with electrocardiographic monitoring for bradycardia and QRS complex changes). Calcium should be added at 20 to 40 mg/kg/24 hours or by oral supplements given at 60 to 100 mg/kg/24 hours. Providing vitamin D might also be helpful if longer-term calcium supplementation is needed. Severe hypercalcemia, though rare, should be treated with aggressive saline diuresis with furosemide, followed by restriction of calcium intake and cessation of any calcium or vitamin D supplements. Calcitonin (salmon calcitonin, 4 IU/12 hours intramuscularly or subcutaneously) can also be used for severe hypercalcemia, as can bisphosphonates.

NUTRITION IN ACUTE RENAL INSUFFICIENCY

Children with acute renal failure are extremely catabolic. Urea nitrogen appearance, used as a surrogate for assessing catabolic states, has been found to be elevated in children with acute renal failure (levels of more than 180 mg/kg/day).[47] Although the reasons are not well understood, patients with acute renal failure require higher caloric input to balance the increased metabolic rate associated with the renal insult and to reduce accumulation of nitrogenous wastes, acids, and potassium.

A number of studies have evaluated the potential benefits of nutritional therapies in acute renal failure. For example, in one double-blind study in adults, a combination of 50% glucose and amino acids (compared with glucose alone) improved renal recovery.[48] However, another similar study was unable to show any difference in renal recovery.[49] In practice, the optimal nutritional prescription should be tailored to the individual patient, providing adequate protein and caloric energy. Marked protein restriction in pediatric patients with acute renal failure is unwise. In considering the therapy for acute renal failure in oliguric patients, the clinician often must choose between marked fluid restriction or early dialysis or ultrafiltration. Early dialysis seems most reasonable and is currently recommended.[36–38]

Various continuous renal replacement treatments can permit nutritional support but concomitantly contribute to nitrogen losses as amino acids and small peptides are filtered across the dialysis membranes. Recently, Maxvold and colleagues determined that both continuous venovenous hemotiltration (CVVH) and continuous venovenous hemodiafiltration (CVVHD) lead to losses, but these are offset by the ability to feed the very ill child with acute renal failure.[38] Glutamine, lysine, proline, alanine, and arginine were lost in the greatest amounts, representing more than 50% of amino acid losses.[38]

In the child subjected to marked fluid restriction, nutritional support via oral feedings fortified with Polycose and medium-chain triglycerides can be accomplished. However, it is not uncommon for children with acute renal failure to be nauseated and anorexic. In such patients, enteral feedings given continuously through a nasogastric tube using specially designed renal diets,[6] which are initially diluted and then gradually increased to full strength as tolerated, might be a better alternative. These formulas can also be augmented with Polycose and medium-chain triglycerides for added calories. Alternatively, parenteral nutrition using a high glucose concentration (25%), 20% lipid emulsion,

and essential amino acids can be given through central lines to supply partial or full nutritional support.

Protein intake in the nondialyzed child with acute renal failure should be at least 0.6 g/kg/day and increased while daily electrolyte, glucose, calcium, magnesium, phosphate, blood urea nutrigen (BUN), and creatinine levels are monitored. Patients can be started at a protein intake of 1.5 g/kg/day if on dialysis and 2.5 to 3.0 g/kg/day during continuous renal replacement therapy (along with folic acid and water-soluble vitamins).

The active form of vitamin D is also recommended, that is, 1,25 dihydroxyvitamin D_3 (calcitriol) or 19-nor-1(alpha), 3(beta), 25-trihydroxy-9,10-secoergosta 5(Z),7(E),22(E)-triene (paricalcitol), because renal conversion will be reduced in acute renal failure, and the half-lives of active vitamin D or paricalcitol are relatively shorter than that of the monohydroxylated form.[50] It is also important to note that paricalcitol is not yet approved for children by the US Food and Drug Administration (FDA).

Metabolic acidosis is frequently found concurrent with acute renal failure and can be treated with the enteral or parenteral addition of acetate as a sodium salt. If an elevated anion gap is present, suggesting increased lactate production or hepatic insufficiency, oral or parenteral bicarbonate can be used instead of acetate. However, for positive anion gap metabolic acidosis, the clinician is obligated to search for and treat the etiology of the metabolic acidosis (eg, sepsis or hypoxia). The clinician must remember that with hyperalimentation containing calcium, bicarbonate must be given through a separate line (eg, Y-tubing connections) or with low calcium concentration to avoid calcium precipitation. Many of the considerations for nutritional management of the child in the intensive care unit apply in acute renal failure.[51]

NUTRITION IN CHRONIC KIDNEY DISEASE

Renal insufficiency creates a state of metabolic imbalance proportional to the decline in renal function. Pediatric patients face not only the challenge of maintaining metabolic homeostasis in the face of renal dysfunction but also that of achieving somatic growth. Growth, in turn, is ultimately dependent, in part, on overall nutritional status. Metabolic requirements for improving growth are multifactorial and are affected by disparate factors, including patient compliance, genetics, psychosocial issues, infection, dialysis, and side effects of medications.

Chronic kidney disease (CKD), defined as a reduction in GFR to less than 70 mL/min/1.73 m^2, often occurs long before end-stage renal disease develops (defined as filtration of less than 12 mL/min/1.73 m^2). CKD in children can originate from a variety of causes, but all children with CKD require attention to nutrition. Depending on the degree and etiology of nephron loss, nutritional therapy can play a role in either slowing or stabilizing the decline in renal function or could serve to improve overall quality of life. Furthermore, when glomerular filtration is severely compromised, limitations and alterations in dietary intake can help to prevent metabolic disturbances.

The nutritional goal for the child with advancing CKD is to maximize growth and development. Table 36-3 is a partial list of supplemental formulas. Because infants, especially, demonstrate poor catch-up growth, protein and calorie intake should not be restricted; this can lead to stunting. Other specific abnormalities, such as metabolic acidosis, renal osteodystrophy, and hormone unresponsiveness, can further affect the growth failure seen in children with CKD.

Growth failure is the major manifestation and primary nutritional management problem for the child with CKD. Table 36-4 provides a summary of specific dietary recommendations for children of different ages with various degrees of CKD. For those children with renal insufficiency from infancy, in which one-third of a child's growth normally occurs, growth decline can result in a permanent loss of growth potential and result in a decrease in ultimate height.[52,53] Infants with CKD present an especially difficult situation. Even with successful conservative management of the renal failure, growth sufficient for transplantation with an adult kidney might not be achieved. Despite the emphasis on nutritional support, our lack of a complete understanding of how the uremic condition inhibits growth prevents optimization of nutritional prescription and results in empiric supplemental feeding.

Growth deficits are most dramatic in infants who have had renal insufficiency from early in life. A few months of delayed therapy in such infants can result in severe growth stunting, with a poor chance for recovery and catch-up growth. Nutritional requirements for these children are thought to be altered to some degree by uremia. Only limited data are available for this special group of patients. A study of 12 infants with renal insufficiency showed that forced feeding regimens augmented the weight velocity curve after age 2 years but did not improve length velocity curves.[54] In this study, protein-calorie supplementation was given orally or enterally through nasogastric tube or gastrostomy using 30-calorie Similac PM 60/40 (Ross Laboratories) with Polycose (9% protein, 36% fat, and 55% carbohydrate). This supplementation gave 141% of the RDA for protein intake. Despite this supplementation, the babies still demonstrated loss in length and head circumference, even into the second year of life. Hyperparathyroidism was demonstrated in this group and was believed to contribute overall to the short stature.[54]

Many children with chronic renal failure have polyuria, and nutritional support should include both sodium and water supplementation, which can help to maintain or improve the growth rate. For example, Parekh and colleagues[55] supplemented 24 children who had chronic renal failure with a dilute, sodium-supplement, high-volume regimen (enteral formula diluted with water to a caloric density of 0.3 to 0.5 kcal/mL, supplemented with 2 to 4 mEq of sodium as NaCl, $NaHCO_3$, or both, per 100 mL of formula). The regimen resulted in stabilization or improvement in their growth.[55] The formulas that were used included Nepro, Suplena (both Ross Laboratories), Similac PM 60/40, and SMA (Wyeth-Ayerst Laboratories) and were provided in volumes of 180 to 240 mL/kg in each

TABLE 36-3 Some Enteral Supplements for Patients with Renal Disease

Infant Formulas

- For increased energy requirements and/or fluid restrictions, fortify by increasing formula concentration and using modular components.
- Optimize digestibility using similar proportions of fat, protein, and carbohydrate. Begin by adding 2 kcal/oz from Polycose and 2 calories from medium-chain triglycerides, gradually increasing as tolerated.
- Osmotic load of high-calorie formula should be less than or equal to 450 mOsm/kg H_2O renal solute load.
- Maximize calcium-to-phosphate ratio (1.4:1) using infant formula such as Similac compared with Similac PM (2:1).
- Modular components
  - Polycose: 2 kcal/cc liquid, 23 cal/tbsp powder. Note that glucose polymers in Polycose increase osmolality slightly
  - Promod: 28 cal/scoop (5 g protein, < 44 mg calcium, < 15 mg sodium, < 65 mg potassium, and < 33 mg phosphorus (whey protein concentrate)
  - Vegetable oil: 8 cal/cc, not well tolerated in higher amounts (> 2 tsp/oz)
  - Medium-chain triglycerides: 7.7 cal/cc, stays in solution better than vegetable oil and is usually better tolerated in larger amounts

Formulas for Older Children

- Aminaid: very low-protein formula (19 g/L), 2 cal/cc, no added vitamins or minerals, short-term use only, expensive
- Suplena: low-protein formula (30 g/L), 2 cal/cc, with vitamins, low in phosphorus, magnesium, and vitamins A and D
- Nepro: moderate protein (69 g/L), 2 cal/cc, with vitamins, low in phosphorus, magnesium, and vitamins A and D
- NuBasics: relatively high-protein, palatable formula
- NutriRenal: calorically dense (2.0 kcal/mL); 14% of calories as high biologic value protein
- Renalcal: calorically dense, low electrolyte

Oral Supplements for Caloric Support in Patients with Progressive Renal Failure

Shake

6 oz sorbet/sherbert	16.2 g protein
4 oz nondairy creamer	115 mg phosphorus
2 tbsp chocolate syrup	70 mg calcium
	206 mg sodium
	544 kcal/300 cc

Enteral Nutrition Supplements

Predialysis patients

Suplena, Ensure, Isocal

Hemodialysis and peritoneal dialysis patients

- Underweight: Nepro, Isocal HCN,* Magnacal (2.0 kcals/mL); if not tolerated, try lower-osmolarity formulas, such as Ensure Plus/Plus HN,* or Sustacal HC*; monitor K levels
- Overweight with protein malnutrition: Replete, Sustacal,* Isocal HN, Ensure HN, Comply*
- With protein malnutrition: Sustacal*, Isocal HN, Ensure HN
- With protein-energy malnutrition: Nepro, Magnacal, Isocal HCN,* Ensure Plus HN,* Sustacal HC

For manufacturers and composition, see American Dietetic Association. Clinical guide to nutrition care in end-stage renal disease. 2nd ed. American Dietetic Association; 1994.

*For older children.

24-hour period. This led to an intake of 100 to 160 kcal/kg per 24 hours and about 2 to 2.5 g/kg of protein daily. Thus, these were intakes at or higher than the RDA for age.

Ledermann and colleagues showed that enteral feeding prevented or even reversed weight loss and growth retardation in children with chronic renal failure and end-stage renal disease.[56] Others had similar results.[57] Kari and colleagues showed that enteral feeding did not worsen lipid subfractions in chronic renal failure.[58,59] Additional studies are supportive of the concept that enteral feeding is very helpful in this group of children.[60,61]

Protein Handling in Chronic Kidney Disease

As noted above, a normal protein intake is tolerated under the right circumstances in a child with CKD. But can a low-protein diet slow progression of renal disease? Dietary protein reduction has been shown to slow the progression of renal decline in adult animals and humans, whereas it appears that, at least in immature uremic animals and renal-insufficient infants, decreases in protein intake retard growth more than excessive protein intake does.[62,63] Few studies in which protein intake was decreased in children are available. In one multicenter, prospective, controlled clinical trial of 24 infants with chronic renal insufficiency, randomized either to a low-protein or a control diet, linear growth was compromised in the low-protein group.[62] Neither group had increases in GFR, but the low-protein group did not achieve energy intakes equivalent to those of the control group, and this in and of itself could have stunted growth.[61] Success in this study was also limited by anorexia, parental and patient interactions, and primary care resistance to nasogastric feedings. Caution must be exercised with institution of low-protein diets and careful attention paid to growth parameters.

Protein-energy malnutrition often occurs in the course of CKD. This can affect renal function in several ways, independent of hydration status. In renal failure, renal tubular concentrating ability is decreased, as is the capacity to eliminate sodium and acid. Renal diluting capacity is also decreased, and malnutrition can worsen this problem, leading to fluid overload. However, malnutrition reversal is not easily effected, even in a child without intrinsic renal disease, in whom caloric intake might need to be between 140 and 160 kcal/kg/day and as high as 200 kcal/kg/day.[16,64,65] Despite aggressive nutritional management, the uremic child does not have the same response as does a child with simple protein-energy malnutrition.[64,66] Additionally, there is some evidence to suggest that certain types of caloric supplementation could be counterproductive as carbohydrate supplementation can reduce the child's ingestion of other foods, in effect without net protein-energy ratio change.[53] Nevertheless, we strongly advocate the early and consistent use of protein-calorie supplementation to attempt growth restoration, if not catch-up growth.

Carbohydrate Handling in Chronic Kidney Disease

Although no simple explanation is available, uremic children are often carbohydrate intolerant. Glucose use abnormalities in renal insufficiency include relative insulin resistance and hyperinsulinemia, prolonged insulin and glucagon clearance, and elevations of other hormones, such as PTH, glucagon, and catecholamines. These are all related in part to reduced GFR and, therefore, clearance by the kidney. When protein intake is reduced or dialysis is initiated, glucose intolerance can be seen to improve.[64]

TABLE 36-4 Daily Fluid and Nutrient Recommendations for Children with End-Stage Renal Disease

	Energy	*Protein*	*Sodium*	*Potassium*	*Calcium*	*Phosphorus*	*Vitamins*	*Trace Minerals*	*Fluids*
Predialysis (> 15% GFR)									
Infants	Min. of RDA for statural age	RDA for statural age	1–3 mEq/kg	1–3 mEq/kg	Supplement as needed	Restrict high-content foods, use low-content formula	1 cc multivitamin drops + vitamin D metabolite	Supplement Zn, Fe, Cu if needed	Min. maintenance level
Children/ adolescents	Min. of RDA for height age	Min. of RDA for height age	1–3 mEq/100 kcal expended	Unrestricted until K rises	Supplement as needed	—	Multivitamin, vitamin D	Supplement Zn, Fe, Cu if needed	With edema, insensible loss + urinary output
Predialysis (< 15% GFR)									
Infants	Min. of RDA for statural age	1.5–1.6 g/kg	1–3 mEq/kg	1–3 mEq/kg	Supplement as needed	Restrict high-content food; use low-concentration formula	1 cc multivitamin drops + vitamin D metabolite	Supplement Zn, Fe, Cu if needed	With edema, insensible loss + urinary output
Children/ adolescents	Min. of RDA for height age	Max. of RDA for height age	1–3 mEq/100 kcal expended	Unrestricted until K rises < 10% GFR	Supplement as needed	500–1,000 mg	Multivitamin, vitamin D	Supplement Zn, Fe, Cu if needed	With edema, insensible loss + urinary output
Hemodialysis									
Infants	Min. of RDA for statural age	RDA for statural height	1–3 mEq/kg	1–3 mEq/kg	Supplement as needed	Restrict high-content food; use low-concentration formula	1 cc multivitamin, 1 mg FA, vitamin D	Supplement Zn, Fe, Cu if needed	Insensible loss + ultrafiltration capacity + urinary output
Children/ adolescents	Min. of RDA for height age	RDA for height age	1–3 mEq/100 kcal expended	25–50 mEq if needed	Supplement as needed vitamin C, Bc, vitamin D	500–1,000 mg	1 mg FA, 50–100 mg	Supplement Zn, Fe, Cu if needed	Insensible loss + urinary output
Peritoneal Dialysis; IPD									
Infants	Min. of RDA for statural age	2.5–3 g/kg	1–3 mEq/kg	1–3 mEq/kg	Supplement as needed	Same as for HD	Same as for HD	Same as predialysis	Insensible loss + ultrafiltration capacity + urinary output
Children/ adolescents	Min. of RDA for height age	Usually halfway between HD and CAPD	1–3 mEq/100 kcal expended	25–50 mEq if needed	Supplement as needed	Same as for HD	Same as for HD	Same as predialysis	Insensible loss + urinary output
Peritoneal Dialysis; CAPD									
Infants	Min. of RDA for statural age	3–4 g/kg	3 mEq/kg ± depending on edema and BP	1–3 mEq/kg; may not be needed	Supplement as needed	Liberalize based on serum levels	Same as for HD	Same as predialysis	Insensible loss + ultrafiltration capacity + urinary output
Children/ adolescents	Min. of RDA for height age	3 g/kg 2–5 yr; 2.5 g/kg 5–10 yr; 2 g/kg 10–12 yr; 1.5 g/kg > 12 yr	Usually unlimited; 85–174 mEq	Usually unlimited; 25–50 mEq	Supplement as needed	240 cc milk or equivalent milk product	Same as for HD	Same as predialysis	Not needed
Transplant									
Infants	RDA for statural age after ideal weight/length achieved	3 g/kg	1–3 mEq/kg	Unlimited	Ad libitum	May need very high intakes; supplement as needed	Usually not needed unless malnourished prior to transplant, vitamin D possible	Not needed	Not needed
Children/ adolescents	RDA for height age; no concentrated sweets for 6 weeks post transplant	2–3 g/kg	130–174 mEq, less if edema and BP elevated	Unlimited	Unlimited	May need high intakes; supplement as necessary	Usually not needed unless malnourished prior to transplant, vitamin D possible	Not needed	Not needed

Adapted from Nelson and Stover.[43]

BP = blood pressure; CAPD = continuous ambulatory peritoneal dialysis; FA = folic acid; HD = hemodialysis; GFR = glomerular filtration rate; IPD = intermittent peritoneal dialysis; RDA = Recommended Dietary Allowance.

Carbohydrate supplementation can also increase triglyceridemia and lead to obesity without increasing lean body mass or growth. Patients should be encouraged to eat complex rather than simple carbohydrates.

Lipid Handling in Chronic Kidney Disease and Renal Insufficiency

Children with chronic kidney disease and renal failure often have lipid derangements, most commonly similar to those seen in type IV hyperlipidemia or in familial endogenous hypertriglyceridemia.[67–76] Thus, elevated triglyceride and elevated very-low-density lipoprotein (VLDL) levels occur; high-density lipoprotein (HDL) levels are low. Although the significance of these abnormalities is not fully known, their presence is thought to represent an increased risk of atherosclerosis. Possible reasons for the abnormalities include increased fat in the diet, decreased lipoprotein lipase, and hepatic triglyceride lipase activity. Carnitine deficiency, often present in renal insufficiency, theoretically could decrease fatty acid transport from the cytoplasm of cells to the mitochondria.[72]

There is recent experience in treating children with hyperlipidemia. The abnormal lipoprotein metabolism seen in renal disease reflects interactions among many factors—the disease itself, medications that affect lipids (eg, glucocorticoids and immunosuppressive medications such as sirolimus), diet, obesity or malnutrition, and familial factors. Conclusive data about efficacy compared to safety have led to a lack of certainty about therapy. However, use of dietary manipulation, statins, fibrates, and resins that bind bile acids is gaining favor.[73]

Practical Aspects of Nutritional Management in Renal Insufficiency

Major reasons for dietary intervention include dehydration, sodium depletion, metabolic acidosis, and preexisting malnutrition. The worsening of anorexia by metabolic acidosis can further inhibit nutritional intake. Thus, treating chronic acidosis is important.

Growth quantification can be conveniently achieved by monthly measurements of length, weight, and head circumference and permits early identification of growth failure and slowed height velocity. Table 36-5 provides a list of data that should be obtained and compiled at each visit to develop or modify the dietary prescription.

Calcium-phosphate homeostasis is altered in CKD by changes in PTH and vitamin D levels. Metabolic acidosis leads to a decrease in bone mineralization, release of bone buffers, and changes in protein conformation and can inhibit linear growth. Many factors can alter the balance of ionized versus bound plasma calcium, including acidosis and hypoalbuminemia (which are commonly seen in both chronic renal failure and nephrotic syndrome). Additionally, these renal diseases, which affect renal function, also cause increases in PTH and vitamin D metabolism. With progressive renal insufficiency, defective bone mineralization and secondary hyperparathyroidism or renal osteodystrophy require attention to plasma concentrations of calcium, phosphorus, 1,25-dihydroxyvitamin D, and PTH.[77,78]

The active form of vitamin D is 1,25-dihydroxyvitamin D. The 25-hydroxylation takes place in the liver, and 1α–hydroxylation takes place in the kidney. Active vitamin D has been available for some years as calcitriol, and its therapeutic use has increased in recent years. Dihydrotachysterol (DHT) becomes biologically active because of a 3-OH group that can rotate, making a pseudo 1α-OH group. Once 25-hydroxylation occurs in the liver, resulting in 25-OH-DHT, transport of calcium across the intestine increases. DHT has a shorter duration of action and greater potency than vitamin D_2 and is recommended over vitamin D_2. Vitamin D_2 has a narrower therapeutic window and is highly lipophilic; thus, it promotes adipose retention and poses problems for treatment of hypercalcemia.

Hypercalcemia can occur with any vitamin D preparation and is commonly seen with calcitriol, although it is usually mild and quickly reversible because active vitamin D has a short half-life. Although some early studies suggested that calcitriol therapy might hasten renal failure, this concern has largely been disproved by subsequent studies. Indeed, children do well with calcitriol, and bone histomorphometry results greatly improve.

Maintenance of normal serum calcium and phosphorus levels becomes extremely important in preventing renal

TABLE 36-5 Data Obtained for Dietary Prescription Adjustment

Measurements
Weight (for peritoneal dialysis or CAPD, weigh with full abdomen)
Height
Head circumference
Skinfold thickness
Estimated midarm muscle area
Pubertal stage
Three-day dietary history
Biochemical profile
Electrolytes, BUN, creatinine
Calcium, magnesium, phosphate
Alkaline phosphatase
Cholesterol, trigycerides
Total protein, albumin
Assessment of contributions of medications to biochemical balance
Calcium binders can contribute potassium:
Kphos 3.7 mEq K^+/tab;
Fleets PhosphoSoda 6 mEq K^+/mL
Potassium adsorbants contribute 100 mg sodium/g
Acetates contribute sodium (1 mEq/cc) or potassium
Phosphate supplements may contribute potassium:
Neutra-Phos (potassium phosphate), 14 mEq K^+/packet;
sodium phosphate, 7 mEq K^+/packet
Assessment of phosphate binder status
Calcium-containing: see Table 36-2
Phos-Lo
Renagel
Assessment of vitamin prescription
Vitamin D analogs
Water-soluble vitamins
Assessment of anemia and iron status
Assessment of dialysis efficacy if applicable
Hemodialysis: URR or Kt/V and protein catabolic rate
Peritoneal dialysis PET
CAPD-urea nitrogen appearance

BUN = blood urea nitrogen; CAPD = continuous ambulatory peritonial dialysis; PET = peritoneal equilibration test; URR = urea reduction ratio.

osteodystrophy. Calcitriol is now commonly used, with starting dosages of 0.01 to 0.05 μg/kg/day. DHT has been used for more than 25 years at dosages beginning at 15 mg/kg/day (in the morning) and can be given either in tablet form (0.1 to 0.2 mg tablets) or as a capsule (0.25 mg/mL). For children who weigh less than 15 kg, the capsule can be diluted in corn oil, and a tuberculin syringe can be used to give dosages of less than 25 mg/day. Calcium supplements, as calcium carbonate or calcium citrate, can be given to improve serum levels at dosages shown in Table 36-2 (400 to 1,200 mg/day, depending on age); Table 36-2 provides a short list of calcium supplements together with the available calcium supplied by each when given in supplemental form.[18]

Prevention of renal osteodystrophy is accomplished only with frequent monitoring of serum phosphorus, calcium, alkaline phosphatase, and PTH levels; adjusting vitamin D supplementation; and following monthly growth parameters. Normalization of serum calcium values can take several weeks. Current recommendations based on studies in adults have advised the limitation of calcium supplementation to provide sufficient amounts to achieve a "normal" value but not to exceed it because coronary artery calcifications have been seen in patients in their early twenties.

Because intestinal phosphate absorption is also increased with the use of calcitriol, the addition of phosphate binders might be needed to control serum phosphate levels. Many phosphate binders can also contribute to oral calcium intake. Calcium carbonate or calcium citrate, when used as phosphate binders, needs to be taken with meals and for supplementation between meals. It should be noted that when other active vitamin D preparations that have less effect on the gut—for instance, paricalcitol[50]—are shown to be safe and effective in children, they might be preferable.

Phosphorus levels can be controlled simply by limiting dietary phosphate intake when there is still only a moderate decline in GFR (eg, when GFR falls below 50% of normal). Although phosphorus is present in nearly all foods to some extent, milk products, nuts, nut butters, dried peas and beans, and whole grains (such as whole wheat, bran, and corn meal) are relatively high in phosphorus. Patients can be instructed to aim for a phosphorus intake of 1 g/day. As GFR falls toward end-stage disease levels, phosphorus can be restricted to 600 mg by prescribing a low-protein diet, which is not advised for growing children.

Phosphate excess must be treated, but phosphate binders that contain aluminum, which can lead to bone disease, should be avoided.[79,80] Preparations that contain calcium carbonate or calcium acetate bind phosphate in food when given with meals and also act as a source of calcium supplementation when given between meals to promote optimal absorption. These compounds can also be given at bedtime if the patient is not on nighttime feeds. Sevelamer can lower phosphate without concomitant calcium and can be helpful in individuals with high calcium levels.[81,82] There are presently no liquid formulations of either calcium acetate or sevelamer. It should be noted that sevelamer combined with liquids creates a sticky "glue" that can clog gastrostomy tubes.

As renal function declines, particularly below 25% of normal, dietary potassium intake often must be adjusted by avoiding certain foods high in potassium (eg, apricots, bananas, cantaloupe, dates, figs, orange juice, avocados, beans, potato with skin, spinach, tomatoes, nuts, certain cereals, and milk products). Salt intake might also need to be curtailed by limiting high-sodium foods such as prepackaged and processed foods (eg, lunch meats, frankfurters, canned foods, soups, certain sodas, certain cereals, salted nuts, nut butters, some cheeses, and milk products). An exception is the infant or child with tubular sodium and potassium wasting, who might need supplements even as renal function is markedly decreased.

Obviously, the list of foods to be avoided increases as renal failure worsens, and such restrictions progressively make the diet less palatable. Being presented with lists of foods that can no longer be enjoyed can be overwhelming. Dietary advice should be focused on specific areas that need adjustment for the particular child. The dietary prescription should be evaluated with each visit. Not only are children with renal failure restricted by dietary prescription, but as they lose renal function, many have poor appetites, an altered sense of smell, early satiety (with delayed gastric emptying), and weight loss, despite increased nutritional requirements and higher protein catabolic rates. In this setting, oral supplementation with a variety of preparations tailored for the patient with chronic renal failure can be helpful (with choice based on cost, convenience, and palatability).

Children who are not yet on dialysis should have nutritional intake that provides calories for both maintenance and catch-up growth (Table 36-6). Ideal caloric intake for children with renal failure is not known but can begin at 90 to 100 kcal/kg/day or even higher for infants—98 to 110 kcal/kg/day. Adolescent girls might need 40 to 47 kcal/kg/day and adolescent boys 45 to 55 kcal/kg/day (caloric and protein recommendations are based on height and age). Infants might need 2.2 g/kg/day of protein, and the protein requirement can increase to between 2.4 and 4.0 g/kg/day in the infant on peritoneal dialysis (see below).

Concentrating infant formulas can result in very high renal solute loads and lead to obligate water losses. It is advisable to add vegetable oils, medium-chain triglycerides, and carbohydrate supplements (Polycose) to increase the number of calories in standard formulas (carbohydrate and fat should be in similar proportions) to maintain palatability. Formulas such as SMA, Similac (Ross Laboratories), and Similac PM 60/40 have lower renal solute loads and higher calcium-to-phosphate ratios than most other formulas do. Use of formulas such as these is advisable over breast-feeding, which can be difficult in infants who are poor feeders and require volume determination. If oral feedings do not provide adequate caloric intake, continuous overnight nasogastric feedings are indicated to achieve adequate intake.

For older children, blenderized shakes or enteral nutritional supplements can be used to achieve adequate caloric intake. Table 36-3 provides a short list of high-

calorie supplements that can be given daily as needed for caloric support. Additionally, depending on the level of renal function and electrolyte stability, sweet foods such as cake or donuts; bagels with cream cheese; Popsicles; fruit in heavy syrup; margarine, butter, or jam on bread; white sauce on cooked vegetables; and whipped cream can be tried. Adding Polycose powder or liquid to drinks, hot or cold cereal, or puddings might also be effective in raising caloric intake.

Despite all efforts, poor appetite often persists in the child with renal failure. The decreased appetite commonly seen in uremic children is not readily explainable, although children with failing kidney function frequently maintain proportionate height for weight and body mass. One contributing factor could be changes in taste (eg, sweet and sour foods can taste bitter to uremic children).[83–85] Eating frequent small meals; keeping favorite snacks or hard candy on hand; adding flavorings such as lemon, garlic, or pepper to improve taste; and avoiding cooking odors can help overcome anorexia and nausea.

NUTRITION IN DIALYSIS PATIENTS

For the undersized child with end-stage renal disease, height age rather than chronologic age should be used to determine adequate dietary allowance. The daily dialysate glucose should be incorporated into the oral intake for determination of daily calories in the child on continuous ambulatory peritoneal dialysis (CAPD) or other forms of peritoneal dialysis. This intake is estimated to be about 10% of the total calories for children 2 to 10 years of age.[78] Even though synthetic diets can maintain uremic adults for long periods of time, there seems to be no advantage to using synthetic diets over appropriate conventional diets in children. Whether increased energy consumption can promote nitrogen sparing in children is not clear, and this might not be an ideal way to replenish lean body mass. Thus, the initiation of early dialysis, provision of additional calories, and prescription of recombinant human growth hormone can benefit some children, particularly anorexic ones,[64] and

TABLE 36-6 Predialysis Fluid and Nutrient Recommendations for Children with Near End-Stage Renal Disease

certainly is worth trying in a child whose growth velocity and weight gain are declining.

Uremia is associated with anorexia and consequent decreased caloric intake, depression, changes in taste perception,[83–85] and a susceptibility to infections, all of which worsen preexisting malnutrition.[64] This can be compounded by severe preexisting malnutrition, especially in patients in whom protein restriction is used to prolong the time to dialysis.[86–90] Nutrient metabolism can be impaired by endocrine and metabolic changes (eg, insulin resistance and impaired glucose use, alterations in lipid metabolism, and a relatively high protein catabolic rate).[91–93] Uremic patients have been found to have an insulin growth factor inhibitor that is thought to diminish the anabolic effects of growth hormone. Additionally, PTH is thought to contribute, in a yet undefined way, to net negative nitrogen balance. Metabolic acidosis, even in the absence of renal failure, is a strong curtailer of growth and contributes to protein breakdown, despite an adequate protein-energy supply. During the dialysis process, between 2 and 15 g of amino acids can be removed per day, depending on dialysis modality.[94,95]

It is important to quantify dialysis delivery on a regular basis as Kt/V (measurement of dialysis adequacy) has been shown to correlate with dietary protein intake.[91] Reliance on predialysis BUN level as an indicator of adequate nutrition is no longer considered sufficient because a low BUN level can be the result of poor intake as well as adequate dialysis.

Nutritional Aspects of Peritoneal Dialysis

Nutritional aspects of peritoneal dialysis have been incorporated into the recommendations of the Dialysis Outcomes Quality Initiative, which examines evidenced-based data to develop standards for the care of persons with renal disease.[96] Although peritoneal dialysis can substitute for many aspects of renal function, it also creates new metabolic and nutritional problems for the patient with end-stage renal disease.[97–100] Whereas some patients do show improved appetite and nutritional status, others, despite the lowering of BUN and creatinine levels, have persistent anorexia and nausea, compounded by inefficient removal of small molecules, abdominal distention, and discomfort with dialysate fills. Furthermore, appetite suppression owing to glucose in the dialysate can occur (dialysate glucose can supply up to 700 kcal and represents an absorption of 100% of glucose per dialysate fill).

Protein loss via the dialysate will occur—5 to 15 g of albumin per day, depending on whether the child's peritoneal membrane transport characteristics are high or low.[99] Albumin losses during episodes of peritonitis can increase dramatically, to as much as 10 to 30 g/day, and can persist for several weeks.[99] Dialysate glucose concentration, along with dialysate lactate and acetate, can also exacerbate hyperglycemia, hyperinsulinemia, hypertriglyceridemia, and weight gain.[95] The amount of glucose a patient can be expected to absorb over a daily cycle can be estimated with the following formula[99]:

$$y = 11.3\,x - 10.9$$

where y is glucose absorbed in grams per liter and x is the average dialysate concentration of glucose in grams per deciliter.

Malnutrition in patients on peritoneal dialysis can be demonstrated by muscle wasting; by low levels of serum albumin, transferrin, and other liver-derived proteins; and by abnormal amino acid levels.[95] Of all of the chemistries determined in the clinical laboratory, serum albumin and creatinine are best correlated with increased morbidity,[99] reflecting the fact that peritoneal dialysis cannot replace full renal function. Hypoalbuminemia or poor dialysis, reflected by inadequate Kt/V, might not be seen during the first year of treatment but are common after a longer time on chronic peritoneal dialysis (18% in the first year versus 42% after 1 year).[91] Less adequate dialysis with time is not significantly different from that experienced by patients on hemodialysis (see below).

The cause of hypoalbuminemia in patients on peritoneal dialysis is not thought to be a result of renal failure per se but rather of a separate process, protein malnutrition. Nevertheless, nutritional supplementation does not always seem to restore body stores of albumin. Other processes, such as endocrine imbalance involving growth hormone, cortisol, or thyroid hormone levels, can affect albumin synthetic rates. Additionally, inflammation, which can affect the proportion of acute-phase reactants, as well as albumin losses in urine or across dialysis membranes, can affect levels. In a recent study in adults,[97] hypoalbuminemia was found to be secondary to reduced albumin synthesis and not related to dialysis prescription, protein intake, or albumin losses. It appeared that decreased albumin synthesis was, in part, a response to inflammation involving acute-phase components, including insulin-like growth factor (IGF)-I.

Practical Aspects of Nutrition in Peritoneal Dialysis

Fluid and nutrient recommendations for children on peritoneal dialysis are listed in Table 36-7 according to age group. To achieve positive nitrogen balance, an adolescent might need 0.75 g/kg/day of "high-quality" protein (for nondialyzed, nonuremic patients); with CAPD, protein requirements increase to 1.2 g/kg/day.[98] Although many authors discuss "high-quality" protein supplementation, what high-quality protein is and whether it makes a difference has not been established. It might be more important that the taste of the food be acceptable.[64] Protein requirements should be balanced with concurrent caloric intake and the level of physical exercise. For infants, protein requirements can vary depending on how they are dialyzed and how much protein is lost in the dialysate. As one would expect, higher protein intake is required with more exchanges per day.

Sodium, potassium, and fluid intakes tend to be more liberal in peritoneal dialysis patients than in hemodialysis patients. Infant formulas tend to be low in sodium; therefore, supplementation with sodium chloride or sodium bicarbonate, depending on the presence or absence of systemic acidosis, can be provided. For infants whose fluid intake needs to be restricted, formulas can easily be concentrated to 24 kcal

per ounce. Monitoring of serum phosphorus and potassium is advised when concentrated formulas are used.

As an infant grows, the formula used can be advanced to one with higher caloric and protein contents (such as Pediasure, Nepro, or Suplena). We do not recommend the use of cow's milk as formula because it contains higher amounts of phosphorus and potassium. Recommendations for appropriate formulas for nutritional support for infants and children undergoing routine peritoneal dialysis can be found in Table 36-3. For phosphorus control, formulas such as Similac PM 60/40 and SMA, and for control of both phosphorus and potassium, S-29 (Wyeth-Ayerst Laboratories) can be used. If used long term, S-29 needs to be supplemented with sodium, chloride, calcium, vitamins B_6 and B_{12}, and folic acid. Sodium chloride or sodium bicarbonate can be used for supplementation, particularly in infants with residual renal function who waste sodium in their urine and for those with renal tubular acidosis.

For children on peritoneal dialysis, micronutrient needs, especially resulting from vitamin losses, are expected to be greater than for those on hemodialysis because large molecules and proteins are lost in the peritoneal dialysate. This finding is largely based on information from adult patients on CAPD. Water-soluble vitamins (vitamins B_6 and C, folic acid, and thiamin) are lost in dialysis. Vitamin C and folic acid intakes are usually low with potassium-reduced and low-protein diets. Vitamin C replacement should be used with caution to avoid the possibility of oxalate deposition in organs such as heart and kidney and in blood vessels. The fat-soluble vitamins are not as readily dialyzable and additional supplementation is generally not recommended, except for the active form of vitamin D. Commercial formulas for infants and children are supplemented with vitamins; however, additional supplementation using liquid or chewable forms is routinely used.

A unique study of pediatric patients on peritoneal dialysis showed that serum levels of vitamins A, B_1, B_2, B_6, and B_{12} and folic acid were elevated.[101] Indeed, the peritoneal dialysate contained large amounts of vitamin C. The authors questioned the need to supplement with multivitamins while these children (6 to 13 years of age) were asymptomatic.[101] There are several vitamin supplements available now[101,102] that are designed for dialysis patients; Nephrocap (Fleming and Company) and Nephro-Vite (R&D Laboratories) have no vitamin A or D. Carnitine, a water-soluble amino acid, is important in the transport of long-chain fatty acids across mitochondrial membranes, ultimately providing muscles with energy.

In peritoneal dialysis, low carnitine levels have been observed, and supplementation at 30 mg/kg is recom-

mended to improve the response to cardiac contractility, improve erythropoietin therapy, and reduce triglyceride levels (see Table 36-7). Additionally, in regions where the water supply contains less that 0.77 ppm of fluoride, supplementation is routine. Children on peritoneal dialysis should not have fluoride supplementation because this puts them at risk for fluorosis and damage to their permanent teeth.[78]

A number of recent studies examine the effects of using amino acids in dialysis fluids to promote growth and also consider peritoneal transport properties because these affect growth.[47,103–107]

Nutritional Aspects of Hemodialysis

Dialysis Outcomes Quality Initiative recommendations for hemodialysis also comment on nutritional aspects of hemodialysis.[108] As is the case for peritoneal dialysis, the recommendations for children are largely based on opinion and consensus rather than on hard data.[108] Many of the nutritional considerations for peritoneal dialysis are the same for the child on hemodialysis. Thus, the foregoing discussion about nutritional aspects of peritoneal dialysis in children will not be repeated. Table 36-8 lists fluid and nutrient recommendations for children of various ages receiving chronic hemodialysis treatments.

Hemodialysis can contribute to amino acid losses when glucose-free dialysate is used (up to 8 g of free amino acids per session in an adult). This loss is further exacerbated by the choice of membrane, which contributes to the negative nitrogen balance seen in these patients. Synthetic polyacrylonitrile membranes have decreased losses relative to cellulose membranes.[100] The inflammatory reaction could be initiated by dialyzer membrane choice (biocompatible to bioincompatible), which activates the complement system.[109] However, many authors believe that hemodialysis-associated protein catabolism is not a simple function of increased protein degradation or a function of cuprophane membranes. As a result, recommendations for protein intake are higher: 1.2 g/kg/day of high-quality biologic protein, in combination with a minimum of 35 kcal/kg/day (see Table 36-8 for age-specific guidelines).

The balance of carbohydrate to lipids should be one-third carbohydrate and two-thirds fat, with a 2:1 ratio of polyunsaturated to saturated fat. As mentioned earlier, serum albumin provides a marker for nutritional evaluation. With improved caloric intakes, serum albumin does rise. However, other markers (eg, transferrin) are dependent on a number of other factors, such as iron stores, that might not reflect an accurate nutritional picture and can make interpretation difficult.[108]

Malnourished Dialysis Patients

As long as reversible causes of malnutrition have been addressed and treated, oral or parenteral supplementation is not necessary. However, nutritional intervention should be considered in patients who, for whatever reason, cannot take in the recommended protein and calories. As in other types of malnourished children, enteral feedings are preferable to parenteral routes. Table 36-3 lists oral supplements that can be used to augment deficient diets. In the pediatric population, interdialysis supplemental

TABLE 36-8 Fluid and Nutrient Recommendations for Children on Hemodialysis

PTH = parathyroid hormone.

amino acids and carnitine do not result in improved amino acid or lipid profiles.[54,110,111] The institution of tube feeding for enteral supplementation is recommended for children who cannot consume the "required" calories and for those who are growing poorly, more than two standard deviations below the mean (below the 3rd percentile for height and weight).

Although tube feeding can impose an additional complication on an already busy care schedule, growth outcome can be improved in infants when tube feeding is begun early. Recent reports from several centers indicate that normal growth can be obtained in children who receive tube feedings.[56,112–115] Either nasogastric or gastrostomy tubes can be used to deliver supplemental calories. Chronic placement of nasogastric tubes has been used successfully by some; however, complications (eg, frequent removal by the child, vomiting, gastroesophageal reflux, aspiration, sinusitis, recurrent otitis media, and gastric irritation with possible perforation) can occur.[115] Gastrostomy tubes might be preferable to chronic nasogastric tube placement and can be placed percutaneously with a minimum of anesthesia. Adverse complications of gastrostomy tubes are leakage at the exit site, blockage, malabsorption or diarrhea, and infection at the exit site. Additionally, reliable use of nasogastric tubes might be difficult because it is a major undertaking for all involved.

The method for giving enteral supplementation consists of either a continuous drip or repeated bolus feedings during the day. For infants on CAPD, drip feedings can be organized for dialysis periods, balanced with bolus feedings.[78] Other factors that can modify the net monthly caloric intake and growth gain include psychosocial factors: economic and social situation of the parents, the age and number of siblings, the relationship and availability of the support system, including primary care medical staff and family, and the ease of access to the hospital or clinics. Parenteral nutrition can be given to patients who cannot tolerate oral feeds, whether because of gastrointestinal intolerance or intercurrent illness. Total parenteral composition for patients on dialysis should include 10 to 15% concentrated mixture of essential and nonessential amino acids, along with 20% lipid infusion, providing up to one-third of the caloric intake. Potassium, phosphorus, and magnesium might need to be added, with caution, to the TPN and monitored closely.

Patients with metabolic acidosis who are treated with acetate- and lactate-based dialysates and TPN solutions can become acetate intolerant secondary to systemic acetate transfer exceeding their maximal metabolic capacity, generally in the setting of intercurrent illness; this can contribute to decreased oxygen delivery to tissues and disturb hemodynamics.[116] Provision of bicarbonate, either by using specially composed dialysate or adding bicarbonate to the TPN (use caution with calcium-containing fluid) can treat this. Trace minerals and water-soluble vitamins should also be provided.

Intradialytic parenteral nutrition (IDPN) provides parenteral nutrition during regular hemodialysis sessions. Overall, the success of this type of supplementation has not been impressive. Most studies that show a benefit do so only marginally, with small improvements in weight and amino acid profiles.[117–120] No study has shown a change in morbidity or mortality. Under special circumstances in which there is moderate malnutrition, poor appetite, and low serum albumin, a short course of IDPN might be helpful. The goals of IDPN therapy are to provide maximum caloric and protein substrates in conjunction with enteral feedings so as to improve protein synthesis, prevent weight loss, improve appetite, and provide a sense of well-being.[96] IDPN formulations provide concentrated dextrose solutions (D50 to D70) and concentrated amino acid solutions (10 to 15%). Lipids usually are not introduced in the initial administration but are added later in either 10 or 20% forms. IDPN is very expensive and so should be carefully considered.

An interesting alternative for patients on CAPD is to use amino acids instead of dextrose dialysate. In one prospective, randomized, crossover study of seven malnourished children on CAPD,[116] appetite and serum albumin levels improved with amino acid dialysate, and there was effective ultrafiltration and creatinine clearance. However, there was no additional proven nutritional benefit. Qamar and colleagues reported that using a dialysate that contained amino acids was helpful in a small group of children ($N = 7$) on continuous cycling peritoneal dialysis who participated in a prospective, randomized, crossover study in which they received either amino acid dialysate or dextrose dialysate.[103] Each modality was used for 3 months and then subjects crossed over to the alternate regimen for another 3 months. The amino acid dialysis was comparable to the dextrose dialysis with respect to creatinine clearance and ultrafiltration, and plasma urea was higher during amino acid dialysis. Additionally, appetite and total body nitrogen increased in at least half the patients. Further study might be needed to identify a subset of patients who could benefit from this sort of substitution.

In another (short-term) study, 10 children on chronic hemodialysis were provided with IV amino acid supplementation at 0.25 g/kg during dialysis thrice weekly for a month, taken off for a month, and then given supplements plus carnitine at 25 mg/kg at the end of each session. No child was on recombinant human growth hormone (rGH), and all had dietary intakes of at least 75% of the RDA. Nine patients gained weight during the study, although one lost weight. Carnitine had no effects on plasma amino acids or lipids. No results of long-term studies are available.[111]

Despite progress made by dialysis as a means of controlling the impact of end-stage renal disease, growth in children on dialysis still remains a problem. The factors that contribute to this are many and include calorie-protein deprivation, intermittent and persistent metabolic acidosis, electrolyte deficiencies, uremic toxins, renal osteodystrophy, hormonal disturbances, pyschosocial issues, age at onset, and the natural history of the primary disease.[121] Dialysis modalities, including hemodialysis, continuous peritoneal dialysis, and CAPD, have been examined with respect to their effects on growth nutrition so that children can receive the most beneficial maintenance dialysis until transplantation. It is clear that dialysis

alone is not able to prevent the growth failure seen frequently in children with end-stage renal disease.

In several studies, CAPD has been shown to facilitate better growth relative to hemodialysis.[121–127] Some children receiving hemodialysis are found to grow normally (at predialysis rates) and another two-thirds are found to have moderate to severe growth impairment (catch-up growth is not seen).[123] In a recent study, 80 children on CAPD did show improved growth when there was improvement in metabolic parameters and metabolic acidosis, additional caloric supplementation from dialysate glucose (5 to 10% of the RDA), and lower BUN levels. Disappointingly, in this study, despite aggressive nutritional management and high protein intake for all modes of dialysis, the percentage of calories that patients actually took in was 100% of the RDA.

Regardless, aggressive nutritional support for infants and children on chronic dialysis is recommended and provides for maintenance of growth or improved growth while awaiting transplantation.[63,78] All efforts should be made to diagnose and treat chronic renal failure as early as possible and to integrate the family into a well-designed program of routine visits for biochemical, dietary, and clinical review.

TRANSPLANTATION

Nutritional intervention in patients with renal transplantation might at first seem unnecessary. Indeed, the onset of a normal GFR increases appetite and sense of well-being. However, changes in body composition are common and are modulated by multiple factors, including gender, age, income, energy intake, and, in particular, glucocorticoids and immunosuppression, which affect fluid retention and fat accumulation. Recent studies have added to the growing body of data indicating that cardiovascular disease is accelerated in transplant recipients in concert with the acquired weight gain and other cardiovascular disease risk factors. Indeed, elevated body mass index is a strong independent risk factor for patient mortality and allograft failure, at least in adults.[128]

Drug-induced metabolic issues, in addition to weight gain, often include hyperlipidemia, hyper- or hypokalemia, hypertension, interference with metabolism and action of vitamin D, glucose intolerance, hyperuricemia, and hypercatabolism of protein. Additionally, exacerbation of preexisting disease processes (eg, calcium malabsorption, hyperparathyroidism, hyperlipidemia) can also be found. Nutritional management for the transplantation patient can be divided into three periods: pretransplantation, acute post-transplantation, and long-term post-transplantation. The goal for all phases is to improve the new graft's longevity by careful attention to nutritional and metabolic states.

In the pretransplantation period, the patient's nutritional status should be optimized to minimize surgical risk, complications, and length of hospital stay.[129] Patients range from those who will undergo preemptive transplantation to those who have been treated with dialysis for varying periods of time. Nutritional assessment can expose aspects of undernutrition requiring supplementation or correction before transplantation. Specifically, calcium-phosphate balance should be adjusted as needed, with larger doses of phosphate binders and the addition of, or increase in, vitamin D supplementation. Ideally, metabolic and nutritional issues should be addressed as the patient approaches the time of transplantation. However, despite best efforts, optimal nutrition often is not achieved.

Acute post-transplantation management focuses on stabilizing an allograft that functions well.[129–132] The use of corticosteroids, a virtually universally used class of medicine, stimulates appetite and can make weight control difficult. Counseling at this stage with advice about total caloric intake, desired percentage of carbohydrates, possible behavior modification techniques, and exercise can be beneficial. Many patients who have renal transplants are entering puberty or are already in puberty. A number of medications can lead to changes in body or facial appearance, such as puffy cheeks or jowls caused by corticosteroids. Such changes can be detrimental to ego stability and lead to poor compliance. The effect of corticosteroids on carbohydrate metabolism, including increases in insulin and insulin resistance, along with glycosuria, is well known.[130] Minimization of carbohydrate intake (40 to 50% of caloric intake in pediatric patients) has been shown to help reduce the cushingoid side effects of corticosteroids. Curtailing intake of dessert-type items, some cereals, and additives (syrup, ketchup) is helpful; juices and fruits, which are considered complex carbohydrates, can be used in moderation.[132–134]

Ultimately, a plan can be formulated that prescribes protein intake for early and later phases of transplantation, lipid intake and composition, and calcium, phosphate, and vitamin D use. Additionally, if patients have been on corticosteroids (eg, for treatment of nephrosis or systemic lupus erythematosus) prior to allograft placement, attention should be given to carbohydrate metabolism. Iron intake should be assessed, and, if needed, supplementation should be given, along with sodium restriction and supplementation with water-soluble vitamins.

Immunosuppressive drugs (eg, cyclosporine, azathioprine, and corticosteroids) decrease protein anabolism through diminished uptake of amino acids,[133] inhibit deoxyribonucleic acid (DNA) and ribonucleic acid synthesis,[135] and increase protein catabolism by augmenting hepatic gluconeogenesis.[136] Immediately post transplantation, high doses of glucocorticoids are given, the effects of which combine with stress from surgery. If rejection occurs, treatment with high-dose IV methylprednisolone might be given, leading to marked protein catabolism. In combination with preexisting protein depletion, problems such as poor wound healing and susceptibility to infection can be seen.

Protein intake should begin at 2 to 3 g/kg/day immediately following transplantation, along with sufficient calories and a low intake of carbohydrates, which can be tapered over the next several months to the RDA for the appropriate age group[129] (Table 36-9). Although higher-protein diets are indicated for the early post-transplantation period, optimal dietary prescription on maintenance

immunosuppression might conflict with issues such as long-term renal function, stability, and growth. Some data suggest that even patients on low-dose maintenance corticosteroids (0.15 to 0.2 mg/kg/day) with optimal allograft function have elevated protein catabolism—as evidenced by muscle wasting, poor wound healing, and delicate skin—and dietary intake of more than 1.0 g/kg/day of protein is necessary to reduce signs of protein depletion.[136]

It is not uncommon to find elevated blood pressures during the immediate post-transplantation period, when drugs such as cyclosporine and corticosteroids are used in high dosages. Sodium, therefore, should be restricted (no salt added to the diet, maximum 2 g sodium per day) and liberalized carefully as the medications are tapered.

Although cyclosporine can result in mild elevations of potassium secondary to renin and aldosterone suppression, patients can experience acute post-transplantation diuresis. Additionally, diuretic and corticosteroid therapy, together with hypomagnesemia, the possible presence of renal tubular dysfunction, and ileal conduits with gastrointestinal losses, can all contribute to elevated potassium levels. Typically, potassium levels can be managed without dietary intervention or reduction in cyclosporine dosage.

A large diuresis is characteristic of the post-transplantation period and begins at about the time of the vascular anastomosis. Even though large volumes of fluid are given postoperatively, the etiology of this diuresis is not completely understood. Contributing factors include preoperative and interoperative expansion of extracellular fluid volume, osmotic diuresis caused by urea, diuresis and natriuresis owing to denervation of the transplanted kidney, proximal tubular dysfunction, resetting of glomerulotubular balance, or medullary ischemia. Nevertheless, judicious fluid replacement must be achieved, adjusting volume and type of fluid administered based on urinary composition. It is not uncommon to find significantly elevated fractional excretion of sodium, along with glucosuria and aminoaciduria. Most commonly, for living-donor transplants, hypotonic solutions (0.45% normal saline) can be administered without potassium. In some patients, elevated magnesium losses, the administration of diuretics, or both can precipitate potassium losses and will require changes in therapeutic strategy as the type of loss changes.

Concurrent hypomagnesemia will require magnesium replacement to correct hypokalemia. A strategy for volume control can be anticipated, and fluid should be replaced at twice maintenance with close monitoring and appropriate treatment of hemodynamic and homeostatic changes, including daily weights. Patients receiving cadaveric renal transplants present a somewhat different problem, particularly because of their higher incidence of delayed graft function. This situation precludes planning preset replacement fluids; however, the usual of maintenance fluid plus urine output volume can be used to start.

Pediatric patients who receive transplantation are commonly on vitamin D supplementation. As mentioned earlier, despite maximal efforts, alterations in calcium-phosphate-PTH balance are not uncommon, together with a range of

TABLE 36-9 Fluid and Nutrient Recommendations for Pediatric Transplant Recipients

Age	*Infant (0–1 yr)*	*Toddler (1–3 yr)*	*Child (4–10 yr)*	*Adolescent (11–18 yr)*
Energy	Same as for predialysis after ideal weight and length achieved	Same as for predialysis after ideal weight and height achieved	Same as for predialysis after ideal weight and height achieved	Same as for predialysis after ideal weight and height achieved
Protein (g/kg)	Usually 3 initially; RDA after approximately 3 mo	Usually 2–3 initially; RDA after approximately 3 mo	2–3 initially; RDA after approximately 3 mo	2 initially; RDA after approximately 3 mo
Sodium	1–3 mEq/kg initially	1–2 g initially; unrestricted when HTN and edema no longer present	Usually 2–3 g initially; unrestricted when HTN and edema no longer present	Usually 2–4 g initially; unrestricted when HTN and edema no longer present
Calcium	Ad libitum; supplement if necessary to RDA	Ad libitum; supplement if necessary to RDA	Ad libitum; supplement if necessary to RDA	Ad libitum; supplement if necessary to RDA
Potassium	Unrestricted unless needed	Unrestricted unless needed	Unrestricted unless needed	Unrestricted unless needed
Phosphorus	May need very high intakes; supplement as necessary	May need very high intakes; supplement as necessary	May need very high intakes; supplement as necessary	May need very high intakes; supplement as necessary
Vitamins	Usually not necessary unless severely malnourished prior to transplantation; vitamin D as needed, depending on phosphorus-calcium balance	Usually not necessary; vitamin D as needed	Usually not necessary; vitamin D as needed	Usually not necessary; vitamin D as needed
Trace minerals	Generally unnecessary; supplement iron as needed	Generally unnecessary; supplement iron as needed	Generally unnecessary; supplement iron as needed	Generally unnecessary; supplement iron as needed
Fluid	Ad libitum	Ad libitum	Ad libitum	Ad libitum

HTN = hypertension; RDA = Recommended Dietary Allowance.

accompanying renal osteodystrophy. In our experience, pediatric patients often have pronounced hypophosphatemia following transplantation. They develop hypocalcemia and hypomagnesemia secondary to post-transplantation diuresis, have a renal tubular phosphate leak (either PTH dependent or PTH independent), and have gastrointestinal losses. This occurs in both cadaveric and living-donor kidney transplant recipients. This hypophosphatemia can still be seen even 6 months following graft placement.[44]

Early supplementation with vitamin D_3 for patients with PTH-independent hypophosphatemia can ameliorate and prevent further decrements in phosphate and calcium; the vitamin D can later be tapered according to response. Even though the transplanted kidney is capable of dihydroxylating vitamin D, corticosteroid treatment can contribute to a renal phosphate leak via its effect on vitamin D metabolism.[136] The active form of vitamin D is recommended because its half-life is significantly shorter than that of the monohydroxylated form (3 to 7 days versus 6 to 18 weeks), which facilitates management.

Persistent post-transplantation hyperparathyroidism (PTH-dependent hypophosphatemia, normocalcemic or mildly hypercalcemic) can be managed with oral phosphorus supplementation. Consuming skim milk (1 g phosphorus per liter) is an easy and cost-effective way of replacing phosphorus. Whole milk, with its higher fat content, can aggravate diarrhea and hyperlipidemia, and phosphate supplements, in addition to inducing diarrhea, might provide an acid load that might not be buffered appropriately (some patients continue to have urine bicarbonate wasting). In some cyclosporine-treated patients, addition of potassium and sodium loads from phosphate supplements can aggravate hypertension and parathyroid balance.

Obesity or weight gain and hyperlipidemia are not uncommon among renal transplantation patients. Not only do patients feel better after transplantation, but they are encouraged to consume more calories. The concurrent use of corticosteroids stimulates appetite, and insufficient exercise can persist as a carryover of the pretransplantation phase. Thus, the caloric expenditure might be insufficient for the actual intake, resulting in rapid weight gain. Exercise programs should be advised to restore normal energy expenditure.

Intake of dietary fats should include both monounsaturated and polyunsaturated fats, with the overall intake being between 30 and 50% of total calories to minimize the hypercholesterolemia and hyperlipidemia described during this period.[136] Generalized hyperlipidemia can be seen with patients treated with azathioprine and prednisone, and hypercholesterolemia is found in patients receiving cyclosporine. Therefore, on most post-transplantation medical regimens, patients are likely to exhibit elevations in both cholesterol and triglyceride levels. Prednisone is strongly associated with hyperlipidemia, related in large part to insulin resistance in peripheral tissues with impaired synthesis of lipoprotein lipase and lipoprotein synthesis.[137] Other factors that can adversely affect serum lipid levels include diuretics and beta-adrenergic agents used to treat hypertension.

Elevations of uric acid can be found following transplantation concomitantly with cyclosporine or azathioprine treatment. This is particularly so with cyclosporine administration, especially if diuretics are used. It is believed that the decreased excretion of urate explains the elevation of uric acid seen with cyclosporine use. Despite levels of urate in the range of 8 to 14 mg/dL, gouty arthritis is uncommon, and adequate management consists of limiting dietary purines, reducing or eliminating diuretic treatment, and administering colchicine.

Frequently, elevations of serum calcium are found following transplantation, either early, transiently, persistently, or a combination of these. Persistent secondary hyperparathyroidism (correlating with serum PTH levels and the extent of renal osteodystrophy), along with phosphate deficiency and abnormalities in vitamin D metabolism, contributes to the observed hypercalcemia. Despite the brisk diuresis seen following transplantation, many patients have sustained PTH elevations, some even 3 years after transplantation. It could be that gastric absorption of calcium and renal tubular leak are aggravated by corticosteroid treatment. Management of mild to moderate post-transplantation hypercalcemia should include oral phosphate supplementation (Table 36-2), magnesium administration (Table 36-2), vitamin D administration, and hydration. Subtotal parathyroidectomy should be reserved for refractory, severe hypercalcemia.

Synthesis

The challenge of maintaining maximal nutritional standards for patients with renal insufficiency in all stages is formidable, and the best achievements can be less than ideal. One must consider that surgical intervention and dialysis (either peritoneal dialysis or hemodialysis) are not without risk and inconvenience for families. The actual benefit of caloric maximization for predialysis patients is endorsed. Clearly, the emphasis should be on growth, particularly for infants with chronic renal failure, in whom catch-up growth is so rare. Increasingly, our experience with growth hormone administration to patients at the predialysis, dialysis, and transplantation stages has expanded; results have shown significant improvements—for some, in both height and weight percentiles. Nevertheless, our expectations of growth for patients with renal insufficiency should be tempered by the need for further research and study of the ideal plan for all children with renal insufficiency.

NUTRITIONAL CONSIDERATIONS IN GLOMERULAR DISEASE: NEPHROTIC SYNDROME

Nephrotic syndrome is an example of a glomerular disease in which dramatic nutritional alterations occur. Nephrotic syndrome results from increased glomerular permeability to albumin and other macromolecules of intermediate molecular weight, leading to massive proteinuria (1 g/m^2/day or 40 mg/m^2/hour or more), hypoproteinemia, hyperlipidemia, and edema. Systemic manifestations and consequences of nephrotic syndrome are responsible for much

of the morbidity and mortality seen with this condition.[138] The most common form of nephrotic syndrome in children is minimal-change disease, which is usually responsive to corticosteroid administration. The management of nephrotic syndrome involves treatment of acute symptoms concomitant with the administration of corticosteroids (with or without other medications), fluid control, and diet modification.[139]

Acute Management of Nephrotic Edema

Many patients tolerate considerable proteinuria and moderate hypoalbuminemia without developing massive edema.[140] However, severe generalized edema can occur with profound hypoalbuminemia (albumin level below 1.5 g/dL). Massive ascites and pleural effusion can occur, and occasionally painful scrotal or labial edema occurs. Any of these situations can cause much discomfort, together with difficulty in carrying out daily activities. Marked fluid overload, severe intravascular depletion, or infection are indications for hospitalization.

If blood volume is normal, 25% albumin (1g/kg over 3 to 4 hours) is given, followed by IV furosemide (1 to 2 mg/kg) either halfway through or after the albumin infusion. This can be repeated once a day for 2 or 3 days until an adequate diuresis occurs. Albumin infusion must be given with great care, owing to potential adverse effects from sudden fluid shifts, which can lead to pulmonary edema. Albumin should be infused during the daytime, when sufficient staff are present to monitor the patient closely. Albumin infusion should be reserved for very severe edema with problems as noted (never for cosmetic reasons only) because it leads to only temporary improvement of serum albumin level when a patient is nephrotic. It is crucial to limit fluid intake during and after albumin infusion so that weight loss will occur.

There are two contraindications for 25% albumin infusion. The first is increased blood volume, as assessed by elevated blood pressure, distended jugular veins, signs of pulmonary edema, or congestive heart failure. The infusion of 25% albumin can lead to rapid fluid shift from the interstitial to the vascular space in such patients and can lead to pulmonary edema, congestive heart failure, and possible death.

The other contraindication is decreased blood volume, as assessed by the presence of orthostatic hypotension (a drop of 15 to 20 mm Hg in systolic blood pressure with postural change from supine to upright), tachycardia, decreased capillary refill, decreased urine output, or low random urine sodium (less than 20 mmol/L). Patients with decreased blood volume should receive 5% albumin at 10 cc/kg over 1 to 2 hours, prior to more concentrated infusions. This solution contains normal saline as the solvent (130 to 160 mEq/L). However, 5% albumin is expensive and not always on hand, and 0.9% NaCl alone, although easily available, rarely stays in the intravascular space. In nephrotic patients, infusion of normal saline alone will lead to worsening edema and will not expand vascular volume, except transiently. Thus, if 5% albumin is not available, a patient with volume depletion should receive 10 cc/kg of a 1:5 dilution of 25% albumin (diluted in normal saline). For example, in a 20 kg child, the dose of 10 cc/kg = 200 cc; thus, 40 cc of 25% albumin is added to 160 cc of 0.9% NaCl to provide a total volume of 200 cc.

Dietary Management of the Nephrotic Child

Fluids and Electrolytes After stabilization of intravascular volume, the nephrotic patient needs to have fluid restricted to insensible losses (400 cc/m^2) plus urine output (or less, for weight loss) for several days until onset of diuresis or until stable. If salt intake is limited, the urge to drink is limited to some extent. Thus, sodium intake both during relapses and during corticosteroid therapy should be restricted with a no added sodium diet. Severe sodium restriction, equivalent to 1 to 2 mEq Na/kg/day or 23 to 46 mg/kg/day (maximum 30 mEq/day or 690 mg/day), is necessary for patients who have poor response to diuretics. It can initially be difficult to persuade a child that food with no added salt tastes good; it can take up to 3 months to change taste preference. Because the majority of nephrotic patients have relapses, a no added salt diet should be continued even when the patient is in remission and off corticosteroids.

The edematous nephrotic patient might have hyponatremia on laboratory evaluation, despite sodium retention. Low values of sodium are not an indication for increased sodium supplementation as this will lead to a vicious cycle of increasing edema.

Dietary Protein Although endogenous protein synthesis can be augmented by increased intake of dietary protein, urinary protein losses also increase with increased intake. Additionally, changes in glomerular hemodynamics resulting from increased dietary protein intake can accelerate the progression of the possible underlying renal disease.[141] The dietary protein intake in the nephrotic child should meet the RDA for age, which should provide enough intake to avoid an impact on growth curve in the developing child. Recently, a soy protein diet has been reported to limit proteinuria in adult nephrotic patients.[142,143] This has not been studied in children, but adding soy protein to meals is not harmful.

Lipids Hyperlipidemia in nephrotic syndrome is caused, at least in part, by an increase in hepatic cholesterol synthesis in response to increased hepatic albumin synthesis. Persistently elevated serum cholesterol can lead to atherosclerotic disease and hasten the progression of renal disease.[141] In experimental animal models of nephrotic syndrome, hyperlipidemia promotes mesangial damage, glomerular sclerosis, and permeability of the glomerular capillary wall.[144]

Nonpharmacologic treatment of hypercholesterolemia in childhood nephrotic syndrome is suggested as most patients enter periods of remission and normalize their cholesterol. In the nephrotic child, 20% of energy should be delivered from protein; total fat intake should be limited to 28% of total caloric intake (with 8% from saturated, 8% from polyunsaturated, and 12% from monounsaturated fat), as suggested by the National Cholesterol Education Program.

Pharmacologic therapy for hyperlipidemia is not needed in most nephrotic children as hyperlipidemia usually corrects itself when the level of albumin increases during remission. In individuals with corticosteroid-resistant nephrotic syndrome, hyperlipidemia can present a long-standing problem. In these rare cases of prolonged hyperlipidemia with abnormal high-density lipoprotein (HDL) to low-density lipoprotein (LDL) ratio and high triglyceride levels, treatment with antilipogenic drugs might be indicated, especially if there is a concomitant family history of hyperlipidemia.

A soy-based vegetarian diet can be somewhat effective in treating hyperlipidemia.[142–144] Soy protein ingested in amounts of 20 to 50 g/day is associated with decreasing serum concentrations of total cholesterol, LDL cholesterol, and triglycerides but does not significantly affect HDL cholesterol. Such effects are significantly related to the initial serum cholesterol values, with the best result (reduction of cholesterol by 19.6%) when used in severe hypercholesterolemia (cholesterol level above 335 mg/dL). The soy diet has been reported to have an additional favorable effect on nephrotic proteinuria (which could be a direct consequence of partial correction of the hypercholesterolemia). However, the soy protein vegetarian diet should be used with caution in children because of its decreased content of vitamin B_{12}, vitamin D, and other important nutrients. It might be useful to implement soy protein as the primary protein element of the diet (eg, 230 mL of soy milk contains 4 to 10 g of soy protein, 28 g of soy flour has 10 to 13 g of soy protein, and 1,103 g of tofu has 8 to 13 g of soy protein).

Because omega-3 fatty acids found in coldwater fish have some lipid-lowering effect,[144] they can also be added to the daily diet. Although therapy with lipid-lowering agents is presently being attempted in children with unremitting nephrotic syndrome, few data exist.[145–149] In one brief report of 12 children,[148] statins appeared to be effective in a marked reduction of total and LDL cholesterol, although no overall change in the course of the nephrotic syndrome was noted. Recently, eight children were reported as having responses to gemfibrozil,[149] although the course of their disease did not appear affected either. Long-term controlled studies with statin therapy are needed to further document or negate their renoprotective role in refractory nephrotic syndrome.

Calcium and Phosphate Metabolism In prolonged, corticosteroid-resistant nephrotic syndrome, some patients have urinary losses of vitamin D binding protein and its accompanying vitamin, leading to a vitamin D–deficient state with resulting mild impairment of intestinal absorption of calcium and reduction of plasma ionized calcium concentration. This can lead to secondary hyperparathyroidism. Adding 400 IU of cholecalciferol (vitamin D_3) plus 800 mg of calcium to the diet per day will meet the FDA dietary requirements for children and should be sufficient for most nephrotic patients. In cases of suspected deficiency, serum levels of calcium and vitamin D must be measured and the supplemental dose of vitamin D adjusted.

NUTRITIONAL ISSUES IN RENAL TUBULAR DISORDERS

The renal tubules reabsorb the vast majority of filtered plasma water as well as solute, amino acids, and sugars. In addition, the tubules secrete numerous substances. For this reason, renal tubular disorders, depending on the tubular segment involved, can affect nutritional balance. An example of a proximal tubular dysfunction (cystinosis) and one of a collecting dysfunction (nephrogenic diabetes insipidus) serve to illustrate the problems that can ensue from such imbalances.

Cystinosis

Cystinosis, a rare autosomal recessive storage disease resulting from defective transport of cystine across the lysosomal membrane, is the most common cause of secondary Fanconi syndrome in children.[150,151] The stored cystine is poorly soluble and crystallizes within the lysosomes of many cell types, leading to widespread tissue and organ damage. In the infantile nephropathic form of cystinosis, which is the most common form, the kidney is severely affected early in life owing to stored cystine crystals within the proximal tubule, leading to deformation and damage with subsequent uncontrollable wasting of sodium, potassium, phosphate, calcium, magnesium, bicarbonate, tubular proteins, carnitine, glucose (without leading to hypoglycemia), and water.

Patients with the infantile nephropathic form of cystinosis present with the initial symptoms in infancy, frequently before the age of 1 year. Initial symptoms include polydipsia, polyuria, vomiting, loss of appetite, and subsequent failure to thrive. The first signs might go unrecognized for several months, until patients present dramatically, often during the course of a mild viral illness, with severe dehydration, serum electrolyte imbalance, and metabolic acidosis. Initially, many patients might be misdiagnosed with diabetes mellitus, diabetes insipidus, dwarfism, rickets, or failure to thrive.

Management of Acute Dehydration The initial management of dehydration in a cystinotic child requires the administration of large amounts of fluids and electrolytes, often exceeding any known or so-called acceptable limits. The intravenous fluid requirements in this situation might be more than twice that expected for the patient's size. In cystinotic children, the obligate urine volume is often several liters per day and must be meticulously measured and replaced during hospitalization. The initial reconstitution of wasted nutrients should be performed with the use of large-vein access, preferably a central line if the patient is severely affected.

The IV rehydration fluid should contain glucose, isotonic saline, potassium, and bicarbonate, in amounts generously exceeding the standard IV fluid composition. A good starting infusion consists of 5% dextrose in 0.45% NaCl with 40 mEq/L KCl and 80 mEq/L sodium bicarbonate. This mixture can be adjusted, depending on serum laboratory values: sodium, potassium, chloride, bicarbonate,

and glucose should be measured every 6 hours and calcium, phosphorus, magnesium, total protein, albumin, BUN, and creatinine once daily. Aggressive management is advisable to prevent nutritional deterioration with each episode of dehydration. As soon as the dehydration is under control, efforts should turn to increasing caloric intake.

Caloric preparations should follow RDAs: carbohydrates at 60 to 65%, protein at 10 to 15%, and lipids at less than 30%. Caloric intake should aim to achieve weight gain. The formula used to calculate catch-up growth in patients with failure to thrive can serve as a useful initial guideline:

$$\text{Catch-up growth (kcal/kg)} = \frac{120 \text{ kcal/kg} \times \text{median weight for current height}}{\text{current weight (kg)}}$$

Free access to water or other fluids is of great importance because cystinotic patients easily become dehydrated. For example, a water container should be placed at the bedside during the night.

When the patient becomes free of acute gastrointestinal symptoms (no longer having frequent episodes of vomiting, gagging, abdominal pain, or diarrhea) and eats well, a regular diet should be restarted, supplementing individually determined amounts of sodium, potassium, bicarbonate, and phosphate to achieve normal serum levels. Supplementation with the active form of vitamin D and with carnitine if serum total carnitine level is below 20 μmol/L is helpful.[150,151]

If the patient is a poor eater and oral feeding is unsuccessful, high-calorie oral supplementation in the form of shakes, puddings, or Polycose (up to 15 mL added to 30 mL of water [15 mL = 6 g of Polycose; 1 g of Polycose gives 3.8 kcal]) should be given. If the patient fails to take supplements or has an inappropriately low intake because of poor appetite or vomiting, gastric tube placement can be helpful. The decision to use gastric tube feeding needs to be made quickly (within 6 to 8 weeks) so that patients can meet their caloric needs for age without further delay. This permits improvement in linear and ponderal growth, while still allowing daytime oral feeding to the patient's preference. Prior to the placement of a gastric tube, the upper gastrointestinal tract should be evaluated with an upper gastrointestinal series, nuclear medicine studies of gastric emptying, a pH probe, or a combination of these. If severe or complicated reflux is documented, fundoplication should be considered during gastric tube placement.[152]

If a patient already has a gastrostomy tube in place, high-calorie formula (30 kcal/oz) should be resumed slowly after an acute illness, increasing by tolerable increments daily. The choice of formula for cystinotic patients can be divided into three categories, based on the patient's status:

1. For patients with abnormal gastrointestinal tract function, Peptamen, which is an elemental/semi-elemental formula, is appropriate.
2. For patients who are not in renal failure, a high-calorie, moderate-protein formula is recommended, such as Ensure Plus, Sustacal HC, Resource Plus, Nutren 1.5, Comply, Isocal HN, Ensure HN, Isosource, Osmolite HN, or Isosource HN.
3. For patients with constipation or chronic diarrhea, a formula containing fiber is recommended, such as Jevity, Newtrition Isofiber, Enrich, Sustacal with Fiber, or Compleat.[153]

If a cystinotic patient cannot tolerate any form of enteral feeding, TPN is indicated. The hyperalimentation should consist of RDA amounts for protein, carbohydrate, and lipids (see above), supplementing required electrolytes in increasing amounts depending on the patient's serum levels. Frequently monitor serum levels (initially daily, then twice a week, then weekly when the patient is stable) and the patient's weight, adjusting the volume and caloric content. Such patients might need double the volume required for maintenance of normal patients of the same weight. To achieve catch-up growth, the caloric requirements are in general higher than calculated for age.

Chronic Management Chronic management of nutritional needs in the cystinotic child should address the method of feeding (oral, gastric, or jejunal tube or central line hyperalimentation), type of diet, electrolyte supplementation, and medications. Our data[154] suggest that there are gastrointestinal abnormalities even in very young children with cystinosis, although earlier reports have suggested that such problems were found only in older patients.[155] There is at least a subgroup of cystinotic patients who present before age 1 year with severe gastrointestinal involvement manifested by daily episodes of vomiting, poor oral intake and subsequent growth retardation, frequent alternating episodes of diarrhea and constipation, and recurrent abdominal pain with flatulence. Some of these patients have been diagnosed as having swallowing dysfunction and gastrointestinal dysmotility (gastroesophageal reflux, delayed gastric emptying, or episodes of pseudo-obstruction).

Many other patients have not been evaluated, as these symptoms are ascribed to cystinosis and β-mercaptoethylamine therapy itself. In any young cystinosis patient presenting initially with gastrointestinal problems, we strongly advocate early formal evaluation for gastrointestinal dysmotility with pH probe, upper gastrointestinal studies, and manometry followed by a trial of management with gastrointestinal acid production antagonists (H_2 blockers, dyspeptic agents) and gastrointestinal prokinetic agents (metoclopramide, cisapride, erythromycin). We also advocate early consideration of gastric tube placement and initiation of high-calorie formula feeding, optimally overnight for 12 hours while allowing ad libitum feeding during the day.

Cystinosis patients have been found to have predilections for salty and spicy foods, along with specific food texture preferences, which are unique for each patient. They are very picky eaters with poor appetites, who as young children (less than age 2) have cravings for foods such as spicy Mexican food, hot sauce, hot peppers, hot dogs,

American cheese, pizza, popcorn, potato chips, lemon juice, sauerkraut, and pretzels and refuse more nutritious foods. Encouragement to eat well-balanced diets might be unsuccessful and create many unnecessary arguments, leading to total food aversion.

Overnight tube feeding can dramatically improve weight and height gain in these children. When there is severe feeding dysfunction (including strong gagging at the sight of food), aid from a feeding team, which should include a psychotherapist, to evaluate and manage swallowing dysfunction is needed. To teach the child that eating is a social event, it is important to have the child sit with the family at mealtimes and slowly introduce small amounts of food. Gastric tube dependence is common in this group, at least for the first few years. As the patients mature, their feeding dysfunction improves, and with the use of medications and socialization, tapering gastric tube feeding might be feasible. Some parents prefer to retain the tube even after the child's feeding pattern is improved so that it can be used for medications because these patients need to take many different medications that have a bad taste, and gastric tube delivery makes life easier for the child and the family.

There are also a few cystinotic patients with severe gastrointestinal dysmotility who cannot tolerate even gastric tube feeding, despite therapy with many prokinetic agents. These patients need to be carefully managed with IV hyperalimentation for months to years until subsequent trials of gastric or jejunal tube feedings are successful. In our center, we have one patient who required several years of TPN via the central line. Jejunal tube feeding was eventually restarted with the use of epidural anesthesia and IV erythromycin to counteract visceral hyperalgesia and episodes of pseudoobstruction. The patient was gradually weaned off the epidural anesthesia and continued on gastric tube erythromycin therapy, cimetidine, and cisapride.

Indomethacin, a prostaglandin synthetase inhibitor, is reported to have marked beneficial effects on appetite improvement by decreasing polyuria and, subsequently, polydipsia.[156,157] Indomethacin might be a helpful adjunct to nutritional management. Its use should be limited to patients with normal or stable renal function, and the patient should be monitored closely during therapy because indomethacin can lower GFR, although this is reversible by decreasing the dose. Indomethacin can also induce gastritis or stomach ulcers. Because cysteamine is also ulcerogenic, patients begun on indomethacin must be carefully monitored.

NEPHROGENIC DEFECTS IN URINARY CONCENTRATION

In the collecting duct of the renal tubule, antidiuretic hormone binds to receptors in the basolateral cell membrane and leads to an increase in water permeability.[158] Although antidiuretic hormone has effects in other segments of the nephrons, its primary effect is in the collecting duct. A variety of disease processes can lead to lack of responsiveness to antidiuretic hormone. These range from hereditary nephrogenic diabetes insipidus to chronic renal insufficiency and drug effects. Prompt recognition of this type of defect, especially in the neonate with hereditary nephrogenic diabetes insipidus, is very important.

The nutritional issues relating to nephrogenic defects of urinary concentration stem from the solute load needed for growth in the face of an inability to concentrate the urine. For example, a 10 kg infant receiving a standard diet of 30 mOsm for each 100 kcal metabolized will require about 300 mOsm as a minimal solute load. If normal, this infant is likely to produce urine of 600 mOsm/kg water and thus excrete 500 mL of urine per 24 hours. However, if such an infant cannot produce a urine more concentrated than 100 mOsm, the volume needed would be 3 L. An obligate urine volume of this magnitude leads to the need to drink vast quantities of water, leading to inadequate caloric intake. However, a reduction in solute intake can also be difficult to accomplish and still provide adequate calories. For infants, low-solute formula or breast milk should be used. Sodium intake should be kept to a minimum in the older child.

The use of thiazide diuretics can be helpful in decreasing urine volume by as much as 50%, although mechanisms of action remain elusive. It is thought that thiazides work in these conditions by increasing proximal NaCl and water resorption in the proximal tubule, and thus decreasing distal tubular flow. Furthermore, thiazides block resorption of NaCl in cortical diluting segments. Patients taking thiazides for this indication should also reduce sodium intake. Adjunctive medications have included amiloride hydrochloride, especially in lithium-induced polyuria. Nonsteroidal anti-inflammatory drugs, such as indomethacin, suppress renal prostaglandin synthesis and, by as yet unknown mechanisms, decrease polyuria. Because nonsteroidal anti-inflammatory drugs can adversely affect renal function in the face of volume contraction, these agents should be used with care in children with concentrating defects.

CHAPTER 37

INFLAMMATORY BOWEL DISEASE

Rob Heuschkel, MD, MBBS, MRCPCH,
John A. Walker-Smith, MD, FRCP, FRACP, FRCPCH

From the earliest clinical descriptions of children with Crohn's disease, it was clear that significant undernutrition is a major feature of the disease. Furthermore, growth retardation, which may have a nutritional component, is a common clinical manifestation. Although, on occasion, undernutrition and short stature may be a feature of chronic ulcerative colitis (UC) in children, these manifestations are less prominent in this disease.

Early reports of nutritional therapy in children with inflammatory bowel disease (IBD) were thus aimed at the restoration of normal nutrition. More recently, a body of evidence has shown that in children with Crohn's disease, nutritional therapy has a specific anti-inflammatory action in addition to its ability to restore their nutritional status to normal. Unfortunately, there is no such firm evidence in children with UC, yet here also the provision of adequate nutrition still remains important.

The value of nutritional therapy in Crohn's disease chiefly centers on the use of exclusive enteral nutrition in the treatment of active disease. Enteral nutrition may be defined as the provision of a liquid formula diet by mouth or by tube into the gastrointestinal tract.[1] Bottle feeding of normal infants is excluded from this definition. Although it is now clear that oral feeding may be highly effective, research began with liquid formulas administered by intragastric tubes. The technique of tube feeding goes back at least as far as 1872, with a report by Clouston in *The Lancet* on forcible feeding,[2] whereas the work of Widdowson in 1947 drew attention to the adverse effect of malnutrition on human disease in general.[3] The advent of effective parenteral nutrition then made clinicians aware how dramatic the benefits of nutritional rehabilitation from malnutrition could be. The development of a range of complete formula diets of varying compositions, designed for a range of situations, has now made enteral nutrition a highly desirable and practical alternative to parenteral nutrition.

It was Giorgini and colleagues in 1973 who first suggested that treatment of malnutrition could lead to resolution of inflammation in a child with Crohn's disease.[4] They described resolution of terminal ileal inflammation on barium follow-through after a period of elemental diet. In adults with Crohn's disease, Logan and colleagues produced evidence that protein and lymphocyte loss from the gut decreased during feeding with an elemental diet.[5] Then, in Quebec, Morin and colleagues described four children with Crohn's disease whose growth failure responded to an elemental diet,[6] and this was confirmed in larger studies.[7,8] In France, an elemental diet was given to children with Crohn's disease by continuous nasogastric infusion. This was called constant rate enteral alimentation (CREN), but it was a cumbersome technique that was not popular with the children. They used a complex regimen using oligopeptides, whereas others reported the use of a high-osmolality amino acid–based elemental formula. At St. Bartholomew's Hospital in London, a semielemental diet using extensively hydrolyzed milk protein given intragastrically was shown in a small study to be as effective as conventional steroids in the induction of a clinical remission.[9] Most importantly, however, this study showed that there was no short-term growth while the patients were on steroid therapy, whereas enteral nutrition led to short-term growth acceleration. In subsequent follow-up studies, it was shown that this could, on occasion, be sustained for some time if the child remained in remission even when back on a normal diet after the period of nutritional therapy.[10] Central to this approach to therapy was the concept of a period of 6 to 8 weeks of enteral nutrition followed by a graded return to a normal diet.

ROLE OF DIET IN THE ETIOLOGY OF INFLAMMATORY BOWEL DISEASE

The etiology of IBD remains one of the greatest challenges in gastroenterology today. The presence of unexplained gut inflammation has inevitably led researchers to try to identify factors in our diet that may trigger, or even cause, IBD. Although it appears highly likely that there are several environmental factors involved in the etiopathogenesis of IBD,[11,12] the evidence that some of these may be dietary remains tempting.

It was initially suggested that the adoption of an urban lifestyle may lead to an increase in the incidence of IBD, with increases occurring much more rapidly than could be explained by genetic factors alone.[13,14]

Patients with a recent diagnosis of Crohn's disease have been shown to consume greater quantities of sucrose

than control groups,[15] although this was not confirmed in patients with UC.[16] Whether a diet low in fiber leads to an increased risk of Crohn's disease remains in dispute.[17] Many of these studies have had methodologic problems and, as a result, make it difficult to confirm that dietary differences antedated the development of disease. Reif and colleagues, however, again showed that a high level of sucrose intake (> 92 g/day) occurred before symptom onset in patients with both UC and Crohn's disease (odds ratio [OR] = 5.3 and 2.8, respectively); in contrast, fructose and fiber consumption were both negatively associated with a risk for IBD.[18] This carefully controlled study also reported an increase in fat consumption prior to a diagnosis of IBD. These findings were mirrored by Geerling and colleagues, who reported an increased risk of developing UC in those with a high consumption of monounsaturated and polyunsaturated (mainly n-6 polyunsaturated fatty acids) fats as well as vitamin B_6.[19] Overall, these findings suggest nothing more than that a low-residue, highly refined diet is associated with the development of IBD, whereas a high-fiber diet, rich in fruit and vegetables, may be more protective. Large, prospective, epidemiologic studies will be necessary to adequately control for the many confounding variables that could affect this type of data.

Conflicting evidence is also available on the role of butyrate in the pathogenesis of UC. Data suggest that butyrate levels decrease in the distal colon,[20] with the ability of colonic mucosa to use butyrate being reduced even in macroscopically "normal" mucosa of patients with quiescent UC.[21] However, the response of distal UC and so-called diversion colitis to butyrate enemas has not been striking.[22,23] Dietary sulfates have been implicated in reducing the ability of colonocytes to use butyrate by their conversion to toxic sulfides such as H_2S,[24] although luminal levels of sulfides do not appear to be significantly higher in patients with UC than in normal controls.[25] However, along with a putative role of oxidant injury in the pathogenesis of UC, all of these mechanisms appear more likely to be involved as mediators of the injury in UC rather than primary etiologic factors.

It is also of note that researchers have been accumulating evidence over a number of years implicating the food-borne pathogen *Mycobacterium avium* subsp *paratuberculosis* in the pathogenesis of Crohn's disease. Although detailed discussion of this is beyond the scope of this chapter, the presence of this organism in the food chain and its persistence in milk, despite pasteurization, along with the characteristic T helper 1 immune response it evokes, continue to hold interest.[26] However, well-controlled clinical trials have failed to show any benefit of antituberculous therapy.[27] Larger, population-based cohort studies are still needed to better define the importance of this and other specific dietary risk factors.

NUTRITIONAL COMPLICATIONS OF IBD

The chronic and relapsing nature of intestinal inflammation inevitably impacts on a patient's nutritional status. However, nutritional state is determined not only by the dietary intake but also by the patient's age, type of disease, and disease distribution, as well as disease activity. These factors all contribute to the wide range of nutritional complications seen, from almost none in a child with mild distal UC to the most severe nutritional consequences of chronically active disease in a child with panenteric Crohn's disease. Nutritional complications are rarer in children with UC, although a severe pancolitis may present with acute weight loss and significant iron deficiency anemia.

Caloric Deficiency and Growth Failure

The mechanisms surrounding the anorexia and undernutrition seen in IBD are complex and still poorly understood. As well as food avoidance as a result of abdominal pain or diarrhea, the reduction in caloric intake is attributable to the consequences of the systemic inflammatory response.[28] Protein-energy malnutrition may occur as a result of unchecked disease activity, with the associated anorexia being largely mediated by the proinflammatory cytokines interleukin (IL)-1 and tumor necrosis factor (TNF). The activity of these cytokines leads to lean tissue loss,[29] reduced voluntary motor activity,[30] and protein synthesis, with a concomitant increase in protein catabolism.[31] This state of increased need may not be met during active inflammation and thus leads to chronic undernutrition. Protein intakes up to 1.5 g/kg body weight may be required per day to achieve adequate nutrition, with excessive supplementation perhaps even being counterproductive during the acute inflammatory state.[32] Increased protein oxidation and worsening of the nitrogen balance may result if overfeeding occurs during inflammation.[33] Calorie intake in children with Crohn's disease has been reported to be 43 to 82% of recommended values, yet with adequate calorie supplementation, improvements in linear growth can be achieved.[34–36] However, simple nutritional restitution may be insufficient to achieve adequate growth, suggesting that other factors are also important in mediating growth retardation.[37] An elegant study by Azcue and colleagues demonstrated an inappropriately maintained resting energy expenditure (REE) in children with moderately active Crohn's disease when compared with children with anorexia nervosa and similar degrees of malnutrition.[38] This relative increase in energy expenditure, together with the voluntary reduction in intake, further compromises nutritional status and hence optimal growth. Careful animal experiments, which did not look at body composition, suggest that it is the reduced caloric intake that is largely responsible for the weight loss seen in active colitis. However, in this animal study, although able to restore calorie intake and body weight to normal, nutritional supplementation was unable to restore linear growth. At least in this animal model, 30 to 40% of growth impairment is likely to be a direct result of the inflammatory process.[39]

Particularly in children with Crohn's disease, active disease can have a profound and lasting effect on long-term growth,[40] and this is covered in greater detail later in the chapter. Although it is well documented that up to 90% of children with Crohn's disease may present with impaired height velocity,[41] Hildebrand and colleagues also reported

a subnormal growth velocity (< –2 SD) in 24% of prepubertal children with UC compared with 40% in those with Crohn's disease.[42]

Osteoporosis

Owing to the fact that this complication is largely a problem of adult life, it is easy to forget that the accumulation of peak bone mass occurs during adolescence and early adult life. The implications of a substantial interruption in this process are only now becoming clearer as better long-term bone density data are becoming available.

Much attention has focused on trying to tease out the relative importance of the factors that lead to reduction in bone mineral density (BMD) in patients with IBD. As the most important determinants of peak bone mass appear to be age and genetic potential, these confound almost all studies in IBD trying to identify possible predictors such as nutritional status, disease duration, activity and distribution, and steroid therapy. However, despite these shortcomings, it appears that up to 40% of adults with established IBD have osteopenia (T ≤ –1.0; –1 to –2.5 SD from the mean of young adults), whereas around 10% have osteoporosis (T ≤ –2.5; > 2.5 SD from the mean of young adults) when compared with age- and sex-matched controls.[43] The relative importance of disease activity, nutritional status, and cumulative steroid consumption remains debated. A large adult study did identify chronic steroid exposure as the only significant risk factor for the staggering 40% increased risk in osteoporotic fractures in adults with Crohn's disease.[44,45] Furthermore, it appears that BMD is no different to healthy age-matched adult controls within the first 6 months following symptom onset.[46] Interpretation of BMD in the pediatric IBD population remains a problem in the face of significant pubertal and bone age delay.[47] However, up to 30% of children are still likely to have a significantly reduced BMD,[47,48] with children with Crohn's disease tending to be more affected. Overall, therefore, both unchecked inflammation and chronic steroid exposure lead to loss of bone mass.[49]

The impact of nutritional status is unclear as the correlation with BMD may well be confounded by disease activity. Although aggressive nutritional restitution is likely to minimize the chance of nutritionally dependent bone loss, whether supplementation with vitamin D and/or calcium provides added benefits remains to be determined by placebo-controlled studies. Identification of children at greatest risk is important as urinary calcium excretion, plasma 25-hydroxyvitamin D levels, and a baseline bone density scan allow monitoring and subsequent supplementation of documented deficiencies. There is great potential for bone remodeling if children are in good clinical remission. Following presentation with osteoporotic vertebral fractures and in a good nutritional state, a 16-year-old patient with Crohn's disease displayed a dramatic recovery of vertebral height within 3 years of largely steroid-free therapy that controlled his disease activity.[50]

The fact that the consequences of osteoporosis occur so long after the diagnosis of IBD in childhood makes it imperative for pediatricians to be aware of the BMD data now accumulating on adults with IBD. Several larger series are now reporting the clear association with lifetime steroid dose and the increased risk of osteoporotic fractures.[44] An ideal combination may be enteral nutrition and azathioprine or 6-mercaptopurine in the treatment of children with more severe Crohn's disease. It is now clear that treatment regimens minimizing steroid therapy and relying on nutritional therapy or other steroid-sparing agents do not lead to the reduction in BMD seen in patients receiving corticosteroids. Patients with a lifetime steroid exposure of 12.9 g have a significantly lower BMD than normal controls, whereas those with < 2 g lifetime exposure are comparable to age-matched healthy controls.[51] However, it is also clear that osteopenia does occur in steroid-naive patients.[52] Unchecked inflammatory activity may lead to calcium and vitamin D malabsorption, which, in turn, increases parathyroid hormone secretion and further bone resorption.[53] Patients with small bowel disease and/or resections are therefore also at risk of long-term osteoporosis.

Micronutrient Deficiencies

Identifying and treating macro- and micronutrient deficiencies are problematic for two main reasons. There is the initial difficulty of finding an accurate and reliable measure for each specific nutrient deficiency, followed by the inherent variability of a disease characterized by a remitting/relapsing course. There is also the impact of medical therapies and surgical interventions on nutrient status, for example, sulfasalazine inhibiting folate absorption and corticosteroids limiting calcium absorption. Clinically relevant micronutrient deficiencies in patients with IBD are unusual, and most are likely to occur when receiving long-term total parenteral nutrition (TPN).[54] Nonetheless, significant subclinical deficiencies in vitamins and certain trace elements have been reported.

Vitamin B_{12} deficiency occurs most often in patients with active terminal ileal Crohn's disease or following a resection of this part of the intestine. In addition to the usual consequences of these deficiencies, low serum vitamin B_{12} and folate levels may result in an elevation of homocysteine and hence contribute to a hypercoagulable state,[55] with folate supplementation leading to a reduction in homocysteine levels.[56] Patients with IBD are also at risk of developing fat-soluble vitamin deficiency. A significant deficiency of both vitamins A and E has been documented in 16% of children with IBD, with moderate to severe disease activity leading to a deficiency in over 40% of children.[57] Whether this was a consequence of a poor dietary intake or disease activity was not made clear. The range of vitamin deficiencies in patients with long-standing IBD is wide. Two comprehensive studies documented deficiencies in biotin, folate, betacarotene, thiamin, and vitamins A, E, and C in 40 to 90% of adults, despite inactive disease and adequate dietary intakes.[58,59]

Iron deficiency anemia is difficult to diagnose in children with Crohn's disease. Both the anemia of chronic disease and the variability in serum ferritin as part of the acute-phase response make clear guidelines impossible. Low values of serum ferritin (< 15 μg/dL) certainly confirm iron deficiency, but this may also be present at much higher values. Combining the more stable serum transferrin receptor with serum fer-

ritin has been of benefit in adults,[60] whereas a small pediatric study suggested that basic red cell ferritin was a more reliable measure in the presence of inflammation.[61] Variable absorption and the common gastrointestinal adverse effects of oral iron also make the response to treatment difficult to interpret.[62] This, together with the potential exacerbation of colitis by the oxidative stress of oral iron supplementation, has led to successful trials of parenteral iron and erythropoietin use.[63,64]

Trace elements are reduced in up to 50% of patients with active IBD,[59] with zinc deficiency being the most common.[65] The latter has been implicated in the maintenance of intestinal barrier function by regulating tight-junction permeability, with supplementation leading to a reduction in gut permeability in both animal models of colitis and adults with active Crohn's disease.[66]

Many micronutrients are also antioxidants (vitamins A, E, and C and selenium); thus, adequate supplementation may help counteract some of the oxidative stress that contributes to ongoing gut inflammation. Both serum selenium and erythrocyte glutathione peroxidase activity have been inversely correlated to plasma TNF-α levels in patients with active Crohn's disease.[67]

Other Nutritional Consequences of IBD

Patients with long-standing IBD may, of course, also suffer the nutritional consequences of their therapies. Sulfasalazine is most notable for its impact on folate metabolism by competitively inhibiting dihydropteroate reductase, but folate rarely requires supplementation. Patients with severe ileitis or a significant ileal resection may develop steatorrhea, which, in turn, binds available free calcium, thus preventing calcium from binding to oxalate. High concentrations of luminal oxalates may lead to hyperoxaluria and renal calculi.

INDICATIONS FOR NUTRITIONAL TREATMENT

The indications for nutritional intervention differ among the different types of IBD. However, adequate nutritional support is an essential part of the long-term management of any chronic inflammatory disorder. In most cases, this involves the provision of nutritional supplements to complement an otherwise inadequate intake and may involve anything from overnight nasogastric feeds to long-term support on home parenteral nutrition. For UC, no exclusively nutritional therapy has been shown to be therapeutically effective. In contrast, over many years, patients with active Crohn's disease have responded well to exclusive enteral nutrition. There have only been anecdotal reports of patients with indeterminate colitis responding to exclusive enteral nutrition, although the responders are likely to be those with a more Crohn's disease–like phenotype.

Ulcerative Colitis

There have been no studies showing that any form of nutritional intervention, used as sole therapy, can induce a remission in patients with active UC. Two randomized, prospective studies clearly showed that there was no role for exclusive TPN and bowel rest in the management of acute UC.[68,69] Although there were some nutritional advantages in the group on TPN, these were outweighed by the complications reported at the time.

Although often not as severe as in patients with Crohn's disease, malnutrition does occur in children with UC.[70] However, although exclusively nutritional therapies are of no benefit in treating acute UC, nutritional support plays a vital role in minimizing further morbidity. Up to 10% of children with UC present with weight and height z scores ≤ -2,[71] and, inevitably, nutrition is compromised in acute disease, both by a reduced oral intake and by increased losses of both protein and blood from the gut mucosa.[72] Although the concept of continuing enteral feeds during an episode of acute colitis may raise concerns in some, the evidence clearly suggests that equal nutritional improvement occurs with TPN and total enteral nutrition in active colitis.[73] Not only does the latter lead to fewer complications, it is also less costly, more physiologic, and much simpler to provide. However, there continue to be absolute contraindications to enteral nutrition (Table 37-1).

Although dietary supplementation plays a role in acute UC, there is no evidence that specific dietary exclusions are of benefit in the long term. Well-balanced, healthy diets that include normal amounts of dietary fiber are to be encouraged. Short-term studies suggest improved gastrointestinal symptoms on isphaghula husk,[74] although initial data that suggested that diets low in fiber were linked to an increased risk of colon cancer have now been refuted in large epidemiologic surveys in women.[75]

Crohn's Disease

In children with Crohn's disease, there are several reasons for nutritional intervention (Table 37-2).

Exclusive Enteral Nutrition Exclusive enteral nutrition is indicated as a first-line therapy in any child with acute Crohn's disease, provided that there are no absolute contraindications to enteral nutrition per se. The issue of whether enteral nutrition is as effective as steroid therapy at inducing a remission has been hotly debated for some time. However, what is clear from the pediatric literature over the last 20 years is that an exclusively nutritional therapy can be highly effective at inducing a remission from active disease.[76–78] The best results appear to be in those children with newly diagnosed disease,[79] although the pediatric evidence does remain limited in terms of the number of children reported. Large adult studies,[80,81] as well as some of the smaller pediatric studies,[78] suggest that disease distribution does not affect the efficacy of the treatment. Colonic disease appears to respond as well as terminal ileal disease, with a

Supplemental enteral nutrition for maintenance of disease remission
Nutritional support to maintain adequate weight gain
Dietary supplementation of specific vitamins/minerals

similar reduction in inflammatory markers, disease activity, and improved mucosal histology.[77] More recent retrospective data, however, suggest that clinical remission with isolated colonic disease may only be about 50%, compared with about 75 to 80% in the presence of any macroscopic ileal involvement.[82] Although there is only anecdotal evidence on the response of oral and perianal Crohn's disease to exclusive enteral nutrition,[83] the authors have made use of exclusive enteral nutrition as an adjunct in treating severe perianal Crohn's disease.

Adverse effects to using exclusive enteral nutrition in Crohn's disease are very rare. However, we reported a case of refeeding syndrome in a child following her presentation with severe Crohn's colitis. A rapid loss of weight over the preceding 4 weeks, followed by treatment with exclusive polymeric nutrition, led to a dramatic fall in serum phosphate and signs of hypervolemia in the first few days of treatment.[84] It is important to remain aware of this complication when refeeding previously malnourished children with Crohn's disease as adequate supplementation in the first few days can prevent serious complications.

Perioperative Nutritional Support Preoperative undernutrition has long been known to adversely affect surgical outcome. Although surgical outcome is related to the nutritional state of the patient,[85] short-term preoperative use of TPN is insufficient to dramatically improve the nutritional status. Even 7 to 10 days of preoperative parenteral nutrition in malnourished "cancer" patients achieved only a 10% reduction in postoperative complications.[86] Parenteral nutrition may replace acute nutritional deficits in the immediate perioperative period and may also reduce the length of small bowel resection in adults with Crohn's disease.[87,88] Uncontrolled studies in adults with IBD also suggest that there is a reduction in postoperative complications following preoperative parenteral nutrition,[89] yet it appears most effective in patients with severe malnutrition and highly active disease.[90]

Improvements in the medical management of children with IBD are likely to continue reducing the need for surgery, yet recent studies still suggest that almost 60% of adults with Crohn's disease will require an operation.[91] Older pediatric data showed that up to 80% of children with Crohn's disease were needing surgery in the 15 years following diagnosis.[92] Emergency surgery may be unavoidable in a small number of children who present with fulminant colitis; however, the majority will require surgery for treatment-resistant disease.

Although children with acute, severe UC will require close monitoring of fluid and electrolytes in the perioperative period, they are less likely to have had a long period of active disease leading to chronic malnutrition.

Despite persistently active, treatment-resistant disease, surgery can often be planned some weeks in advance. In these circumstances, optimizing nutrition over a period of 4 to 6 weeks is likely to result in a much better postoperative course. Provided that inflammatory activity and symptoms allow, several weeks of exclusive enteral nutrition in children with severe Crohn's disease can lead to nutritional restitution prior to surgery. In isolated cases, the use of TPN for several weeks may also be justified in preparation for surgery if enteral access is impossible. However, clinicians can be forced to compromise in the face of severe treatment-resistant disease, for which disease activity does not allow time for any improvement in nutritional state, and surgery should then not be delayed.

Postoperative support for all children, irrespective of the type of abdominal/perianal surgery, should involve institution of enteral feeds as soon as possible. Adult evidence demonstrates no increase in complications when patients are fed enterally within 48 hours of colectomy.[93] Very early use of enteral supplements reduces early postoperative complications even in undernourished adults and leads to a better weight gain, as well as an improvement in physical and mental quality of life.[94] Routine use of postoperative TPN in well-nourished patients should be discouraged as it increases complication rates.[95] However, provision for TPN should still be made if enteral feeding is likely to be delayed for more than 1 to 3 days in any undernourished child who is likely to suffer a long convalescence without achieving full enteral feeds.

NUTRITIONAL TREATMENT OF ACTIVE CROHN'S DISEASE

In severe malnutrition, there is clear evidence of a secondary immune dysregulation.[96] Both T cell numbers and secretory immunoglobulin A levels are consistently reduced, and there are also defects in bacterial phagocytosis, lysozyme, and interferon (IFN) production. Although today's children with Crohn's disease are not often severely malnourished, they are certainly well below their expected percentile for weight.[97] It is therefore quite clear that this degree of malnutrition does little to attenuate tissue damaging immune responses.

Parenteral Nutrition

The advent of parenteral nutrition in the early 1970s proved useful in managing intractable cases of Crohn's disease,[98] and its use became more widespread as an alternative primary therapy for severe disease.[99] As would later be clearly demonstrated for enteral nutrition,[40] it was parenteral nutrition that was first shown to reverse growth failure in children and adolescents with active Crohn's disease.[35,100] However, as awareness of the septic and thrombotic complications associated with an indwelling line increased, the use of parenteral nutrition in Crohn's disease declined. Although it still appears to be as effective as elemental nutrition in the short-term treatment of acute disease,[101] its complications, practical difficulties, and

expense limit its use. Furthermore, TPN induces mucosal atrophy and increases bacterial translocation,[102] something that is entirely preventable by luminal nutrition.

The combination of intravenous nutritional support and complete bowel rest has not been shown to be more effective in treating active disease than either exclusive enteral nutrition or TPN with oral feeding.[103] In a controlled study, 58 to 71% of all groups achieved a clinical remission, indicating that bowel rest per se has no added effect on the disease but that improved nutrition in any form has clinical benefit. However, there have also been a number of case series suggesting that exclusive parenteral nutrition may be of significant benefit in severe Crohn's colitis,[87] with at least one study documenting endoscopic healing of mucosal ulcers on exclusive parenteral nutrition.[104] Despite this, the preference for nutritional support in most cases remains an enteral feed.

There has been limited success (35%) in achieving fistula closure on exclusive TPN,[105] with any improvement not being sustained once the patient is back on a normal diet. In view of other therapies, such as octreotide and anti-TNF-α antibody, TPN now has only a very limited role in the management of these fistulae.

Children only rarely have bowel resections large enough to require long-term home parenteral nutrition support. However, if in adults less than 100 cm of jejunum or less than 50 cm of small bowel with an intact colon remain, long-term parenteral nutrition is often necessary.[106] Yet over 70% of these patients will be on a full oral diet within 12 months of starting home parenteral nutrition.[107]

Enteral Nutrition

Elemental Diet An elemental feed is a chemically defined diet whose protein source is amino acids or short-chain peptides, with short-chain carbohydrates and added fat, minerals, and vitamins. The National Aeronautics and Space Administration (NASA) had initially designed elemental diets for astronauts.[108] This was with the intention of providing a nutritionally complete diet of which as much as possible would be absorbed. However, although absorption was limited mainly to the upper small bowel, the diet did not prevent the production of stool, as had been hoped.

Nutrition was initially used in IBD as an adjunct in malnourished patients with growth failure. Elemental diets were developed and first used as sole therapy for IBD in adults in the 1970s.[109] It was then shown that nutrition had a beneficial effect on disease by reducing the increased gut permeability characteristic of Crohn's disease.[5] Logan and colleagues studied seven adults with extensive jejunoileal Crohn's disease.[5] They showed a reduction in both gut protein and gut lymphocyte loss during a period of elemental feeding. This was the first report demonstrating that an elemental diet could directly improve gut function, probably by reducing bowel inflammation.

In 1973, Giorgini and colleagues reported the first successful use of enteral nutrition in treating a child with acute Crohn's disease.[4] It was then shown that enteral nutrition was effective in treating a series of children with Crohn's disease. Successful use in combination with drug therapy led to a further study by the same group, which first showed exclusive CREN to be as effective as steroid therapy in inducing a remission.[110] Although both of these studies had few patients, they gave the first insights into the possible benefits of nutritional therapy as treatment for childhood Crohn's disease. In addition to achieving disease remission, nutritional therapy was also found to have beneficial effects on inflammatory masses and fistulae.[6,110] Simultaneously, both Morin and colleagues and O'Morain documented that an elemental diet improved linear growth in several children with active Crohn's disease.[6,111]

A variety of devices, formulas, and regimens were then used to feed patients intragastrically. Continuous feeding and then overnight feeds predominated for the induction of remission.[7–9] Supplementation of an elemental diet with glutamine, a gut-specific metabolic fuel, did not further improve efficacy, although the small numbers in this study make conclusions difficult. [112]

Semielemental Diet Once elemental diets had achieved their first successes, short-chain peptide–containing diets were suggested as a better nitrogen source than amino acids.[113] Silk and colleagues refuted previous evidence that free amino acids were better absorbed than di- and tripeptides.[113] By using an intestinal perfusion technique in adults, they were able to demonstrate better absorption of amino acids from both casein and lactalbumin hydrolysates than from an equimolar feed of free amino acids. Not only was there a more uniform absorption of amino acids, but the hydrolysates had a beneficial effect on jejunal absorption of water and electrolytes. There followed the first small randomized study of seven to eight children in each group, in which overnight nasogastric feeding of a semielemental diet was compared to prednisolone treatment in children with predominant small-bowel Crohn's disease.[9] A four- to five-chain amino acid–based diet was as effective as steroids at achieving a remission in active Crohn's disease. It again confirmed the North American finding that there was a clear acceleration in growth in the group not taking steroids.[6]

Polymeric Diet It therefore appeared that steroids may have an efficacy similar to semielemental feeds in the induction of remission. Several adult studies reported the efficacy of a whole-protein diet compared with both that of elemental diets and steroids. Raouf and colleagues and others all found polymeric diets to be as effective as an elemental diet in inducing remission.[114–117]

Polymeric diets were also shown to be as effective as conventional steroid treatment. Gonzalez-Huix and colleagues confirmed this in adults and Ruuska and colleagues and Beattie and colleagues in children.[76,78,118] Ruuska and colleagues, in a well-planned but small study (N = 19), showed a polymeric diet to be as effective as steroids in inducing a remission in children with acute Crohn's disease.[78] A further great advantage in using a polymeric diet then became clear. Although almost all children previously required feeding by intragastric tube,

whole-protein formulas such as AL110 (Nestlé-Clintec), used by Beattie and colleagues,[76] and Nutrison Standard (Nutricia, Finland), used by Ruuska and colleagues,[78] were palatable enough for daily oral consumption. Children rarely required a nasogastric tube to complete their entire nutritional needs. This provided a considerable improvement in the quality of life for children on several weeks of nutritional therapy.

The most recent and most definitive cohort study to date, by Fell and colleagues,[77] shows that a whole-casein, polymeric diet (Modulen IBD, Nestlé Clinical Nutrition), rich in transforming growth factor (TGF)-β, is well tolerated and achieves a clinical and histologic remission. Twenty-nine consecutive patients were treated with the exclusive enteral diet for an 8-week period. Although over half had mild disease, 12 had moderate to severe disease with a pediatric Crohn's disease activity index (PCDAI) > 30.[119] A nasogastric tube was required only in one patient for the first 2 weeks of treatment. Only 2 of 29 patients failed to show any clinical response, one with severe colonic disease and the other with an inflammatory mass requiring surgery. Twenty-three of 29 patients achieved a complete remission on PCDAI scoring. The PCDAI fell dramatically within 2 weeks of starting the diet but continued to fall until 8 weeks of treatment. There was significant macroscopic and histologic improvement after treatment, with mucosal healing occurring in the terminal ileum and colon of 8 and 2 patients, respectively. Serum TNF-α and mucosal messenger ribonucleic acid (mRNA) for IL-1β and IL-8 were significantly reduced in both the terminal ileum and the colon after treatment. IFN-γ was significantly reduced and TGF-β was elevated in the terminal ileum alone. There is no direct evidence that the TGF-β in the enteral formula is responsible for the up-regulation of mucosal TGF-β. Nonetheless, this study strengthens the findings by Breese and colleagues that polymeric enteral nutrition alone can achieve an improvement in histology and a complete normalization of some of the mucosal mRNA of proinflammatory cytokines involved in tissue damage.[120]

The lipid composition of some polymeric diets has been held responsible for some of the variability in their efficacy.[121] High long-chain triglyceride concentrations have been associated with a poorer response in treating active Crohn's disease, with suggestions that the high linoleic acid concentration may be responsible,[122] although high concentrations of medium-chain triglyceride in the feed do not affect its short-term efficacy.[123] However, the only two randomized studies have been unable to show a difference in efficacy between formulas containing either low or high amounts of long-chain triglyceride.[124] Only one randomized study appeared to show a significant difference in remission rates depending on the fatty acid composition of the polymeric feeds. Gassull and colleagues reported a significantly better clinical remission rate in adults after 4 weeks of an exclusive enteral feed rich in n-6 fatty acids compared with one high in monounsaturated fats (52% versus 20%, respectively).[121] Why this conflicts with previous evidence remains unclear,[114] although the high percentage of synthetic oleate (79% of total fat) in this study may mask beneficial effects previously seen with formulas containing different fatty acid profiles.

There is limited evidence of milk intolerance in adults with active Crohn's disease. True lactase deficiency is an unusual cause of symptoms in adults with active Crohn's disease[125]; however, up to 46% complained of gastrointestinal symptoms related to milk intake. In contrast, exclusive enteral feeding with lactose-free, whole-casein diets has not been associated with intolerance in children with active disease.

Steroids versus Enteral Nutrition Contrary to these striking pediatric findings, large adult trials and meta-analyses of the adult data have found steroids to be more effective than enteral nutrition at inducing remission in active Crohn's disease.[80,81,115,126] The meta-analysis by Griffiths and colleagues, although including both children and adults, excluded most of the smaller pediatric studies.[126] This large review ($N = 413$) reported that steroids were significantly more effective in achieving a remission than enteral diets (OR = 0.35, 95% confidence interval = 0.32 to 0.58). Like other analyses, this study also relied on clinical disease activity indices to document clinical remission rates, but these tended to favor steroid therapy by their reliance on a patient's general feeling of well-being. As a result, conclusions from these studies are frequently and inappropriately applied to children, despite there being clear differences between adult and pediatric patients. Most children have had much shorter disease duration and tend to be much more compliant with therapy. Furthermore, no comment is made on the differing adverse effects and abilities of the two treatments to heal gut mucosa, with steroids having been well documented to have limited effects on gut inflammation.[127] As yet, no analysis has detected a significant difference in efficacy between elemental or polymeric diets.[128]

Despite the several small pediatric studies that suggest a useful role for enteral nutrition in active Crohn's disease, the view has thus prevailed that enteral nutrition is less effective than steroid therapy. A meta-analysis of pediatric data was performed to maximize the available pediatric data.[129] Despite limited numbers of truly randomized children, sensitivity analyses allowed the authors to arrive at valid and important conclusions. The summary data clearly showed enteral nutrition to be as effective as steroids in the treatment of children with active Crohn's disease. Furthermore, to overturn this finding and demonstrate that steroids were significantly more effective than enteral nutrition would be close to impossible given the outcomes of the pediatric studies reported to date. All of these studies principally address efficacy as their primary outcome measure, largely ignoring the very different side-effect profiles of each therapy. Corticosteroids have many significant adverse effects, whereas oral enteral nutrition has almost none.

Enteral Nutrition and Crohn's Colitis There remains the further question of whether enteral nutrition is less effective at treating Crohn's colitis than Crohn's ileitis. Early use

of enteral feed was limited to children with predominantly small bowel disease,[130] with a suggestion that colonic disease was unresponsive to nutritional management.[131] More recent evidence from Thomas and colleagues, Ruuska and colleagues, and Fell and colleagues, however, supports the value of nutritional therapy in large bowel and small bowel disease.[77,78,132] The improvement in colonic mucosal cytokine profiles after enteral nutrition provides hard evidence that there is an effect on colonic disease.[77] Larger studies in adults also confirm that disease location does not appear to influence the response to treatment.[80,126,133]

However, a more recent retrospective analysis of 60 children treated with exclusive enteral nutrition suggested that disease distribution may be relevant in the response to nutritional therapy. Children with any macroscopic ileal inflammation were significantly more likely to achieve a clinical remission than those children with colonic involvement alone (75% versus 50%).[82] Despite this, many individuals with Crohn's colitis continue to respond extremely well, still making exclusive enteral nutrition the first choice for any child with Crohn's disease, irrespective of their disease distribution.

Food Reintroduction

There has long been uncertainty as to the best way of reintroducing adults and children to their "normal" diet after a period of exclusive enteral nutrition. The evidence for any of these different practices is very limited, with most approaches having been selected by experienced clinicians on the basis of theories prevalent at the time.

The best-described reintroduction program is based on the stepwise introduction foods, starting with the least allergenic.[134] One new food is introduced every 48 hours and, if not tolerated, reintroduced at the end of the program. This systematic but quite laborious program not only allows individual foods to be identified if causing immediate symptoms but also gives the patients several more weeks on reasonable quantities of enteral nutrition while their normal diet is re-established. The most frequently implicated foods causing discomfort in adults are cereals, dairy products, and yeast,[134] although in children only a very small minority require exclusion of specific items from their diet. In a 2-year follow-up study of about 100 adults, the relapse rate was only just significantly lower in the group excluding dietary products that caused symptoms compared with those maintaining a normal diet ($p = .048$). However, in a randomized controlled trial of an exclusion diet following a remission induced with an elemental diet, subsequent rechallenge and double-blinded challenges in adults with Crohn's disease proved that specific dietary exclusions did not persist.[135] There is thus insufficient evidence to routinely suggest exclusion of specific food items in children with Crohn's disease.

Other units use less evidence-based but more practical reintroduction programs, which range from the immediate introduction of a full diet to a graded introduction over 3 weeks, with the ad libitum diet increasing by 25% each week, along with the simultaneous reduction in enteral nutrition.

ENTERAL NUTRITION AS MAINTENANCE THERAPY IN CROHN'S DISEASE

There has been much interest in whether dietary modification may prolong a remission in Crohn's disease.

Initial studies suggested that intermittent use of exclusive enteral nutrition for 1 month in every 4 could not only reduce steroid requirement and reduce disease activity but could also increase the long-term growth rate in children with Crohn's disease.[136] Although this intermittent use of exclusive enteral nutrition may have had a role in managing patients with otherwise intractable disease and a previous good response to enteral nutrition, repeated and prolonged use of exclusive enteral diets in most adolescents is difficult and mostly unnecessary. Given the availability of other, currently more effective maintenance agents, compliance with supplements of enteral nutrition is likely to be much greater if these can be shown to be effective.

Low-residue diets are not indicated in the maintenance of remission in Crohn's disease. Unless required as a dietary modification in the presence of fibrosing/stricturing disease, they have not been shown to prevent disease relapse.[137]

A retrospective study in which a normal ad libitum diet of children with Crohn's disease was supplemented with an additional 30% of the recommended daily calorie intake as polymeric feed led to the halving of relapse rates within the first 12 months.[138] Small controlled studies also suggest an advantage to simple long-term calorie supplementation per se,[139] although larger, more definitive studies are still awaited. However, it is highly likely that a long-term nutritional supplement, in combination with a well-tolerated immunosuppressant, will provide the optimal maintenance therapy for most children with moderate to severe Crohn's disease.

Attempts at supplementing diets with specific anti-inflammatory agents continue, with fish oils receiving particular attention. Their effects on reducing mucosal eicosanoids (particularly leukotriene B_4 and thromboxane A_2) have been widely reported.[140] The n-3 fatty acids present in fish oils may also inhibit IL-1β and TNF production.[141] In addition, they also decrease platelet responsiveness and thus may act to reduce the multifocal gastrointestinal infarctions that have been reported as early pathogenic steps of Crohn's disease.[142,143] Several large placebo-controlled randomized studies have been performed on adults with both Crohn's disease and UC,[144;145] but, unfortunately, many of the data remain conflicting. Although different methodology makes generalizations difficult, several important issues are raised. Although low-dose regimens cause no appreciable adverse effects,[146] compliance with high-dose fish oils in adults is poor, making long-term maintenance therapy in children even less attractive. Belluzzi and colleagues found that supplementation with 2.7 g of n-3 fatty acids reduced the relapse rate in adults with Crohn's disease,[144] whereas another large study failed to confirm any benefit over placebo in using either > 5 g/day of n-3 fatty acids or maintaining a diet low in carbohydrate (84 g/day).[145] However, despite no clear-cut clinical benefits, significant changes are reported on a mucosal

level. Colonic inflammatory cell infiltrates are reduced and the synthesis of leukotriene B_4 and thromboxane A_2 is downregulated after supplementation with n-3 fatty acids.[145] It may therefore be that further refining of the composition, formulation, and dose is required before fish oil supplements become an accepted part of maintenance therapy.

Other, more specific dietary interventions have been reported to prolong remission in Crohn's disease. Although none of these have been assessed in larger, placebo-controlled studies, they offer interesting clues to the role dietary modification may play in maintaining disease remission. A small study randomizing patients to a diet low in microparticles suggested significant benefits in disease activity and remission rates after 4 months when compared with 10 patients on a normal diet.[147] Diets low in refined sugars have not been found to prevent relapse rates in adults with Crohn's disease.[148] Similarly, the presence of yeast in the diet of patients with Crohn's disease may potentiate disease relapse, but larger studies are necessary before firm conclusions may be drawn.[149]

As the importance of gut microflora in the etiology of IBD is increasingly recognized, so has the prospect of modulating it by means of "functional foods" gained much support. Although discussion is beyond the scope of this chapter, the mechanisms of action and potential implications of this exciting new field are great for patients with chronic intestinal disease driven by enteric flora. It is quite clear that, over the next few years, we are likely to see larger, placebo-controlled trials of both pro- and prebiotics. Prebiotics are the complex sugars such as fructo-oligosaccharides and inulin, which pass into the colon undigested, where they may be selectively fermented by certain probiotic species.[150] Attempts to maintain remission in both UC and pouchitis with combined probiotic combinations have proved quite successful,[151] although *Lactobacillus GG* alone may have a role in improving gut barrier function and clinical status in children with Crohn's disease.[152]

If long-term nutritional support is required, most children will tolerate a more palatable polymeric formula by mouth. However, some children will require supplementation by tube. Although short-term support can be given via a nasogastric tube, longer-term needs should be met via a more permanent device. Where nutritional support is needed for several months, placement of a percutaneous endoscopic gastrostomy (PEG) is ideal. Despite initial reservations about possible complications from the formation of fistulous tracts, PEG placement has now been documented to be uncomplicated in selected adults and children with IBD.[153] In patients receiving corticosteroids, adhesion of the gastric to the abdominal wall may be delayed; thus, early "pulling" of the PEG could lead to tract disruption.

ROLE OF ENTERAL NUTRITION ON GROWTH AND DEVELOPMENT

Epidemiology of Growth Failure

After the onset of symptoms but before a diagnosis of Crohn's disease is made, up to 46% of children will have a reduced height velocity, with only 12% having a normal height velocity up to the time of diagnosis.[41] In contrast, only 3 to 10% of children with UC may present with reduced height velocities at diagnosis.[42] Although many of these data are now over 10 years old, and an accurate diagnosis may now be made more quickly, it is clear that untreated Crohn's disease has profound implications on a child's growth potential. Motil and colleagues reported in a cross-sectional study of their pediatric IBD patients that 23% had a z score < –1.64, with 50% of these having a bone age delayed by > 1 year over their chronologic age.[151] Physicians caring for children with IBD, particularly Crohn's disease, therefore have the unique opportunity to try and modify the impact that both disease and therapy have on the growth rate of their patients.

A delay in presentation is associated with a significantly greater degree of growth impairment at diagnosis.[71] Despite management within tertiary centers, 49 to 65% of children with Crohn's disease have a reduced height velocity in early puberty, with growth velocity remaining less than 4 cm/year during the first 1 to 2 years of therapy.[42,154] Hildebrand and colleagues reported a mean z score for height of –0.6 2 years after diagnosis in 46 consecutive children with Crohn's disease.[42] Griffiths and colleagues reported that of 67 consecutively diagnosed children with Crohn's disease followed to maturity, about two-thirds maintained or increased their z scores for height.[155]

The outcome of many of these studies reflects management in which the mainstay of therapy was often corticosteroids and so does not include the more recent move to the earlier use of steroid-sparing agents.

Etiology of Growth Failure

The growth failure seen in children with IBD is multifactorial, with inflammation, undernutrition, and steroid therapy being its principal determinants.

Initial evidence suggested that chronic undernutrition was the main factor in the growth failure seen in children with IBD,[35] with studies confirming that simple nutritional restitution improved the linear growth of children with Crohn's disease.[34,36] Children with active Crohn's disease have a relative insufficiency of dietary intake when compared with children of the same age,[132] although they may compensate with an increased intake between disease relapses.[154] However, simply increasing the calorie intake, as seen in patients on steroids, does not confer the same benefit on growth as a lower calorie intake received on exclusive enteral nutrition.[132] The presence of low levels of insulin-like growth factor I (IGF-I) in children with active Crohn's disease strengthens this association as the relationship between IGF-I and malnutrition is now clear.[156] Both IGF-I and its carrier protein, IGF binding protein 3, are increased significantly by treatment with exclusive enteral nutrition.[157,158] Further evidence that inflammation, not only nutritional factors, plays a role in determining growth can be seen in studies of children undergoing surgery for active IBD. Although postoperative catch-up growth is not documented by all authors, several authors show a clear growth spurt occurring after the removal of an

inflamed segment of bowel.[159] Although this is most striking in prepubertal children, the benefit is still substantial if surgery is carried out before the final stages of puberty.[160] This response may, of course, in part be the result of improved postoperative nutrition. However, Varille and colleagues neatly documented that even children undergoing localized resections for stricturing disease had a significant reduction in REE and an increase in nitrogen use 4 weeks after surgery, despite maintaining preoperative nutritional and steroid regimens.[161]

There now seems little doubt that ongoing inflammatory activity plays a key role in the inhibition of growth.[162] Down-regulation of proinflammatory cytokines by enteral nutrition may partly improve growth by reducing IL-6, a potent inhibitor of IGF-I. [163] There is a dramatic reduction in C-reactive protein, with a concomitant increase in IGF-I and IGF binding protein 3, within 14 days of commencing exclusive enteral nutrition.[76,77] This clearly indicates that enteral nutrition also has a more rapid, direct anti-inflammatory action in addition to its longer-term nutritional benefits. As has been confirmed in children with rheumatoid arthritis, systemic inflammation, as well as malnutrition, reduces IGF-I.[164] Direct inhibitory effects of proinflammatory cytokines such as TNF-α on developing growth plates and a down-regulation of IGF-I by IL-6 are both likely to contribute to growth retardation.[165,166] The additional suppression of appetite by TNF-α, the failure to down-regulate the REE during malnutrition in Crohn's disease, and the exacerbation of bowel symptoms by food intake all add to the final reduction in height velocity.[38,167]

Enteric losses during active disease can also contribute to the decline in nutritional state. Children with small bowel Crohn's disease have varying degrees of malabsorption, with some of the hypoalbuminemia occurring as a result of enteric losses.[168] The most important determinant of hypoalbuminemia is the systemic inflammatory response. Although protein loss through an inflamed mucosa does occur, it is usually modest and nonspecific and occurs in association with loss of globulins. The hypoalbuminemia seen in Crohn's disease is more frequently associated with the hypergammaglobulinemia occurring as a result of the acute-phase protein synthesis. The latter is principally mediated by IL-6.[169] Furthermore, a sustained protein intake of less than 0.4 g/kg/day is necessary to achieve any reduction in serum albumin.[170]

Bile acid malabsorption may occur not only in children with active terminal ileitis as systemic effects of ileal inflammation may lead to malabsorption in the proximal small bowel.[171] As a result, fat malabsorption may occur in some children with Crohn's disease. In addition, low concentrations of vitamins A and E and zinc have been shown to correlate more with disease activity than nutritional state,[57,172] suggesting that depletion occurs during the acute inflammation rather than as a result of chronic malabsorption.

Ongoing growth failure in the first years after diagnosis may be attributable to several factors. Growth velocity can be delayed well beyond nutritional restitution and normalization of inflammatory indices. This, together with the frequent use of high-dose steroids to achieve the initial remission, up to 85% of children in some studies,[152,173] may arrest normal growth for many months after diagnosis. However, the most recent data suggest that it is neither the disease distribution nor the pubertal stage at diagnosis that determines final adult height but rather the use of corticosteroids during puberty.[174] Children who were diagnosed with Crohn's disease during puberty and were treated with corticosteroids were significantly shorter as adults when compared with those who did not receive corticosteroids. In this study, this was the only independent predictor of final adult height.

Nutritional Treatment of Growth Failure

Over 20 years ago, several small studies confirmed the central role of nutrition in the long-term management of growth failure in children with IBD. Motil and colleagues concluded that neither low-grade chronic inflammation nor low-dose corticosteroid use reduced whole-body protein synthesis and that it was adequate dietary supplementation that led to a significant increase in growth velocity of children with growth failure.[175,176] This was confirmed by others as nutritional therapies became more practical for the treatment of acute Crohn's disease.[6,34] Sanderson and colleagues were the first to establish the benefit of enteral nutrition over steroid therapy on short-term growth in children with newly diagnosed Crohn's disease.[9]

MECHANISM OF ENTERAL NUTRITION

Despite the wealth of information that exists about the benefits of enteral nutrition, the mechanisms of action remain largely unclear (Table 37-3).

The most frequently advanced theory is that the bacterial flora within the gut lumen is modified by enteral nutrition. The clinical evidence of any difference in flora between patients with Crohn's disease and normal controls remains slim. It was shown in the late 1970s that there are higher bacterial counts within the terminal ileum of patients with active disease.[177] Studies at that time also suggested a reduction in fecal flora after enteral nutrition.[178] It is now clear that increasing severity of systemic disease is associated with an increase in the adherence of fecal bacteria to the enterocytes,[179] and this does not appear to be related to the degree of local mucosal inflammation. The response of acute Crohn's disease to antibiotic therapy further implicates the bacterial flora in the disease pathogenesis,[180] although antibiotics such as the quinolones and metronidazole have other immunomodulatory effects in addition to their antimicrobial actions.[181] The organisms that appear to be increased in the lumen of patients with Crohn's disease include *Bacteroides*, *Eubacterium*, and *Peptostreptococcus*.[182] Elegant work on mice that develop spontaneous colitis (T-cell receptor α knockout) has confirmed that feeding with an elemental diet prevents bowel inflammation.[183] Unlike the mice fed the elemental diet, the mice that are fed regular chow and then develop colitis are colonized by *Bacteroides vulgatus* in > 80% of cases. Furthermore, instilling this strain into the rectum of the elementally fed mice led to development of a

typical T helper 2–type T cell–induced colitis. Further animal work has shown that an elemental diet may reduce the progression of granulomatous enteritis by modulating the activation of T cells, the production of nitric oxide, and the generation of oxygen free radicals.[184,185]

The reduction in antigenic load that accompanies exclusive enteral nutrition may also contribute, at least in part, to bowel rest. However, a whole-protein diet, and even an ad libitum diet together with some parenteral nutrition, appears to be as effective as an exclusive elemental diet at inducing a remission.[76-78,103] The efficacy of polymeric diets and recent evidence that dietary supplementation with enteral nutrition may prolong a remission both suggest that reducing luminal antigens may play only a modest role in the efficacy of this therapy.[135]

Whether enteral nutrition per se has a direct and/or indirect immunoregulatory effect remains speculative. Degrees of moderate protein malnutrition have been associated with poor immune function. In rodents, protein deprivation leads to impairment of the mucosal immune response, as well as depletion of a population of T cells that control oral tolerance.[185,186] This would suggest that poor nutrition inhibits T cells that down-regulate the gut's response to foreign antigens. Enteral feeding may therefore have an indirect effect on the immune response by restoring an adequate nutritional status.

More recently, the direct influence of luminal content on immune function has been studied. Sanderson provided evidence that luminal content can influence epithelial cell gene expression within the gut.[187] Short-chain fatty acids, such as butyrate, are bacterial metabolites from unabsorbed carbohydrates. Butyrate induces secretion of IGF binding proteins by a complex process involving histone deacetylation.[188] Butyrate has also been shown to potentiate the secretion of IL-8 by intestinal epithelial cells (Caco-2) if these are stimulated with either lipopolysaccharide or IL-1β. Lipopolysaccharide was able to induce IL-8 secretion only if these cells were preincubated with butyrate, implying direct effects of the latter on gene regulation.[189] Epithelial cell gene regulation by luminal products thus appears to be able to influence intestinal inflammation through release of inflammatory cytokines. Up-regulation of the chemokine macrophage inflammatory protein 2 increases local neutrophil recruitment.[190]

It has also been suggested that the presence, or absence, of individual components of enteral feeds is important in immune regulation. The putative advantage of high TGF-β levels in both AL110 and CT3211 (~ 24 ppm) is based on the large body of experimental evidence that this cytokine has the ability to down-regulate other proinflammatory cytokines.[191] Fell and colleagues demonstrated mucosal up-regulation of TGF-β within the terminal ileum after an 8-week course of TGF-β-rich CT3211.[77] It is still unclear whether this is related to the increased luminal presence of TGF-β or is simply an epiphenomenon of tissue repair.

It may also be that enteral nutrition plays a direct role in promoting the mechanisms involved in epithelial healing. There are numerous peptides involved in the restoration of a disrupted epithelial barrier. The ulcer-associated cell lineage secretes cytoprotective peptides that promote epithelial healing. Among them are epidermal growth factor, TGF-α, human spasmolytic peptide, and the family of trefoil peptides.[192] The trefoil peptides in particular have been shown to be vital in protecting against mucosal damage.[193] Enteral nutrition may contribute toward the maintenance of mucosal integrity by boosting the proliferation of the ulcer-associated cell lineage.[194]

Although the theory of "bowel rest" has its supporters, others continue to feel that adequate nutrition alone can induce remission and growth in these patients.[195] Kirschner and colleagues demonstrated improved growth in children simply fed an extra 1,000 kcal/day.[34] The same group later confirmed that improved nutrition not only increased linear growth but also returned previously low levels of IGF-I to normal in children with active Crohn's disease.[196] Thomas and colleagues confirmed this finding with an elemental feed, which was as effective at increasing IGF-I as prednisolone yet better promoted linear growth.[157]

There are likely to be many mechanisms responsible for the clinical efficacy of enteral nutrition. It is clear, however, that the luminal environment is crucial to the expression of mucosal disease. Our ability to regulate specific aspects of this environment by nutritional or other means remains a great challenge. The multitude of variables that may be important in achieving a disease remission makes identification of single factors extremely difficult. Current attention is focused on modifying enteral formulas in line with the recent evidence on dietary fats, while continuing to ensure their clinical efficacy and tolerability.

Mucosal Healing

Greater emphasis has recently been placed on the ability of treatments to achieve mucosal healing of the gut mucosa.[197] Breese and colleagues gave an initial indication that enteral nutrition was able to down-regulate intestinal mucosal inflammation.[120] Enteral nutrition was as effective as cyclosporin and steroids in reducing the percentage of IL-2-secreting cells in the terminal ileum after treatment, whereas it appeared to be more effective than steroids at reducing the percentage of IFN-γ-secreting cells. Furthermore, it was only the enterally fed group that showed significant histologic improvement. Despite being only a small study, Breese and colleagues raised two important issues: that enteral nutrition may be able to heal mucosa and that mucosal cytokine analysis following treatment did not necessarily correlate with either clinical or histologic indices of remission.[120]

The mucosal cytokine responses of a much larger cohort of children were reported by Fell and colleagues.[77] Although clear clinical and histologic remission was achieved in over 70% of children, cytokine profiles also dramatically improved with a polymeric diet alone. The dramatic down-regulation of the potent proinflammatory cytokines IL-1β, IFN-γ, and IL-8 is the most concrete evidence to date that enteral nutrition acts at the mucosal level (Table 37-4).

The issue of whether clinical, endoscopic, histologic, or immunologic remission should be the gold standard remains a matter of personal practice.[197] If we are to believe that the presence of chronic inflammation predisposes to long-term complications and malignancy,[198] it may be a state of immunologic remission at the mucosal level that should be achieved in children with a lifetime of Crohn's disease ahead of them.

BODY COMPOSITION, ENERGY EXPENDITURE, AND PROTEIN METABOLISM

It has become clear that in both adults and children, active gut inflammation is associated with alterations in body composition. Although substrate metabolism during active Crohn's disease resembles that during starvation, this is more a consequence of malnutrition and may be easily reversed by treatment with exclusive enteral nutrition.[38,199] Body mass index (BMI), lean body mass, and fat mass are all decreased in children with IBD, and this may be related to poor calorie intake.[175] A higher BMI and lean body mass were both positively correlated with increased BMD, factors that again stress the importance of adequate nutrition in maximizing long-term BMD.[200]

Enteral nutrition provides a simple but effective treatment for children with Crohn's disease. Not only does it appear to influence disease activity directly, it also appears to have clear benefits on growth and nutrition.

Early evidence suggested that REE was increased in patients with inactive Crohn's disease.[201] It now appears, however, that if the REE is calculated per unit of lean body mass (LBM), it is the same in active Crohn's disease as it is in normal controls.[38] The REE/LBM ratio was found to be significantly lower in children with anorexia nervosa than in normal controls. When comparing these controls with malnourished noninflammatory disease with children with active Crohn's disease, the authors showed that the appropriate physiologic response to starvation is lost during active inflammation. Thus, this inappropriately elevated REE further contributes to weight loss. On treatment with elemental feed, their absolute REE did increase to above normal levels but per unit of LBM remained only within the normal range. This study also showed that an elemental diet was significantly better than steroids at accruing lean body tissue and was again better at achieving linear growth.

Despite the documented increase in energy intake by children on steroids compared with those on an elemental diet, the latter group have a significantly greater rise in their median height velocity standard deviation score after 4 weeks on an elemental diet.[157] Adequate calorie intake alone in the presence of steroid therapy (124% of Recommended Dietary Allowance) is thus unable to achieve optimal growth. The short-term growth suppressant effects of prednisolone probably override any advantage conferred by the improved calorie intake.[202] IGF-I levels appeared greater after steroid treatment than after enteral nutrition, yet a significant increase in IGF-I was only associated with greater height velocity after an elemental diet.[157]

The rate of protein turnover in six children with chronically active Crohn's disease receiving steroids was considered to be similar to that of normal adolescent controls,[175] although their nitrogen balance was found to increase fourfold during nutritional supplementation.[176] Another small study compared the effect of steroids ($n = 3$) and elemental feed ($n = 3$) after the first 7 days of treatment in acute Crohn's disease.[203] Labeled L-leucine studies showed an equal increase in protein turnover after 7 days of treatment, whereas in the steroid-treated group, this was at the expense of total-body protein stores. Clinical improvement was similar in each group. In a more recent study by Thomas and colleagues, rates of protein turnover were also elevated in active Crohn's disease.[204] Labeled L-leucine studies and mass spectrometry analysis showed an equal reduction in protein turnover to normal levels, both by steroids ($n = 4$) and by elemental feed ($n = 6$). This study only assessed protein turnover after several weeks of

treatment and only after effective recovery and nutritional restitution were almost complete.

Royall and colleagues published evidence in 30 adults with active Crohn's disease that proportionate increases in body fat, protein, and water occurred after 21 days of elemental nutrition.[205] In this study, a sustained remission was achieved only in patients who showed a gain in total-body nitrogen.

Further evidence that optimizing nutrition may contribute to a clinical remission arises from the study by Slonim and colleagues.[206] The combination of a protein-rich diet (> 2 g/day) together with subcutaneous growth hormone led to a significant reduction in CDAI within 4 months in a small group of adults with moderate to severe Crohn's disease. Increased uptake of amino acids and improved intestinal and muscle protein synthesis are mechanisms that are likely to be important in mediating this effect.[207,208] Direct effects of growth hormone on IGF-I are not felt to be as significant as no correlation was found between IGF-I levels and clinical response.

FUTURE DIRECTIONS

From the above discussion, it is abundantly clear that nutrition still has a major role to play in the management of children with IBD and in particular those with Crohn's disease. Although exclusive enteral nutrition is clearly effective in many children with active Crohn's disease, it remains difficult for some children and their families to complete prolonged courses. Work is continuing to assess whether long-term supplementation of a normal diet prolongs remission.

Palatable whole-protein formulas are being modified to include higher percentages of n-3 fatty acids, whereas the addition of probiotics to feeds is also already under way.

Work also continues on isolating the specific factors within formulas that may directly act on mucosal inflammation. Up-regulation of mucosal TGF-β may be a direct result of higher levels of TGF-β within a formula (Modulen IBD, Nestlé), whereas further characterization of the gut microflora in children with IBD may allow specific supplementation with specific prebiotics, substrates that selectively stimulate the growth of certain favorable probiotic species.

CONCLUSIONS

Despite the ever-increasing choice of therapies available to children with IBD, the role of nutrition remains central to their optimal management. The impact of bowel inflammation on growth and development cannot be underestimated. As final adult height is determined during the pubertal growth spurt, it is crucial to minimize the impact that both the disease and its therapies may have on a child's growth potential.

We strongly suggest that exclusive enteral nutrition remains the best primary therapy for the treatment of all children presenting with a new diagnosis of Crohn's disease, apart from those with severe perianal disease. Thereafter, the challenge is to maintain a lasting remission, particularly during puberty. This is likely to be best achieved with early use of immunosuppressants such as azathioprine or 6-mercaptopurine, hoping to minimize steroid use. Continued vigilance of undernutrition and appropriate use of dietary supplementation remain essential to an optimal outcome.

The consequences of developing a chronic inflammatory disease during childhood will be felt long after a child is handed over to our adult physician colleagues. Increased risks of osteoporotic fractures, high rates of surgery, and a reduced final height are only some of the areas in which nutritional therapy is vitally important. The ability of therapies to achieve healing of the gut mucosa is of utmost importance in children who have a lifetime ahead of them. Although dietary therapies do not yet play a significant therapeutic role in maintenance therapy for IBD, it is likely that evidence about potential disease-modifying dietary supplements will continue to appear. It is important that as more potent immunologic agents become available to treat these diseases, we do not forget the therapeutic role of nutrition in Crohn's disease, its absence of adverse effects, and its proven impact on growth and gut mucosa.

Although newer therapies may require less commitment from families and medical teams, their unknown long-term safety profile will make enteral nutrition an excellent choice for children with Crohn's disease for many years to come.

CHAPTER 38

PEDIATRIC HIV INFECTION

Tracie L. Miller, MS, MD, Colleen Hadigan, MD, MPH

Nutritional problems of human immunodeficiency virus (HIV)-infected children are common, pervasive, and often frustrating to treat. Because of the strong link between immunity and nutrition, which are outlined in this and other chapters, clinicians caring for HIV-infected children need to attend to nutritional problems by trying to help children achieve normal growth. Scientific studies are emerging on the importance of nutrition in both predicting and improving clinical outcomes, such as hospitalization rates and survival. This chapter provides current background information on pediatric HIV infection and the associations between nutrition and HIV. Focus also turns to the emerging problem of the metabolic syndrome in HIV-infected children. Furthermore, the growth patterns of HIV-infected children, pathogenesis of nutritional disorders, and current diagnostic and therapeutic interventions are presented. It is hoped that this chapter both provides practical advice to clinicians caring for HIV-infected children and serves as a basis to stimulate much needed scientific research in this area.

PEDIATRIC AIDS EPIDEMIC

Despite the dramatic progress that has been made over the past decade regarding the detection, diagnosis, and treatment of HIV infection, it is a chronic disease that continues to carry high morbidity and mortality rates. The World Health Organization estimated that, by the end of 2001, about 40 million people worldwide were living with HIV/acquired immune deficiency syndrome (AIDS); 2.7 million of these were children.[1] In 2001, there were 800,000 newly infected children under the age of 15 years and 580,000 AIDS-related deaths in this age group. About 90% of children under 13 years of age with HIV infection in the United States have acquired it from their HIV-infected mother. Almost all new cases of HIV infection in children can be attributed to vertical transmission from the mother to infant because complete screening of blood products was initiated in 1985. Maternal risk factors include intravenous drug use, heterosexual contact, and previous transfusion or transplantation. Other known risk factors for pediatric HIV infection include hemophilia or being a recipient of some other blood product. Similar risk factors exist in Europe, except for the special circumstance in Romania, where most children acquired HIV through contaminated needles and syringes. Although mother–infant transmission has diminished substantially in the United States with increased use of pre- and perinatal antiretroviral therapy, as many as 30% of pregnant women in regions of sub-Saharan Africa are HIV infected, with limited access to such treatment. In addition, more than 70% of deaths in infants under 5 years of age are attributable to AIDS in this part of the world.[1] In developing countries, half of the HIV-infected individuals are women of childbearing age. Children in developing countries who have HIV infection are especially affected by the endemic problems of protracted diarrhea and severe malnutrition.

HIV, a ribonucleic acid (RNA) virus that belongs to the Lentivirinae family, was first isolated in 1983.[2] The virus has a particular tropism for the CD4 surface antigen of cells, and the binding of HIV to the CD4 receptor initiates the viral life cycle, which is mediated by the HIV-1 envelope glycoprotein (gp)120. The binding of gp120 to CD4 leads to events that cause fusion of the virus into the host membrane, with subsequent steps leading to replication of the virus within the host cell. The proviral DNA within the host cell may also remain latent for varying amounts of time until cellular activation occurs. Human T lymphocytes and monocytes or macrophages are the primary cells that are infected with HIV, although numerous other cell lines have been reported to be infected as well. The net biologic effect on the immune system of children with HIV infection is the progressive decline in CD4-positive T lymphocytes, leaving children susceptible to opportunistic and recurrent bacterial infections.

NUTRITION AND IMMUNITY

Malnutrition is the most common cause of immunodeficiency worldwide. Nutritional status and immunity have long been linked in many disease situations. Before HIV was described, *Pneumocystis carinii* pneumonia and Kaposi's sarcoma, known opportunistic diseases, were first described in otherwise healthy, but malnourished, children and adults in developing nations.[3,4] This association led investigators to conclude that nutrition alone can impact on the immunologic response of an individual. In malnourished children, there is a profound involution of lymphoid tissues, including thymic atrophy and diminished paracortical regions of lymph nodes.[5] In young infants and children, protein-calorie malnutrition increases the risk of death several-fold by increasing the susceptibility to infec-

tion.[6] In many countries, mortality rates increase from 0.5% in children whose weight-for-height percentage of standard is greater than 80% to a mortality rate of 18% in children whose weight-for-height percentage of standard is less than 60%.[7] In other diseases, such as cystic fibrosis and cancer, nutritional status has been linked closely to survival rates and morbidity. With leukemia and lymphoma, the incidence of infection with *Pneumocystis carinii* is higher in patients with protein-calorie malnutrition.[4]

Biochemically, protein-calorie malnutrition leads to changes in several aspects of the immune system that are similar to the immunologic changes in HIV infection. Cell-mediated immunity, microbial function of phagocytes, complement systems, secretory antibodies, and antibody affinity are consistently impaired in patients with significant malnutrition. Additionally, deficiencies of micronutrients, especially zinc and iron, as well as many others, may also have deleterious effects on the immune system. Other aspects of immunity that are altered by protein-calorie malnutrition include impaired chemotaxis of neutrophils, decreased lysozyme levels in serum and secretions, and interferon production in antibody response to T-dependent antigens. A child with protein-calorie malnutrition may also have impaired mucosal immunity with lowered concentrations of secretory immunoglobulin (Ig)A in the saliva, nasopharynx, and tears compared with well-nourished control children. Figure 38-1 illustrates the significant and close interaction between nutrition and immunity. This topic is discussed in greater detail in Chapter 20, "Malnutrition and Host Defenses."

Because many of the immunologic changes in malnutrition are similar to those found in children infected with HIV, malnutrition has been proposed to act as a cofactor of immune dysfunction by influencing both susceptibility to HIV infection and progression of the disease. It is logical to expect that augmenting the nutritional status of an HIV-infected child may improve the function of an already compromised immune system. Preliminary evidence to support this notion is presented later in this chapter.

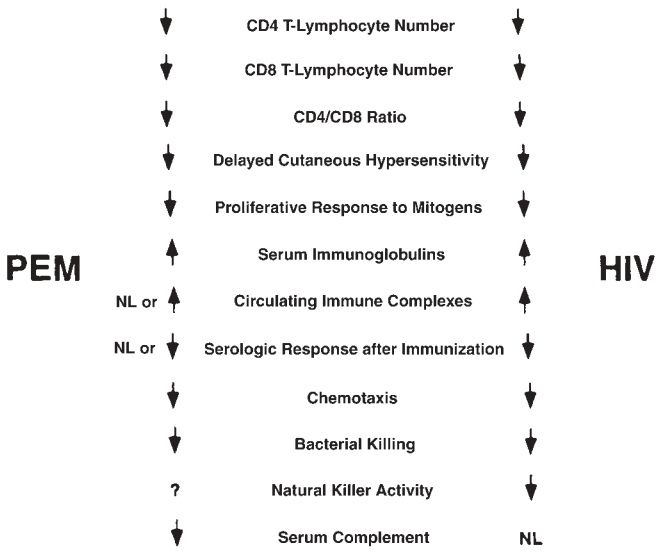

FIGURE 38-1 Diagrammatic representation of immunologic abnormalities associated with malnutrition and human immunodeficiency virus (HIV) infection. NL = normal; PEM = protein-energy malnutrition.

GROWTH AND BODY COMPOSITION OF HIV-INFECTED CHILDREN

Growth

Nutritional problems are common in infants and children with HIV infection, and the wasting syndrome is considered one of the major AIDS-defining illnesses.[8] As of 1998, HIV wasting rose from the fifth to the second most common AIDS-defining illness in children in the United States.[9] Most, if not all, children with HIV infection will experience nutritional abnormalities during the course of their illness. Even in the era of antiretroviral therapy, failure to thrive defined as weight for age z-score ≤ –2.0 SD is common in HIV-infected children in the United States and was found in 37% of perinatally infected children at 1 year of age.[10] In this study, failure to thrive was also associated with a significantly increased mortality rate by 36 months of age (36.3% versus 14.3% among HIV-infected children without failure to thrive). Weight loss and gastrointestinal symptoms are one of the most common presenting symptoms of HIV disease in developing countries. In a Tanzanian study, 200 children with severe malnutrition and controls who were matched for age, sex, and area of residence were screened for evidence of HIV infection.[11] Twenty-five percent of the malnourished group were HIV positive compared with 1.5% of the control group. These authors recommend routine screening for HIV infection in malnourished children in developing nations because there is a high likelihood that they will be HIV positive.

Acute malnutrition is manifested by more of a decline in weight than in height, with lower weight-for-height percentiles. Chronic nutritional deprivation will result in below-standard weight and height with near-normal weight for height. This is a growing child's adaptation to undernutrition. The following section summarizes recent studies that evaluate growth in HIV-infected children. In some HIV-infected children, abnormalities in height growth velocity precede weight changes and may reflect altered endocrine function, as is described in future sections.

In general, children with HIV infection have similar birth weights and are at no higher risk of prematurity than children who are not HIV infected but who are born to HIV-infected women,[12] although several studies found differences between groups at birth.[13–15] In a prospective study of infants born to HIV-infected women in the United States, as early as 6 months of age and up through age 5 years, HIV-infected infants had significantly lower weight-for-age and height-for-age z-scores than their HIV-exposed but uninfected counterparts.[10] Thus, growth abnormalities may begin postnatally and may develop even in asymptomatic children.

A natural history study of somatic growth in pediatric HIV infection is being conducted in the United States (Women and Infants Transmission Study [WITS]). An analysis of 282 infants born to HIV-infected women

revealed that, at birth, HIV-infected infants were 0.28 kg lighter and 1.64 cm shorter than uninfected infants, and these differences persisted after controlling for the effects of maternal drug and alcohol use.[16] HIV-infected children had a progressive decrement in weight, length, and body mass index (BMI) extending to 18 months of age. The authors also identified early and sustained decrements in head circumference. Preliminary data from 10 years of follow-up in this same study demonstrate considerable progressive growth decrements, with as much as an 8.9 kg weight and 8.0 cm height deficit among HIV-infected children at 9 years of age.[17]

In developing nations, other confounding factors exist, which could explain different outcomes relating to growth. In one study of 822 HIV-infected pregnant women from Tanzania, low birth weight was associated with maternal advanced-stage HIV, but malaria, any helmintic infection, and intestinal parasites were also strong predictors of low birth weight.[18] Infant HIV infection was not associated with low birth weight but was predictive of being small for gestational age. In a study from Malawi, 362 children born to HIV-infected women (92 infants HIV infected) and 686 infants born to noninfected women were evaluated at birth and followed for 2 years.[14] HIV-infected infants had significantly lower weight for age at birth and lower length for age by 5 months of age. Infants born to HIV-infected mothers who were not perinatally infected initally weighed less and were shorter than infants born to HIV-seronegative mothers, but this difference disappeared by 24 months. A prospective cohort study from Rawanda of 318 HIV-infected and 309 HIV-seronegative women was conducted to determine growth parameters in their offspring.[19] Birth weight was significantly lower among infants born to HIV-infected mothers compared with those born to HIV-seronegative mothers. Length, head circumference, and placental weight were also reduced between the two groups.

Additional studies in children with hemophilia have documented poor growth as a prognostic indicator to progression to AIDS. HIV-positive children with hemophilia who downwardly crossed 15 percentile points in height or weight for age on two repeated measurements were found to have a greater likelihood to progress to AIDS.[20]

Body Composition

Weight loss, or a decrease in growth velocity, is a simple marker to diagnose the wasting syndrome in children with HIV infection. However, using weight as the only marker of nutritional status can be misleading because weight can be confounded by symptoms such as vomiting and diarrhea. Also, hydration therapy may increase body weight while not truly reflecting an actual improvement in nutritional status. A more accurate measure of nutritional status is body cell mass, which refers to the nonadipose cellular mass and is roughly equivalent to the intracellular water volume.

Anthropometry and body composition studies can give clues to the potential etiology of a nutritional disorder. The body's first (and normal) response to starvation (inadequate food intake) is the preferential loss of body fat, which can be reflected in diminished triceps skinfold thickness measurements or other measurements of body fat. When fat stores are depleted, wasting of lean body mass occurs. In contrast, cachexia or wasting refers to the preferential and inappropriate loss of lean body mass over fat mass, with or without concomitant weight loss. Cachexia has been described previously in patients with cancer but more recently has been found in patients with HIV infection, including children. Cachexia may be mediated by chemical intermediates such as cytokines and is discussed in the section on pathogenesis.

Several studies using various methods to assess body composition have been performed in HIV-infected children. We reported body composition measurements of 89 children born to HIV-infected women, of whom 52 children were HIV infected. Lean body mass, as measured by arm muscle circumference, was significantly less in the HIV-infected group by 2 years of age. There were no differences in fat mass between the two groups of children.[12] In a cross-sectional study of HIV-infected children treated with nucleoside reverse transcriptase inhibitors, Fontana and colleagues compared bioelectrical impedance measurements of fat-free mass (FFM) in 86 HIV-infected children (mean age 6.9 years) and 113 healthy controls (mean age 7.7 years).[21] These investigators found that FFM was lower in HIV-infected children compared with controls; however, when FFM was evaluated as a percentage of total body weight, there was no difference between groups. Weight for age and FFM z-scores < –2.0 were associated with increased risk of death (relative risk 11.4 and 5.1, respectively), with weight for age serving as a stronger prognostic indicator than FFM. Arpadi and colleagues used dual-energy x-ray absorptiometry (DXA) and also found reduced FFM but normal fat stores among HIV-infected children compared with uninfected controls, regardless of whether growth failure was also present.[22] These findings indicate that poor growth and decreased FFM are a considerable problem for children living with HIV infection and that these parameters have a significant deleterious effect on survival.

The introduction of highly active or combination antiretroviral therapy (HAART) has revolutionized the management of HIV infection in adults and children. Much recent attention has focused on the potential impact of HAART on growth and body composition as well as immune function and survival. For example, as part of the Pediatric AIDS Clinical Trials Group 219 Study, the effects of the introduction of protease inhibitor (PI) therapy were assessed in 906 HIV-infected children between 3 months and 18 years of age.[23] In this study, initiation of PI treatment was associated with small but statistically significant increases in height and weight z-scores. In a prospective longitudinal study of 67 prepubertal children (mean age at entry 6.8 years) initiating PI therapy, PI treatment resulted in a twofold reduction in viral load and increased weight and weight-for-height z-scores.[24] These improvements and increases in lean body mass as measured by arm muscle circumference were significant even after controlling for exposure to all antiretrovirals, duration of HIV, immune

status, energy intake, and use of megace. In this study, the improvement in height was not statistically significant, and no significant changes in tricep skinfold were identified.

There is also evidence that improvement in growth parameters may be linked to immune response to antiretroviral therapy. Verweel and colleagues found that both weight and height improved after initiation of HAART but only in a subset of children who demonstrated viralogic response defined as 1.5 or greater log reduction in HIV RNA.[25] Furthermore, a Swiss study assessing a cohort of 44 prepubertal HIV-infected children found that children with stunting prior to initiation of PI therapy experienced statistically significant increases in height-for-age z-scores after 72 weeks of treatment.[26] In this study, there was a significant positive correlation between change in CD4 T-cell count and change in height z-score. These data represent preliminary evidence that effective viral suppression and immune reconstitution with HAART may substantially ameliorate the growth deficits in HIV-infected children. Longitudinal information is needed to determine the potential long-term benefits of antiretroviral therapy on growth and body composition.

PATHOGENESIS OF WASTING IN HIV-INFECTED CHILDREN

The pathogenesis of malnutrition, or the wasting syndrome, in pediatric HIV disease is currently unknown but is most likely multifactorial. A limited number of studies have determined the risk factors for malnutrition in HIV-infected patients, and even fewer have been performed in children. These risk factors include fever, diarrhea, acute infection, and anorexia in a population of predominantly homosexual men,[27] female gender and increasing age in a group of intravenous drug users,[28] and opportunistic infections, drug use, and psychosocial issues in a mixed population of HIV-infected patients.[29] Four potential mechanisms for weight loss include inadequate oral intake, gastrointestinal malabsorption, abnormal energy use, and psychosocial influences. Several factors may be operating simultaneously.

Energy Intake

A variety of potential factors may lead to abnormal intake, as outlined in Table 38-1. For example, inflammation and ulcers of the upper gastrointestinal tract can lead to anorexia owing to odynophagia, dysphagia, or abdominal pain that is associated with eating. In a series at Children's Hospital, Boston, 70% of upper gastrointestinal endoscopies in HIV-infected children revealed abnormal histologic findings.[30] These lesions may be attributable to acid-related injury or infectious agents such as *Candida albicans*, cytomegalovirus, or herpes simplex virus, all of which may cause inflammation and pain with swallowing or after eating. Furthermore, oral ulcers that are attributable to viral agents or idiopathic oral ulcers are common and may cause pain with eating and reduce oral intake.[31]

Pancreatic and biliary tract disease can also cause vomiting and abdominal pain in HIV-infected children, leading to poor oral intake. Pancreatic disease has been linked to medications (eg, nucleoside analogue reverse transcriptase inhibitors [NRTIs], PIs, sulfonamides) and opportunistic infections (eg, cytomegalovirus and mycobacterial disease).[32,33] Biliary tract disease with sclerosing cholangitis and papillary stenosis has been associated with *Cryptosporidium*, cytomegalovirus, and *Microsporidia* infection.[34,35] Primary anorexia, described in patients with cancer and other chronic disorders, may also contribute to inadequate oral intake. It is postulated that increased cytokine production (eg, tumor necrosis factor [TNF]-cachexin, interferon-γ, and interleukin [IL]-1 and -6) may be associated with anorexia. In animal models, administration of exogenous TNF has produced anorexia and cachexia.[36] TNF also causes delayed gastric emptying, which can increase anorexia as well.[37] Currently, the scientific data that implicate these cytokines as mediators of anorexia are controversial. HIV encephalopathy, which can be present in up to 34% of untreated children with HIV infection,[38] may result in the physical inability to consume enough calories to sustain growth. Oral administration of feedings under this condition may also be dangerous

TABLE 38-1 Causes of Malnutrition for HIV-1-Infected Children

Cause	*Mechanism*
Decreased nutrient intake	
Peptic disease	Pain
Opportunistic infections of upper gastrointestinal tract (*Candida*, CMV, HSV)	Pain, dysphagia
Pancreatic/hepatobiliary disease	Pain
Encephalopathy	Discoordinated swallow
Aphthous ulcers	Pain
Primary anorexia	Nausea, CNS, cytokines
Gastrointestinal malabsorption	
Mucosal disease	
Infectious	Bacterial, parasitic, viral
Inflammatory	HIV enteropathy, IBD
Disaccharidase deficiency	Infectious, inflammatory
Protein-losing enteropathy	Infectious, inflammatory
Fat malabsorption	Infectious, inflammatory
Hepatobiliary	
Sclerosing cholangitis	Infectious
Chronic pancreatitis	Infectious, drug-induced
Cirrhosis	HBV, HCV
Increased nutritional requirements or tissue catabolism	
Protein wasting, hypermetabolism, futile metabolic cycling	Fever, infections, sepsis Neoplasms (Kaposi's sarcoma, lymphoma) Medications Release of catabolic factors (cytokines, tumor necrosis factor)
Psychosocial factors	
Poverty	
Illness in biologic family members	
Limited access to health care	
Substance abuse	

CMV = cytomegalovirus; CNS = central nervous system; HBV = hepatitis B virus; HCV = hepatitis C virus; HSV = herpes simplex virus; IBD = inflammatory bowel disease.

owing to the high risk of aspiration in neurologically compromised children. Finally, many medications that HIV-infected children are required to take may result in gastric irritation, vomiting, and nausea. These medications are listed in Table 38-2.

Despite the numerous potential situations that can result in low energy intake, few scientific data exist on children to support this. Oral intake during periods of acute illness has yet to be evaluated in HIV-infected children, although intake is very likely to be poor. We evaluated total energy intake in 26 children with early HIV disease and 16 noninfected children.[39] Total caloric intake and carbohydrate, protein, and fat intake were similar between groups, yet HIV-infected children had lower weight percentiles. These results suggest that mechanisms other than suboptimal oral intake (relative to the Recommended Daily Allowance [RDA]) exist, which cause altered growth and nutrition during stable periods of HIV infection. In an Italian study of 15 asymptomatic HIV-infected children and 18 symptomatic children with a mean age of 42 months, caloric intakes were compared with a control group of noninfected children.[40] In the symptomatically infected group of children, energy, calcium, phosphorus, and iron intakes were below 70% of the RDA more frequently than in the asymptomatic and control groups, although these differences were not statistically significant. Protein intakes were consistently high and above the RDA for most children across groups. There was no correlation between energy intake and nutritional status. Thus, with limited data, it appears that energy intake below the RDA is not common in HIV-infected children during stable periods of disease, and other mechanisms for poor nutrition must come into play.

More data on dietary intake exist in adults with HIV infection. Grunfeld and colleagues found that caloric intake was similar in HIV-positive patients and AIDS patients without opportunistic infections.[41] AIDS patients with secondary infections had a 36% lower energy intake coincident with a 5% weight loss. Resting energy expenditure (REE) in AIDS patients was greater than the other two groups. Thus, it appears that a combination of increased REE and inadequate oral intake in a group of patients with active secondary infections may be responsible for the significant weight loss over the study interval. Abrams and colleagues prospectively evaluated the relationship between dietary intake at baseline and the development of AIDS over a 6-year period in 296 HIV-positive men.[42] They found that with the exception of energy, zinc, thiamin, and vitamin E, reported nutrient intakes from food alone exceeded the RDA, and when supplements were included, all micronutrients exceeded the RDA, with the exception of zinc. Nutrient intake was positively associated with CD4 counts at baseline and inversely related to the risks of AIDS. Thus, supporting normal nutrient intake in patients with HIV infection may have a protective effect for progression to AIDS in adult patients.

Gastrointestinal Absorption

Adequate nutrient absorption is essential to maintain growth and nutrition in infants and children. HIV-infected

TABLE 38-2 Medications and Common Gastrointestinal Side Effects

Medication	*Action*	*Side Effects*
Abacavir	NRTI	Nausea, vomiting, abdominal pain, pancreatitis, abnormal liver function tests
Acyclovir	Antiviral	Nausea, abdominal pain, diarrhea, abnormal liver function tests
Amprenavir	Protease inhibitor	Abdominal pain, diarrhea
Azithromycin	Antibacterial	Nausea, vomiting, melena, jaundice
Ciprofloxacin	Antibacterial	Ileus, jaundice, bleeding, diarrhea, anorexia, oral ulcers, hepatitis, pancreatitis, vomiting, abdominal pain
Clarithromycin	Antibacterial	Nausea, diarrhea, abdominal pain, abnormal taste
Combivir (zidovudine/ lamivudine)	Combination	Nausea, vomiting, abdominal pain, abnormal liver function tests, pancreatitis
Dideoxycytidine	NRTI	Nausea, vomiting, abdominal pain
Dideoxyinosine	NRTI	Nausea, vomiting, abdominal pain, pancreatitis, abnormal liver function tests
Efavirenz	NRTI	Nausea, vomiting, abnormal liver tests
Erythromycin	Antibacterial	Nausea, vomiting, abdominal pain
Ganciclovir	Antiviral	Nausea, vomiting, diarrhea, anorexia, abnormal liver function tests
Indinavir	Protease inhibitor	Nausea, vomiting, abdominal pain, diarrhea, changes in taste, jaundice, abnormal liver function tests
Ketoconazole	Antifungal	Hepatotoxicity
Lamivudine	NRTI	Nausea, diarrhea, vomiting, abdominal pain, pancreatitis, abnormal liver function tests
Nelfinavir	Protease inhibitor	Nausea, diarrhea, fatigue, abnormal liver function tests
Nevirapine	NRTI	Stomatitis, nausea, abdominal pain, elevated γ-glutamyl transpeptidase
Pentamidine	Antiparasitic	Abdominal pain, bleeding, hepatitis, pancreatitis, nausea, vomiting
Rifampin	Antibacterial	Abdominal pain, nausea, vomiting, diarrhea, jaundice
Ritonavir	Protease inhibitor	Nausea, vomiting, diarrhea, abdominal pain, pancreatitis, abnormal liver function tests
Saquinavir	Protease inhibitor	Mouth ulcers, nausea, abdominal pain, diarrhea, pancreatitis, abnormal liver function tests
Stavudine	NRTI	Nausea, vomiting, abdominal pain, diarrhea, pancreatitis, abnormal liver function tests
Sulfonamides	Antibacterial	Hepatitis, pancreatitis, stomatitis, nausea, vomiting, abdominal pain
Trisavir (abacavir/ lamivudine/ zidovudine)	Combination	Nausea, vomiting, abdominal pain, pancreatitis, abnormal liver function
Zidovudine	NRTI	Nausea, vomiting, abdominal pain, abnormal liver function tests

NRTI = nucleoside analogue reverse transcriptase inhibitor.

patients are at risk of developing malabsorptive disorders, which can potentially impact on their growth and nutritional status. Possible reasons for gastrointestinal malabsorption in HIV-infected children include infections of the gastrointestinal tract that affect the intestinal architecture, malnutrition alone, or direct or indirect effects of HIV on the intestinal epithelial cell. Infections that are known to affect the small bowel and that may promote malabsorption of nutrients include *Cryptosporidium*, *Isospora belli*, *Microsporidia*, *Mycobacterium avium intracellulare* complex (MAC), *Giardia lamblia*, and rotavirus. These pathogens can injure the intestinal epithelial cell, where critical digestive enzymes are present to digest essential nutrients. Enteric infections may also decrease bowel transit time, thus shortening nutrient contact with the epithelial cell and causing malabsorption. Malnutrition alone can cause villous blunting and secondary malabsorption of nutrients, which would further impact on nutritional status. Malabsorption has also been linked to an "HIV enteropathy," in which the villi are blunted with a hypercellular lamina propria and absence of a detectable enteric pathogen.[43] The presence of HIV in enterocytes is controversial; some investigators have found it by in situ hybridization,[44] whereas others have found it only within the lamina propria, which is rich in lymphocytes and macrophages.[45] An in vitro study of enterocytes showed that HIV-1 exposure, regardless of cell entry, evoked massive disruption of microtubules and inhibited a major sodium/glucose transporter, suggesting a pathophysiologic mechanism for HIV enteropathy and malabsorption.[46] In addition, HIV may affect the maturation of enterocytes and the subsequent expression of digestive enzymes on the brush border.

Children with HIV are also susceptible to small bowel bacterial overgrowth, which can result in malabsorption. Bacterial overgrowth may be attributable to an "AIDS gastropathy," in which the stomach produces only small amounts of hydrogen chloride, allowing bacterial pathogens to escape the acid barrier of the stomach and colonize the duodenum, where they may live and grow, using essential nutrients.[47] Additionally, "iatrogenic" hypochlorhydria occurs with the administration of acid-blocking agents. In a recent study of HIV-infected adults, small bowel bacterial overgrowth was infrequently identified, regardless of the presence of diarrhea, and when found was not associated with hypochlorhydria.[48]

Evidence to support the presence of malabsorption in HIV-infected children comes from a limited number of pediatric studies.[49–53] Twenty-eight HIV-infected children from Children's Hospital, Boston, and Boston City Hospital were evaluated for gastrointestinal malabsorption.[49] Over 60% were found to have some degree of carbohydrate malabsorption by D-xylose testing or lactose hydrogen breath testing. Carbohydrate malabsorption was not associated with nutritional status or gastrointestinal symptoms. Lactose malabsorption was found in 40% of children who were tested while free of known enteric infection. Abnormal D-xylose absorption was associated with an active enteric infection. Yolken and colleagues documented lactose malabsorption as well, but in association with clinical symptoms and weight loss.[50] In an Italian study, intestinal function of 47 symptomatically infected children was compared with that of 50 noninfected children with diarrhea and 48 healthy children.[51] Intestinal absorption was measured using the steatocrit method to determine fat absorption, fecal concentration of α_1-antitrypsin as a measure of protein absorption, and D-xylose absorption. Fecal fat loss was detected in 30%, carbohydrate malabsorption in 32%, and protein loss in 17% of HIV-infected children. Investigators found that intestinal dysfunction was not associated with diarrhea, poor growth, enteric agents, or degree of immune dysfunction but was significantly different from that of healthy control children. In a similar series, Sentongo and colleagues identified fat malabsorption in 39% of 44 HIV-infected children, but no patient had exocrine pancreatic insufficiency, and there was no relationship between steatorrhea, growth, HIV viral load, or CD4 count.[52] Thus, although malabsorption is fairly common, it cannot account for all of the gastrointestinal symptoms or malnutrition in HIV-infected children.

Metabolism

Increased energy metabolism of HIV-infected children can contribute to malnutrition by increasing the child's caloric demands to maintain weight and sustain growth. Total daily energy expenditure is the sum of energy needed to maintain a child at rest, the energy needed for activities of daily living, and the thermic effect of eating. Measurements of REE through indirect calorimetry and total daily energy expenditure through techniques such as doubly labeled water studies and whole-room calorimetry will enable investigators to determine the metabolic rates of HIV-infected patients.

There are limited studies in the pediatric HIV population that delineate resting or total daily energy expenditure, although more studies have been performed in the adult HIV population. In a small study of nine HIV-infected children without recent opportunistic infections, REE was measured using indirect calorimetry.[54] There was a strong correlation between measured REE and predicted estimates of energy needs, and all subjects met the RDA for calories and protein based on dietary recall. Additional literature on children generally shows no differences in REE or total energy expenditure between children with growth failure and those with normal rates of growth.[54–57] However, these studies have been performed in clinically stable children; metabolism in sicker children is likely to be much higher. One study has determined whole-body protein turnover in children with HIV-1 and found that increased protein turnover is associated with low weight and height.[58] There was no correlation with other markers of intermediary metabolism.

In adults with HIV, an active opportunistic infection appears to cause significant increases in resting metabolic rates. Melchior and colleagues studied REE in 165 malnourished patients with HIV infection.[59] The mean REE was 11% higher in the HIV-infected patients with no secondary infections compared with the control group and was 34% higher in HIV-infected patients with an active

infection. An increased metabolic rate, coupled with the findings of diminished energy intake, could be responsible for the significant weight loss.[41]

In patients without active secondary infections, resting metabolic rates are also increased. Hommes and colleagues studied REE of a group of 18 HIV-infected men who were free of clinically active opportunistic infections for at least 2 months.[60] Patients with AIDS or AIDS-related complex (ARC) had 9% higher rates of REE when compared with 11 healthy volunteers. They found no differences between patients and controls in plasma concentrations of catecholamines, thyroid hormones, cortisol, or TNF, except for lower concentrations of norepinephrine in the study patients. In the absence of acute infections, increased REE may contribute to the weight loss seen in patients with AIDS or ARC. Furthermore, Slusarczyk and colleagues evaluated the REE of 53 HIV-infected male volunteers. REE was significantly different between Walter Reed stage 0 (less symptomatic) and Walter Reed stage 3 and 4 patients (more symptomatic) (1.11 kcal per minute versus 1.45 kcal per minute, respectively).[61] These findings emphasize the need to stratify patients according to disease severity because pooling patients of all stages may not have shown a difference among HIV-infected individuals.

Suttmann and colleagues correlated resting energy metabolic rates to weight loss in HIV-infected adults.[62] REE differed significantly from predicted values in 40% of the patients, with 7% of the patients showing marked increased resting expenditure and 13% of the patients with decreased metabolic rates. Increased resting expenditure was found during all clinical stages of HIV diseases and was not strictly associated with a degree of immune impairment, presence of diarrhea, Kaposi's sarcoma, or nutritional status or wasting. Twenty-seven patients were evaluated longitudinally, and 11 lost more than 5% of their initial body weight during the observation period. Weight-losing patients were normometabolic before but showed a significant increase in REE during the follow-up period, in which there was weight loss (an increase of 7% of predicted values). The degree of deviation from estimated REE was strongly associated with the degree of weight loss. Thus, in this study, increased REE is not always a constant feature of HIV infection and is not associated with clinical and laboratory parameters of immune deficiency but occurs during weight loss and may be a causative factor for weight loss.

In contrast, Kotler and colleagues studied five clinically stable patients with AIDS and HIV-negative control subjects.[63] They found that the AIDS patients were hypometabolic compared with the control subjects and concluded that short-term energy balance can be maintained in clinically stable patients with AIDS. Hypometabolism, in this circumstance, was an appropriate metabolic response to the combination of body cell mass depletion and nutrient malabsorption.

Thus, similar to other controversial topics in the HIV literature, discrepancies in metabolic outcomes are possibly attributable to the variability of disease expression in patients infected with HIV. This emphasizes the need for small studies of patients with similar entry characteristics or larger studies in which modifiers of the outcomes can be controlled properly.

Cytokines

Altered metabolic rates may be attributable, in part, to chemical messengers such as cytokines. This hypothesis is supported by experimental and animal studies. The cachectin hypothesis was first described by Beutler and Cerami, who noticed that patients with chronic infections have significant weight loss that is associated with hypertriglyceridemia and reduced clearance of triglycerides by lipoproteins.[64] They postulated that a decrease in triglyceride clearance could lead to a decrease in fat storage and wasting of lean body mass as a result of the inability to use fats as a reserve source for energy. In animal studies, supernatants from activated macrophages induced weight loss when given daily to rodents.[65] This factor in the supernatant was subsequently isolated and named cachetin; it was later discovered to be the cytokine TNF. Other cytokines, such as IL-1 and the interferons, have similar effects.

Subsequently, specific cytokines, such as TNF, IL-1, and IL-6, have been associated with infectious, inflammatory, and wasting disorders. They share remarkable similarities in their biologic properties. These cytokines appear to be among the body's key mediators of acute response to inflammation and infection, leading to the shunting of protein and energy sources away from the lean body compartments. Systemically, IL-1 exerts catabolic effects on liver, fat, and connective tissues. IL-1 induces hepatocyte synthesis of acute-phase proteins while depressing serum albumin synthesis by decreasing transcription of RNA coding for albumin. IL-1 also has the ability to reduce serum iron and zinc, which has implications for its role in nonspecific resistance to infection. In cancer patients, TNF has been implicated as a signal molecule that may induce severe weight loss and may be related, in part, to the profound systemic suppression of lipoprotein lipase with subsequent lipemia.[66]

Increased levels of TNF in AIDS patients have been reported,[67] although some studies suggest that there are no significant differences in TNF levels between patients with AIDS and appropriate control subjects.[68,69] However, active secondary infections may increase TNF levels in AIDS patients.

Cytokines, as described above, alter metabolic processes in non-HIV populations. In patients with HIV, cytokines can cause ineffective use of energy substrates. Hellerstein and colleagues studied hepatic lipogenesis in HIV-infected adult patients and correlated it with peripheral cytokine levels.[69] Both symptomatic HIV-infected patients with normal CD4 counts and HIV-infected patients with weight loss had elevated hepatic lipogenesis compared with noninfected controls. Hepatic lipogenesis correlated with interferon-α levels in the fasted state in the patients with HIV infection and weight loss. Other cytokines were not correlated with increased hepatic lipogenesis. In addition to increasing the hepatic synthesis of fatty acids, TNF also mobilizes free fatty acids by stimulat-

ing peripheral lipolysis. The net result, "futile cycling," the process by which fatty acids are shuttled from adipose tissue to liver and back to adipose tissue, uses energy ineffectively. The process results in increased metabolic rates, with greater caloric needs to maintain nutrition.

The net effect of cytokines for patients infected with HIV is nonproductive use of precious energy substrates. Approximately 28% of calories are lost if lipogenesis from carbohydrate precedes its oxidation. Roubenoff and colleagues found that loss of lean body mass was driven by catabolic cytokines and not by inadequate dietary intake or hypogonadism.[70] Other investigators have found similar associations, independent of viral load.[71] Limited studies in children showed increased IL-6 activity, as well as low insulin-like growth factor (IGF)-I and increased viral load, to be associated with growth impairment.[57] The net effect of elevated cytokine levels may contribute to the relative hypermetabolism seen in HIV-infected patients. Because depression of immune function secondary to malnutrition is potentially reversible, nutritional rehabilitation in HIV-infected children may significantly lower serum cytokine levels by positively improving immunologic function, decreasing opportunistic infection, and diminishing HIV replication. This, in turn, would decrease cytokine production. With lower TNF and IL-1 production, promotion of HIV replication would be decreased, and the systemic effects of these cytokines, such as the wasting and malabsorptive symptoms, would be reduced.

Endocrine Disturbances

Although not the main focus of this chapter, endocrine abnormalities may contribute to growth failure in HIV-infected studies. In a subset of children, a decrease in height growth velocity precedes changes in weight, with resulting increases in weight-for-height percentiles. The exact etiology of this growth pattern is unclear, yet it suggests problems with endocrine regulation of linear growth. A study examining IGF-I secretion of HIV-infected children showed that IGF-I secretion was diminished in both asymptomatic (45% of children) and symptomatic (86% of children) HIV-infected children and was associated with growth failure. Less clear association with thyroid function was found.[72]

Psychosocial Factors

Psychosocial factors are also important contributors to suboptimal nutrition of HIV-1-infected children. An unstable home environment and inadequate emotional and social support have been shown to be factors for growth problems in both HIV-1-infected and non-HIV-1-infected children by many mechanisms, including growth hormone (GH) deficiencies.[73–75] Children with HIV-1 infection are at risk for living with parents who are ill, who have limited access to social services and support, and who may have ongoing problems with drug and substance abuse.[76] Investigators have found maternal crack and cocaine use during pregnancy to be a predictor of growth and nutritional problems for the child.[10,16] This finding is not unique for HIV-1 as it has been reported in other non-HIV-1 cohorts.[77] Children born to drug-using women are often small, suggesting that drugs have a prenatal effect, but the postnatal home environment is likely to influence growth as well. Current studies have also found that home care providers can both positively or negatively influence the functional status of HIV-1-infected children.[73]

MICRONUTRIENTS

Micronutrients have been linked to immunomodulation, both in vivo and in vitro, and are an area of active investigation in HIV-infected patients. Extensive work with micronutrients has been performed in laboratory animals. Deficiencies of pyridoxine, folic acid, vitamin A, vitamin C, and vitamin E result in impaired cell-mediated immunity and reduced antibody responses. Vitamin B_6 deficiency results in decreased lymphocyte response to mitogens, yet a moderate increase in betacarotene intake may enhance immune responses. With zinc deficiency, there is lymphoid atrophy and decreased delayed cutaneous hypersensitivity responses. Likewise, zinc deficiency in animals can reduce the number of antibody-forming cells in the spleen and impair natural killer activity. Clinically, wound healing is impaired. Excessive zinc can depress neutrophil function and lymphocyte responses. Iron is important for bacterial growth as well as the function of neutrophils and lymphocytes. Deficiencies of iron may reduce bacterial multiplication but may also impair lymphocyte proliferation response to mitogens and antigens. Clinically, in patients with iron deficiency, lymphocyte response to tetanus toxoid and herpes simplex antigen is low. Overall, in animal models, it is clear that selected vitamin and micronutrient deficiencies impact on immune function in many ways.

Because of the close link between immunologic function and micronutrients, it is logical to expect that low micronutrient levels can affect susceptibility to infection. For HIV-infected children, whose immunologic function is already compromised, further alterations of immunologic function, through micronutrient deficiencies or excesses, may synergistically decrease resistance to infections. Current studies of micronutrients and HIV infection are outlined in the following section.

General Studies

There are increasing data available on the micronutrient status of children with HIV infection. Eley and colleagues evaluated 60 HIV-infected children in Cape Town, South Africa, and in this cohort, vitamin deficiencies were frequently identified: vitamin A (80%), retinol binding protein (85%), vitamin B_6 (37%), vitamin E (37%), zinc (20%), and copper (25%).[78] Sixty-two percent of children had two or more deficiencies, and deficiencies were more common and more severe in children older than 24 months. Only 5% of patients were found to have low vitamin B_{12} levels. In a large series of symptomatic HIV-infected children (n = 71) in Italy, 48% were iron deficient and 66% had anemia, and this was positively associated with markers of malabsorption.[79] Micronutrient deficiencies appear to be common and may be linked to immune function and disease progression.

In adults, Tang and colleagues showed a relationship between total vitamin A intake and progression to AIDS, but it was U-shaped; the lowest and highest quartiles of intake did poorly, whereas the two middle quartiles demonstrated a significantly slower progression to AIDS.[80] They also found that increased intake of zinc was significantly associated with an increased risk of progression to AIDS. In a final multinutrient model, vitamin A, niacin, and zinc remained significantly associated with progression to AIDS, whereas vitamin C was only marginally significant.

Vitamin A

In earlier work, Semba and colleagues studied the association between plasma vitamin A, immunologic status, and clinical outcome during HIV infection.[81] In a cohort of 179 subjects with intravenous drug use, 15% of HIV-positive patients had low plasma vitamin A levels, significantly different from the HIV-negative control patients. Vitamin A deficiency was associated with increased mortality in HIV-infected patients, with a relative risk of 6.3 (95% confidence interval [CI] 2.1 to 18.6). However, more recent data available from HIV-infected children in North America found vitamin A deficiency to be relatively uncommon, and vitamin A concentrations did not appear to be related to mortality in this population.[82]

Vitamin A deficiency and supplementation, however, may have a significant role in HIV disease transmission and progression in areas of the world where vitamin A deficiency is more prevalent. Vitamin A deficiency in pregnant HIV-positive women was associated with increased risk of vertical transmission.[83,84] In a trial of vitamin A supplementation in Tanzania, HIV-infected children experienced a 63% reduction in all-cause mortality with vitamin A supplementation compared with placebo.[85] In a longitudinal observational study of 194 HIV-infected children in Uganda, low plasma betacarotene levels, but not vitamin A levels, were predictive of increased mortality. This and other studies, however, show a relationship between low vitamin A levels and poor growth in HIV-infected children.[85,86] For example, in a placebo-controlled trial of vitamin A supplementation in Tanzania, including 50 HIV-infected children, vitamin A–treated children under 18 months of age experienced a 2.8 cm greater height increase compared with placebo.[87] One potential mechanism for this beneficial effect on growth may be improved gut permeability (ie, reduced permeability with vitamin A), which was shown with perinatal vitamin A supplementation in HIV-infected infants.[88]

B Vitamins and Folate

Baum and colleagues studied vitamin B_6 status in HIV-infected adults.[89] In this study, vitamin B_6 was significantly associated with decreased lymphocyte responsiveness to mitogens and reduced natural killer cell cytotoxicity. Vitamin B_6 was not related to CD4 cell number. Thus, vitamin B_6 is an important factor of immune function, and, as noted previously, vitamin B_6 deficiency was detected in 37% of HIV-infected children in one series.[78]

Dowling and colleagues studied vitamin B_{12} and folate in 35 HIV-infected men, of whom 16 were asymptomatic.[90] Serum vitamin B_{12} was normal or above normal in all patients, coincident with high vitamin B_{12} intake. Lower red blood cell folate was found in only 3 patients, but levels were lower overall in the more symptomatic group. Folate intake was low in 36 to 56% of patients.

Folic acid absorption was studied in 25 HIV-infected patients after an oral folic acid dose, with blood samples taken sequentially over 3 hours.[91] Absorption of folic acid was significantly impaired in patients, regardless of the stage of the disease. Thus, intestinal absorption of folate and other nutrients may be responsible for abnormal blood levels.

Antioxidants

Oxygen radicals are generated during normal metabolism, yet production may increase during infection, malnutrition, stress, or drug therapy. Patients with HIV infection are subject to all of these factors, which can increase oxygen free radicals. Catalase (an important hydrogen peroxide scavenger) was studied in adult patients with advanced HIV infection.[92] As HIV disease progressed from asymptomatic infection to AIDS, serum catalase activity increased sequentially, reflecting or compensating for antioxidant deficiencies in HIV-infected patients. Potent nutritional antioxidants include vitamin E and selenium.

Vitamin E may have independent effects on immunomodulation. Studies in laboratory and farm animals suggest that vitamin E doses in excess of the RDA increase the immune response and improve host resistance to microorganisms. In laboratory studies, vitamin E inhibited nuclear factor-κB activity by TNF (this normally induces HIV replication). Clinically, vitamin E supplementation is beneficial in reducing the incidence or severity of infectious diseases in elderly persons.[93]

Selenium is a potent antioxidant and is also an important cofactor for immune function in humans. Recently, in vivo studies have shown the importance of this element in protecting cells from HIV activation and the effects of TNF through increasing glutathione peroxidase activity.[94] In one cross-sectional study, HIV-infected children had low glutathione levels, which correlated with CD4 cell count.[95] As well, in a cohort of patients studied at Children's Hospital, Boston, 61% of the patients had a low serum selenium level.[96] Selenium levels significantly correlated with weight z-score, albumin levels, and CD4 counts, suggesting a strong relationship with nutrition and immunity. Dworkin and colleagues reported 12 adult patients with AIDS compared with 27 healthy controls and found that there was a significant difference in whole blood selenium and red blood cell selenium levels in those patients with AIDS.[97] They also found that myocardial biopsies in AIDS patients demonstrate significant selenium deficits.[98] These data may provide a link between a selenium deficiency in cardiomyopathy and AIDS.

Trace Metals

Serum copper and zinc have also been studied in HIV-infected patients. A study by Graham showed that serum copper levels were higher and zinc levels lower in HIV-infected adult patients who progressed to AIDS than

seropositive patients who did not progress.[99] In a logistic regression model, they found that higher serum copper levels (odds ratio [OR] 2.23 [95% CI 1.02–4.87]) and lower serum zinc levels (OR 0.3 [95% CI 0.14–0.66]) predicted progression to AIDS independently of baseline CD4 lymphocyte levels, age, and calorie-adjusted dietary intake of both of these nutrients. In an open treatment study of HIV-infected children with a CD4 count < 500/mm^3, supplemental zinc was administered for 1 month. Although 69% of the children had low zinc levels at baseline, supplementation did not have an effect on p24 antigen or CD4 count.[100] Zinc's role in metabolic function has been well studied. It is important in the stabilization and function of metabolic enzymes, including those involved in protein synthesis, catabolism, energy metabolism, and RNA and DNA synthesis. Regeneration of gut epithelium, stabilization of brush border enzymes, and improved immune function are all proposed mechanisms for zinc's beneficial effects in acute diarrhea. In a randomized, placebo-controlled study of non–HIV-infected infants and toddlers with acute diarrheal illnesses (n = 937) in India, zinc supplementation resulted in significant reductions in stool frequency and duration of illness.[101] Given the prevalence of zinc deficiency among HIV-infected children, it is possible that zinc supplementation may be of particular benefit in children with HIV and diarrheal illness, but this needs to be investigated further.

DIAGNOSTIC EVALUATION

Because malnutrition and wasting are common in most HIV-infected children, routine nutritional assessment should be performed every 3 months in every child who is at risk for acquiring HIV infection. Careful consideration of the pattern of growth will lead to an investigation of nutritional versus endocrine dysfunction. Subtle changes in growth and altered nutrient intake can be detected. The nutritional assessment should include measures of weight, height, head circumference, triceps skinfold thickness (to measure fat mass), and muscle circumference (to measure muscle mass). A detailed dietary history and recall should be ascertained regardless of the child's nutritional condition. Dietary advice or encouragement should be reinforced at each visit. Figure 38-2 outlines a clinical algorithm of diagnosis and management of HIV-infected children with nutritional abnormalities.

If a child shows evidence of malnutrition (Table 38-3), nutrient losses should be evaluated in addition to nutrient intake. Clinical symptoms should be determined with the focus on gastrointestinal problems, such as vomiting, abdominal pain, and diarrhea. A complete physical examination will provide clues. The child should be evaluated for oral thrush, abdominal pain, and gross or occult blood in the stool. Laboratory studies should include a hemogram, liver function studies, pancreatic enzyme levels, including a lipase level, and a complete evaluation for enteric pathogens. Studies such as an upper gastrointestinal contrast series, upper gastrointestinal endoscopy, and abdominal ultrasonography may provide a definitive diagnosis. If clinical symptoms warrant, a complete gastrointestinal absorption evaluation should be performed, including a lactose hydrogen breath test, D-xylose absorption study, and 72-hour fecal fat collection.

Serum micronutrients should be assessed in malnourished or wasted HIV-infected children. Vitamins A, E, and D should be measured, especially if there is liver, biliary tract, or pancreatic disease. Serum zinc and selenium should be measured and may be low; if so, they should be replaced to optimize immune function. As other micronutrients such as vitamin B_6, vitamin B_{12}, iron, and copper may be depressed, they should also be measured in malnourished children.

It may also be important to evaluate a child's energy needs. Studies such as indirect calorimetry (to measure resting metabolic rate) and doubly labeled water studies (to measure total daily expenditure) are useful tools. However, these tests are impractical in a clinical setting not equipped to perform them owing to their expense and time required to complete them. In a practical sense, the best estimation of energy needs for an HIV-infected child is the child's response to a diet enriched in calories, with accurate documentation of caloric intake and type of food.

NUTRITIONAL INTERVENTIONS

Oral Supplementation

Nutritional interventions should be instituted when the child fails to meet growth standards, as defined in Table 38-3. In general, a proactive approach to nutritional guidance is preferred when early nutritional interventions are more effective than during the later stages of HIV disease. Nutritional therapies should be instituted in parallel with treatment for other ongoing systemic or gastrointestinal diseases. Oral nutritional therapies, in most patients, should be tried initially. Formula caloric density should be increased by concentration or adding fat or carbohydrate. If the child is eating solids, adding a high-fat supplement, such as butter or margarine, may be helpful. Efforts should be made to increase formula volume as much as can be tolerated. Because a precise estimation of caloric needs is usually not available, the caloric goal, in general, should be targeted at 50% above the RDA for age and sex. Other nutritional requirements are shown in Table 38-4, although these requirements are considered minimal, and more may be required if the child has clinical and biochemical evidence of nutritional deficiencies. Formula composition should be prescribed according to the extent of nutrient malabsorption. If the child has clinical symptoms indicating a malabsorption of lactose (diarrhea, bloating, flatulence), then a lactose-free diet is indicated. Caution is advised, however, in prescribing a lactose-free diet if the child has no clinical symptoms of lactose malabsorption as limiting lactose may also restrict the foods that are the most enjoyable and richest in calories. In addition, an oral lactose supplement may be added in some cases of lactose intolerance. A protein hydrolysate formula should be considered if the child has evidence of gastrointestinal mucosal dysfunction with malabsorption of fats and proteins.

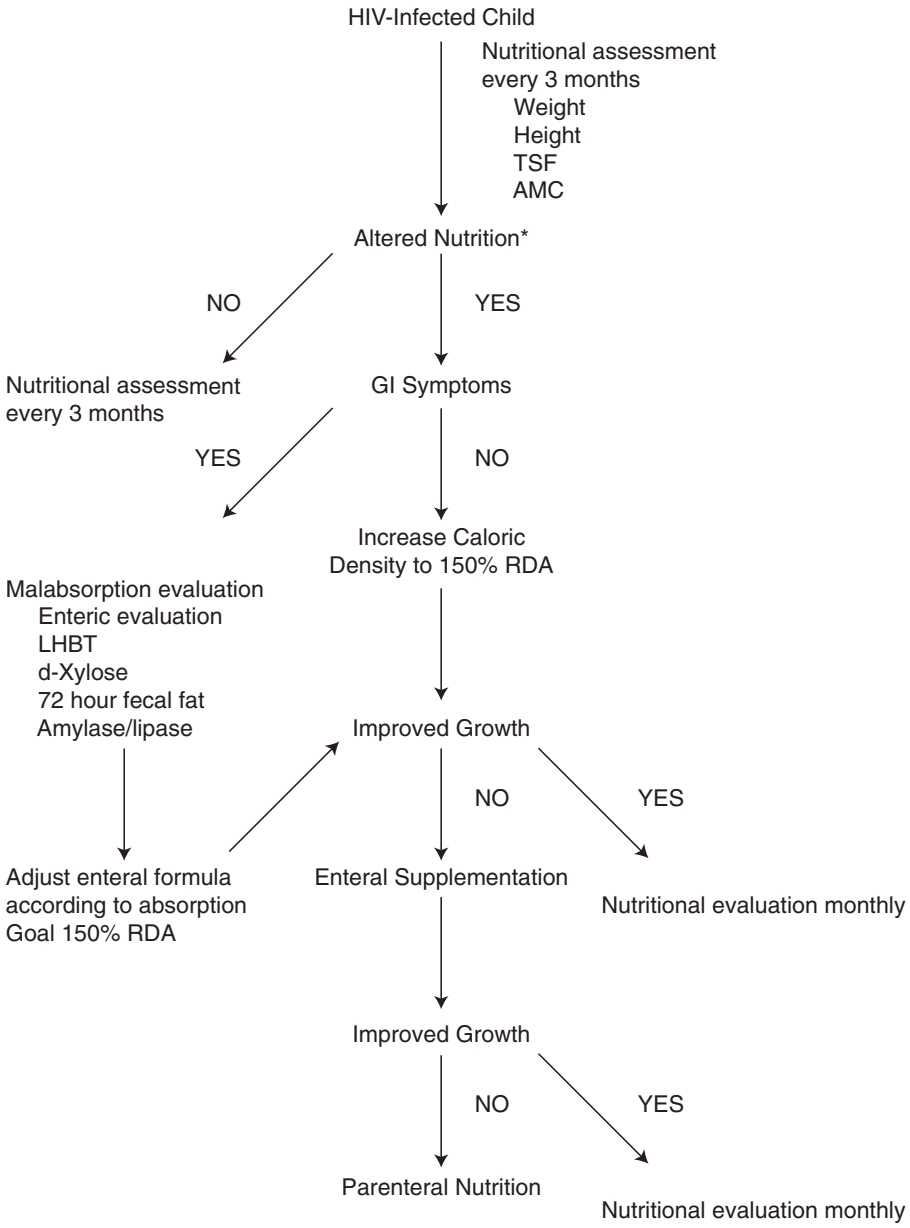

FIGURE 38-2 Algorithm for monitoring, diagnosing, and treating malnutrition associated with human immunodeficiency virus (HIV) disease in infants and children. AMC = arm muscle circumference; GI = gastrointestinal; LHBT = lactose hydrogen breath test; RDA = Recommended Dietary Allowance; TSF = triceps skinfold.

Breast milk is generally considered the best nutrition for infants worldwide because it contains factors that protect the infant against pathogens. Breast-feeding also fosters the mother–infant bond. Unfortunately, women with HIV infection can transmit the virus to their infant through breast milk; therefore, breast-feeding in this circumstance is strongly discouraged in countries where other safe feeding options exist.

Enteral Supplementation

If oral interventions fail because the child cannot consume adequate calories to sustain growth, enteral supplementation should be considered. Nasogastric tube feedings should be instituted first to document the child's ability to gain weight with supplemental enteral feedings. Nighttime feedings are most practical because they allow the child to eat normally throughout the day. Complications relating to nasogastric tube feedings include sinusitis and the technical inability of the caretaker to administer the feedings or place the tube. If delivery of feedings through a nasogastric tube improves growth, then placement of a more permanent device, such as a gastrostomy tube, should be considered. A gastrostomy tube provides easy access to the stomach with less physical and emotional trauma to the child.

Table 38-3 Clinical Indicators of Malnutrition in HIV-Infected Children

Weight growth velocity < 5% for more than 2 mo
Decrease in 1 major growth percentile for weight
Weight or weight-for-height percent standard < 90%
Weight for height < 5%
Loss of > 5% of lean body mass
Serum albumin < 3 g/dL

In addition, recent studies show that gastrostomy tube placement results in significant improvements in medication compliance and reductions in medication administration time in children with HIV infection.[102,103]

In a study of 23 HIV-infected children from Children's Hospital, Boston,[104] weight and weight-for-height z-scores increased with gastrostomy tube feedings. This increase in weight and weight for height was coincident with an increase in caloric intake. Fat stores, as measured by triceps skinfold thicknesses, increased in parallel with weight and weight for height, with no appreciable effect on lean body mass. Additionally, children who gained weight with gastrostomy tube feedings were hospitalized less in the 6 months after gastrostomy tube placement and had a 2.8-fold reduction in risk of dying. Children with higher age-adjusted CD4 T-lymphocyte counts and lower weight-for-height z-scores at the initiation of enteral supplementation were more likely to gain weight. In a more recent study, Guarino and colleagues evaluated the effects of enteral (n = 16) and parenteral (n = 46) nutritional therapy for HIV-infected children with malnutrition and evidence of diarrhea or malabsorption.[105] More than 80% of patients receiving enteral therapy gained > 5% of their baseline weight, and enteral therapy was associated with significant increases in CD4 cell count. In addition, enteral therapy improved gut absorption, with 75% of patients experiencing normalization in the xylose absorption test. Combined, these findings suggest that early nutritional intervention is indicated in children with HIV infection and may improve morbidity and survival.

Parenteral Nutrition

Parenteral nutrition should be reserved for HIV-infected children who continue to lose weight on an aggressive enteral program, who have severe recurrent or chronic pancreatic or biliary tract disease, or who have intractable diarrhea with weight loss. The placement of a central venous catheter can provide venous access that is often difficult to obtain in terminal stages. Central venous catheters present an additional risk for sepsis, and studies in adults and children with HIV infection present conflicting results regarding the risk of infection.[106,107]

Limited data are available on the benefits of total parenteral nutrition (TPN) in children with HIV infection. In the series reported by Guarino and colleagues, 46 HIV-infected children with malnutrition and malabsorption received a median of 157 days of TPN.[105] Although CD4 cell count, weight, and xylose absorption all improved significantly in the patients receiving enteral therapy (n = 16), these measures improved on TPN but not significantly. One possible explanation for the difference in findings between TPN and enteral nutritional support is that this was an observational study, and patients on TPN had more advanced disease, as indicated by a lower baseline CD4 count (154 cells/mm^3 for enteral patients versus 55 cells/mm^3 for TPN patients). In addition, 58.7% of TPN patients versus 18.8% of enteral patients died during the follow-up period, which may be related to increased risk of infection with central lines and TPN but may also reflect the practice of reserving TPN for late- and end-stage patients. Further study is needed to determine the appropriate role of TPN therapy in the setting of HIV infection in children.

Other Nutritional Therapies

Appetite Stimulants Megestrol acetate, a synthetic orally active progesterone, widely used to treat breast cancer, has shown promising results as an appetite stimulant in adults with HIV infection. The mechanism of weight gain with megestrol acetate is under investigation, but preliminary findings show that it has an effect both on behavior (ie, food intake) and metabolism by the induction of lipogenic enzymes and fat synthesis.[108] A prospective, randomized, double-blind, placebo-controlled trial of megestrol acetate in 271 HIV-infected adults found that 64.2% of patients who received 800 mg megace per day gained 5 pounds or more compared with 21.4% of those receiving placebo.[109] These patients also reported an improvement in overall well-being and had an increase in lean body mass, appetite, and caloric intake as well. Lean body mass increased, although total body water did not change, implying a significant increase in cellular body mass.

Oster and colleagues studied the effects of megestrol acetate, 800 mg daily, on body weight, composition, caloric intake, and mental outlook in patients with AIDS who had cachexia.[110] One hundred patients with AIDS who had lost 10% or more of their ideal body weight were

Table 38-4 Nutritional Requirements for HIV-Infected Children

Nutrient	*Requirements per Day**
Total calories	100–150% RDA for age and sex
Protein	100–150% RDA for age and sex
Vitamin A	400–1,000 µg retinol
Vitamin D	400 IU
Vitamin E	3–10 mg d-alpha-tocopherol
Vitamin K	5–80 µg
Vitamin C	30–60 mg
Thiamin	0.3–1.1 mg
Riboflavin	0.4–1.3 mg
Niacin	5–15 mg
Vitamin B_6	0.3–1.6 mg
Folate	25–180 µg
Vitamin B_{12}	0.3–2.0 µg
Iron	6–15 mg
Zinc	5–12 mg
Selenium	10–55 µg

*Requirements reflect the clinical nutritional state of the child; more may be needed if there is biochemical evidence of deficiency. Ranges reflect increasing needs for age and sex.

randomly assigned to placebo or megestrol acetate. Patients receiving megestrol acetate had greater caloric intake, resulting in weight gain of predominantly fat. Body water, lean body mass, and survival were not significantly different between the two groups. There are few reports on the use of megestrol acetate in children with HIV infection. Clarick and colleagues evaluated the effects of megestrol acetate in 19 HIV-infected children for a median of 7 months at doses between 4.0 and 8.5 mg/kg/day and found increased weight z-scores with continued therapy but no improvement in linear growth.[111] The authors also reported that poor weight gain and/or weight loss occurred after megestrol acetate was withdrawn. More recently, the same group noted adrenal suppression with corticotropin stimulation testing in 7 of 10 HIV-infected children treated with megestrol acetate compared with 0 of 10 HIV-infected children not on megestrol acetate.[112] Therefore, use of megestrol acetate may be beneficial for weight gain and improved appetite in HIV-infected children, but caution is warranted, particularly when discontinuing or withdrawing therapy.

Dronabinol (Δ^9-tetrahydrocannabinol) is another appetite stimulant that has been used in adult HIV-infected patients. It was approved for use in the United States in 1986 for treatment of chemotherapy-induced nausea and vomiting, although it was found to stimulate appetite as well. A randomized, placebo-controlled study of dronabinol was performed on 139 patients.[113] Appetite stimulation, measured by visual analog scale, was maintained or increased in patients receiving dronabinol. After at least 2 months of treatment with dronabinol, 38% of patients gained greater than or equal to 2 kg of weight. Altered mental status was the primary adverse effect for this medication. Currently, there are no dosing recommendations for children.

Growth Hormone GH is being used as a therapeutic agent to improve lean body mass and weight in HIV-infected patients. It improves nitrogen balance, is anabolic, improves serum protein levels, and promotes lipid mobilization and protein synthesis in burn and postoperative patients. Because it appears that fat oxidation is inappropriately suppressed, at the expense of glucose and amino acid oxidation, recombinant human GH (rhGH) is starting to be evaluated in both the adult and the pediatric HIV populations. Heijligenberg and colleagues examined 24-hour GH and IGF-I levels in eight asymptomatic HIV-infected men, eight clinically stable AIDS patients, and eight healthy controls.[114] No differences were demonstrated in 24-hour GH profiles or IGF-I levels among the three groups, suggesting that HIV disease per se does not affect the GH-IGF-I axis. In contrast, profound abnormalities in GH have been demonstrated among patients with AIDS wasting.

Mulligan and colleagues studied the anabolic effects of rhGH in patients with wasting in six HIV-positive men, with an average weight loss of 19%, and six healthy HIV-negative, weight-stable controls.[115] Weight increased promptly and progressively and urinary nitrogen excretion decreased during treatment with GH. REE increased, protein oxidation decreased, and lipid oxidation increased during treatment. There was increased glucose flux and moderate increases in fasting plasma triglyceride, glucose, and insulin levels. Thus, short-term human GH treatment increased protein anabolism and sparing, as well as lipid oxidation effects, which should increase body cell mass with chronic therapy.

Subsequently, Schambelan and colleagues conducted a longer-term, randomized, placebo-controlled study in 178 HIV-infected patients with the wasting syndrome.[116] Over 12 weeks, weight and lean body mass increased significantly in the rhGH-treated patients compared with the placebo-treated patients. In contrast, total body fat decreased significantly in rhGH- versus placebo-treated patients. Total body water increased by 6% and accounted for a substantial portion of the increase in FFM in GH-treated patients. Furthermore, side effects of arthralgias and myalgias, including carpal tunnel syndrome, were seen significantly more often in patients treated with GH compared with placebo (50% versus 35%). Numerous other therapies have been employed to initiate weight gain in patients with HIV infection. These include essential fatty acid supplementation (n-3 fatty acids), specific vitamin and antioxidant replacements, pancreatic enzymes, testosterone replacement, and cytokine inhibitors such as pentoxifylline and thalidomide. As well, studies are under way evaluating the effects of exercise and aerobic training in patients with HIV infection. Unfortunately, there are no therapies discovered to date that universally prevent or reverse nutritional derangements in HIV-infected patients.

Malnutrition has historically been the condition that has been most prevalent and targeted for treatment in children with HIV infection in developed countries. However, a syndrome of fat redistribution and lipid and glucose abnormalities, referred to as "lipodystrophy," has been identified among increasing numbers of HIV-infected patients receiving potent combination antiretroviral therapy. This syndrome, which is discussed below, has been recognized in children as well and may pose an important challenge in the nutritional and metabolic management of children living with HIV/AIDS in the future.

HIV-ASSOCIATED LIPODYSTROPHY

Shortly after the widespread introduction of HAART, a constellation of metabolic abnormalities and changes in body fat distribution were recognized among many HIV-infected patients (Table 38-5).[117–119] The loss of subcutaneous fat stores and increased adiposity of the abdomen and dorsocervical fat pad were reminiscent of congenital and acquired forms of lipodystrophy, and this term has been used in the HIV population. Although the exact cause of these metabolic and body composition changes has not been identified, there is increasing evidence that both protease inhibitors and NRTIs contribute directly to this lipodystrophy syndrome.[120–122]

In addition to significant and often disturbing changes in fat distribution, patients may develop hypertriglyc-

TABLE 38-5 Clinical and Biochemical Abnormalities Associated with the Lipodystrophy Syndrome in Children

Clinical Features	*Laboratory Features*
Increased abdominal (visceral) fat	Hyperlipidemia
Increased waist-to-hip ratio (not reliable in growing children)	Increased triglycerides
Buffalo hump	Increased total cholesterol
Fat atrophy	Increased low-density lipoprotein
Wasting of extremities	Decreased high-density lipoprotein
Wasting of buttocks	Insulin resistance
Loss or thinning of facial fat, prominence of nasolabial fold	Normal to increased serum glucose
No change to increased weight	Increased insulin
Fatigue and weakness	Increased C peptide
	Decreased glucose tolerance/insulin resistance

eridemia, insulin resistance, and diabetes. In a study of patients (n = 71) presenting with complaints of fat redistribution, Hadigan and colleagues found increased prevalence of hypertriglyceridemia (> 200 mg/dL) low high-density lipoprotein cholesterol (<35mg/dL), impaired glucose tolerance, and diabetes compared with age-, sex-, and BMI-matched control subjects from the Framingham Offspring Cohort.[119] Investigation is ongoing to determine precisely how antiretroviral medication(s) and other factors may contribute to lipodystrophy. In addition, preliminary studies show that the use of lipid-lowering therapies and insulin-sensitizing agents may help ameliorate the metabolic complications of lipodystrophy.[123–125] The long-term effects of insulin resistance, hyperlipidemia, and fat redistribution remain unknown, but there is considerable concern for increased cardiovascular disease risk in patients affected by HIV-associated lipodystrophy.

Several studies have been conducted to evaluate whether pediatric patients with HIV infection receiving HAART are also experiencing changes in body fat distribution or metabolic abnormalities. Arpadi and colleagues assessed body fat distribution in 28 prepubertal HIV-infected children with DXA scans and 29% had evidence of lipodystrophy (defined as fat atrophy and trunk fat accumulation).[126] The presence of lipodystrophy was positively associated with PI use (OR 7.0) and stavudine use (OR 9.0) in this population. In a similar cross-sectional study, Jaquet and colleagues identified lipodystrophy (defined as subcutaneous fat atrophy and/or truncal adiposity) in one-third of the HIV-infected children evaluated.[127] There was a trend toward a statistically significant increase in fasting insulin levels in those children with lipodystrophy but no association with PI use or exposure to other antiretroviral agents. Other studies comparing children exposed to PIs and PI-naive children show increased levels of total cholesterol, low-density lipoprotein cholesterol, and triglycerides with PI use.[128,129] Clearly, more research is needed to determine the effects of HAART on fat redistribution, lipids, and glucose homeostasis in children, particularly given the potential lifelong exposure to HAART, which may be required for HIV viral suppression. In addition to the potential increased risk of diabetes and cardiovascular disease, children may also experience as yet unappreciated abnormalities in pubertal development and bone health in relation to metabolic complications of HIV and lipodystrophy.

CONCLUSION

Great strides have been made over the past two decades regarding the detection, prevention, and virologic treatment of HIV in childhood, with the basic understanding of the interaction between nutritional status and HIV becoming better understood. The cause of nutritional problems in patients with HIV-1 infection is complex and likely multifactorial. It is clear, however, that malnutrition of HIV-infected children is among the most serious, chronic, and difficult to treat problems confronting clinicians caring for HIV-infected children, especially in developing countries. Clinicians should be aware of nutritional problems, and close surveillance on nutrition should be conducted on all children who are at risk for HIV infection. Early, aggressive nutritional interventions are indicated. As a treatment strategy, improving nutritional status of HIV-infected children may improve clinical outcome.

Although the incidence of malnutrition in developed countries has decreased with HAART therapy, other metabolic problems can arise. The long-term risks of HAART on HIV-1-infected children are unknown. Close surveillance for the emergence of insulin resistance, dyslipidemias, and premature cardiovascular disease will be important as children with perinatally acquired HIV-1 age into adulthood. Further investigations on the short- and long-term nutritional and metabolic effects of HAART therapy are needed. Investigators should continue to study the effects of oral hyopglycemic agents, lipid-lowering medications, and health-style changes on cardiovascular risk factors for HIV-infected children with lipodystrophy.

CHAPTER 39

EXOCRINE PANCREATIC DISEASE INCLUDING CYSTIC FIBROSIS

Kevin Gaskin, MD, FRACP, Jane Allen, PhD, DipNutrDiet

Exocrine pancreatic diseases (EPDs) associated with maldigestion and malabsorption of both macro- and micronutrients are common causes of acute and chronic malnutrition in tertiary pediatric referral populations. They are characterized clinically by excessive fecal losses of undigested fat and protein, with resultant oily stools and, in some, severe hypoproteinemia with edema. Descriptions of patients with "bacon fat" or "melted butter" stools are commonplace and serve to emphasize the excessive fat and energy losses, which can exceed 50% of the fat/energy ingested.[1] It is not surprising that with such losses, undiagnosed or untreated patients with these disorders present with variable degrees of and often severe undernutrition and require careful investigation and treatment. This chapter highlights the variety of disorders associated with EPDs in childhood, their pathophysiology, nutritional consequences, and an approach to their investigation and management from a nutritional perspective.

EXOCRINE PANCREATIC DISEASES IN CHILDHOOD

Following the original reports describing the pathology of cystic fibrosis (CF) of the pancreas,[2,3] a variety of inherited and acquired EPDs of childhood have been described, as per Table 39-1. Of the inherited disorders, CF is the most common, occurring in 1 in 2,500 to 1 in 4,000 live births,[4] with Shwachman-Diamond syndrome (SDS) estimated to be on the order of 1 in 10,000 to 1 in 100,000.[5–7] The other inherited disorders are rare, with only isolated anecdotal reports.[8–11] Of the acquired disorders, the incidence of tropical calcific pancreatitis and pancreatic disease owing to protein-energy malnutrition is essentially unknown, but one would suspect that they are among the most common EPDs in children worldwide.

Although many of the disorders are rare, elucidation of the underlying mechanism of the disorder or assessing the influence of an isolated enzyme/coenzyme deficiency on digestion, for example, has contributed to the understanding of normal physiology of the exocrine pancreas, the pathophysiology of pancreatic diseases, and the process of normal digestion. SDS, for instance, is associated with lipomatosis of the exocrine pancreas and acinar cell hypoplasia, with preservation of the ductal system. This "ductal model" of the exocrine pancreas has provided ductal fluid and electrolyte secretion data during pancreatic stimulation tests for comparison with similar data from CF patients.[12,13] The latter were known to have poor fluid and electrolyte secretion in response to secretin,[14] but it was unknown as to whether this was related to destruction of pancreatic tissue or to the underlying fluid and electrolyte secretion deficit in CF. Careful comparison of data from the CF and SDS control populations demonstrated a similar decline of fluid and electrolyte secretion with a decline in acinar function in both populations, indicating that pancreatic destruction did contribute to the impaired fluid and electrolyte secretion in CF.[12,13] However, the data also demonstrated that for any level of acinar function, the CF patients had significantly lower HCO_3^- and Cl^- secretion,[12,13] thus indicating that the underlying epithelial secretion deficit in CF was a major factor contributing to the impaired fluid and electrolyte secretion observed during pancreatic stimulation tests. The discovery of isolated colipase deficiency has also helped our understanding of normal fat digestion. In vitro, pure pancreatic lipase activity is completely inhibited in the presence of supramicellar concentrations of bile acids normally found in duodenal contents.[15,16] The heat-stable cofactor colipase, with a mol-

ecular weight of 10,000, however, relieves this inhibition,[17,18] and lipase is activated in a linear fashion with increasing concentrations of colipase activity. Absence of colipase impairs lipase activity and fat digestion, as subsequently demonstrated in vivo in patients with inherited colipase deficiency or in CF or SDS patients with relative colipase deficiency.[19,20]

MOLECULAR BASIS/PATHOPHYSIOLOGY OF ENDOCRINE PANCREATIC DISEASES (EPDs)

The molecular basis for many of the inherited diseases, for instance, CF and inherited pancreatitis, has been found over the last decade, and one would anticipate that similar data will be forthcoming with the other disorders, for example, SDS, in the near future. The following is a summary of the recent developments.

Cystic Fibrosis

The cystic fibrosis transmembrane conductance regulator gene (*CFTR*) was located on the long arm of chromosome 7 in 1989.[21,22] The gene product, the CFTR protein, was subsequently demonstrated to be a cyclic adenosine monophosphate (cAMP)-dependent chloride channel on the apical membrane of the epithelial cells.[23] There are now at least 1,000 *CFTR* mutations described in CF patients, and the majority would be regarded as rare or personal mutations. The most common, ΔF508, is found on 70% of CF chromosomes or 90% of the alleles of patients of mid- and northern European origin, with 50 to 55% being ΔF508 homozygotes, 35 to 40% ΔF508 compound heterozygotes, and 5 to 10% non-ΔF508 compound heterozygotes.[24] In southern European and other Mediterranean populations, ΔF508 is less common, occurring on 50% of CF chromosomes in white southern Europeans and only 30% of chromosomes of Ashkenazi Jewish patients.[25,26]

As per Table 39-2, *CFTR* mutations have been categorized into five classes according to defects in the biosynthesis and function of the mutated CFTR protein.[27]

In Classes I and II, the mutated CFTR protein fails to localize in the cell membrane, and in Class III, although located in the cell membrane, channel function is very impaired. In Classes IV and V, the CFTR protein locates appropriately in the cell membrane. However, in Class IV, conductance of Cl^- is reduced, and in Class V, although Cl^- conductance is normal, the splice mutations result in a reduction of the amount of CFTR protein produced, thus effectively reducing net Cl^- transport.

The above classification of *CFTR* mutations reflects not only the defects in biosynthesis, insertion into the cell membrane, and Cl^- conductance but also some of the phenotypic features of CF. Of specific importance is the correlation with pancreatic phenotype. The latter includes pancreatic-insufficient (PI) patients who have fat malabsorption and those who are pancreatic sufficient (PS) with sufficient endogenous enzyme production to produce normal fat absorption.[20] In any large CF population, 80 to 90% of patients are PI and 10 to 20% PS.[28] The PI patients usually have two of the Class I, II, or III mutations (so-called "severe" mutations, examples of which are ΔF508 homozygotes, ΔF508 compound heterozygotes with another severe non-ΔF508 mutation). In contrast, PS patients have at least one of the Class IV or V mutations (so-called "mild" mutations), noting that even if combined with a severe mutation, for example, ΔF508/R117H, the mild mutation R117H appears dominant and confers the milder disease.[29,30]

As indicated above, in vivo pancreatic secretion studies in CF have demonstrated that CF patients have impaired pancreatic HCO_3^-, Cl^-, and fluid secretion, and these changes are present irrespective of the degree of glandular destruction.[12,13] How mutations of *CFTR* influence these changes is not entirely clear. Previously, one model suggested that *CFTR* mutations impaired cAMP-stimulated acinar-ductal Cl^- secretion and luminal Cl^- concentration was low.[31] Low luminal Cl^-, in turn, did not drive the Cl^-/HCO_3^- exchanger; thus, ductal HCO_3^- secretion was also impaired. However, in normal duct cell models, secretin-driven HCO_3^- secretion occurs in the absence of luminal Cl^- and possibly occurs by a conductive pathway.[32] Moreover, others have shown that HCO_3^- accumulates in normal ductal cells via a basolateral cell membrane Na^+–$nHCO_3^-$ cotransporter, which is dependent on the electrogenic gradient owing to membrane depolarization caused by CFTR cAMP-dependent Cl^- secretion on the luminal apical cell membrane.[33] *CFTR* mutations interfere with Cl^- secretion, membrane depolarization, and thus HCO_3^- entry and secretion from the cell.

Although the mechanisms of impaired Cl^- and HCO_3^- pancreatic ductal secretion are the subject of intense investigation, the ultimate effect is inadequate alkalinization of pancreatic duct contents. In a CF mouse model, the latter has been shown to interfere with the normal endocytosis of zymogen granule membranes and the solubilization of zymogen granule–associated proteins, including glycoprotein 2.[34] This leads to dilatation of the lumen and accumulation and aggregation of glycoprotein 2 and is consistent with the known early pancreatic pathology in CF humans, that is, duct protein accumulation and obstruction, with inflammatory changes proximal to the obstruction and

TABLE 39-2 Classification of *CFTR* Mutations Reflecting Biosynthetic Defects and Function

Class I
Defective protein production
Frameshift and nonsense mutations
Unstable messenger ribonucleic acid
Class II
Defective *CFTR* processing; includes ΔF508 as most common mutation
Class III
Defective regulation of *CFTR*
Mutations can dramatically impair channel function, G551D
Class IV
Defective channel conduction, eg, R117H
Class V
Abnormal splicing of *CFTR*
Partial or complete reduction of channel function, eg, 2789+5G to A

subsequent acinar and small duct destruction and replacement by fibrofatty tissue.

Non-CF Disorders

The molecular pathogenesis of several of the non-CF pancreatic diseases has been investigated over the last decade, including SDS, Pearson's pancreatic marrow syndrome (PPMS), pancreatic agenesis, and hereditary pancreatitis. Preliminary work suggests that the gene for SDS is near the centromere on chromosome 7.[35] It is hoped that further work in this area will define the gene and its product and identify mutations specific for SDS. Correlation of specific mutations with the phenotypic features will be of significance, particularly if some mutations are associated with bone marrow malignancy. Mitochondrial DNA basepair deletions have been demonstrated in PPMS,[36] and a single case of pancreatic agenesis has been associated with a single-nucleotide deletion within codon 63 of the insulin promoter factor gene at 13q22.1.[37] Of equal interest, mutations in the cationic trypsinogen gene at chromosome 7q35 have been identified in the autosomal dominant disorder hereditary pancreatitis.[38] Continuing work elucidating the molecular basis for these disorders should also help to unravel the mechanisms of how the defects lead to the specific disease and also provide specific diagnostic tests for each of these disorders.

From a functional perspective, SDS, PPMS, Johanson-Blizzard syndrome (JBS), and pancreatic agenesis can all be associated with PI. Unlike CF, ductal function appears to be well preserved, but acinar cell hypoplasia is predominant. Both SDS and JBS patients can have severe lipomatosis of the pancreas, but PPMS patients appear to have extensive pancreatic fibrosis in association with their severe sideroblastic anemia.

CLINICAL MANIFESTATIONS

Although PI is common to all of the EPDs and is associated with macro- and micronutrient deficiencies, many of the disorders are multisystem diseases and have nutritional complications owing to nonpancreatic involvement, for instance lung, liver, and gut disease in cystic fibrosis; bone marrow disease in both SDS and PPMS; developmental delay in JBS, SDS, and PPMS; and diabetes mellitus in CF and pancreatic agenesis. The following text highlights those complications with nutritional implications for CF and non-CF disorders.

Cystic Fibrosis

The major manifestations of cystic fibrosis are outlined in Table 39-3. Although most are gastrointestinal/hepatic in origin, such complications, except for liver failure, portal hypertension, or surgery for meconium ileus, rarely are life threatening. In contrast, pulmonary disease accounts for over 90% of the mortality and is the major cause of morbidity and hospitalization in this disorder.

Pulmonary Disease CF lung disease is characterized by thick tenacious secretions obstructing the bronchial tree, recurrent suppuration, the development of bronchiectasis, severe lung fibrosis with cyst formation/emphysema, and, terminally, respiratory failure. The presentation and course of the pulmonary disease vary considerably among individual patients with CF, with some developing severe disease during their childhood years and others with relatively mild disease persisting into their adult years.[39] In the modern era, many factors contribute to this variability, including early diagnosis and institution of chest therapy with antibiotics, nutritional status, *Pseudomonas* lung colonization, the emergence of antibiotic-resistant infections, the cross-contamination of patients with infections, and the genetic variability of the disease. In regard to the latter, PS patients exhibit better preservation of lung function, maintaining an average near-normal lung function to age 30,[28] and have a median survival into the midfifties. On the other hand, PI patients suffer significant deterioration of lung function during their early adult years, and median survival is only into the thirties. The greater survival of the PS patients is likely related to their "mild" genotypes, and although the more severe disease in the PI group is at least

partly contributed to by their "severe" genotype, the large variation in lung disease and progression at any one age in this group suggest that other factors, including environmental and nutritional, contribute to this variation.[40]

Lung disease per se can contribute to the development of malnutrition. Recurrent infections, antibiotic therapy, and severe pulmonary dysfunction are anorexigenic. Severe disease with recurrent coughing can also exacerbate gastroesophageal reflux with esophagitis and further impair appetite. These interdependent effects may not only prevent the patient from achieving recommended high energy intakes but may also reduce the energy intake below that recommended even for normal subjects.[41] Equally important, lung disease, lung infections, inflammatory mediators, and drugs (eg, β-agonists) can substantially increase energy expenditure in excess of 20% above normal energy expenditure in a large number of patients.[42–44] This energy "wasting" is a significant factor interfering with the maintenance of normal nutritional status in CF and becomes even more critical in patients with anorexia.

Gut and Liver Disease CF patients can experience a wide variety of gut and liver complications, as outlined in Table 39-3. Gastroesophageal reflux disease (GERD) with esophagitis occurs in at least 10% of the population.[45] Of importance, some patients will admit only to symptoms of water brash and heartburn on direct interrogation. Many will have anorexia and weight loss, and, in some, these may be the only presentation of their esophagitis. The presence of the typical symptoms or unexplained anorexia and weight loss should alert the physician to the possibility of GERD, and investigations, including contrast radiology and endoscopy, should be considered. Conservative therapy with proton pump inhibitors usually provides a considerable improvement in symptomatology, including appetite, and if not, surgical intervention with laparoscopic fundoplication could be necessary depending on the severity of lung disease.

Patients with distal intestinal obstruction syndrome (DIOS), gallstones, or common bile duct disease present with recurrent abdominal pain postprandially and may restrict their dietary intake to alleviate their pain. DIOS should be apparent clinically with a mass palpable usually in the right iliac fossa. Radiologic examination is mandatory to confirm the diagnosis, and abdominal ultrasonography is necessary to exclude complex disease, including associated intussusception or appendiceal disease. Lavage therapy with the polyethylene glycol–containing colonoscopy lavage solutions (eg, Golytely, USA; Colonlytely-Dendy, Victoria, Australia; Glycoprep, Pharmatel, Thornleigh, Australia) is required to wash out the impacted fecal masses. Failure of this therapy should initiate further investigation, including contrast radiography and/or colonoscopy, to exclude other diseases, including fibrosing colonopathy, Crohn's disease, and, in the adult patient, colonic/ileal malignancy. Patients with biliary tract disease and biliary colic will require abdominal ultrasonography to exclude cholelithiasis and biliary tract dilatation and hepatobiliary scintigraphy to screen for bile duct stenosis.[46,47] Persistent pain with associated weight loss and deterioration of liver function tests may necessitate further imaging with contrast cholangiography or magnetic resonance imaging cholangiography prior to possible surgical intervention.[46]

Some small intestinal diseases, including giardiasis and celiac disease, can contribute to the nutritional problems of CF patients as they can induce anorexia and exacerbate problems with diarrhea and malabsorption. In one study using a fecal antigen test, 30 of 107 (28%) CF patients tested positive for *Giardia*.[48] The positivity increased with age, with 44% of those over 20 testing positive for the antigen in contrast to the controls, of whom 11% under 5 years of age and none over 10 years were antigen positive. Single-stool microscopy confirmed the presence of *Giardia* cysts in 44 and 43% of the CF and control groups, respectively, proportions that are not dissimilar to those in comparison with small bowel biopsy results. Although giardiasis most commonly causes a watery diarrhea in non-CF patients, it can be associated with steatorrhea and also severe protein malabsorption and hypoproteinemia. Considering these findings and the suggested increased susceptibility of CF patients to acquire giardiasis in the above study, CF patients experiencing diarrheal symptoms outside of their normal bowel movement pattern should be investigated further and treated appropriately with metronidazole.

Celiac disease is an alternative diagnosis for patients with anorexia, persistent steatorrhea, or deterioration of bowel movement pattern despite compliance to adequate enzyme therapy. It has been documented in CF adults with a prevalence of 1 in 1,258 in a US survey[49] and may be even higher in European communities, where screening of non-CF populations suggests prevalence rates of > 1 in 100.[50] As yet, there are no studies confirming the reliability of antiendomysial antibody testing in CF populations, and small bowel biopsy remains the gold standard test for this disorder. Given the similarity of symptoms of CD with giardiasis, small bowel biopsy would be the ideal test to prove or exclude these complications in the absence of optimal noninvasive tests.

Since the early 1990s, a new entity, fibrosing colonopathy, has been described in CF patients.[51] Pathologically, there are extensive areas of noninflammatory fibrosis affecting the lamina propria, causing bowel wall thickening and long fusiform strictures in the ascending, transverse, and/or descending colon. Clinically, patients can present with intestinal obstruction, abdominal pain, anorexia, weight loss, and/or chylous ascites and may require surgical intervention to alleviate the obstruction.[52] Two case-control studies have attributed fibrosing colonopathy to the use of high-dose lipase preparations and the ingestion of enzyme dosage in excess of 20,000 U of lipase/kg/day or in excess of 6,000 U of lipase/kg/meal; thus, current recommendations encourage patients to restrict their total daily dose to < 10,000 U of lipase/kg of body weight.[53,54]

Pancreatic Disease As indicated in the introduction, there are two pancreatic phenotypes in CF, namely PI and PS, based on the presence of fat malabsorption (a fecal fat > 7% of fat intake) and normal fat absorption (fecal fat ≤ 7%

of fat intake). This terminology arose out of quantitative pancreatic stimulation test studies in children and young adults with CF or SDS, demonstrating that PI patients had less than 1 to 2% of normal pancreatic colipase/lipase secretion, respectively, and PS patients from 1% to within the control range (over 50% of average normal colipase/lipase secretion),[20] that is, PI patients had insufficient endogenous enzyme secretion to prevent fat malabsorption and PS patients had sufficient enzyme secretion to give normal fat absorption. Whereas in older childhood and adult populations, PI patients comprise 80 to 90% of the patients,[28] in newborn screened populations, 60 to 70% are PI and 30 to 40% PS.[55] The latter reflects preservation of exocrine acinar function in the younger population and deterioration of pancreatic function in some PS patients who ultimately become PI. This phenomenon accounts for the presentation of some PI patients in nonscreened populations during later childhood. Patients in this category (PS to PI) in general have "severe" pancreatic genotypes, but one should be aware of the occurrence of recurrent pancreatitis in those with "mild" genotypes and that recurrent pancreatitis could induce PI during their adolescence or adult years.[56]

Untreated patients with PI have average fecal fat losses of 40%, but they can exceed 50% of fat intake.[1] Nitrogen losses are also excessive, with some reaching 50% of nitrogen intake.[57] The wide range of fat malabsorption evident in PI patients is largely unaccounted for. Some of the variability (fecal fat from 10 to 25% of fat intake) is accounted for by the decline in residual enzyme/cofactor secretion, that is, from < 1 to < 0.5% of enzyme secretion.[20] However, the increase of fecal fat above the 25% level is enigmatic. It may relate to the variable output of nonpancreatic pregastric lipases,[20] duodenal bile salt concentrations,[58] or the interference of nonhydrolyzed phospholipids on triglyceride digestion.[59] Irrespective of this variation, the nutritional consequences of these losses, as outlined in Table 39-4, are evident in patients from nonscreened populations and include wasting, stunting, hypoproteinemia, and essential fatty acid (EFA) deficiency with a seborrheic dermatitis. Associated fat-soluble vitamin deficiencies may contribute to early morbidity.

In terms of management, it is essential to determine the pancreatic phenotype and thus the necessity or otherwise for oral pancreatic enzyme replacement therapy (OPERT). In this regard, the time-honored gold standard test is a 3- to 5-day fat balance study with measurement of weighed dietary fat intake and fecal fat output and expression of the latter as a percentage of the former. The test provides reliable and accurate data, as evident by comparison with pancreatic stimulation test data.[20] It allows longitudinal follow-up of individual patients in assessing and reassessing response to OPERT and for the presence of other intestinal disease that may exacerbate fat malabsorption. As such, it has been an ideal investigative tool, particularly in determining the efficacy of OPERT. Unfortunately, many laboratories and clinics do not undertake fat balance studies as handling fecal material is unesthetic, undesirable, and potentially hazardous.

Consequently, there has been a proliferation of tests, including serum measurements of pancreatic enzymes, for example, trypsinogen, the PABA (para-aminobenzoic acid) test, and ^{13}C triglyceride–labeled breath tests. Others have used spot fecal samples for measurements of pancreatic enzymes, including chymotrypsin and fecal elastase (FE-1). Sensitivity and specificity of ^{13}C-labeled breath tests for assessing PI and PS are high at over 90% but are noninformative regarding the degree of steatorrhea in PI patients or the degree of residual pancreatic function in PS patients. FE-1 has been touted as a simple test with ease of collection and performance on spot fecal samples.[60] However, until recently, the vast majority of the patients studied were PI CF patients or normal subjects, and little was known regarding other childhood pancreatic or intestinal disease.[61,62] Nevertheless, in non-CF adults with chronic pancreatitis, FE-1 was more sensitive and specific and had higher practicability and lower cost than the ^{13}C mixed-triglyceride breath test for assessing pancreatic function.[63] A recent publication has evaluated FE-1 in PI and PS of CF and non-CF origin and in patients with intestinal diseases alone in comparison with controls.[64] The test had a sensitivity of 98% and specificity of 93.6% to identify patients with steatorrhea owing to PI with a positive predictive value

of 89.9% and a negative predictive value of 99%. Sensitivity and specificity in CF patients in predicting PI were both 100%, but noteworthy among the PS non-CF group, 30% had low FE-1 (< 100 μg/g stool). The latter was similar to one of the large original adult studies in non-CF patients with chronic pancreatitis in which in a group classified as having moderate pancreatic disease (approximately less than 25% of normal enzyme secretion on pancreatic stimulation tests with normal fat absorption), over 50% had low FE-1 < 100 μg and would have been misclassified as PI on the basis of the FE-1 alone.[65] Clearly, however, the results in the CF population are encouraging but less so in the non-CF group with pancreatic disease. One should be aware that FE-1 has not provided information to date on the degree of residual function in PS patients and cannot be used as a specific guide as to the efficacy of enzyme therapy.

OPERT is required for patients with proven PI. There is no current evidence that OPERT is efficacious for PS patients who maintain normal digestion and absorption owing to their own endogenous enzyme production. OPERT has changed substantially over the last two decades. Prior to 1980, the delipidated porcine pancreatic powder was administered either directly as the powder mixed with food or in gelatin capsules. Efficacy in most patients was poor, reducing average fat excretion from 40 to 25 to 30% of fat intake and often with excessive doses capable of causing hyperuricemia. The lack of efficacy was shown in both non-CF and CF patients to be related to gastric acid pepsin destruction of enzymes, which could be alleviated by adjunctive therapy with gastric acid suppression. Subsequently, the microspheric preparations were developed and marketed. These products have an outer gelatin capsule containing multiple microspheres, which contain the enzyme powder. The microspheres have an outer pH-sensitive coating resistant to acid dissolution but soluble in an alkaline environment and thus should pass through the stomach and into the small intestine before they dissolve and release their enzyme contents. In studies of mainly older children and adolescents, that is, > 30 kg in body weight, increasing doses to a maximum of 25 to 30 standard 5,000 IU lipase-containing capsules improved steatorrhea to an average 12 to 15% of fat intake, with 40 to 50% of patients having a fecal fat < 10% of fat intake.[66–68] We have thus used a regimen of one capsule (5,000 IU) of lipase/kg of body weight/day to a maximum of 30 capsules/day and have demonstrated normal growth from early infancy to late childhood with this regimen.[55,69] Others adhere to the more complex regimen of providing an enzyme dose per gram of fat ingested. Whether this will be advantageous in the long term remains to be proven, but provided that the enzyme dose is kept below 10,000 U lipase/kg/day and preferably below 5,000 IU lipase/kg/day, then safety is reasonably ensured in terms of developing fibrosing colonopathy.

Other Pancreatic Diseases

The above discussion of pancreatic dysfunction is also relevant to the non-CF pancreatic diseases. Specific features of these diseases are described in Table 39-5. In addition to maldigestion and malabsorption of nutrients, recurrent infections and antibiotic therapy in SDS, severe sideroblastic anemia and transfusion therapy in PPMS, diabetes in pancreatic agenesis, and developmental delay in JBS may contribute to poor intake and exacerbate undernutrition in these patients. Long-term outcome in the non-CF disorders in the main is unknown given that most of these disorders have been recognized only in the last two to three decades. In SDS, however, there is a known propensity for these patients to develop bone marrow malignancies, such as acute myeloid leukemia, and, currently, research activity is under way to determine factors or markers that may predict this occurrence, including myelodysplasia and the presence of monosomy 7 and isochromosome 7q.[6] An interesting feature of SDS is that although most are PI at diagnosis in the first year of life, up to 50% or more will become PS at a later age.[70] Reasons for this improvement in pancreatic function are unknown, but it will be important to determine if it is mutation related and whether these patients with improving pancreatic function have less of a risk for developing bone marrow malignancy.

NUTRITION IN EXOCRINE PANCREATIC DISEASES

The introductory remarks regarding the various pancreatic diseases emphasize that many are multisystem diseases

that interfere with the nutritional status of the patients involved. To date, most of the clinical nutritional research has been directed at CF, and there are large gaps in our knowledge about the nutritional outcomes of the non-CF disorders, at least partly related to their rare occurrence. The following description is thus mostly concerned with the nutritional status of CF patients.

The first reports on growth and nutritional status in CF documented that a large proportion of patients were wasted and/or stunted,[71,72] and through the 1970s, growth failure was regarded as being inherent to the underlying disease process. However, a large cross-sectional study from the Toronto clinic (Royal Alexandra Hospital for Children) in 1980 demonstrated, as per Table 39-6, that over 40% of patients had achieved the 50th percentile for height and only 10% were at or below the 3rd percentile.[73] Males had achieved similar percentiles for weight, but females appeared to be disadvantaged, with 16% being below the third percentile over age 8 years. These data contrasted with other clinics, including our own clinic in Sydney, where 13% of males and 21% of females were stunted over age 8 years and 33% and 42% of males and females, respectively, were wasted.[74] Clearly, the Toronto clinic had demonstrated that they could achieve near-normal linear growth in their patient population; thus, growth failure could not be readily attributed to the underlying disease process. Independent observers suggested that the growth advantage achieved in the Toronto clinic was directly related to their dietary policy, that is, their clinic had adhered to a high-quantity normal-quality diet with at least 40% of the energy intake as long-chain triglyceride,[75,76] in contrast to the more universal policy in other clinics of using a low-fat diet to control malabsorption. Energy intakes on low-fat diets averaged 80% of the Recommended Dietary Intake (RDI) for energy compared with the 113% achieved on the higher-fat diet in Toronto.[41,76,77] Subsequently, others demonstrated improvement in growth parameters over the short term with reversal of the low-fat diet policy.[78] We have also observed an improvement in growth at our own clinic over a 10-year period following a change of dietary policy with a major increase in the fat content of the diet, with a marked improvement in both linear growth and weight, particularly in the female population, as seen in Table 39-6. These data provided further evidence supporting the concept that growth failure in CF was nutritionally related and could be reversed and improved with the consumption of a high-energy, normal-quality, fat-containing diet.

Significantly, in 1980, the Toronto clinic also reported median survival of their population to the early thirties, and this was at least 10 years in advance of survival reported by other Canadian and US clinics.[73] These data suggested that as the only difference between the Toronto and other clinics was their nutritional policy and outcome, then these could be major factors contributing to the difference in survival. Subsequently, a direct comparison between the Toronto clinic with a "high-fat" diet policy and the Boston clinic with a "low-fat" diet policy demonstrated a near 10-year survival advantage to the Toronto patients, although average spirometric lung function parameters at 20 years were virtually identical.[79] Most clinics have now reversed their dietary policy to emulate the Toronto clinic and have not only shown improvement in growth but also an improvement in median survival to the late thirties and early forties.

Longitudinal growth studies for most non-CF diseases are not available, except in SDS. The latter appear to maintain a normal linear growth velocity but usually at or below the 3rd percentile throughout childhood.[80] The linear growth percentile does not increase with the institution of OPERT, and this suggests that short stature in SDS is inherent to the disease and possibly related to the underlying bone complications.

Nutritional Complications of EPD

The major nutritional complications of EPD are summarized in Table 39-4. These complications are common to all of the diseases except for salt depletion resulting from excessive sweat salt losses in warmer climates in CF patients. The origin of the nutritional complications/deficiencies relates to nutrient balance, that is, whether nutrient intake is adequate for maintenance of normal function and growth in the context of excessive nutrient losses owing to maldigestion and malabsorption or excessive use as observed with elevated energy expenditure in CF.

Macronutrients

Macronutrient intakes have been documented in several studies of CF patients using recall methods, food frequency questionnaires, and weighed diets.[41,75–78] Protein

intakes are usually well in excess of RDI, reaching in one study an average 200% RDI in a group of well-nourished patients and 170% in a malnourished group on relatively low-fat diets.[41] In contrast, as alluded to above, although those on normal-quality diets could achieve energy intakes on average in excess of 110% of recommended,[76] those on low-fat diets consistently averaged only 80 to 90% of their required energy.[41] The latter energy intake for malnourished patients leads to a decline in their nutritional status, with associated wasting and stunting of growth in the longer term. Recovery from the malnourished state is difficult for most as energy intakes may have to reach 150 to 200% of RDI for prolonged intervals for catch-up growth to occur, and usually invasive nutritional support is required to achieve these high energy intakes.[68]

As evident from Table 39-6, although most clinics now have liberalized the dietary fat content, there are still a significant number of CF patients who are wasted in their older years. Many of these patients experience anorexia, which is contributed to by a number of the complications of this disease, as outlined in Table 39-3. Lung, gut, and liver/biliary tract disease; recurrent infections; antibiotic therapy; psychosocial/behavior problems; and micronutrient deficiencies, including salt depletion, can all interfere with appetite, impairing dietary intake. Although lung disease and pulmonary infections manifest clinically, reflux and esophagitis, biliary tract disease, and micronutrient deficiencies may not be clinically obvious and will need to be excluded in the anorexic patient. Equally, patients without obvious physical complications may have psychosocial/behavioral problems and disordered eating behavior, either alone or in combination with physical problems, and thus will require careful investigation and management.[81,82] Equally in the other EPDs, recurrent infections, bone marrow disease with anemia and neutropenia, liver disease, and developmental delay can contribute to impaired nutrient intake.

Macronutrient maldigestion and malabsorption are classic characteristics of PI, leading, as indicated in the introduction, to substantial fat and protein losses from the gut. However, the marketing of microspheric/microtablet forms of OPERT has markedly decreased stool fat and protein losses to, on average, below 15% of nutrient intakes. Thus, in the current era of OPERT, lipase doses of up to 5,000 IU/kg/day should prevent major nutrient gut losses. Notwithstanding these comments, there has been a perceived difficulty in many centers to the use of either powdered preparations or microspheric OPERT in infancy. As a result, the use of medium-chain triglyceride (MCT) semielemental formulas has been advocated in these centers for CF infants as, purportedly, fat absorption was markedly improved with MCT without enzyme therapy.[83,84] However, in both studies, fecal fat was estimated by the Van de Kamer method, which does not measure MCT, so the fecal fats were underestimated. When, in fact, the appropriate technique for measuring fecal MCT was used, it was clearly demonstrated that enzymes were required for MCT digestion, that is, the use of an MCT formula did not obviate the need for OPERT.[85]

Increased energy expenditure also contributes to the negative energy balance in patients with CF. Feigel and Shapiro first demonstrated a doubling of oxygen consumption in cultured fibroblasts from CF patients compared with controls,[86] a finding confirmed by others when studying CF nasal epithelium.[87] Several studies subsequently reported varying elevation of resting (REE) or total energy expenditure (TEE) in CF subjects and suggested that the elevation was related directly to the combination of malnutrition and lung disease.[42–44,88] However, Shepherd and colleagues contended that the increase was intrinsic to the underlying disease as TEE in CF infants seemingly with minimal lung disease was increased when compared with controls.[88] Two studies later disputed these findings.[89,90] Fried and colleagues, in a group of male CF adolescents/young adults with normal lung function, were unable to demonstrate significant differences in REE between two groups with PI and another with PS, and average values were only minimally above (104%) normal predicted values.[89] Furthermore, in a retrospective analysis, they showed a curvilinear relationship between REE and forced expiratory volume (FEV_1), so that as FEV_1 decreased below 75% predicted, REE increased exponentially.[89,91] These findings were also supported by a study of newly diagnosed CF infants, in whom there was no difference in energy expenditure between controls and various genotypic groups of CF infants.[90] However, in the study of Fried and colleagues, there were only nine patients in each of the ΔF508 compound heterozygote PI and PS groups, and the latter demonstrated a near 20% reduction in REE when expressed per fat-free mass, despite having lower average lung function than the PI group.[89] Furthermore, in the CF infant study, the standard deviation among the groups of CF infants varied from 30 to 70% of the average values compared with only 21% in the control group. Values for the PS patients were also not provided; thus, it was difficult to determine whether the CF results were lowered to the normal range by the PS patients' results.

Other studies have disputed these findings. O'Rawe and colleagues demonstrated in three genotypic groups (ΔF508/ΔF508, ΔF508/other, and non-ΔF508/non-ΔF508) average REEs of 121%, 109%, and 104%, respectively.[92] Seemingly, this disproved the above as multiregression analysis did not show a relationship with pulmonary dysfunction. However, average FEV_1 percent predicted was low in the ΔF508/ΔF508 group (56%) and also in the ΔF508/other group (63%), and these data therefore appeared confirmatory of the effect of lung dysfunction elevating REE. In a more recent study of 104 CF patients with both males and females with near-normal lung function (FEV_1 percent predicted 87% and 83% for males and females, respectively) and 131 age-matched controls, REE was highly significantly elevated in CF females, and the average REE in PI patients adjusted for fat-free mass was 110% of the PS value, despite similar pulmonary function.[93] The female disadvantage had been recognized by other investigators.[94] Of importance, these recent studies, although not negating that a large proportion of the increase in REE in CF is contributed to by deteriorating

lung function, do emphasize the significant increase in females and those with the PI phenotype and the necessity for a larger energy intake than normal, even at an early age, in these groups of patients. Further investigation of the gender difference is warranted considering previous reports of a poorer prognosis for CF females.[73]

Essential Fatty Acid Metabolism

EFA deficiency (EFAD) has been well described in patients with CF.[95,96] Clinical deficiency with seborrheic dermatitis, poor wound healing, thrombocytopenia, anemia, and increased propensity for infections may be present in PI infants prior to treatment of PI but is far less evident in older PI patients receiving a normal diet and appropriate OPERT.[97] Older PI patients, however, have subclinical/biochemical deficiencies of blood and tissue EFA levels, particularly showing decreases of linoleic acid and increased palmitoleic, oleic, and eicosatrienoic acids. Although some have suggested that EFAD is a primary abnormality and unrelated to malabsorption,[98] others have suggested that EFAD is evident only in patients with < 5% of normal exocrine pancreatic function and, furthermore, can be improved by optimizing OPERT and dietary intake.[99]

There has been considerable recent interest in EFA metabolism in a CF knockout mouse model without functional *CFTR*.[34] These animals demonstrate an elevated arachidonic acid (AA)-to-docosahexaenoic acid (DHA) ratio in tissue that normally expresses *CFTR*, for example, lungs, pancreas, and small intestine, compared with wild-type controls. Of significance, early dilatation of pancreatic ductules in the CF mouse can be normalized with supplemental DHA and normalization of the tissue AA-to-DHA ratio. In CF humans, the average AA-to-DHA ratio in nasal epithelium and monocytes from PI patients is two to three times that observed in controls, and the same phenomenon was observed in six PS patients, although, in the latter, there was considerable overlap with control data.[100] Further work is currently under way. Priorities include determining the optimal dose and method of delivery and toxicity/safety margins for humans given the high doses required in the knockout mouse. In addition, given that the mouse model has no functional CFTR, one is left to assume that the effect of DHA on improving the pancreatic pathology is by up-regulating alternate chloride and fluid secretion. This aspect also requires further investigation. Until these studies are completed, one would have to caution against routine DHA supplementation of human CF patients.

Micronutrients

Micronutrient deficiencies have been described in EPD, particularly in patients with CF. These have included fat-soluble vitamin deficiencies, vitamin B_{12} deficiency, trace metal deficiencies, and salt depletion.

Fat-Soluble Vitamins Fat-soluble vitamin deficiencies A, D, E, and K are well documented in CF PI patients.[101–110] Most descriptions of deficiencies have occurred in patients prior to diagnosis and commencement of OPERT and in an era where OPERT was suboptimal, that is, prior to microspheric therapy. Clinical evidence of deficiency is unusual in patients on optimal diets and OPERT, although it has been described in noncompliant patients and those with evidence of liver disease. Clinic policies vary considerably regarding vitamin supplementation, although the latter would appear unnecessary in PS patients and PI patients who normalize their fat absorption on OPERT and maintain normal serum vitamin levels and coagulation profiles. Omission of fat-soluble vitamin supplementation in PS patients is certainly reasonable, and, in fact, declining levels in this group are a useful strategy for monitoring pancreatic function and should alert the physician to the development of PI and instigate further investigations.

Vitamin A Infants with vitamin A deficiency may present with a bulging fontanelle owing to benign intracranial hypertension.[101] Older patients present with night blindness, xerophthalmia, corneal xerosis, and ulceration with Bitot spots. Although night blindness is usually associated with very low serum vitamin A levels (< 0.5 μmol/L), subtle impairment of dark adaptation tests was associated with serum levels from 0.2 to 1.4 μmol/L, which overlapped the range in those with normal adaptation of 0.5 to 2.1 μmol/L.

Vitamin D Frank clinical rickets and osteomalacia are unusual phenomena in CF populations,[103] but subclinical/biochemical rickets with low serum 25-hydroxycholecalciferol levels are common in northern hemisphere patients.[104,105] Low 25-hydroxyvitamin D levels are very unusual in patients in Australia, presumably related to year-round exposure to sunlight.

Vitamin E Vitamin E deficiency has been best described in non-CF patients with either persistent cholestasis or in the rare disorder abetalipoproteinemia. Early signs include loss of deep tendon reflexes and impaired position and vibration sensations. Untreated deficiency may be associated with the development of ataxia, tremors, dysarthria, proximal muscle weakness, and external ophthalmoplegia, and these more severe symptoms may have a variable response to vitamin E repletion therapy. In infancy, CF patients may present with a hemolytic anemia and may have concomitant hypoproteinemia and poor weight gain.[111] In screened populations, nearly 40% of infants have low serum α-tocopherol levels, and in some 10%, low levels may persist despite seemingly optimal oral replacement.[112] In older patients and through adolescence, clinical symptomatology and low serum vitamin E levels are unusual, particularly in PI patients with normal absorption on OPERT or PS patients. Regular monitoring of levels with supplementation to maintain levels > 7 to 8 μg/mL would appear appropriate.

Vitamin K Vitamin K deficiency is associated with a coagulopathy and hemorrhagic manifestations. It has been described in CF infants prior to diagnosis and in patients with persistent cholestasis. Monitoring and maintenance of

normal coagulation profiles, particularly in patients with persistent steatorrhea, are appropriate.

Water-Soluble Vitamins Water-soluble vitamins are well absorbed by CF patients. The exception is vitamin B_{12}. Normally, the vitamin B_{12}–intrinsic factor complex is bound to R proteins, and prior to binding to the specific terminal ileal receptors, the R proteins need to be separated from the vitamin B_{12}–intrinsic factor complex. This process requires pancreatic proteases; thus, there is a theoretic possibility that untreated PI CF patients can develop vitamin B_{12} deficiency. This is unlikely to occur in patients receiving optimal OPERT. On the contrary, terminal ileal resection, as could occur in infants with complex meconium ileus, could seriously impair vitamin B_{12} absorption, and such infants may require prolonged parenteral supplementation.

Trace Metals Trace metal deficiencies, particularly zinc and selenium, have been described in CF populations but usually in association with protein-energy malnutrition. Selenium deficiency associated with a cardiomyopathy in non-CF populations is likely a geographic phenomenon as it was not evident in a US CF study but was present in a Scottish study.[113,114]

Salt Depletion Salt depletion owing to excessive sweat salt losses occurs not infrequently in patients residing in or visiting warm to hot climates. Depending on age, activity, and ambient temperature, salt losses can exceed 10 g/day. Whereas the older patient has access to salt, younger patients, particularly infants, are at risk from salt depletion if not receiving appropriate oral salt supplements. Symptoms are nonspecific and include lethargy, anorexia, nausea, and vomiting, but they may rapidly escalate and produce frank signs of dehydration, poor perfusion, and collapse. Gut symptoms with nausea, vomiting, and abdominal distention may predominate as a result of hypokalemia and the ensuing gut dysmotility with paralytic ileus. Patients presenting in this manner may be misdiagnosed as having mechanical intestinal obstruction and may not receive appropriate salt replacement until circulatory collapse ensues. Classically, on measuring serum electrolytes, patients have hyponatremia and hypochloremia but also evidence of hyperaldosteronism with hypokalemia and a metabolic alkalosis with associated tetany. Intravenous salt replacement is usually required to treat symptomatic patients. In patients with evidence of poor perfusion and dehydration, intravenous therapy with a bolus dose of normal saline 10 to 20 mL/kg should be given immediately and replacement therapy continued over the next 4 to 5 hours with normal saline, depending on the patient's response. Potassium can be replaced following establishment of urine flow and monitored by measurement of serum electrolytes. Patients less severely compromised may respond to oral electrolyte solutions or simple oral salt replacement, but if nausea and vomiting prevail, intravenous replacement will be required.

Nutritional Assessment

Nutritional assessment is an essential element of the management of CF patients both at diagnosis and on a regular basis thereafter. Normal growth usually indicates patient well-being, but, in contrast, impaired growth signifies activation or exacerbation of lung disease or the onset of gut complications, which require investigation and management.

At diagnosis, all patients require examination with height and weight, head circumference measurements, assessment of muscle and subcutaneous fat wasting, and examination for macro- and micronutrient deficiencies, including edema. Baseline biochemical parameters should include fat-soluble vitamin levels, coagulation profile, hemogram, serum albumin, and, if available, serum EFA levels. Pancreatic status should be assessed preferably with a 3- to 5-day fat balance study but, if unavailable, one of the other tests as indicated previously. Beyond infancy, a fecal fat in excess of 7% indicates PI and conversely ≤ 7% PS and the necessity or not, respectively, for OPERT. In infants < 6 months of age, a fecal fat > 10% of fat intake or, if breastfed > 2 g/day indicates PI and the necessity to start OPERT.

In follow-up, accurate growth measurements are the simplest and most important clinical data to obtain to assess patient well-being from a nutritional point of view. Patients should be questioned in regard to their appetite, the occurrence of heartburn, water brash, abdominal pain, and constipation, that is, in an attempt to elicit gastrointestinal complications. Abdominal examination should be undertaken to look for hepatomegaly and splenomegaly and the presence of fecal masses in the right lower quadrant. Older patients can be asked about night blindness, and in younger infants, the fontanelle should be examined to assess for vitamin A deficiency. Deep tendon reflexes should be elicited to determine early-onset vitamin E deficiency and the ribs and long bones examined for evidence of rickets. Biochemically, patients should have, at least on an annual basis, a hemogram, coagulation profile, serum electrolytes, albumin, liver function tests, fat-soluble vitamin levels, and a blood glucose performed.

More elaborate nutritional studies, including indirect calorimetry and body composition studies, are performed at some clinics but usually in the context of a clinical research project. The possible exception is the routine measurement of bone mineral density with dual-energy x-ray absorptiometry (DXA) because of the reported high incidence of osteoporosis and osteopenia in older children and adolescents with CF.[115]

Repeat assessments of pancreatic function are required in PS patients who have developed symptomatology suggestive of steatorrhea or in PI patients who are not responding to their OPERT. The latter can be reliably tested only with formal fat balance studies, and if fat malabsorption is in excess of 20% of fat intake on a standard OPERT regimen, the patient may require adjunctive gastric acid suppression with histamine (H_2) receptor antagonists or proton pump inhibitors.

Nutritional Management

Nutritional guidelines for the management of EPD are outlined in Table 39-7, noting that salt supplementation

is required only for CF patients and that PS patients irrespective of the underlying disorder can adhere to a normal diet. The aim of these nutritional guidelines is to ensure that PI patients achieve normal linear growth and weight gain. Diets for children in Western countries ensure a high protein intake well in excess of the recommended. Energy requirements, however, will vary from patient to patient depending on the degree of residual malabsorption, response to OPERT, and the variable increase of energy expenditure.

As indicated above, OPERT doses equivalent to 5,000 lipase U/kg/day achieve average fat losses of 12 to 15% of fat intake in fat balance studies. Most patients will achieve values < 20%, and nearly half of the patients normalize their fat excretion below 10% of fat intake. Approximately 10% of patients have suboptimal responses to their OPERT and maintain fat excretions in excess of 20% of fat intake. They should be further investigated to exclude small intestinal disease (celiac disease and giardiasis) and also biliary tract complications. In the absence of these complications, the use of adjunctive gastric acid suppression therapy with proton pump inhibitors or H_2 receptor antagonists may improve fat excretion by elevating upper intestinal pH and thus ensuring dissolution of the microspheres and release of enzyme at a pH more optimal for their activity.[67] Many clinics permit patients to self-modulate OPERT doses according to their clinical symptoms. However, in this group with suboptimal response to OPERT, a "dose-creeping effect" is seen, with often large doses of enzymes in excess of 20,000 lipase IU/kg/day and in some instances over 50,000 lipase IU/kg/day being considered. These patients have an increased risk of developing fibrosing colonopathy, and this practice should be discouraged.

Energy intake should also be modified depending on the variability of energy expenditure. CF patients, for instance, those with chronic lung disease or those experiencing acute exacerbations of their lung disease, can demonstrate REE in excess of 150% of predicted. Failure to meet these requirements leads to weight loss and, if persistent, to growth failure. Thus, although recommendations for average energy intake of 115 to 120% of RDI are not unreasonable between exacerbations of pulmonary disease, a degree of flexibility in terms of dietary advice is required.

The recommendations for micronutrient supplements also have to be considered in regard to the presence and degree of malabsorption. PS patients usually maintain normal serum vitamin levels and coagulation profiles without supplementation. Similarly, a large proportion of PI patients who are compliant to OPERT have normal fat absorption and do not demonstrate vitamin deficiencies based on monitoring of serum vitamin levels; thus, vitamin supplementation is of questionable value in this group. We would recommend at least annual monitoring rather than encumber the patients with yet another medication. The recommendation for salt supplementation applies specifically to those children residing in warm to hot climates or those in more temperate climates who undertake strenuous exercise.

TABLE 39-7 Nutrient Requirements in Pancreatic Insufficiency including Cystic Fibrosis

Nutrient	*Requirement*
Protein	> 120% of RDI
Energy	Variable, depending on disease status, but in PI patient should average near 120% RDI with 40% as LCT and 3–5% as EFA
Vitamins

> 5 yr	3–5 g/d

Adapted from Gracey M et al.[116]
*If serum levels and coagulation profile are normal, patients may not need supplement.
†Not required if exposed to sunlight throughout the year.
‡Double salt dose in hot weather or during strenuous exercise.
Can use vitamins A, D, E, and K (Scandipharm) or vitamins A, B, D, E, and K (Technipro): 4–10 yr, 1 cap daily; > 10 yr, 2 caps daily; 0–1 yr, 1 mL daily; 1–3 yr, 2 mL daily; or Micelle A & E, 1–2 mL daily or Aquasol E (Rover Pharmaceutical, PA) 1 ml daily.
EFA = essential fatty acid; LCT = long-chain triglyceride; PI = pancreatic insufficient; RDI = Recommended Dietary Intake.

Special Circumstances ***Infant Nutrition.*** In the pre-microspheric OPERT era, OPERT was presented to infants in a powdered form, usually mixed with food. Many infants developed mouth ulcers, impairing nutrient intake; thus, alternative regimens were formulated. Considering also that human milk and soy formulas had been associated with the development of hypoproteinemia, predigested MCT-containing semielemental formulas were introduced into the management of CF infants.[83,84] As they, purportedly, improved fat absorption, this obviated the need for OPERT and avoided the oral complications seen with powdered OPERT. However, long-term growth rates were suboptimal, suggesting that as energy intakes were appropriate, there were ongoing unrecognized problems with malabsorption.[116] Others indicated that the earlier studies had not used the modified technique for measuring MCT in stools and thus had underestimated the degree of malabsorption.[85] Furthermore, they demonstrated that, using the correct technique, average fecal fat on Pregestimil alone was 26% of fat intake and improved to < 9% with the concomitant use of OPERT.[85] These results questioned the routine use of semielemental formulas, given their high cost, but comparative studies with human milk or standard cow's milk formulas were unavailable, and the feeding of semielemental formulas became standard practice in CF clinics.[117]

Breast-feeding was, in fact, not recommended because of its lower protein content and the frequent occurrence of hypoproteinemia at presentation in PI patients in unscreened populations. In the early 1980s, several centers commenced neonatal screening for CF, and, as a result, PI patients were diagnosed and commenced on OPERT at an

early age. A re-evaluation of breast-feeding in this population demonstrated that breast-fed PI infants could maintain normal average growth to age 2 years, which was at least comparable to those given humanized cow's milk formulas and clearly better than those on predigested formulas who had suboptimal standardized weight scores.[69,117] Breast-feeding is thus entirely appropriate in the context of neonatal screening, in which there is early recognition and treatment of PI, but has yet to be evaluated in a non-screened population in which older PI infants may be severely malnourished and hypoproteinemic at diagnosis.

***Invasive* Nutrition.** Most patients with CF adhering to a high-quantity energy intake diet with normal quality in terms of fat content achieve normal growth rates throughout childhood and adolescence.[73] Nevertheless, as per Table 39-6, a substantial proportion of patients are both underweight and stunted, even in the modern era. Many anecdotal studies have demonstrated that nocturnal tube feeding of this group of patients can improve weight gain and linear growth and can even restore growth to the previous normal growth channels.[118,119] Some of the short-term studies not only improved growth but also demonstrated improvement in spirometric lung function and a decline in pulmonary infections. However, these studies were uncontrolled with small numbers; thus, the beneficial effects on lung disease could not be determined.

Subsequently, three large studies over at least 12 months were conducted at three different centers.[120–122] They demonstrated improvement in growth, and whereas one demonstrated a mild improvement in FEV_1 percent predicted in the treatment group, the other two suggested that the expected decline in lung function was prevented in the treatment group. However, the number of patients in each study was small, that is, 10 to 20 per treatment or control cell; thus, the effect of improving growth on pulmonary function in malnourished subjects remains contentious. Recommendations regarding the type of formula used (elemental, polymeric), the feeding technique (nasogastric, gastrostomy, jejunostomy), duration of use, etc, vary from clinic to clinic. We have used a nocturnal feeding regimen with a polymeric formula, Ensure Powder (Abbott), which, on reconsitution, has a fat content of 35.5 g/L. We have advised patients to use an enzyme dose providing approximately 1,000 lipase U per gram of fat, so if receiving a liter of the formula, they would take $7 \times 5{,}000$ IU capsules, with half the dose given prior to sleep and the other half on awakening.

Nocturnal feeding regimens are demanding on the patients and their families, and the psychological/emotional impact of this therapy is not well documented. Although some cope extraordinarily well and are highly compliant, in others, the burden of the therapy is overwhelming and unsuccessful. Given that improvement of lung function with these regimens is questionable and without information on whether they improve survival, one has to be cautious about recommending this type of therapy. Families need to have education and thorough discussions regarding the commitments needed to ensure success of the therapy and a psychological evaluation to assess their ability to cope with this extra treatment burden. It may well be that this type of therapy in the future will be restricted to compliant patients and potential lung or liver transplantation recipients.

In view of the difficulties frequently encountered with "invasive" nutrition regimens, there has been considerable interest generated by three recent studies on the use of megestrol acetate as an appetite stimulant in CF patients.[123–126] The drug acts directly via the hypothalamus to stimulate appetite and has been used in other anorexigenic/cachetic illness.[127] The most recent study, a double-blind, placebo-controlled study, demonstrated a substantial improvement in average weight gain in the treatment versus control group (5.3 kg versus 1.5 kg, respectively) over 6 months.[125] This is an encouraging result, but the study numbers were small (10 versus 7, respectively), and there is still some uncertainty about long-term adverse events, including adrenal suppression and the occurrence of diabetes mellitus, although they did not occur in this study. Bone mineral density was also said to be stable over the 6 months, but only 7 patients had DXA evaluation of their bone mineral density. Although one can be cautiously optimistic about these reports, clearly, further long-term studies are required to evaluate the potential for adverse events and to determine which patients are likely to benefit from such therapy. One would hope that it could be avoided in the 90 to 95% of patients who, in general, maintain normal growth, but it may well have application in the 5% of patients who do not respond to routine regimens.

CONCLUSION

Many of the EPDs, including CF, are multisystem disorders and require a team approach for delivery of optimal care. Personnel with nutritional expertise are required for monitoring the patient's nutritional status and growth and for educating the patients and their families regarding optimizing dietary intake and OPERT. Patients consuming high energy intakes by avoiding low-fat diets can achieve normal growth and with appropriate vitamin intake can avoid most micronutrient deficiencies. It is essential in addition to monitoring growth and micronutritional status to ensure appropriate but not excessive OPERT ingestion to avoid treatment-related disease such as fibrosing colonopathy. Some patients, despite optimal advice and care, experience growth and nutritional problems and may be candidates for invasive nutrition if they clearly fail to demonstrate a response to specific oral supplementation regimens.

CHAPTER 40

ACUTE AND CHRONIC LIVER DISEASE

Deirdre A. Kelly, MD, FRCP, FRCPI, FRCPCH

The liver has a central role in energy metabolism, nutritional homeostasis, and absorption of nutrients. Severe liver disease, whether acute or chronic, leads to multiorgan failure, which can have significant effects on growth and development in the long term. The pathophysiology of malnutrition in liver disease is complex and multifactorial and has extensive implications (Table 40-1). It is most severe in infants with chronic cholestatic liver disease, who are particularly vulnerable to the effects of malnutrition because of their high energy and growth requirements.[1] This chapter reviews the pathophysiology of malnutrition in pediatric liver disease and current treatment strategies, including liver transplantation.

PATHOPHYSIOLOGY OF MALNUTRITION IN LIVER DISEASE

Prevalence of Malnutrition

Malnutrition is common in children with chronic liver disease. Estimates vary from 50 to 80% in studies from North America and Europe.[2–5] In general, children who present with acute liver disease such as viral hepatitis or fulminant hepatitis are not malnourished at presentation but can become so as a result of their illness.[6]

Reduced Energy Intake

Anorexia is a common symptom in children with either acute or chronic liver disease. They often take in less than the recommended requirements or less than is appropriate for their energy requirements because of increased energy expenditure.[7] The consequent reduction in enteral intake can lead to considerable loss of body stores or lean body mass, which alters body composition.

In children with chronic liver disease, the complications of portal hypertension, such as ascites and hepatosplenomegaly, can lead to malabsorption of nutrients. The treatment of ascites, which includes fluid restriction, the prescription of unpalatable feeds, or both, can exacerbate anorexia and reduce energy intake further.[3]

Carbohydrate Metabolism

Under normal circumstances, the liver receives portal vein blood rich in absorbed glucose, which can be stored in the liver as glycogen or circulated to extrahepatic tissues, especially muscle, where lactate, pyruvate, and alanine are generated by glycolysis.[8,9] In children with liver disease, this substrate supply and use can be abnormal. The loss of glycogen stores in chronic liver disease leads to fasting hypoglycemia and an inability to meet energy demands. In addition, any significant hepatocyte loss, especially in acute liver failure,[10] has an immediate effect on glucose metabolism, leading to hypoglycemia.

In cirrhotic adults, the pancreas secretes increased amounts of insulin, which is not metabolized, either because of portosystemic shunting around the liver or because of reduced degradation owing to hepatic dysfunction.[11] Although there is increased circulation of insulin, glucose uptake in the peripheral tissues, especially muscles, is reduced as a result of insulin resistance. Adult studies suggest that this could be attributable to impaired glycogen synthesis in the muscle, either because of abnor-

mal insulin receptor numbers or affinity.[12,13] These data have not been confirmed in children, but it is possible that similar mechanisms occur, although few children (apart from those with cystic fibrosis) develop overt diabetes mellitus, unlike adults.[12]

Protein Metabolism

Amino acids are absorbed by the intestine directly into the portal vein and transferred to the liver, where they are synthesized into protein or used for energy. The liver is responsible for approximately 10% of plasma protein synthesis; thus, amino acids are constantly recycled.[9,14] Nonessential amino acids are oxidized in both liver and muscle. The seven aromatic essential amino acids (AAAs; arginine, histidine, lysine, methionine, phenylalanine, tryptophan, and threonine) are metabolized in the liver, whereas the three branched-chain essential amino acids (BCAAs; leucine, isoleucine, and valine) are metabolized predominantly in muscle and pass unaltered through the liver to the periphery, where their uptake is regulated by insulin.[15] The liver is also responsible for detoxification of nitrogenous wastes via the urea cycle, leading to the production of ammonia—hence the rise of plasma ammonia in both acute and chronic liver failure.[16]

Reduced hepatic and muscle glycogen stores lead to early recruitment of fat and increased dependence on amino acids as an alternative fuel.[17] Abnormal protein use by the liver leads to a rise in AAAs and a reduction in the BCAAs, which are metabolized in muscle in both children and adults.[18–20] An abnormal ratio of BCAAs to AAAs correlates with histologic damage and encephalopathy in adults[21] and children.[19]

Studies in adults demonstrating abnormalities in BCAA metabolism using studies of BCAA fluxes and protein turnover have given conflicting results. It is possible that the hyperinsulinemia detected in cirrhosis could cause the decreased BCAA levels by increasing BCAA uptake in muscle or adipose tissue. Alternatively, it is possible that there is an increase in liver transamination of BCAAs in addition to abnormal protein turnover.[22] Three recent adult studies demonstrated that protein synthesis can be increased or decreased depending on clinical condition and that muscle wasting is attributable to a relative increase in protein breakdown.[23–25] Those patients who had more efficient protein retention were less malnourished.

A study of protein metabolism in infants with liver disease, which used a whole-body leucine turnover model, demonstrated that muscle protein degradation and protein oxidation were increased, possibly as a result of a reduction in carbohydrate metabolism and the use of protein as an energy supply.[26] In contrast to normal children, muscle protein degradation continued in these children even when they were fed, suggesting that this could be a factor in the muscle loss common in infants with chronic liver disease.

In addition to protein synthesis and degradation, the liver is the site of synthesis of all of the coagulation factors except factor VIII, von Willebrand's factor, which is synthesized by vascular endothelial cells.[27,28] Thus, coagulopathy is an early sign of significant acute or chronic liver failure.

In chronic liver disease, these metabolic changes result in muscle wasting, hyperammonemia, hypoalbuminemia, hypoglycemia, hypolipidemia, and reduced circulating triglyceride levels secondary to the increased fat oxidation. Hypoalbuminemia is associated with a reduction in plasma oncotic pressure, exacerbating the development of ascites and peripheral edema. In acute liver failure, the main effects of deranged protein metabolism are hyperammonemia and abnormal coagulation.

Fat Metabolism

Most dietary fat is in the form of long-chain triglycerides (LCT) and is an excellent energy source.[29] The first step in fat digestion is emulsification in the stomach, followed by hydrolysis of triglycerides by pancreatic lipase in the intestinal lumen and then micellar solubilization of di- and monoglycerides by bile acids, which are then transported into the enterocytes. Once in the enterocytes, fatty acids are re-esterified and chylomicrons are formed and removed via the lymphatics through the portal system to the liver and other tissues.[29]

In contrast, medium-chain triglycerides (MCTs) do not depend on micellar solubilization for absorption and can be transferred directly from the enterocytes to the portal circulation without re-esterification.[29,30] In the liver, free fatty acids are metabolized into triglycerides or oxidized for energy. The very-low-density lipoproteins (VLDL) and high-density lipoproteins (HDL) are synthesized in the liver, as is cholesterol, which is the precursor for many hormones, vitamins, and bile acids.

In all forms of chronic liver disease, there is reduction in the synthesis and secretion of bile salts, although this is more severe in cholestatic diseases such as biliary atresia. Up to 50% of LCTs, fat-soluble vitamins, and essential polyunsaturated fatty acids (PUFAs) might not be absorbed because of reduced biliary secretion and reduction in intraluminal bile concentration.[31–33] In contrast, 95% of water-soluble lipids, such as MCTs, which do not depend on bile solubility, are absorbed even in cholestatic infants[34] and form the basis for nutritional replacement.[35]

Fat malabsorption can also be affected by portal hypertension, which leads to congested gastric and intestinal mucosa, and by small bowel overgrowth in the Roux-en-Y blind loop created by a Kasai portoenterostomy. In addition, therapy such as cholestyramine to reduce pruritus can exacerbate steatorrhea because it binds bile salts, decreasing micellar solubilization.

Pancreatic function is usually normal except in children with Alagille syndrome, in which pancreatic lipase can be reduced.[34,36]

Long-Chain Polyunsaturated Fatty Acids

Long-chain polyunsaturated fatty acids (LCPs) such as arachidonic acid and docosahexaenoic acid (DHA) are essential nutrients in infancy. LCPs, in particular DHA, play a major role in the development of visual acuity and mental development in the first year of life, particularly in preterm infants.[37–40] The main source of LCPs is maternal,

in the last trimester of pregnancy and through breast-feeding, because breast milk is a rich source of LCPs, containing both arachidonic acid and DHA in a combination of phospholipid and triglyceride forms.

Studies in adults have demonstrated that LCP deficiency can develop either from malabsorption of long-chain fat and essential fatty acids or from reduced synthesis or function of the Δ-6-desaturase enzyme required for the de novo synthesis of very-long-chain (20–22) carbon PUFAs from their essential fatty acid 18-carbon dietary precursors.[41,42]

Children with cholestatic liver disease have normal LCP and DHA levels at birth but can become deficient within 8 to 12 weeks,[43] either from malabsorption of LCTs, from prescription of formula feeds rich in MCTs, or as a result of inadequate liver desaturase enzyme activity.[41,44,45]

Fat-Soluble Vitamin Deficiency

Chronic liver disease affects vitamin absorption, metabolism, and storage. Reduction in bile salt secretion leads to malabsorption of the fat-soluble vitamins A, D, E, and K. Fat-soluble vitamin deficiency can develop within 6 to 12 weeks of birth, depending on body stores and availability of vitamin supplementation. Vitamin A deficiency can also develop secondary to reduction in protein synthesis or depletion of hepatic stores. Vitamin D deficiency can occur either from fat malabsorption or from reduction in hepatic 25-hydroxylation. Vitamin K deficiency arises partly from fat malabsorption and partly from a reduction in intake, particularly in breast-fed infants.

Because the liver has a central role in lipoprotein metabolism and cholesterol synthesis, hypercholesterolemia and hypertriglyceridemia are common in chronic liver disease. There can be increased synthesis of cholesterol esters as a result of loss of hepatic lecithin cholesterol acyltransferase, which can alter lipoprotein fractions. In cholestatic liver disease such as Alagille syndrome, unusual lipoproteins, such as lipoprotein X, are produced with cutaneous xanthomata and hemolysis from alterations in red cell and platelet membranes.[46]

In terminal liver disease, however, the reduction in cholesterol synthesis leads to hypocholesterolemia, which is a poor prognostic sign.[47]

Growth Hormone/Insulin-Like Growth Factor Axis

Growth failure in chronic liver disease can be exacerbated by an impaired growth hormone/insulin-like growth factor (IGF-I) axis[48,49] because IGF-I and its major circulating binding protein, IGF-BP3, are synthesized in the liver. It seems that IGF-I is nutritionally regulated[50] because there is animal evidence that nutrients influence synthesis and action of IGF-I and its binding proteins at many levels, including defects in pre- and post-translational expression. Thus, protein malnutrition not only decreases the IGF-I production rate but can also increase serum clearance and degradation. Evaluation of growth hormone, growth hormone binding proteins, and IGF-I in children with protein-energy malnutrition, before and after nutritional rehabilitation, has confirmed the role of malnutrition in these hormones.[51]

Children with chronic liver disease have low plasma levels of IGF-I despite elevated levels of growth hormone, which could be a result of diminished hepatic synthesis or malnutrition or related to end-organ insensitivity to IGF-I.[52,53]

Increased Energy Expenditure

Adult studies have produced conflicting data on energy expenditure, but the situation is different in a growing child. A number of studies have indicated an increase in energy requirements of up to 140% in children with chronic liver disease.[54,55] Mechanisms implicated include portosystemic shunting and ascites, abnormal intermediate metabolism, and the energy demands of specific complications, such as sepsis and variceal hemorrhage. Children with acute liver failure also have excess energy expenditure and requirements because of multiorgan failure, but this has not been specifically studied.

Trace Elements and Metals

Biochemical deficiencies of water-soluble vitamins such as thiamin and pyridoxine can occur and lead to nutritional cardiomyopathy and peripheral neuropathy.[56] Trace metal deficiencies include iron deficiency secondary to gastrointestinal bleeding or diminished intake and zinc and selenium deficiencies caused by reduced enteral intake, malabsorption, or increased losses.

Consequences of Malnutrition

Many different nutrient deficiencies occur in children with chronic liver disease (Table 40-2), and malnutrition per se can increase liver dysfunction because of the energy required for synthesis, storage, and detoxification. Children with progressive cholestasis, such as those with biliary atresia or Alagille syndrome, develop significant fat malabsorption, which leads to steatorrhea, fat-soluble vitamin deficiency, essential fatty acid deficiency, loss of fat stores, and a reduction in growth (Table 40-2 and Table 40-3). Essential fatty acid deficiency can present with a skin rash, whereas DHA deficiency is associated with abnormalities in visual function, as demonstrated by electroretinograms in cholestatic infants.[43]

Fat-soluble vitamin deficiency is more common and can be detected biochemically before clinical symptoms, which are obvious only with severe deficiencies, appear. Clinical signs and symptoms of vitamin A deficiency are rare but include night blindness, xerophthalmia, and keratomalacia.[57] Vitamin D deficiency leads to hypocalcemia, hypophosphatemia, rickets, and pathologic fractures, particularly in infants who are rarely exposed to sunlight or who have inherited metabolic liver disease and a renal tubular disorder. Deficiency of vitamin E leads to hemolysis, peripheral neuropathy, and occasionally visual loss.[58,59] Vitamin K deficiency can present as hemorrhagic disease of the newborn, particularly in breast-fed babies who are given insufficient vitamin K at birth.[60] It leads to coagulopathy, which is exacerbated by decreased synthesis of liver-dependent clotting factors. In vitamin K deficiency secondary to fat malabsorption, parenteral vitamin K will

TABLE 40-2 Clinical Manifestations of Malnutrition in Liver Disease

Nutritional Deficit	*Clinical Manifestation*
Protein-energy malnutrition	Stunting, muscle wasting, motor developmental delay
Fat malabsorption	Steatorrhea, loss of fat stores
Essential fatty acid deficiency	Peeling skin rash
Vitamin A deficiency	Conjunctival and corneal drying, night blindness
Vitamin E deficiency	Peripheral neuropathy, ophthalmoplegia, ataxia, hemolysis
Vitamin D deficiency reduced bone density	Osteopenia, rickets, fractures,
Vitamin K deficiency	Bruising, epistaxis, coagulopathy
Zinc deficiency	Acrodermatitis, anorexia, poor growth
Hypercholesterolemia	Xanthomata
Immunosuppression secondary to reduced cell-mediated immunity	Systemic infections

improve the coagulation profile, whereas it will be ineffective in parenchymal liver disease.[61]

Metabolic bone disease with reduced bone density is usually observed in end-stage liver disease.[62] Although malabsorption of vitamin D is a factor, the etiology is more complex as normal levels of vitamin D do not prevent bone demineralization.[62] Children with liver disease have a higher incidence of dental caries and enamel hypoplastic defects, which could be related to nutritional deficiency or to bone disease. They also have discolored teeth as a result of hyperbilirubinemia.[63]

Trace element and mineral deficiencies include iron deficiency with anemia and zinc deficiency, which leads to acrodermatitis, immunodeficiency, and altered protein metabolism; both zinc and selenium deficiency can exacerbate growth failure and poor protein synthesis.[2]

In the course of chronic liver failure, fat malnutrition develops first, as demonstrated by loss of fat stores. Protein malnutrition is a late development and is associated with a reduction in muscle bulk, stunting, and significant motor developmental delay. In time, children with significant malnutrition will have impaired growth and psychosocial development[64,65]; thus, malnutrition is not only an important indication for liver transplantation but also one of the most important prognostic factors for survival post liver transplantation.[64–66]

TABLE 40-3 Anthropometric Definitions in Children with Liver Disease

Acute malnutrition	Decreased weight for height Decreased triceps skinfold or midarm muscle area
Chronic malnutrition	Decreased height for age
Severe malnutrition	< 2 SDS below the mean < 3rd percentile

SDS = standard deviation scores (z-scores), 0 = 50th percentile.

Nutritional Assessment

Accurate nutritional assessment is essential to the management of children with acute or chronic liver disease. It is important to start with a comprehensive clinical history, feeding history, and careful physical examination. Serial anthropometric examination is critical and can identify early malnutrition. Standard weight and height ratios are of little value in children with liver disease because of misinterpretation caused by fluid overload, ascites, and visceromegaly. Many researchers, using sophisticated methods such as whole-body potassium and dual-energy x-ray absorptiometry (DXA) scanning, have demonstrated that body weight underestimated the incidence of malnutrition by 50% in both adults and children,[3,12] and for this reason, simple methods of measuring body composition, such as body impedance analysis, are not reliable in children with liver disease.[67,68]

Thus, the assessment of malnutrition should be performed using a number of parameters, such as triceps or subscapular skinfolds, midarm circumference, and arm muscle measurements (midarm muscle area).[1,69] Triceps skinfold and midarm circumference are useful indicators of body fat and protein and serial recordings demonstrate early loss of fat stores before weight and height changes become obvious.[1,69] Although linear growth is a sensitive parameter, it is a late sign of growth failure in infancy; stunting (or negative height velocity) might not be apparent until 1 year of age (Table 40-3).[70]

Growth data are best expressed as standard deviation scores (or z-scores) related to the median value for the child's age and sex in which the z-score of 0 = 50th percentile. This is particularly useful for comparisons between centers and for evaluation of new feeds.

Biochemical evaluation of vitamin deficiency is a useful adjunct to nutritional assessment. Plasma vitamin A levels can be measured but might not reflect hepatic stores.[71] Plasma betacarotene, or the ratio of plasma retinol to retinol binding protein, can be helpful.[71] Vitamin E deficiency is monitored by serum vitamin E levels or the ratio of vitamin E to total lipids. Vitamin D deficiency is evaluated by measuring serum levels of calcium, phosphate, and alkaline phosphatase, whereas the diagnosis of rickets is confirmed by radiographic examination of the wrist or knee. In some centers, it is possible to measure 25-hydroxyvitamin D levels. Vitamin K deficiency is identified by measuring coagulation times and monitoring the response to parenteral vitamin K.

Acute malnutrition is evidenced by loss of weight compared to height and loss of fat stores, whereas chronic malnutrition is documented by stunting and reduction in the height-for-age index (Table 40-3).

Indications for Nutritional Therapy

The aim of nutritional therapy is to prevent or treat malnutrition by providing adequate calories for energy and sufficient nitrogen for protein synthesis, to restore plasma amino acid imbalance, to prevent vitamin and trace element deficiency, and to achieve normal growth and activity. The need for nutritional support is often underestimated, par-

ticularly in infants with liver disease, who might have an increased appetite in the first few months of life.

Children who are at particular risk for developing malnutrition include the following:

- Children under 2 years of age who have severe cholestasis (serum bilirubin > 70 mmol/L [4 mg/dL])
- Those with progressive liver disease such as biliary atresia or severe familial intrahepatic cholestasis
- Those with end-stage liver failure awaiting liver transplantation
- Children with recurrent hepatic complications such as ascites and bleeding varices

Strategies for Nutritional Support

Increased Energy Intake Because the resting energy requirements of infants and children with liver disease are increased,[54] it is important to increase the energy intake to 140 to 200% of estimated average requirements. In cholestatic infants, this can be achieved by using concentrated formulas (the formula is concentrated by 13 to 15%, which increases the number of kilocalories from 67 to 80 per 100 mL) or by supplementing milk feedings with extra carbohydrate and fat to produce a feed with an energy density of 4.18 kj/mL (1 kcal/mL or more). As such a feed can have a high osmolality (500 to 800 mmol/L), it should be introduced gradually to establish intestinal tolerance (Table 40-4). Caloric supplementation added to drinks can be effective for older children. If there is no response to an increase in energy intake alone, nocturnal enteral feeding by nasogastric tube might be required (Figure 40-1).

Medium-Chain Triglycerides Because fat is an important calorie source, with an energy value of 8 to 9 kcal/g, it is a major source of energy for infants. Because absorption is deranged in liver disease, the fat content of the diet needs careful consideration. Low-fat diets are no longer considered appropriate, but an increase in the MCT content will reduce steatorrhea.[32,35,44] Hydrolyzed-protein infant formulas, such as Pregestimil (Mead Johnson), which contain 50% MCTs, will maximize fat absorption and improve steatorrhea,[44,72] but formulas with more than 80% MCTs can lead to essential fatty acid deficiency.[44] Although MCTs are a useful energy source, there is no evidence that growth improves with formulas with a high MTC content,[73,74] so it is necessary to increase the total fat intake with both LCTs and MCTs. This will increase the overall amount of fat absorbed and improve growth despite increasing steatorrhea.[35] In practice, this means supplementing feeds with approximately 50% MCTs with essential fatty acids. In older children, MCT oil can be added to meals and should be balanced by fats with high LCP content.

Long-Chain Polyunsaturated Fatty Acids The malabsorption of long-chain fats in chronic liver disease means that it is important to ensure adequate intake of LCPs. The minimal intake of linoleic acid recommended for infants is 1 to 2% of energy in a ratio of linoleic to linolenic acid of 5:15.1.[39]

MCT = medium-chain triglyceride.

The LCPs, or PUFAs, can be supplemented by the addition of soybean or rapeseed oil, whereas LCP supplementation is provided in dietary products such as egg yolk (which is rich in arachidonic acid) or fish oil (which is rich in DHA). Alternatively, infants can be given conventional LCP-supplemented formulas, which are commercially available.[75]

Structured Lipids Recently, chemically defined structured lipids have been developed to increase absorption of both medium- and long-chain and essential fatty acids.[76] These lipids combine pure MCTs with LCTs, resulting in a triglyceride that contains combinations of short-, medium-, and long-chain fatty acids on a single glycerol backbone, which should be absorbed like MCTs. To date, clinical studies in adults have evaluated structured lipids in postoperative patients receiving parenteral nutrition and demonstrated that they were safe and effective when compared to LCP emulsion.[77,78] Although clinical studies of these modified lipids in children are currently in the preliminary stages,[79] studies in rats have demonstrated improved fat absorption and reversal of essential fatty acid deficiency in vitro in caco-2 cells.[80,81] If successful, there might be considerable benefit for cholestatic infants.

Carbohydate Carbohydrate is a major source of energy and is particularly useful for increasing calorie intake. It can be given as a monomer, short-chain polymer, or starch, but complex carbohydrates such as maltodextrin or glucose polymer restrict the osmolality of the feed while maintaining a high energy density of more than 1 kcal/mL. This allows fluid restriction if necessary while providing up to 20 g/k/day of carbohydrate. In infants, glucose polymers are best added to milk feeds, whereas in older children, they can be provided as supplemental drinks.

Protein

Historical advice, which restricted protein in advanced end-stage liver disease, is now considered inappropriate in both children and adults.[82,83] Children with end-stage liver disease require minimal protein intake of approximately 2 to

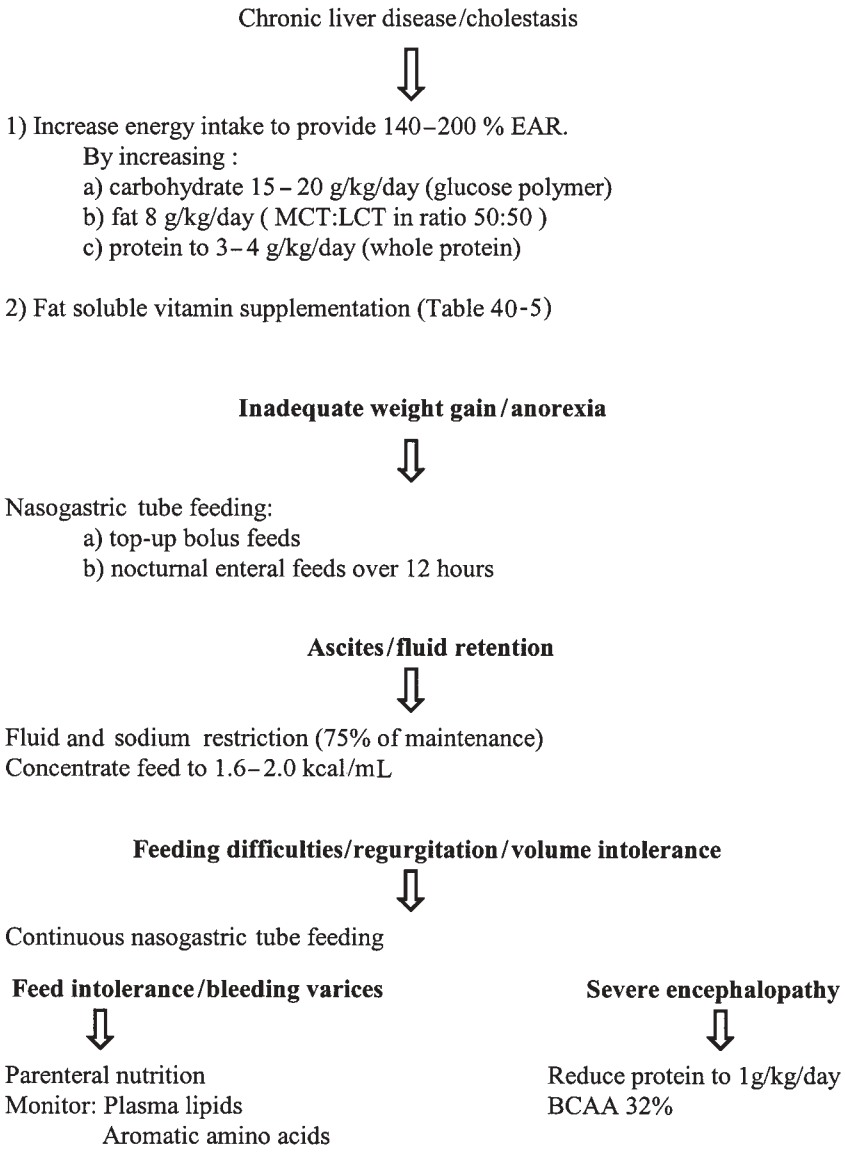

FIGURE 40-1 Nutritional support for chronic liver disease. BCAA = branched-chain amino acid; EAR = estimated average requirement; LCT = long-chain triglyceride; MCT = medium-chain triglyceride.

3 g/kg/day but will tolerate up to 4 g/kg/day without developing encephalopathy or a significant increase in plasma amino abnormalities.[84] Severe protein restriction (less than 2 g/kg/day) might be required for acute, severe encephalopathy but should be avoided in the long term as it can lead to endogenous muscle protein consumption.[54] There is no necessity to use semielemental diets or protein hydrolysates because there is no evidence of protein malabsorption.

In view of the abnormal arachidonic acid-to-BCAA ratio, there has been considerable interest in the use of a modified amino acid formulation designed to improve this imbalance. Numerous studies in adults have not demonstrated a clear benefit for BCAA nutritional supplementation, despite the evidence that BCAAs did improve nitrogen retention and protein synthesis; their effect on patient outcome was not proven.[85]

There is both animal and clinical evidence that suggests that BCAA-enriched formulas could have significant nutritional benefit in children. BCAAs increased weight gain, protein and muscle mass, body composition, and bone mineral density in an animal model of biliary obstruction.[86] A study that compared a feed containing 32% BCAAs with a standard feed demonstrated improved lean body mass in children awaiting liver transplantation but no improvement in amino acid levels.[87] In another study in infants with liver disease, the effect of a modified amino acid feed containing 50% BCAAs was compared with an isonitrogenous formula containing 22% BCAAs by measuring whole-body protein turnover.[55] The BCAA-supplemented feed improved protein retention when compared with the standard formula by suppressing endogenous protein catabolism and normalizing the plasma amino acid profile. Formulas rich in BCAAs, complete with MCTs and vitamin and mineral supplements, have been developed for use in infants, and oral supplements rich in BCAAs are available for older children, but both are particularly unpalatable.

Attempts to use BCAA supplementation to treat hepatic encephalopathy in adults could be of value in those patients with advanced encephalopathy,[88] but similar studies have not been performed in children.

Vitamin and Mineral Supplementation

Both water- and fat-soluble vitamins should be supplemented in children with chronic liver disease. Supplementation should be based on plasma levels of selenium, zinc, calcium, and magnesium. Iron supplementation might be required in children with chronic blood loss.

Fat-soluble vitamins are required in all children with prolonged or cholestatic liver disease (Table 40-5). Most children will be maintained adequately on oral fat-soluble vitamin administration, but monthly intramuscular administration is occasionally required for children with severe cholestasis.

Mode of Delivery

Nutritional supplementation should be provided enterally for as long as possible because it has a number of advantages over parenteral feeding. Not only is it cheaper and more physiologic, but it maintains gastrointestinal tract immunity, reduces bacterial overgrowth, and maintains the integrity of the gut barrier to microorganisms.[89,90] It is also essential to maintain normal feeding behavior. Few children with end-stage liver disease will be able to tolerate the increased calorie intake necessary to prevent or reverse malnutrition orally; thus, nasogastric tube feeding is indicated for children who have no nutritional response to an increase in calorie intake or who become anorexic.

Despite anxiety about using nasogastric feeding in children with esophageal varices, there is no evidence that the use of modern soft Silastic nasogastric tubes is harmful. Nocturnal feeding is the method of choice because it allows calorie supplementation while maintaining normal oral feeding during the day. For infants with severe liver disease, nocturnal feeding can be beneficial because it will prevent fasting hypoglycemia and reduce protein catabolism. Continuous enteral infusion might be required in children with severe malabsorption or feed intolerance. Intensive enteral nasogastric feeding has effectively reversed malnutrition in infants and children with liver disease and can transform the child's affect and increase voluntary intake.[35,84,91] Under normal circumstances, it should be possible to provide nocturnal or continuous nasogastric feeding at home with appropriate support from a nutritional care team including a dietitian, a liaison nurse, and clinicians.

Gastrostomy tube placements might be preferable in older children but should be avoided in children with severe portal hypertension because of the development of stomal varices. In children with stable compensated liver disease (eg, cystic fibrosis), percutaneous endoscopic gastrostomy might be beneficial.

Growth Hormone Therapy

In view of the disruption of the growth hormone/IGF-I axis, it is tempting to prescribe growth hormone therapy for children with significant growth failure, but this has not proven beneficial in two studies of its use in children with end-stage liver disease.[92,93]

Parenteral Nutrition

In view of the well-recognized hepatobiliary complications that occur in premature infants with short-gut syndrome or intestinal failure, parenteral nutrition has been used cautiously in children with liver disease. Particular concern has focused on whether the potentially toxic components of parenteral nutrition could be exacerbated in children with established chronic liver disease or cholestasis. There is no evidence that amino acids, carbohydrates, or lipid emulsions are any more toxic in children with established liver disease, although amino acid levels and plasma lipids need careful monitoring.

Although aluminum toxicity is well recognized in parenteral nutrition and can lead to bone disease, there is no evidence that it is implicated in parenteral nutrition liver disease or that it exacerbates the metabolic bone disease associated with chronic liver disease.[94,95] In contrast,

TABLE 40-5 Assessment and Management of Nutritional Deficiency in Pediatric Liver Disease

Deficit	*Investigation*	*Management*
Energy	Calorie intake, energy expenditure, anthropometry (body cell mass [TBK], DXA)	Increase calorie intake, achieve 130–150% EAR, nocturnal enteral nutrition, continuous enteral nutrition
Protein	Plasma proteins (albumin), BCAA/AAA ratio, protein stores (muscle mass, TBN)	Provide adequate protein, (3–4 g/kg/d), BCAA-enriched protein (32%), albumin infusion (if serum albumin < 25 g/L)
Fat	Triceps skinfolds, body composition, EFA deficiency, plasma lipid profile	Improve fat absorption (MCT:LCT, 50:50), provide saturated fats high in EFA, ? supplement DHA
Fat-soluble vitamins	Plasma 25-OH-D (skeletal X-rays, DXA), prothrombin time ([< 138 c] INR = 1), plasma vitamin E and A	Light exposure, vitamin D-1-α (50 ng/kg), vitamin K (2.5–5 mg/d), vitamin E (50–400 IU/day as TPGS), vitamin A (5,000–10,000 IU/d)
Water-soluble vitamins	Specific levels, blood count	Supplement as requested
Minerals	Specific levels, cardiac evaluation	Supplement as requested

AAA = aromatic amino acids; BCAA = branched chain amino acids; DHA = docosahexaenoic acid; DXA = dual-energy x-ray absorptiometry; EAR = estimated average requirement; EFA = essential fatty acids; INR = international normalized ratio; LCT = long-chain fatty acids; MCT = medium-chain fatty acids; TBK = total body potassium; TBN = total body nitrogen; TPGS = tocopherol polyethylene glycol-1000 succinate.

chromium toxicity has been reported in animals on parenteral nutrition. Although both serum and urine chromium levels are higher in children on long-term parenteral nutrition, there is no correlation with liver disease.[96]

Manganese toxicity in children on long-term parenteral nutrition has recently been reported, however.[97–99] Although 79% of children on long-term parenteral nutrition had whole-blood manganese concentrations above the reference range, children with impaired liver function had the highest manganese levels. There was a significant correlation between whole-blood manganese levels, aspartate amino transferase ($r = .63$, $p = < .001$), and total plasma bilirubin ($r = .64$, $p = < .001$). Eleven children had both high manganese levels and cholestasis; four of these died. In the seven survivors, whole-blood manganese declined when the supplements were reduced or withdrawn. Although manganese is toxic to both brain and liver, it is not clear whether the high manganese levels led to cholestasis or were secondary to it because manganese is excreted in the bile. Nevertheless, it is likely that manganese toxicity exacerbates cholestasis in children with established liver disease; thus, monitoring of manganese levels is particularly important in this group.[100]

In general, the use of parenteral nutrition in children with established liver disease is for short-term purposes only; thus, they are unlikely to develop biliary sludge and gallstones from the prescription of parenteral nutrition alone,[101,102] although prescription of ursodeoxycholic acid (15 to 20 mg/kg) might be of value.[103]

Parenteral nutrition should be considered in children with chronic liver disease only if they cannot be enterally fed because of feed intolerance or secondary to complications such as recurrent variceal bleeding or abdominal sepsis. As stated above, there is no evidence that short-term parenteral nutrition is associated with hepatobiliary dysfunction or an increase in cholestasis; it can improve nutritional status in the short term. Standard amino acid and lipid solutions are well tolerated in stable patients, and lipids can be particularly beneficial in achieving adequate calorie intake. If encephalopathy develops, the amino acid content of the feed can be reduced to 1 to 2 g/kg/day; lipid administration requires careful monitoring in children with severe liver dysfunction, hepatic encephalopathy, or sepsis.

Although MCT emulsions have been suggested for adults with advanced liver failure, intravenous MCTs should be used with caution in children because incomplete oxidation can occur, producing metabolic acidosis.[104] Parenteral structural lipid emulsions have not yet been evaluated in children.

The use of parenteral nutrition is particularly important for children with acute fulminant hepatitis who are awaiting liver transplantation because they are hypercatabolic. Standard formulas should be used, although the volume needs to be restricted to 75% of maintenance and the concentration should be increased to maintain glucose levels (> 4 mmol/L). There is no need to reduce protein content, particularly if the patient is electively ventilated. As indicated above, intravenous use of BCAAs for the treatment of hepatic encephalopathy or coma has not been evaluated in children, although they can be of value in adults.

Behavioral Feeding Problems

Behavioral feeding problems are common in this group of children, particularly in infants who have had long-term nasogastric feeding. Feeding problems are compounded by the use of unpalatable feeds, medications, and excess parental anxiety about feeding and growth.

Strategies to prevent behavior problems include daytime feeding to provide oral stimulation and encouraging children to experiment with flavors and textures appropriate to their age. The success of these techniques is dependent on a multidisciplinary approach involving a clinician, nurse specialist, dietitian, clinical psychologist, speech therapist, and play therapist.[35]
