CHARLES SPIELBERGER

Editor-in-Chief
CHARLES D. SPIELBERGER

University of South Florida
Tampa, Florida, USA

Charles D. Spielberger is Distinguished Research Professor of Psychology and Director of the Center for Research in Behavioral Medicine and Health Psychology at the University of South Florida. Author, co-author, or editor of more than 350 professional publications, Spielberger's current research focuses on anxiety, anger, curiosity, depression, job stress, and lifestyle factors that contribute to the etiology and progression of cancer and cardiovascular disorders. His *State-Trait Anxiety Inventory* (1970, 1983), with translations in 66 languages and dialects, has become a standard international measure of anxiety. He has served as President of the International Association of Applied Psychology, the International Council of Psychologists, and the International Stress Management Association and was the 100th President of the American Psychological Association.

Preface

During the past 50 years, there has been remarkable progress in the articulation of psychological theory, increasingly sophisticated reports of empirical research, and a dramatic expansion in professional applications of psychology in all areas of modern life. Applied psychology requires both a sound scientific foundation and attention to the practical problems that are encountered in applying psychology to an infinite variety of life settings. Growing public recognition of the potential contributions of psychology to solving life's problems has also fostered rapid growth in the number of psychologists who are engaged in research and in professional practice throughout the world.

The need for an authoritative publication that reviews and evaluates the numerous applications of professional psychology has been recognized for a number of years, and has been of special interest to the members of the International Association of Applied Psychology (IAAP), the world's oldest and largest membership organization of individual psychologists. The interests and concerns of IAAP members, who reside in more than 80 countries, have been strongly noted by former IAAP presidents Edwin A. Fleishman, Claude Levy-Leboyer, and Harry C. Triandis.

Significant contributions to international applications of psychology were explicitly recognized and discussed in the context of their diverse societal settings by Bernhard Wilpert in his Presidential address at the IAAP's 24th International Congress of Applied Psychology in 1998. It was my honor and pleasure to succeed Professor Wilpert as President of the IAAP at this Congress, which was held in San Francisco, California, and to begin participating in discussions to identify the most important contributions to applied psychology that are reported in this encyclopedia.

The development and current status of applied psychology can be best understood by examining the historical evolution of the field, which is cogently described by Helio Carpintero, the official Historian of the IAAP. In his overview article on the history of applied psychology, Carpintero highlights the benefits resulting from psychologists joining together to form professional associations that have facilitated the development and integration of psychological theory and research and that have stimulated and guided more effective applications of psychology in professional work.

Founded in 1920 as the *Association Internationale des Conférences de Psychotechnique* (International Association for Psychotechnology), the IAAP adopted its present name in 1955. Edouard Claparède convened and chaired the first meeting of the association, held in Geneva, Switzerland in 1920, and served as its President for more than 20 years. Meetings were held in a number of European cities, including Barcelona, Milan, Paris, Moscow, and Prague. An excellent history of the evolution and development of applied psychology and the IAAP can be found in the address given by former President Edwin A. Fleishman on receiving the 1999 American Psychological Association's Award for Distinguished Contributions to the International Advancement of Psychology (*American Psychologist*, November, 1999, pp. 1008–1016).

For recommending that the IAAP take an active role in sponsoring and developing the *Encyclopedia of Applied Psychology*, we are indebted to George Zimmar, an active IAAP member and former senior sponsoring editor at Academic Press, now Elsevier. The first step in developing the encyclopedia was the appointment of an Advisory Board composed of distinguished colleagues representing all areas of

applied psychology. In addition to recommending the major areas and the specific topics to be covered in the encyclopedia, the Advisory Board identified highly qualified colleagues who would be invited to serve as Section Editors for the selected areas.

The responsibilities of the Section Editors included writing a major article to provide an overview and analysis of their respective areas and working with the Editor-in-Chief and the Advisory Board in identifying the specific topics to be included in each area. They also helped to determine the amount of space to be allocated for each topic and recommended colleagues with outstanding knowledge and expertise to serve as the authors for the individual articles. In addition, the Section Editors reviewed and edited the articles that presented information on the topics that were related to the subject matter that was included in their sections.

The articles that are included in the encyclopedia are presented in alphabetical order, as determined by the title of each article. Consequently, the underlying section organization will not be readily apparent. At the conclusion of each article, the reader is directed to additional articles that include related information. The authors of each article also provide a number of references that are recommended for further reading.

It should be noted, however, that it was not possible to cover all of the many areas of applied psychology. Several emerging areas are not included because we failed to recognize their importance at the time the topics were selected for the encyclopedia. It is also unfortunate that a few authors were unable to meet the deadlines for submitting the manuscripts for their articles.

The *Encyclopedia of Applied Psychology* is truly a product of the collaborative efforts of the members of the IAAP. We are especially indebted to former IAAP Presidents Edwin A. Fleishman, Harry C. Triandis, and Bernhard Wilpert, and to our current president, Michael Frese, for their leadership, encouragement, and tangible contributions to the encyclopedia. For their dedicated contributions to the encyclopedia, I would also like to thank the members of the Advisory Board and the Section Editors, whose names are listed in the front matter. Finally, on behalf of the IAAP, I thank the authors who contributed articles in their areas of expertise and the editorial and production staff of Elsevier for the tremendous amount of time and energy that was needed to bring this large project to fruition.

GLOSSARY

basic skills The skills associated with functional literacy, including reading decoding and comprehension skills, math calculation and problem solving, and writing.

cooperative learning An instructional approach that uses peer groups to facilitate and reinforce learning.

curriculum-based assessment An assessment approach that uses students' progress in their actual curriculum as a measurement point.

emergent literacy The recognition of environmental print that leads to gradual understanding of the role of letters and words in written language.

learning disability A discrepancy between a student's measured ability and actual achievement caused by a dysfunction in a basic neuropsychological process.

learning strategy A voluntary activity students use to facilitate remembering, learning, or problem solving.

mastery learning An instructional approach that allows students to repeat instruction and assessment until competency is achieved.

peer tutoring An instructional approach that uses peers to reinforce classroom instruction by providing individual instruction to students.

phonological awareness Children's awareness of the way in which words sound, particularly rhyme and alliteration and the ability to blend sounds, recognize onset rime (initial sounds), and identify sound units.

retention The practice of requiring a student to repeat a grade or requiring a child of appropriate chronological age to delay entry to kindergarten or first grade.

school readiness The set of skills children need to learn successfully in school.

social promotion The practice of promoting a student to the next grade even when skills or knowledge sets to be mastered at that level have not been mastered.

team teaching An instructional approach that allows teachers, often with different areas of expertise, to share instructional duties.

Prevention of academic failure is a serious challenge because children who fail academically experience significant social and economic challenges throughout their lives. Causes of academic failure include familial, socioeconomic, and cultural issues that lead to a lack of readiness for school, academic, instructional, and motivational problems as well as physiological, cognitive, and neurological barriers to learning. Attempts to help students who are experiencing academic failure fall into three categories: prevention, intervention, and remediation. Preventive approaches

aim to stop academic failure before it occurs. Early intervention programs aim to catch children during key developmental periods and facilitate development and readiness skills. Remediation programs are usually applied when students have demonstrated significant skill deficits and are experiencing significant academic failure. Special education programs often take this form, as do other kinds of academic accommodations for students identified with special needs.

1. DEFINING ACADEMIC FAILURE

A lot depends on children's success in school—their self-esteem, their sense of identity, their future employability. Preventing academic failure means that we, as a society, are much more likely to produce individuals who feel confident about their ability to contribute to the common good, whose literacy skills are competent, and who are able to hold jobs successfully. Thus, prevention of academic failure should be a primary concern for any society. But exactly what is meant by academic failure? What does the term connote? Generations of schoolchildren since the 1920s, when the system of grade progression began, have equated academic failure with retention in grade. School failure meant literally failing to progress onto the next grade, with the assumption that the skills and knowledge taught in that grade had not been mastered. To have flunked multiple grades quickly led to quitting school altogether—the ultimate academic failure.

More recently, academic failure has come to mean a failure to acquire the basic skills of literacy. Students who were unable to read at a functional level, to communicate effectively through writing, and to complete basic math calculations were seen as representing a failure of the academic system even though they might hold high school diplomas. The practice of moving students on from one grade to the next even though they might not have mastered basic competencies associated with lower grade levels is often referred to as social promotion. This type of academic failure led to calls for an increased emphasis on basic skills, that is, the “three R's”—reading, (w)riting, and (a)rithmetic—in public education. Partly in reaction to emphasis on basic skills, a third interpretation of academic failure has also emerged. In this view, academic failure occurs not only when students fail to master basic skills but also when they emerge from school without the ability to think critically, problem solve,

learn independently, and work collaboratively with others—a skill set deemed necessary for success in a digital age. This underachievement symbolizes a significant loss of intellectual capital for a culture. Finally, statistics show that students who do not complete high school are much more likely to need welfare support, have difficulties with the law and police, and struggle economically and socially throughout their lives. Thus, academic failure ultimately means both the failure to acquire the skill sets expected to be learned and the failure to acquire official documentation of achievement by the school system.

2. CAUSES OF ACADEMIC FAILURE

Students struggle academically for many reasons, including familial, socioeconomic, and cultural issues that lead to a lack of readiness for school, academic, instructional, and motivational problems as well as physiological, cognitive, and neurological barriers to learning. Early school failure often occurs because children enter the structured school environment not ready to learn.

2.1. School Readiness

School readiness refers to the idea that children need a certain set of skills to learn and work successfully in school. Often this term refers to whether or not children have reached the necessary emotional, behavioral, and cognitive maturity to start school in addition to how well they would adapt to the classroom environment. To create some consensus about when a child should begin school, states designate a specific cutoff date. If a child reaches a certain age by the cutoff (usually 5 years for kindergarten and 6 years for first grade), the child may begin school. However, cutoff dates are arbitrary and vary considerably across nations, and age is not the best determinant or most accurate measure of whether or not a child is ready to begin school. Research has suggested that we must look at all aspects of children's lives—their cognitive, social, emotional, and motor development—to get an accurate idea of their readiness to enter school. Most important, children's readiness for school is affected by their early home, parental, and preschool experiences.

Stated in its simplest form, school readiness means that a child is ready to enter a social environment that is focused primarily on education. The following list of

behaviors and characteristics are often associated with school readiness:

- Ability to follow structured daily routines
- Ability to dress independently
- Ability to work independently with supervision
- Ability to listen and pay attention to what someone else is saying
- Ability to get along with and cooperate with other children
- Ability to play with other children
- Ability to follow simple rules
- Ability to work with puzzles, scissors, coloring, paints, and the like
- Ability to write own name or to acquire the skill with instruction
- Ability to count or acquire skills with instruction
- Ability to recite the alphabet
- Ability to identify both shapes and colors
- Ability to identify sound units in words and to recognize rhyme

Family environment is very important in shaping children's early development. Some family factors that can influence school readiness include low family economic risk (poor readiness for school is associated with poverty), stable family structure (children from stable two-parent homes tend to have stronger school readiness than do children from one-parent homes and from homes where caregivers change frequently), and enriched home environment (children from homes where parents talk with their children, engage them in conversation, read to them, and engage in forms of discipline such as "time-out" that encourage self-discipline have stronger readiness skills).

Children's readiness to read, in particular, has gained greater attention from educators recently as the developmental precursors to reading have become more evident. During the preschool years, children develop emerging literacy skills—preacademic skills that allow children to develop a disposition to read, write, and compute. Children are ready to read when they have developed an ear for the way in which words sound and can identify rhyme and alliteration, blend sounds, recognize onset rime (initial sounds), and identify sound units in words. Together, these skills are called phonological awareness and usually emerge in children between 2 and 6 years of age. Children with good phonological awareness skills usually learn to read quickly. Children who are poor readers have weak phonological skills, and children who do not learn to read fail in school. Another important readiness skill that helps children

to learn to read is called print awareness. Print awareness means that children are capable of the following:

- Knowing the difference between pictures and print
- Recognizing environmental print (e.g., stop signs, McDonald's, Kmart)
- Understanding that print can appear alone or with pictures
- Recognizing that print occurs in different media (e.g., pencil, crayon, ink)
- Recognizing that print occurs on different surfaces (e.g., paper, computer screen, billboard)
- Understanding that words are read right to left
- Understanding that the lines of text are read from top to bottom
- Understanding the function of white space between words
- Understanding that the print corresponds to speech word for word
- Knowing the difference between letters and words

Children also need to learn book-handling skills such as orienting a book correctly and recognizing the beginning and the end of a book. Children who begin school without these basic readiness skills are at risk for school failure. The use of screening assessments during preschool and kindergarten to identify students who may be at risk for academic failure, particularly in the area of phonemic awareness, has been shown to be a sound method of predicting which children will have difficulty in learning to read. Most likely to be retained in kindergarten are children who are chronologically young for their grade, developmentally delayed, and/or living in poverty.

2.2. Academic, Instructional, and Motivational Reasons

Children who do not master basic reading skills, specifically the ability to automatically decode new words and build a sight word vocabulary that leads to fluency, experience academic failure. By third grade, learning to read has become reading to learn. In other words, in third grade the curriculum becomes focused much less on teaching students to acquire the basic tools of literacy (reading, writing, and computing) and much more on using those tools to learn content, express ideas, and solve problems. At this point, students are likely to be given content textbooks in science and social studies and to read nonfiction for the purpose of gaining new information. Thus, the inability to read effectively and to learn

to study independently often leads to failure at the elementary and middle school levels and also creates profound motivation problems at the high school level that contribute to the ultimate school failure—dropping out.

The inability to master key concepts in pivotal classes such as algebra, now typically taken at the middle or junior high school level, often limits students' ability to proceed in coursework. Students may fail to understand algebraic concepts due to their developmental level. (Many students are still thinking in concrete terms in middle school and have not yet moved into a stage of cognitive thinking allowing them to understand formal logic and manipulate symbols—a developmental source of failure.) In addition, some students might not have automatized basic arithmetic skills, particularly computing with fractions—an academic or instructional failure. Some students may have become turned off to math and accepted self-images that permit poor math skills—a motivational failure. Finally, many students will fail algebra for all of these reasons, and the impact will often be that they will finish school in a nonacademic or basic track or might even drop out.

Thus, academic and instructional reasons for school failure include the effectiveness of the instruction a student has received and the quality of remediation strategies or programs available. The following is a typical example that illustrates academic and instructional reasons for school failure. A teacher reports that a student is having difficulty in getting beyond the primer level in reading and is being considered for retention. The child was assessed as having average intelligence. No behavioral or attention problems were noted. Closer inspections of the student's reading skills indicated that she had poor phonological skills and was not profiting from the type of classroom reading instruction she was receiving that depended heavily on auditory phonics instruction stressing "sounding out words" and matching sound-symbol connections. Appropriate interventions included using techniques to build up a sight word vocabulary through repetition and distributed learning and introducing the student to a visual decoding system to provide her with a method for reading unknown words by analyzing the words and breaking them down into more familiar visual units.

2.3. Physiological, Neurological, and Cognitive Reasons

Imagine a child spending most of the year in kindergarten with an undetected hearing loss that has made it

very difficult for her to benefit from instruction. Imagine another child in first grade struggling to learn because her vision impairment has not been caught or corrected. Similarly, students suffering from a variety of conditions and illnesses, such as childhood diabetes, asthma and allergy-related problems, and sickle cell anemia, may have difficulty in maintaining energy and attention in school due to chronic fatigue and the impact of medications. Children may also suffer from orthopedic or motor impairments that make it difficult for them to explore their environment, interact with others, and/or master tasks that demand motor skills.

Students who suffer from various kinds of neurological disorders or learning disabilities may also have cognitive learning problems that make it difficult for their brains to process information, interpret sounds and symbols efficiently in reading, calculate and understand number concepts, and/or write effectively. Other children may have cognitive deficits, such as mental retardation, that limit their ability to absorb and apply regular classroom instruction. Children with attention deficit disorders have difficulty in directing and maintaining their attention, may exhibit impulsive behavior, and have trouble in interacting independently in typical classroom environments without support. Specialized and/or special education interventions are designed to provide individualized strategies and approaches for students who have physiological-based learning problems interfering with their ability to learn.

3. PREVENTING EARLY SCHOOL FAILURE

3.1. Early Intervention Programs

Programmatic interventions may include developing screening programs to identify children at risk for school failure and to ensure early access to readiness programs already available in the school or community such as Head Start. Many states are now developing guidelines for children age 6 years or under based on the National Association for the Education of Young Children's (NAEYC) list of developmentally appropriate practices. The major challenge facing early intervention programs is to provide developmentally and individually appropriate learning environments for all children. Essential ingredients to successful preschool experiences include small group and individualized teacher-directed activities as well as child-initiated

activities. Quality programs recognize the importance of play and view teachers as facilitators of learning.

3.2. Preventing School Failure in the Elementary Grades

Full day kindergarten (as opposed to half day) programs provide more time for field trips, activity centers, projects, and free play. At-risk students who attend rigorous yet nurturing full day programs have a greater chance of experiencing academic success. Full day kindergarten programs help increase academic achievement as well as decrease the number of children retained in the early elementary grades. Research shows that full day kindergarten programs for children who come from disadvantaged backgrounds lead to stronger achievement in basic skill areas and generally better preparation for first grade.

Table I summarizes the research on full-day kindergarten. Any decisions about whether or not to schedule

full- or half-day programs should recognize that what a child is doing during the kindergarten day is more important than the length of the school day.

The instructional technology that enables classroom teachers to meet the needs of students of different skill levels is already available, but in many cases teachers do not have access to that technology. Reading interventions that provide intensive, early, and individualized help that targets a child's specific weaknesses (e.g., Success for All, Reading Recovery, Direct Instruction) have been shown to be effective in reducing early reading failure. Instructional approaches such as mastery learning, adaptive education, team teaching, cooperative learning, peer tutoring, and curriculum-based assessment are methods that have been shown to produce academic gains in students of all achievement levels in the elementary grades. Recently, technology has offered greater individualization of instruction and increased flexibility in allowing students to progress at their own pace and to respond to instruction.

TABLE I
Research Summary: Full-Day Versus Half-Day Kindergarten Programming

<i>Research on effects of full-day programs on achievement</i>	<i>Research on effects of full-day programs with educationally disadvantaged and low-SES children</i>	<i>Research on other effects of full-day versus half-day programs</i>
Full-day programs increase long-term achievement.	Full-day programs allow for greater opportunity for assessment and screening.	Full-day programs have been shown to raise children's self-esteem, independence, and creativity. There is no evidence that the curriculum is more individualized or innovative.
Full-day programs produce higher reading scores in second and third grades.	Full-day programs result in higher academic and social gains.	Parental involvement is diminished in full-day programs.
Full-day programs result in fewer grade retentions, higher report card marks, and higher scores on standardized tests.	Full-day programs allow for more informal and formal instructional time on an individual basis.	Full-day programs are not found to cause excessive fatigue or stress in children.
Full-day programs provide more time for individualized instruction, academics, and the reinforcement of children's positive self-images.	Full-day programs provide access to nutritional lunch as well as breakfast.	Full-day programs allow for an unhurried relaxed school day with more variety of experiences.
Full-day programs are found to have no effect on achievement.	Title I children have significantly higher achievement in full-day programs.	Children in full-day programs have been shown to be less likely to be dependent, shy, and withdrawn. Children in half-day programs spend more time in large groups than in free play.

Note. SES, socioeconomic status.

4. PREVENTING FAILURE IN THE INTERMEDIATE GRADES AND MIDDLE SCHOOL

Remedial programs, such as the Title I or Chapter 1 programs, have also been used to remediate early skill deficits in reading and math. However, developing intervention programs, such as after-school tutoring and summer school courses, might not be sufficient to make up serious deficits in short amounts of time and cannot take the place of preventive systemic approaches.

The use of learning strategies instruction has been shown to be very effective in improving study skills and performance in middle school students. Because unsuccessful middle school students often lack basic strategic learning skills, intervention programs should also target these areas. Similarly, approaches that use learning, problem-solving, and memory strategies are the most effective interventions in terms of producing actual gains in student achievement in the classroom.

5. PREVENTING ACADEMIC FAILURE IN HIGH SCHOOL

At the secondary level, development of reentry programs for dropouts and alternative education programs, such as those that combine teaching skills with job training, are essential to prevent further academic failure. Research on academic failure at the secondary level has generally examined the relationships between grade retention and attendance, suspension, and self-concept, with an emphasis on the correlation between retention and dropout rates. Academic failure at the high school level is related to attendance and suspension rates. In general, students who are failing do not attend school on a regular basis. In addition, students who have been retained prior to the secondary level are less likely to attend school on a regular basis in junior and senior high school. Furthermore, regardless of the grade in which retention occurs, secondary students who have been retained often exhibit low self-esteem.

Many studies have reported that students who drop out are five times more likely to have repeated a grade than are students who eventually graduate. Being retained twice virtually guarantees that a student will drop out of school, and grade retention alone has been identified as the single most powerful predictor of dropping out. The dropout rate of overage students is appreciably higher than the dropout rate of regularly

promoted students when reading achievement scores are equivalent for the two groups. Even in high-socioeconomic school districts, where students are less likely to leave school, a significant increase in dropout rates has been found for retained students.

Successful programs at the high school level often have two characteristics: (a) one or more individuals who develop relationships with students individually and monitor their progress carefully and (b) some mechanism to allow students who have failed courses and lost credits to regain these credits in quicker than normal time, allowing for graduation at the expected time. Simply put, successful programs must address the motivational issues that have developed by adolescence and the lack of academic achievement identity typically present in students who drop out of school. School-to-work programs that combine vocational counseling with on-the-job experience are successful ways in which to increase a sense of academic competence while connecting to students' current self-concepts and needs.

6. CONCLUSION

Attempts to help students who are experiencing academic failure fall into three categories: prevention, intervention, and remediation. Preventive approaches aim to stop academic failure before it occurs. Early intervention programs from birth to 5 years of age, for example, aim to catch children during key developmental periods and facilitate development and readiness skills. Intervention programs, such as Robert Slavin's Success for All program, aim to intervene as soon as students begin to show signs of slipping behind their peers. Intervention plans may also be designed under Section 504 of the Americans with Disabilities Act, which mandates accommodations in the instructional environment for students who have physical or neurological problems that may interfere with their ability to learn or succeed in a typical classroom. Remediation programs are usually applied when students have demonstrated significant skill deficits and are experiencing significant academic failure. Special education programs often take this form, as do other kinds of academic accommodations for students identified with special needs.

Of course, early identification and prevention of academic problems is always preferable to later intervention and remediation. Thus, systemic solutions that target early reading deficits, independent learning skills, and motivational problems from a developmental

perspective are essential to the prevention of academic failure. Working to change school practices will require sharing the research with educators, conducting evaluations on the outcomes of alternative interventions at the local level, and lobbying at the state level to promote changes in policy and to advocate for alternative service delivery systems that more effectively meet the needs of students experiencing school failure. Successful programs to boost student achievement, however, must attack underachievement in three key areas. These key areas—early reading intervention, acquisition of strategic learning and study skills, and motivation to achieve—are highly related to school failure.

First, acquisition of basic reading skills must be addressed. If students underachieve in the primary grades, it is most often because they have failed to learn to read. Kindergarten screenings should include an assessment of phonological awareness. Children identified with weak skills should be targeted for intervention through phonological awareness training in kindergarten. Prekindergarten programs for high-risk students are recommended. Students should be tracked using curriculum-based assessments of oral reading in the primary grades. Any student who falls behind the average rate of acquisition for his or her class should receive an individualized analysis of reading skill and additional after-school intervention based on that analysis to allow the student to “catch up” to classmates. This early, intensive, and individualized intervention allows for all students to enter the intermediate grades as able readers. Some students with special needs might not progress at the same rate as their classmates, but they too will benefit from early reading interventions.

Second, students must acquire independent learning and study skills during the intermediate and middle school years if they are to maximize achievement and be competitive in the job market of tomorrow. Many students underachieve in middle school because they lack the organizational and learning strategies to master the demands of the upper grades. Embedded approaches to strategy instruction facilitate generalization and encourage students to use all of their mental tools. Assessment of students’ study skills and metacognitive development (i.e., the degree to which they are aware of and control their own cognitive processes) leads directly to specific interventions.

Third, students in high school often underachieve because they lack the motivation to excel academically. They often have failed to incorporate pictures of themselves as successful students into their self-concepts. Through a variety of approaches, including staff in-service, a study skills coach approach to peer tutoring, and an individualized profile of each student’s study style and vocational options, increased academic competence and a value for academic work can be built.

 6. Summary and Future Directions
- Further Reading

This article reviews the field of academic interventions. It describes types and targets of academic interventions; intervention delivery systems; guidelines relating to the selection, implementation, and evaluation of academic interventions; and selected evidence-based strategies.

1. OVERVIEW

Today's educators are encountering increasing numbers and proportions of students who have trouble achieving at grade-level expectations. Whether these students are termed difficult to teach, learning disabled, or at risk, they fail to respond to traditional instructional methods. The need for academic interventions is underscored by reports from the National Assessment of Educational Progress (NAEP) indicating that fewer than one-third of American fourth- and eighth-grade students are performing at proficient levels in reading, mathematics, and writing. Recent federal legislation, including the 1997 reauthorization of the Individuals with Disabilities Education Act, which promotes the use of interventions prior to referral for special education services, and the reauthorization of the Elementary and Secondary Education Act in the No Child Left Behind Act of 2001, with its mandates for empirically validated practices, is also spurring interest in strategies that can enhance teachers' capacity to meet students' needs and students' capacity to respond to instruction.

GLOSSARY

academic enablers Nonacademic skills, behaviors, and attitudes that permit students to benefit from instruction.

academic engaged time The proportion of instructional time in which students are actively engaged in learning.

academic intervention A modification in the classroom environment and/or instructional practices designed to produce positive changes in academic performance.

intervention assistance programs (IAPs) Programs based on a consultation model of service delivery and designed to help teachers provide interventions in the regular classroom for difficult-to-teach students; they are also called prereferral intervention programs.

intervention scripts Detailed guidelines to assist intervention agents in delivering an intervention as intended.

social validity The degree to which an intervention is judged as acceptable and important by intervention participants and stakeholders, including the social significance of the goals, the social acceptability of the procedures, and the social importance of the outcomes.

treatment integrity The degree to which an intervention is implemented as planned.

2. TYPES OF ACADEMIC PROBLEMS

Academic problems may be characterized as skill deficits, fluency deficits, performance deficits, or some combination of these. Skill deficits refer to deficiencies reflecting inadequate mastery of previously taught academic skills. Fluency deficits refer to deficiencies in the rate at which skills are performed accurately. Students with performance deficits possess adequate skills and fluency but do not produce work of satisfactory quantity, quality, or both. Many of the interventions presented in [Table I](#) are designed to enhance skill acquisition and fluency by increasing opportunities to respond to academic material. Others target performance problems by using self-monitoring or contingency-based procedures, especially group-oriented contingencies that capitalize on peer influence to encourage academic productivity and motivation.

3. INTERVENTION DELIVERY SYSTEMS

Academic interventions can be implemented through a variety of delivery systems, including (a) case-centered teacher consultation, (b) small-group or classroom-centered teacher consultation, (c) staff development programs, and (d) intervention assistance programs (IAPs). For academic interventions with a home component, intervention services can be delivered through case-centered parent consultation, parent training programs, or parent participation in IAPs.

3.1. Intervention Assistance Programs

IAPs are based on a consultation model of service delivery and are designed to increase the success of difficult-to-teach students in the regular classroom by providing consultative assistance to teachers. Since the 1990s, IAPs have become widespread, with the majority of states now requiring or recommending interventions prior to special education referral. Several IAP approaches based on collaborative consultative models of service delivery have been developed to meet the needs of difficult-to-teach students in the regular classroom. These models fall into two general categories depending on whether special education personnel are involved. Key factors in successful implementation and maintenance of IAPs include administrative support, provision of high-quality

interventions, and support of teachers during the intervention process. Although an increasing body of evidence supports the efficacy of IAPs in reducing referrals to special education and improving teachers' attitudes toward diverse learners, relatively few studies have documented that IAPs produce measurable gains in student performance, and many of the studies reporting academic improvement suffer from methodological problems.

4. GUIDELINES FOR SELECTING, IMPLEMENTING, AND EVALUATING ACADEMIC INTERVENTIONS

In designing interventions for students with academic problems, intervention effectiveness can be enhanced by following nine guidelines that are presented in [Table II](#) and serve as the foundation for the discussion that follows. The guidelines reflect the importance of balancing treatment efficacy with usability considerations to accommodate the realities of today's classrooms.

4.1. Selecting Academic Interventions

Despite the growing database of evidence-based interventions, studies indicate that teachers and IAPs continue to rely on interventions characterized by familiarity or ease of implementation rather than on those with documented effectiveness. The importance of considering efficacy in intervention selection has been underscored by the Task Force on Evidence-Based Interventions in School Psychology, jointly sponsored by the Division of School Psychology of the American Psychological Association and the Society for the Study of School Psychology and endorsed by the National Association of School Psychologists. Founded in 1998 as an effort to bridge the often-cited gap between research and practice, the Task Force has developed a framework with specific efficacy criteria for evaluating empirically supported intervention and prevention programs described in the literature.

Consultants should also give priority to proactive interventions that help teachers to create learning environments that prevent academic problems from occurring by promoting on-task behavior and productivity rather than using reactive strategies that are applied after problems have already developed. Academic achievement is significantly related to the amount of time allotted for instruction and to academic engagement

TABLE 1
Descriptions of Selected Academic Interventions^a

<i>Intervention</i>	<i>Treatment components</i>	<i>Description</i>	<i>Target(s)</i>	<i>Primary intervention agent(s)</i>
Interventions to improve academic productivity				
Self-management	Goal setting Self-monitoring Self-evaluation Self-reinforcement	Students set goals for work completion and/or accuracy and monitor their own progress	On-task behavior Classwork completion and/or accuracy Homework completion and/or accuracy Academic achievement	Students
Classwide peer tutoring	Increased opportunities to respond Timing Self-management Peer-mediated instruction and feedback Error correction	Students practice oral reading, math facts, or other basic academic skills in pairs	On-task behavior Classwork completion and/or accuracy Academic achievement	Peers
Interventions to improve reading performance				
Listening previewing	Modeling Guided practice Performance feedback Error correction	Students read a passage aloud after listening to a proficient reader read the same passage	Reading accuracy and fluency	Teacher, peers, or parents
Collaborative strategic reading	Strategic instruction Modeling Guided practice and feedback Peer-mediated instruction and feedback	Students learn four basic reading strategies and then work in pairs or groups to implement the strategies	Reading comprehension and vocabulary Study skills	Teacher and peers
Interventions to improve mathematics performance				
Cover-copy-compare	Increased opportunities to respond Error correction Timing Self-instruction, evaluation, and reinforcement	Students respond to questions, compare their answers with instructional prompts, and correct their own errors	Academic productivity, accuracy, and fluency	Teacher

TABLE II
Best Practices in Selecting, Implementing, and Evaluating Academic Interventions^a

-
- A. Select research-based strategies with a documented history of success with the target student population, target setting, and target skill or subskill.
 - B. Give priority to strategies that are proactive in nature and have the potential of enhancing the achievement of groups of students.
 - C. Select interventions that are minimally intrusive, fit into the ecology of the classroom setting, and capitalize on the human and material resources already present in school ecosystems.
 - D. Involve key stakeholders, including teachers, parents, and students themselves, if developmentally appropriate, in the intervention process.
 - E. Be sensitive to cultural diversity issues in the consultation and intervention processes.
 - F. Use a variety of training formats to expand teachers' knowledge of interventions and the intervention process.
 - G. Build in treatment integrity checks to ensure accurate implementation.
 - H. Provide classroom-based assistance to teachers in the form of modeling, guided practice, and feedback during the implementation and evaluation phases.
 - I. Design evaluation strategies for assessing changes in student performance that are reliable, valid, and practical for regular classroom teachers.
-

^aAdapted from *Effective School Interventions: Strategies for Enhancing Academic Achievement and Social Competence* by N. Rathvon, 1999, New York: Guilford Press. Copyright 1999 by Guilford Press. Adapted with permission.

rates, that is, the proportion of instructional time in which students are actively engaged in learning as demonstrated by behaviors such as paying attention, working on assignments, and participating in class discussions. Although all students profit from proactive strategies that increase instructional time and academic engagement, such interventions are especially important for diverse learners, who are more likely to need additional practice on academic tasks to keep up with their grade peers.

Academic interventions should be minimally intrusive so that they can be implemented in regular classroom settings without unduly disrupting instructional and management routines. Interventions with low ecological validity (i.e., strategies that require major alterations in classroom procedures or cumbersome reinforcement delivery systems) are unlikely to become integrated into regular education routines. Priority should also be given

to strategies that benefit more than one student. Traditional case-centered intervention approaches directed at a single low-performing student are of limited utility in enhancing teachers' overall instructional effectiveness and can be very time-consuming. Group-focused strategies are both time- and labor-efficient, are more acceptable to teachers and students alike, and foster a positive classroom climate by incorporating peer influence.

Moreover, intervention targets and procedures should be reviewed in terms of their social validity. Although many interventions target on-task behavior, increasing on-task behavior is less socially significant as an intervention goal than is enhancing rates of academic responding because increasing on-task behavior does not necessarily result in higher student achievement. Although there is little systematic research on the benefits of involving parents and students in designing interventions, input should be obtained from all stakeholders on the acceptability of proposed intervention goals and procedures.

In designing interventions, consultants must be sensitive not only to individual differences but also to differences in cultural values and norms. For example, interventions that provide concrete operant reinforcers for academic performance might be considered unacceptable by individuals from certain cultures. Unfortunately, little research to date has examined the relative efficacy and acceptability of various academic interventions with culturally and linguistically diverse learners. However, by maintaining an awareness of their own ethnocentrism and encouraging an open dialogue throughout the intervention process, consultants will be better prepared to adjust intervention services to address the needs of stakeholders from nonmainstream groups.

4.2. Implementing Academic Interventions

Regardless of the quality of the intervention design and the documented efficacy of the intervention components, no strategy will be effective in improving student achievement unless the teacher implements it accurately and consistently, that is, with treatment integrity. In the absence of treatment integrity measures, there is no way to determine whether changes in academic performance are due to the effects of the intervention or to factors that are unrelated to intervention components. Among the factors influencing treatment integrity are (a) intervention complexity, (b) time and

material resources required for implementation, (c) the number of intervention agents, (d) efficacy (actual and as perceived by the intervention agents and stakeholders), and (e) the motivation of the intervention agents and stakeholders. Strategies for enhancing treatment integrity include (a) delivering interventions by means of a videotape or an audiotape, (b) documenting consultation contacts, (c) using an intervention manual or script, (d) having a written intervention plan, and

(e) providing direct feedback to intervention agents during implementation. Table III presents an intervention script for listening previewing, a strategy targeting reading achievement. Treatment integrity can be assessed by direct observation, videotaping or audiotaping intervention sessions, or teacher-, parent-, or student-completed fidelity checklists.

Consultants seeking to help teachers implement classroom strategies must be prepared to provide

TABLE III
Listening Previewing^a

Overview

Listening previewing, also termed *passage previewing*, has been shown to improve oral reading performance for a variety of student populations. In this intervention, the teacher reads the assigned passage aloud while students follow along silently prior to independent reading. Higher reading rates have been obtained with bilingual learners and students with learning disabilities, as well as with students in general education. Listening reviewing has also been shown to be superior in improving reading performance to previewing by the traditional silent reading method. Variations include using peers, parents, or tutors as passage previewers.

Purpose

To enhance reading accuracy and fluency by providing an opportunity for students to hear what they will read prior to reading it for themselves.

Materials

1. Stopwatch or watch with second hand (for assessment component)
2. Sheets of paper or copies of students' reading passages for marking oral reading errors (optional)
3. Notebooks or folders with loose-leaf paper for graphing words read correctly per minute (WCPM) rates, one per student (optional)

Observation (Select one or both)

Option 1

1. Administer curriculum-based measurement (CBM) oral reading probes to the students in a reading group or a group of selected students by having each student read a 2-minute timed sample from the previous day's reading passage.
2. Calculate each student's WCPM rate by subtracting the number of errors from the total number of words read and then dividing that figure by two (for number of minutes).
3. Record and graph (or have students graph) WCPM rates.

Option 2

1. Calculate scores on reading skill sheets, quizzes, or end-of-unit tests for all of the students in a reading group or for selected students for 5 to 10 days or for several weeks.

Procedure

1. Divide the reading lesson into passages according to the number of students in the reading group.
 2. Tell the students to follow along as you read the first passage aloud.
 3. After completing the first listening preview, have the first student read that passage aloud.
 4. Repeat this process until you have previewed the entire reading lesson and each student in the reading group has read aloud. If desired, record the number of errors (mispronunciations, substitutions, and omissions) on your copy of the passage or on a separate sheet of paper.
 5. Calculate and graph WCPM rates for students in the reading group as often as possible (at least once a week for several weeks) or teach students to chart their own progress on line graphs in their work folders.
-

Continues

Continued

Evaluation (Select one or both)

Option 1

1. Compare WCPM rates for the target students before and after implementation.

Option 2

1. Compare scores on reading skill sheets, quizzes, or end-of-unit tests for the target students before and after implementation.

Variations

1. Have parent volunteers, aides, or peer tutors conduct the listening previews.
2. Divide the class into pairs, with a higher performing student paired with a lower performing student. Have the higher performing students read first to serve as models for the lower performing students.
3. Prerecord (or have aides, parent volunteers, or high-performing students prerecord) selected reading passages for independent listening previews at listening stations in the classroom.
4. To enhance vocabulary and comprehension, have previewers discuss the meaning of important words in the text with the students prior to having the students read.

Notes

Including a self-monitoring component by having students graph their WCPM performance increases motivation and enhances the effectiveness of this intervention.

support with many aspects of the intervention process. Although teachers must implement the strategy, studies suggest that treatment integrity and, ultimately, the success of the intervention are related to the degree to which classroom-based assistance is provided to teachers during implementation. For example, IAPs in which a designated case manager works collaboratively with the referring teacher throughout the implementation process are more likely to report measurable gains in student performance than are IAPs lacking such support systems.

4.3. Evaluating Academic Interventions

Systematically evaluating performance change not only provides information that is useful in monitoring and increasing intervention effectiveness but also contributes to teachers' maintenance of interventions by demonstrating that positive change is occurring.

Although researchers have developed several measures for assessing teachers' perceptions of changes in students' academic performance, it is important to assess actual student outcomes and not merely teachers' or parents' perceptions of improvement. Similarly, researchers have often evaluated the effects of academic interventions in terms of task completion rates without regard for accuracy or the absolute level of achievement. Ultimately, the effectiveness of academic interventions should be evaluated in terms of meaningful changes in students' academic achievement relative to grade-level expectations.

4.3.1. Curriculum-Based Assessment

In recent years, intervention-oriented researchers have developed alternative assessment methodologies to traditional norm-referenced tests with the goal of identifying students in need of supplementary academic services and documenting the effectiveness of school-based interventions. One of these methods, curriculum-based assessment (CBA), refers to a set of procedures

that link assessment directly to instruction and evaluate progress using measures taken from the students' own curricula. Among the many different CBA models, the most fully developed is curriculum-based measurement (CBM), which has become the standard for assessing changes in student performance subsequent to interventions, especially in reading. Developed by Deno, Mirkin, and colleagues at the University of Minnesota Institute for Learning Disabilities, CBM is a generic measurement system that uses brief, fluency-based measures of basic skills in reading, mathematics, spelling, and written expression. CBM is ideally suited to monitoring the progress of students receiving academic interventions because measures are brief (1–3 min), can be administered frequently, and are based on students' own instructional materials. Procedures for conducting CBMs in reading, mathematics, spelling, and written expression can be found in Rathvon's 1999 book.

5. ACADEMIC INTERVENTION TARGETS

Academic interventions can be categorized according to targets as follows: (a) interventions designed to enhance academic productivity, including classwork, independent seatwork, and homework; (b) interventions targeting achievement in specific academic subjects; and (c) interventions targeting what DiPerna and Elliott termed academic enablers, that is, non-academic skills, behaviors, and attitudes that contribute to academic competence. Table I describes empirically validated academic interventions from each of the three categories. The categorization is necessarily somewhat arbitrary because all of the interventions include procedures that facilitate productivity and academic enabling behaviors; however, the interventions in the academic enablers category include the largest number of behavioral and attitudinal components.

5.1. Interventions Targeting Academic Productivity

5.1.1. Self-Management

Self-management techniques involve teaching students to engage in some form of behavior, such as self-observation or self-recording, in an effort to alter a target behavior. Self-management interventions fall into one of two categories: (a) contingency-based strategies with self-reinforcement for the performance of

specified tasks or (b) cognitively based strategies that use self-instruction to address academic deficits. Self-management interventions are especially appropriate for targeting academic problems because they not only enhance students' sense of responsibility for their own behavior but also increase the likelihood that students will be able to generalize their new competencies to other situations. Many academic interventions, including most of those listed in Table I, include at least one self-management component.

5.1.2. Classwide Peer Tutoring

Increased academic responding is associated with higher levels of on-task behavior and achievement. In classwide peer tutoring, peers supervise academic responding so that every student can engage in direct skill practice during instructional periods, leaving teachers free to supervise the tutoring process. Moreover, because peer tutors are provided with the correct answers for tutoring tasks, the strategy permits immediate error correction. Of the several variations of this strategy, the best known is the Classwide Peer Tutoring (CWPT) program developed by Greenwood and colleagues at the University of Kansas to improve the achievement of entire classrooms of low-socioeconomic status urban students. CWPT has been successful in improving academic skills and productivity in a variety of domains, including oral reading, spelling, and mathematics computation, and with both regular education and special needs students.

5.2. Interventions Targeting Academic Achievement

This section discusses some of the best-known and most widely validated interventions in three academic areas: reading, mathematics, and written language.

5.2.1. Interventions to Improve Reading Performance

Reading problems are the most frequent cause of referrals to school psychologists and IAPs. Three sets of skills are required for proficient reading: (a) decoding (i.e., the process leading to word recognition), (b) comprehension (i.e., the ability to derive meaning from text), and (c) fluency (i.e., the ability to read quickly and accurately). Although reading interventions can be categorized according to their primary subskill target, interventions focusing on one subskill

have the potential to improve other competencies due to the interrelated nature of the reading process. The two interventions described in this section primarily target fluency and comprehension.

5.2.1.1. Listening Previewing Listening previewing, one of the best-known stand-alone reading interventions, promotes fluency by providing students with an effective reading model prior to the students reading aloud. Combining listening previewing with discussion of key words in the selection to be read is associated with enhanced outcomes, especially in terms of comprehension. Listening previewing ranks high in both efficacy and usability and has been implemented successfully with regular education students, bilingual students, and students with learning and behavior disorders. Additional information about listening previewing is provided in [Table III](#).

5.2.1.2. Collaborative Strategic Reading Collaborative strategic reading (CSR) combines instruction in comprehension strategies and study skills with collaborative peer practice. Students learn four strategies through direct instruction and teacher modeling: (a) Preview (i.e., previewing and predicting), (b) Click and Clunk (i.e., monitoring for understanding and vocabulary knowledge), (c) Get the Gist (i.e., understanding the main idea), and (d) Wrap-Up (i.e., self-questioning for understanding). After students have mastered the strategies, they implement them within cooperative groups. CSR has been successful in improving reading proficiency in regular education, multilevel, inclusive, and special education settings. Originally designed for use with expository text in content area textbooks, it can also be applied to narrative material.

5.2.2. Interventions to Improve Mathematics Performance

The 2003 NAEP report on mathematics revealed serious deficiencies in math achievement in the general student population. Although the percentage of fourth graders performing at or above the proficient level (29%) was higher in 2003 than in all previous assessment years since 1990, sizable numbers of students failed to reach even the basic level of proficiency (23%). The situation was even more dismal for eighth graders, with only 23% performing well enough to be classified as proficient. Although students with difficulties in learning mathematics constitute a very heterogeneous group, they generally exhibit deficits in one or more of three areas:

(a) computational skills, including the basic operations of addition, subtraction, multiplication, and division; (b) computational fluency, that is, speed and automaticity with math facts; and (c) mathematics applications, including areas such as money, measurement, time, and word problems. Targets of mathematics interventions can be characterized as (a) foundational arithmetic skills (e.g., number knowledge, basic understanding of mathematical operations), (b) acquisition and automatization of basic computational skills, and (c) problem-solving skills. Recent meta-analyses of mathematics interventions with low-achieving students and/or students with disabilities have reported the greatest efficacy for interventions targeting basic skills and the least efficacy for interventions focusing on higher order mathematics skills. Promising intervention components include frequent feedback to teachers and parents regarding student performance, explicit instruction in math concepts and procedures, and peer-assisted learning. The two interventions described in this section use highly structured, multicomponent approaches to enhance basic skills acquisition and fluency.

5.2.2.1. Cover–Copy–Compare The cover–copy–compare (CCC) strategy, originally developed by Skinner and colleagues at Mississippi State University, is a self-management intervention that can be used to enhance accuracy and fluency in a variety of academic subjects. Students look at an academic stimulus (e.g., a multiplication problem for CCC mathematics), cover it, copy it, and evaluate their response by comparing it to the original stimulus. CCC combines several empirically based intervention components, including self-instruction, increased opportunities to respond to academic material, and immediate corrective feedback.

5.2.2.2. Reciprocal Peer Tutoring Reciprocal peer tutoring (RPT) in mathematics, developed by Fantuzzo and associates at the University of Pennsylvania, combines self-management techniques and group contingencies within a peer tutoring format. Although both CWPT and RPT involve peer-mediated instruction, RPT includes self-management and subgroup contingencies, with teams of students selecting and working to obtain their own rewards. RPT has been demonstrated to enhance not only math performance but also students' perceptions of their own scholastic competence. Including a home-based reinforcement component enhances positive outcomes.

5.2.3. Interventions to Improve Written Language Performance

Writing is a crucial skill for school success because it is a fundamental way in which to communicate ideas and demonstrate knowledge in the content areas. Unfortunately, writing problems not only are characteristic of most students with learning disabilities but also are prevalent in the general student population. According to the 2002 NAEP report on writing, only 26% of 4th graders scored at the proficient level, with the percentage dropping to 22% for 12th graders. The pervasiveness of writing problems suggests that poor writing achievement is related less to internal student disabilities than to inadequate writing instruction. During the past decade or so, research on the cognitive processes underlying writing has led to a shift in writing instruction from an emphasis on product (e.g., grammar, mechanics, content) to an emphasis on the processes used to generate written productions (e.g., brainstorming, writing multiple drafts, developing a sense of audience, incorporating feedback from others). As a result, writing interventions increasingly focus on student performance of various aspects of the writing process, including planning, sentence generation, and revising. The interventions in this section target several writing process components, including fluency and compositional elements such as planning and editing.

5.2.3.1. Self-Regulated Strategy Development in Writing Self-regulated strategy development (SRSD) is an instructional approach that combines explicit teaching and modeling of compositional strategies with a set of self-regulation procedures. In a series of studies, Graham, Harris, and colleagues at the University of Maryland have documented that SRSD improves the quantity and quality of narrative and expository writing for students with writing disabilities as well as for normally developing writers. In addition to enhancing writing performance, SRSD is associated with improved feelings of self-efficacy and more positive attitudes toward writing for students. Most applications of SRSD include paired and/or small-group learning activities at specific steps in the training process to provide additional opportunities for feedback and collaboration without direct teacher supervision.

5.2.3.2. Self-Recording of Writing Productivity This intervention uses CBM-type methodology in the context of self-monitoring procedures to increase writing fluency. Self-recording word counts during free writing periods provides students with opportunities for

positively evaluating their own writing fluency and yields useful progress monitoring data by showing teachers when changes in instruction are followed by increases in writing performance rates. Setting writing production goals and self-recording word counts produce increases in the number of words written and improvements in free writing expressiveness without a deterioration in writing mechanics, compared with untimed writing periods. Some variations include individual and group reinforcements for achieving preset goals.

5.3. Interventions to Enhance Academic Enablers

According to DiPerna and Elliott, academic success requires more than skill in performing assigned tasks. That is, although classroom instruction focuses on the acquisition of concepts, knowledge, and skills in academic subjects, students must become active participants in their educational experiences to benefit from that instruction. The two interventions in this category have been widely used as stand-alone strategies or in combination with other intervention components to facilitate achievement and productivity across a range of academic skill domains.

5.3.1. Public Posting

Public posting involves displaying some kind of classroom record (e.g., a chart) that documents student achievement or productivity. Whereas traditional public posting strategies often record incidents of negative behavior (e.g., the names of disruptive or unproductive students), public posting as an academic intervention is a positive strategy that displays student progress in achieving specified academic goals. Originally designed to encourage improvement in individual student performance, small-group and classwide versions that target group achievement and capitalize on positive peer influence have also been developed. Adding individual or group contingencies can enhance outcomes but does not appear to be critical to intervention effectiveness.

5.3.2. School–Home Notes

School–home notes encourage parental involvement in children’s classroom performance, permit a broader range of reinforcers than are generally available to teachers, and have demonstrated efficacy for both

academic problems and behavior problems. School-home communications can be arrayed along a continuum of parental involvement, ranging from notes that merely provide information to notes that ask parents to deliver predetermined consequences contingent on the reported student performance. Although strategies that include home consequences can have powerful effects on student performance, establishing and maintaining an effective school-home communication system can be difficult for even a single student, much less for groups or entire classrooms of unproductive students. Not surprisingly, the majority of published school-home note interventions have targeted individual students or small groups of students, usually in special education settings.

6. SUMMARY AND FUTURE DIRECTIONS

Given the growing diversity and needs of the student population, interest in the development and empirical validation of academic interventions is likely to increase. Although the knowledge base of effective school-based interventions has increased dramatically during the past 15 years, determining which intervention components and which intervention parameters (e.g., intensity, duration, delivery system) are maximally effective for which types of students will be a continuing challenge for researchers and practitioners alike. Additional studies are especially needed to identify strategies that are high in both efficacy and usability for second-language learners and secondary school students with special needs.

 5. Interventions, New Technology, and Future Developments
- Further Reading

Transportation accidents carry great personal, organizational, societal, and economic costs. Applied psychology can derive research inspiration from, and can contribute much to the understanding and eventual prevention of, accidents in all kinds of transportation modes. The applied psychological questions surrounding accidents can vary widely, from issues of perception in an individual driver, to trade-offs made in complex organizations under pressures of scarcity and competition, to biases and heuristics in our understanding of culpability, cause, and control. Further progress on safety in transportation systems hinges in part on contributions from applied psychology.

GLOSSARY

accident Generally unforeseen occurrence with damaging consequences for life, limb, or property.

automation Replacement of human work by machines or computers in many transportation modes; it often creates new human work in form of new knowledge and skill demands and has been linked to the emergence of new kinds of accidents.

chain of events Model of accident causation that captures the multiple subsequent failures necessary to cause an accident (i.e., domino effect); it has recently been challenged by systemic and control models.

regulation Activity of defining rules to govern (transportation) practice and the enforcement of those rules; this often requires large organizations that are nearly always government sponsored and run.

systemic and control models Models that see accidents as a result of loss of control or as a gradual erosion of safety constraints on system design and operation.

1. WHY IS IT IMPORTANT TO UNDERSTAND ACCIDENTS?

Transportation accidents carry tremendous social, environmental, and economic costs. Traffic accidents are among the leading causes of death for people under 34 years of age. In 2002 alone, 42,815 people died in highway accidents in the United States; that equates to more than 117 fatalities per day or 1.51 fatalities per 100 million vehicle miles traveled. The number of injuries hovers around 3 million per year. The economic costs of these accidents are enormous—more than \$230 billion per year for the United States alone. Survivors of transportation accidents often require treatment and rehabilitation and also suffer psychological consequences that may carry over into work and social settings.

The nature and frequency of accidents differ widely among the various transportation modes. For example, the year 1999 witnessed 51 major accidents in commercial aviation and 2768 train-related accidents that were responsible for 932 casualties. At the same time, safety of the various transportation modes varies with geographical location. For example, in terms of casualties, passenger shipping may be less safe than driving in parts of Southeast Asia, and flying may be more dangerous in certain parts of Africa. Indeed, it would seem that the phrase “richer is safer” is true except when considering road traffic accidents in heavily populated, affluent parts of world. All the same, a transportation accident is one of the most common risks to which any member of society is exposed.

2. APPLIED PSYCHOLOGY AND ACCIDENTS

Transportation accidents are interesting from an applied psychology perspective because they are, most basically, about human behavior in applied settings. In fact, accidents are typically about human cognition as much as they are about technical problems and issues. The applied psychological questions surrounding accidents can vary widely, from issues of sensation and perception in an individual driver to shortcuts made by organizational members under pressures of scarcity and competition. Applied psychology as a field of scientific inquiry can use its insights for, and derive much empirical inspiration from, transportation accidents. Indeed, applied psychology in the broadest, most inclusive sense is relevant to transportation accidents.

In studying whether a car driver could have seen a pedestrian, applied psychology may be called on to assess the effect of atmospheric modulation (e.g., rain, mist, dust) on stimulus perceptibility (e.g., the pedestrian). Models exist to calculate so-called atmospheric modulation transfer that can help applied psychologists to reconstruct the existing visibility during a particular occurrence. Additional questions may arise when substance abuse is suspected on the part of the driver; in such a case, applied psychology relies more on models of psychopathology. Much research leverage exists in gauging the (sub)cultural acceptability of consuming alcohol before engaging in transportation activities. Other questions with relevance to applied psychology arise when notable mismatches occur in people’s risk perceptions. For example, people might

not want to use the railroads due to one highly publicized recent fatal accident. If they prefer to drive their cars, they actually expose themselves to the risk of an accident (perhaps even a fatal accident) several orders of magnitude larger than that which would exist while riding the train. Such individual risk assessments are deeply confounded, mixing personal histories, notions of control and destiny, and various kinds of biases and rationalizations (e.g., the availability heuristic) into a rich trove for applied psychology.

Perhaps even more complex are questions surrounding the trade-offs made by professionals who work in transportation systems, leading to issues such as “safety cultures” in transportation systems. Does the commander of the aircraft continue with the approach in bad weather or not? Does the master of the ship sail in the storm or not? Such trade-offs are more than the risk assessments of individual decision makers; they must also be understood as expressions of the preferences and priorities of entire sociotechnical systems that operate in environments of scarcity (e.g., only so many passengers, only so much money to be had) and competition (e.g., somebody else is always ready to take over one’s routes). In efforts to investigate these kinds of trade-offs and other applied problems, psychology has seen a methodological shift accelerate over the past decade or so, with an increasing emphasis on fieldwork and the study of applied settings. It is believed that to understand decision making in actual (transportation) work, where real decisions have real outcomes for real people, psychological researchers must get out of the laboratory and investigate applied settings directly. Issues of confounding factors are dealt with through intensive analysis and interpretation of research results, leading to findings (e.g., on naturalistic decision making) that are both internally valid and exportable to other applied settings.

There is also a role for applied psychology in understanding issues of culpability and control. To what extent, and why, do we judge participants in transportation (e.g., drivers, pilots) to be culpable for the accidents that they “cause”? Such questions are deeply complex and touch on much of what people hope and believe about the world in which they live. The questions are interconnected with yet another set of biases, including the “hindsight bias” that describes how knowledge of outcome profoundly alters one’s perception of the behavior and intentions that led up to that outcome. The hindsight bias also allows one to convert a complex tangled history leading up to an accident into a simple series of binary decisions, where

participants had clear choices to do the right thing or the wrong thing. These questions also inevitably coincide with assumptions about causation, whether justified or not. These tend to be quite problematic and affect applied psychological reasoning around accidents and human intention and behavior.

3. WHY DO ACCIDENTS HAPPEN?

One of the more compelling questions for those involved in transportation is why accidents happen. Indeed, a pressing issue after an accident is often to resolve the question, "What was the cause?" There is, of course, no one or unequivocal answer, and not just because the various modes of transportation may differ widely in their respective etiologies of failure. Models of accident causation develop continually, reflecting not only new insights or access to accident data but also the general scientific spirit of the times. In transportation, the so-called "chain of events" model is popular. In this model, one failure somewhere in the system can be seen to lead to (or trigger) the next, and so on, until this cascade of individually insignificant faults pushes the entire system over the edge of breakdown. For example, a piece of debris on the runway, left there by a preceding aircraft, manages to puncture the tire of a subsequent aircraft. Tire fragments slam into the wing, puncturing the fuel tank and triggering a fire that, not much later, brings down the entire aircraft. The chain of events model is also credited with distributing or refocusing the search for accident causes away from frontline operators (i.e., away from "operator error"), instead identifying higher up supervisory and organizational shortcomings that may have contributed.

However, recent insight into the sociotechnical nature of large transportation accidents, such as disasters involving the Space Shuttles *Challenger* (in 1986) and *Columbia* (in 2003), has exposed the limits of the chain of events model. Most critically, the model presupposes (or even requires) failures so as to cause a failure. This contradicts characterizations of organizational and operational practice preceding accidents as normal everyday routine. Accidents can still happen even if everybody follows the rules and there are no "failures" or "shortcomings" as seen from the perspective of those running and regulating the transportation system. As Perrow suggested in 1984, accidents in these systems may be quite "normal" given their structural properties of interactive complexity and tight coupling. Nothing extraordinary (i.e., no obvious breakdowns or failures) as seen

from inside the system is necessary to produce an accident. For example, aviation is a tightly coupled system, as are railroads. This means that there is little slack to recover if things do start to go wrong. The workings of a railroad system, however, are generally more linear and transparent than those of aviation, with the former allowing for better insight into how to manage the system.

These insights have put pressure on the old label "human error" as an explanation for accidents. Indeed, human error today can no longer be legitimately seen as the cause of accidents; rather, it is seen as an effect, as a symptom, or as a sign of trouble deeper inside the system. Human error is no longer an explanation; instead, it demands one. Human error, to the extent that it exists as a separable category of human performance (which many researchers doubt or deny), is systematically connected to features of people's tools and tasks. This is consistent with the ecological commitment in much of applied psychology, where an analysis of agent-environment mutuality, or person-context couplings, is critical to producing useful insights into the success and failure of transportation (and other) systems.

The latest accident models deemphasize "cause" altogether, noting that it is a deeply Newtonian concept that might not carry over well into an understanding of why complex transportation systems fail, with the *Columbia* accident being a case in point. These models see transportation accidents rather as control problems; as the gradual erosion and eventual loss of control over a safety-critical process, where safety constraints on design or operation are violated. Such models can be reconciled better with increasing evidence that large transportation accidents are nearly invariably preceded by some kind of slow but gradual drift (e.g., away from procedures, away from design specifications) that is hard to notice or characterize as deviant when seen from the inside, that is, from the perspective of participants themselves. The consistent, if slight, speeding that most male drivers exhibit (e.g., nearly always 5 miles per hour over the speed limit) is another example of this. The deviance is normalized; the nonroutine becomes routine, and there is consistent noncompliance. Production pressures (e.g., pressure to be on time, pressure to maximize capacity use) form the major engine behind such drift toward failure in nearly all transportation systems because virtually no transportation system is immune to the pressures of competition and resource scarcity. Recent research debates are not necessarily about the existence or reality of such pressures; rather, they discuss to what extent these pressures consciously affect people's

trade-offs and to what extent people deliberately gamble (and lose if they have an accident). Much research points to the prerational insidious nature of production pressures on people's trade-offs rather than to conscious immoral or risky calculation, although male drivers under 25 years of age might be an exception.

Acknowledging that such sociotechnical complexity underlies most transportation accidents means that safety and risk are really social constructs rather than objective engineering measurements. Risk is constructed at the intersection of social forces and technical knowledge (or the lack thereof). Slogans such as "safety comes first" are mere posturing. They are disconnected from reality where risk is negotiated as subjective social activity and where it will be different in different cultures, different among organizations within a single culture, and even different among subcultures within one organization.

4. REGULATION OF TRANSPORTATION SYSTEMS AND INCIDENT REPORTING

Most, if not all, transportation systems are regulated to some extent. Regulation means that rules are created to govern practice and that the rules are enforced to generate compliance. This often requires large organizations—nearly always public or government agencies—tasked with issuing rules, overseeing practice, and certifying and checking systems, operators, and organizations. The extent of regulation of various transportation modes varies greatly from country to country. In some countries, regulators are criticized for having too close a relationship with the transportation industries they are supposed to regulate and for having a dual and supposedly incompatible mandate (i.e., promoting the use and growth of the transportation system as well as overseeing and monitoring its compliance).

The success of safety regulation depends on the safety level that the transportation system has already achieved. In relatively unsafe transportation modes (e.g., private flying), regulation can pay great and rather immediate dividends. It can help to standardize practice; it can issue, broadcast, and enforce rules and remind operators of them; and it can help to build a corpus of cases on routes to accidents that can be shared in the community. There is often leverage in changing designs (e.g., operator interfaces) to make them more error

resistant and error tolerant. In safer systems (e.g., charter flights), such error-resistant designs have typically evolved further. Accidents are often preceded by so-called "dress rehearsals"—sequences of events similar to real accidents but without fatal outcomes. Learning from those dress rehearsals is encouraged, particularly through incident-reporting systems. However, in ultra-safe transportation systems (e.g., European railroads), overregulation becomes a problem. More rules and more monitoring are no longer accompanied by safety gains; they serve only to increase system complexity and potentially decrease transparency as well as rule compliance. Incident-reporting systems in ultra-safe transportation systems may be of limited value. The typical accident there emerges from routine, everyday banal factors that combine and align in ways that are hard to foresee. Incident reports would neither notice the relevance of those factors nor be able to subsequently project their interplay. This, in fact, is a problem allied with all incident-reporting systems. Reporting is not the same as analysis, which in turn is not the same as learning from potential failure. Just having an incident reporting system in place guarantees little in terms of progress on safety.

5. INTERVENTIONS, NEW TECHNOLOGY, AND FUTURE DEVELOPMENTS

Prevention and improvement strategies vary considerably from one transportation mode to another because many of the factors that affect accident likelihood are mode specific. In general, prevention strategies seek either to minimize the likelihood of a particular kind of harmful event (e.g., a crash) or to minimize its impact (in terms of property damage, injury, or environmental pollution). New technology often plays a dominant role here. Automatic seat belt systems, side impact protection systems, collision detection and avoidance systems, anti-lock breaking systems, double-hull vessels, automated cocoons to keep an aircraft within its prescribed envelope—all of these systems intervene, prevent, and protect in one sense or another. Even though enormous progress is made through such interventions, technology is sometimes a mixed blessing. Airbags may protect mostly drivers who do not wear seat belts (forcing a large majority of other people, who do wear seat belts, to pay a premium on their cars), and automation in virtually all transportation

modes has been associated with the emergence of new human-machine coordination problems (e.g., mode errors, “automation surprises,” people getting lost in display page architectures). Indeed, automation has been associated with the emergence of new types of accidents in virtually all transportation modes, where it has introduced new capabilities and new complexities. One typical signature of accidents in automated transportation systems is the “going sour” scenario, where a small trigger event (i.e., an unusual occurrence or a small failure in a system somewhere), itself innocuous, leads to a series of misassessments and miscommunications between humans and computers. The system is managed into greater hazard due to coordination breakdowns among the various players (both humans and machines). The end result is often an automation surprise, where humans discover that what they thought they had instructed the automation to do was not quite what the automation was doing. More research, much of it in applied psychology, will be necessary to use new technology and other

interventions to their full potential in helping to reduce transportation accidents.

GLOSSARY

acculturation A process of cultural and psychological change resulting from contact between cultural groups and their individual members.

acculturation strategies Variations in the way acculturating groups and individuals attempt to manage the process of acculturation (see Assimilation, Integration, Marginalization, Separation).

acculturative stress A negative psychological reaction to the experiences of acculturation, often characterized by anxiety, depression and a variety of psychosomatic problems.

adaptation The long-term outcome of acculturation, including psychological adaptation (feelings of personal well-being and self-esteem) (and sociocultural adaptation (competence in dealing with life in the new society).

assimilation The acculturation strategy in which people do not wish to maintain their heritage culture, and seek to participate in the larger society.

cultural distance The degree of cultural dissimilarity between two groups, measured by ethnographic indicators, or by an individual's perception of such difference.

cultural identity How individuals think and feel about themselves in relation to their two cultural groups in contact.

integration The acculturation strategy in which people wish to maintain their heritage culture, and seek to participate in the larger society.

larger society An evolving social and political framework representing a civic consensus about how to live together in a culturally plural society.

marginalization The acculturation strategy in which people do not maintain their heritage culture, and also do not participate in the larger society.

multicultural ideology A positive orientation of individuals to cultural diversity in plural societies involving the acceptance of ethnocultural groups and their participation in the larger society.

plural society A society in which a number of ethnocultural groups live together within a shared civic political and economic framework.

psychological acculturation A process in which psychological features of a person change as a result of their contact with other cultural groups.

separation The acculturation strategy in which people maintain their heritage culture, and seek to avoid participation in the larger society.

Acculturation is the process of cultural and psychological change that takes place as a result of contact between cultural groups and their individual members. Such contact and change occur during colonization, military invasion, migration, and sojourning (e.g., tourism, international study, overseas posting). It continues after initial contact in culturally plural societies, where ethnocultural communities maintain features of their heritage cultures. Adaptation to living in culture contact

settings takes place over time. Occasionally it is stressful, but often it results in some form of accommodation. Acculturation and adaptation are now reasonably well understood, permitting the development of policies and programs to promote successful outcomes for all parties.

1. ACCULTURATION CONCEPT

The initial interest in acculturation grew out of a concern for the effects of European domination of colonial and indigenous peoples. Later, it focused on how immigrants (both voluntary and involuntary) changed following their entry and settlement into receiving societies. More recently, much of the work has been involved with how ethnocultural groups relate to each other, and to change, as a result of their attempts to live together in culturally plural societies. Nowadays, all three foci are important as globalization results in ever larger trading and political relations. Indigenous national populations experience neocolonization; new waves of immigrants, sojourners, and refugees flow from these economic and political changes; and large ethnocultural populations become established in most countries.

Early views about the nature of acculturation are a useful foundation for contemporary discussion. Two formulations in particular have been widely quoted. The first, from Redfield and colleagues in a 1936 article, is as follows:

Acculturation comprehends those phenomena which result when groups of individuals having different cultures come into continuous first-hand contact, with subsequent changes in the original culture patterns of either or both groups. . . . Under this definition, acculturation is to be distinguished from culture change, of which it is but one aspect, and assimilation, which is at times a phase of acculturation.

In another formulation, the Social Science Research Council in 1954 defined acculturation as

culture change that is initiated by the conjunction of two or more autonomous cultural systems. Acculturative change may be the consequence of direct cultural transmission; it may be derived from non-cultural causes, such as ecological or demographic modification induced by an impinging culture; it may be delayed, as with internal adjustments following upon the acceptance of alien traits or patterns; or it may be a reactive adaptation of traditional modes of life.

In the first formulation, acculturation is seen as one aspect of the broader concept of culture change (that

which results from intercultural contact), is considered to generate change in “either or both groups,” and is distinguished from assimilation (which may be “at times a phase”). These are important distinctions for psychological work and are pursued later in this article. In the second definition, a few extra features are added, including change that is indirect (not cultural but rather “ecological”), is delayed (internal adjustments, presumably of both a cultural and a psychological character, take time), and can be “reactive” (i.e., rejecting the cultural influence and changing toward a more “traditional” way of life rather than inevitably toward greater similarity with the dominant culture).

In 1967, Graves introduced the concept of psychological acculturation, which refers to changes in an individual who is a participant in a culture contact situation, being influenced both by the external culture and by the changing culture of which the individual is a member. There are two reasons for keeping these two levels distinct. The first is that in cross-cultural psychology, we view individual human behavior as interacting with the cultural context within which it occurs; hence, separate conceptions and measurements are required at the two levels. The second is that not every individual enters into, and participates in, a culture in the same way, nor does every individual change in the same way; there are vast individual differences in psychological acculturation, even among individuals who live in the same acculturative arena.

A framework that outlines and links cultural and psychological acculturation and identifies the two (or more) groups in contact is presented in Fig. 1. This framework serves as a map of those phenomena that the author believes need to be conceptualized and measured during acculturation research. At the cultural level (on the left of the figure), we need to understand key features of the two original cultural groups (A and B) prior to their major contact, the nature of their contact relationships, and the resulting dynamic cultural changes in both groups, and in the emergent ethnocultural groups, during the process of acculturation. The gathering of this information requires extensive ethnographic, community-level work. These changes can be minor or substantial and can range from being easily accomplished to being a source of major cultural disruption. At the individual level (on the right of the figure), we need to consider the psychological changes that individuals in all groups undergo and their eventual adaptation to their new situations. Identifying these changes requires sampling a population and studying individuals who are variably

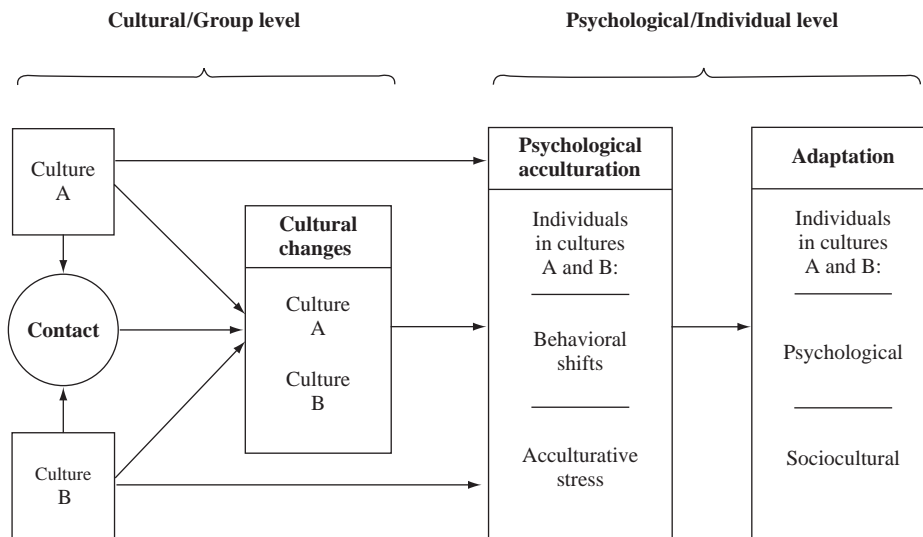

FIGURE 1 A general framework for understanding acculturation.

involved in the process of acculturation. These changes can be a set of rather easily accomplished behavioral shifts (e.g., in ways of speaking, dressing, or eating; in one’s cultural identity), or they can be more problematic, producing acculturative stress as manifested by uncertainty, anxiety, and depression. Adaptations can be primarily internal or psychological (e.g., sense of well-being or self-esteem) or sociocultural, linking the individual to others in the new society as manifested, for example, in competence in the activities of daily intercultural living.

2. ACCULTURATION CONTEXTS

As for all cross-cultural psychology, it is imperative that we base our work on acculturation by examining its cultural contexts. We need to understand, in ethnographic terms, both cultures that are in contact if we are to understand the individuals that are in contact.

In Fig. 1, we saw that there are five aspects of cultural contexts: the two original cultures (A and B), the two changing ethnocultural groups (A and B), and the nature of their contact and interactions.

Taking the immigration process as an example, we may refer to the society of origin (A), the society of settlement (B), and their respective changing cultural features following contact (A1 and B1). A complete understanding of acculturation would need to start with a fairly comprehensive examination of the societal contexts. In the society of origin, the cultural characteristics

that accompany individuals into the acculturation process need description, in part to understand (literally) where the person is coming from and in part to establish cultural features for comparison with the society of settlement as a basis for estimating an important factor to be discussed later: cultural distance. The combination of political, economic, and demographic conditions being faced by individuals in their society of origin also needs to be studied as a basis for understanding the degree of voluntariness in the migration motivation of acculturating individuals. Arguments by Richmond in 1993 suggested that migrants can be arranged on a continuum between reactive and proactive, with the former being motivated by factors that are constraining or exclusionary (and generally negative in character), and the latter being motivated by factors that are facilitating or enabling (and generally positive in character). These contrasting factors were also referred to as push/pull factors in the earlier literature on migration motivation.

In the society of settlement, a number of factors have importance. First, there are the general orientations that a society and its citizens have toward immigration and pluralism. Some societies have been built by immigration over the centuries, and this process may be a continuing one, guided by a deliberate immigration policy. The important issue to understand for the process of acculturation is both the historical and attitudinal situations faced by migrants in the society of settlement. Some societies are accepting of cultural pluralism resulting from immigration, taking steps to

support the continuation of cultural diversity as a shared communal resource. This position represents a positive multicultural ideology and corresponds to the integration strategy. Other societies seek to eliminate diversity through policies and programs of assimilation, whereas still others attempt to segregate or marginalize diverse populations in their societies. Murphy argued in 1965 that societies that are supportive of cultural pluralism (i.e., with a positive multicultural ideology) provide a more positive settlement context for two reasons. First, they are less likely to enforce cultural change (assimilation) or exclusion (segregation and marginalization) on immigrants. Second, they are more likely to provide social support both from the institutions of the larger society (e.g., culturally sensitive health care, multicultural curricula in schools) and from the continuing and evolving ethnocultural communities that usually make up pluralistic societies. However, even where pluralism is accepted, there are well-known variations in the relative acceptance of specific cultural, “racial,” and religious groups. Those groups that are less well accepted experience hostility, rejection, and discrimination, one factor that is predictive of poor long-term adaptation.

3. ACCULTURATION STRATEGIES

Not all groups and individuals undergo acculturation in the same way; there are large variations in how people seek to engage the process. These variations have been termed acculturation strategies. Which strategies are used depends on a variety of antecedent factors (both cultural and psychological), and there are variable consequences (again both cultural and psychological) of these different strategies. These strategies consist of two (usually related) components: attitudes and behaviors (i.e., the preferences and actual outcomes) that are exhibited in day-to-day intercultural encounters.

The centrality of the concept of acculturation strategies can be illustrated by reference to each of the components included in Fig. 1. At the cultural level, the two groups in contact (whether dominant or nondominant) usually have some notion about what they are attempting to do (e.g., colonial policies, motivations for migration), or of what is being done to them, during the contact. Similarly, the elements of culture that will change depend on the group’s acculturation strategies. At the individual level, both the behavior changes and acculturative stress phenomena are now known to be a function, at least to some extent, of

what people try to do during their acculturation, and the longer term outcomes (both psychological and sociocultural adaptations) often correspond to the strategic goals set by the groups of which they are members.

Four acculturation strategies have been derived from two basic issues facing all acculturating peoples. These issues are based on the distinction between orientations toward one’s own group and those toward other groups. This distinction is rendered as a relative preference for maintaining one’s heritage culture and identity and as a relative preference for having contact with and participating in the larger society along with other ethnocultural groups. This formulation is presented in Fig. 2.

These two issues can be responded to on attitudinal dimensions, represented by bipolar arrows. For purposes of presentation, generally positive or negative orientations to these issues intersect to define four acculturation strategies. These strategies carry different names, depending on which ethnocultural group (the dominant or nondominant one) is being considered. From the point of view of nondominant groups (on the left of Fig. 2), when individuals do not wish to maintain their cultural identity and instead seek daily interaction with other cultures, the assimilation strategy is defined. In contrast, when individuals place a value on holding onto their original culture while wishing to avoid interaction with others, the separation alternative is defined. When individuals have an interest in maintaining their original culture while in daily interactions with other groups, integration is the option. In this case, they maintain some degree of cultural integrity while seeking, as members of an ethnocultural group, to participate as an integral part of the larger social network. Finally, when individuals have little possibility of, or interest in, cultural maintenance (often for reasons of enforced cultural loss) and little interest in having relations with others (often for reasons of exclusion or discrimination), marginalization is defined.

This presentation was based on the assumption that nondominant groups and their individual members have the freedom to choose how they want to acculturate. This, of course, is not always the case. When the dominant group enforces certain forms of acculturation or constrains the choices of nondominant groups or individuals, other terms need to be used.

Integration can be “freely” chosen and successfully pursued by nondominant groups only when the dominant society is open and inclusive in its orientation

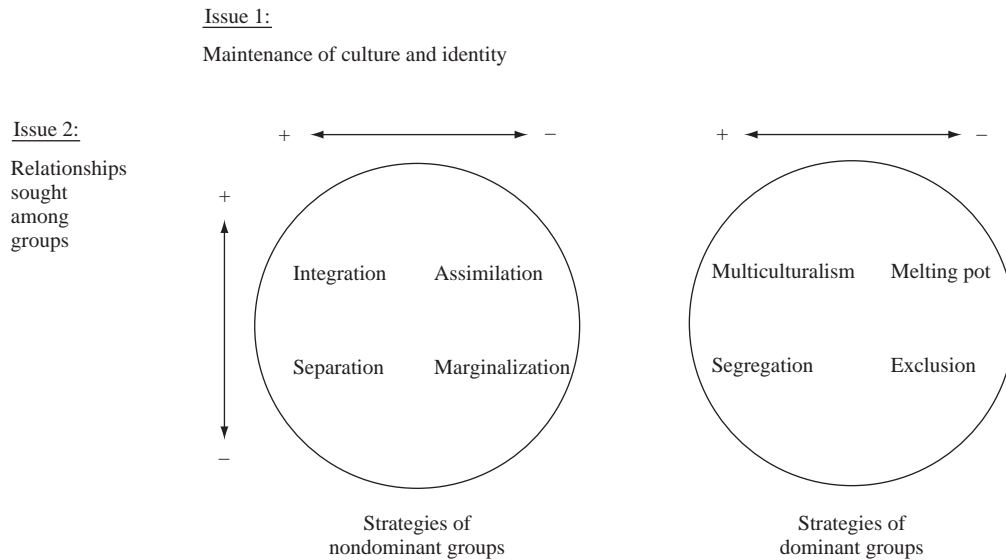

FIGURE 2 Four acculturation strategies based on two issues in ethnocultural groups and the larger society.

toward cultural diversity. Thus, a mutual accommodation is required for integration to be attained and involves the acceptance by both groups of the right of all groups to live as culturally different peoples. This strategy requires nondominant groups to adopt the basic values of the larger society, whereas the dominant group must be prepared to adapt national institutions (e.g., education, health, labor) to better meet the needs of all groups now living together in the plural society.

These two basic issues were initially approached from the point of view of the nondominant ethnocultural groups. However, the original anthropological definition clearly established that both groups in contact would become acculturated. Hence, a third dimension was added: the powerful role played by the dominant group in influencing the way in which mutual acculturation would take place. The addition of this third dimension produces the right side of Fig. 2. Assimilation, when sought by the dominant group, is termed the “melting pot”; however, when it is demanded by the dominant group, it is called the “pressure cooker.” When separation is forced by the dominant group, it is “segregation.” Marginalization, when imposed by the dominant group, is termed “exclusion.” Finally, integration, when diversity is a feature of the society as a whole (including all of the various ethnocultural groups), is called “multiculturalism.” With the use of this framework, comparisons can be made between individuals and their groups and between nondominant peoples and the larger society within which they

are acculturating. The ideologies and policies of the dominant group constitute an important element of ethnic relations research, whereas the preferences of nondominant peoples are a core feature in acculturation research. Inconsistencies and conflicts among these various acculturation preferences are sources of difficulty for acculturating individuals. In general, when acculturation experiences cause problems for acculturating individuals, we observe the phenomenon of acculturative stress.

4. ACCULTURATIVE STRESS

Three ways in which to conceptualize outcomes of acculturation have been proposed in the literature. In the first (behavioral shifts), we observe those changes in an individual’s behavioral repertoire that take place rather easily and are usually nonproblematic. This process encompasses three subprocesses: culture shedding; culture learning; and culture conflict. The first two involve the selective, accidental, or deliberate loss of behaviors and their replacement by behaviors that allow the individual a better “fit” with the society of settlement. Most often, this process has been termed “adjustment” because virtually all of the adaptive changes take place in the acculturating individual, with few changes occurring among members of the larger society. These adjustments are typically made with minimal difficulty, in keeping with the appraisal

of the acculturation experiences as nonproblematic. However, some degree of conflict may occur, and this is usually resolved by the acculturating person yielding to the behavioral norms of the dominant group. In this case, assimilation is the most likely outcome.

When greater levels of conflict are experienced and the experiences are judged to be problematic but controllable and surmountable, the second approach (acculturative stress) is the appropriate conceptualization. In this case, individuals understand that they are facing problems resulting from intercultural contact that cannot be dealt with easily or quickly by simply adjusting or assimilating to them. Drawing on the broader stress and adaptation paradigms, this approach advocates the study of the process of how individuals deal with acculturative problems on first encountering them and over time. In this sense, acculturative stress is a stress reaction in response to life events that are rooted in the experience of acculturation.

A third approach (psychopathology) has had long use in clinical psychology and psychiatry. In this view, acculturation is nearly always seen as problematic; individuals usually require assistance to deal with virtually insurmountable stressors in their lives. However, contemporary evidence shows that most people deal with stressors and reestablish their lives rather well, with health, psychological, and social outcomes that approximate those of individuals in the larger society.

Instead of using the term “culture shock” to encompass these three approaches, the author prefers to use the term “acculturative stress” for two reasons. First, the notion of shock carries only negative connotations, whereas stress can vary from positive (eustress) to negative (dis-stress) in valence. Because acculturation has both positive (e.g., new opportunities) and negative (e.g., discrimination) aspects, the stress conceptualization better matches the range of affect experienced during acculturation. Moreover, shock has no cultural or psychological theory or research context associated with it, whereas stress (as noted previously) has a place in a well-developed theoretical matrix (i.e., stress–coping–adaptation). Second, the phenomena of interest have their life in the intersection of two cultures; they are intercultural, rather than cultural, in their origin. The term “culture” implies that only one culture is involved, whereas the term “acculturation” draws our attention to the fact that two cultures are interacting with, and producing, the phenomena. Hence, for both reasons, the author prefers the notion of acculturative stress to that of culture shock.

Relating these three approaches to acculturation strategies, some consistent empirical findings allow the

following generalizations. For behavioral shifts, the fewest behavioral changes result from the separation strategy, whereas most result from the assimilation strategy. Integration involves the selective adoption of new behaviors from the larger society and retention of valued features of one’s heritage culture. Marginalization is often associated with major heritage culture loss and the appearance of a number of dysfunctional and deviant behaviors (e.g., delinquency, substance abuse, familial abuse). For acculturative stress, there is a clear picture that the pursuit of integration is least stressful (at least where it is accommodated by the larger society), whereas marginalization is the most stressful. In between are the assimilation and separation strategies, with sometimes one and sometimes the other being the less stressful. This pattern of findings holds for various indicators of mental health.

5. ADAPTATION

As a result of attempts to cope with these acculturation changes, some long-term adaptations may be achieved. As mentioned earlier, adaptation refers to the relatively stable changes that take place in an individual or group in response to external demands. Moreover, adaptation may or may not improve the fit between individuals and their environments. Thus, it is not a term that necessarily implies that individuals or groups change to become more like their environments (i.e., adjustment by way of assimilation), but it may involve resistance and attempts to change their environments or to move away from them altogether (i.e., by separation). In this use, adaptation is an outcome that may or may not be positive in valence (i.e., meaning only well adapted). This bipolar sense of the concept of adaptation is used in the framework in Fig. 1 where long-term adaptation to acculturation is highly variable, ranging from well adapted to poorly adapted and varying from a situation where individuals can manage their new lives very well to one where they are unable to carry on in the new society.

Adaptation is also multifaceted. The initial distinction between psychological and sociocultural adaptation was proposed and validated by Ward in 1996. Psychological adaptation largely involves one’s psychological and physical well-being, whereas sociocultural adaptation refers to how well an acculturating individual is able to manage daily life in the new cultural context. Although conceptually distinct, the two measures are empirically related to some extent (correlations between them are in the +.40 to +.50 range). However, they are

also empirically distinct in the sense that they usually have different time courses and different experiential predictors. Psychological problems often increase soon after contact, followed by a general (but variable) decrease over time. However, sociocultural adaptation typically has a linear improvement with time. Analyses of the factors affecting adaptation reveal a generally consistent pattern. Good psychological adaptation is predicted by personality variables, life change events, and social support, whereas good sociocultural adaptation is predicted by cultural knowledge, degree of contact, and positive intergroup attitudes.

Research relating adaptation to acculturation strategies allows for some further generalizations. For all three forms of adaptation, those who pursue and accomplish integration appear to be better adapted, whereas those who are marginalized are least well adapted. And again, the assimilation and separation strategies are associated with intermediate adaptation outcomes. Although there are occasional variations on this pattern, it is remarkably consistent and parallels the generalization regarding acculturative stress.

6. APPLICATIONS

There is now widespread evidence that most people who have experienced acculturation actually do survive. They are not destroyed or substantially diminished by it; rather, they find opportunities and achieve their goals, sometimes beyond their initial imaginings. The tendency to “pathologize” the acculturation process and outcomes may be due partly to the history of its study in psychiatry and in clinical psychology. Second, researchers often presume to know what acculturating individuals want and impose their own ideologies or personal views rather than informing themselves about culturally rooted individual preferences and differences. One key concept (but certainly not the only one) in understanding this variability, acculturation strategies, has been emphasized in this article.

The generalizations that have been made in this article on the basis of a wide range of empirical findings allow us to propose that public policies and programs that seek to reduce acculturative stress and to improve intercultural relationships should emphasize the integration approach to acculturation. This is equally true of national policies, institutional arrangements, and the goals of ethnocultural groups. It is also true of individuals in the larger society as well as members of nondominant acculturating groups.

In some countries, the integrationist perspective has become legislated in policies of multiculturalism that encourage and support the maintenance of valued features of all cultures while supporting full participation of all ethnocultural groups in the evolving institutions of the larger society. What seems certain is that cultural diversity and the resultant acculturation are here to stay in all countries. Finding a way in which to accommodate each other poses a challenge and an opportunity to social and cross-cultural psychologists everywhere. Diversity is a fact of contemporary life. Whether it is the “spice of life” or the main “irritant” is probably the central question that confronts us all—citizens and social scientists alike.

Achievement Motivation in Academics

Dale H. Schunk

University of North Carolina, Greensboro, North Carolina, USA

1. Introduction
2. Background
3. Current Perspectives
4. Promoting Achievement Motivation
Further Reading

Achievement motivation is the desire to excel at effortful activities. Achievement motivation originally was thought of as extending across many areas, but current views conceive of it as more specific to situations. Personal, social, instructional, familial, and cultural factors affect achievement motivation, and parents and educators can help students to improve their achievement motivation.

GLOSSARY

achievement motivation The desire to excel at effortful activities.

attributions Perceived causes of outcomes.

classroom climate The social, psychological, and emotional characteristics of the classroom.

expectancy-value theory Theory predicting that achievement behavior depends on expectations about the outcomes of actions and how much those outcomes are valued.

goal What one is trying to accomplish.

outcome expectations Beliefs about the expected outcomes of one's actions.

peer networks Large groups of peers with whom students associate.

self-efficacy Beliefs about one's capabilities for learning or performing given actions.

Thematic Apperception Test (TAT) Projective personality measure in which people view ambiguous pictures and make up stories or answer questions.

value The importance of an outcome.

1. INTRODUCTION

At the end of her ninth-grade geometry class, Mrs. Lollar passed out the "Problem of the Week" for students to take home and solve. Two students in the class, Ashley and Marella, each have a B+ average. Because the problem of the week is worth extra credit, doing well on it could raise each of their averages to an A. That evening at home, Ashley looked at the problem for a while, spent a little time on it, but then quit without solving it. Marella studied the problem and began to work. When her parents called her to dinner, she was reluctant to come because she was working on it. After dinner, she worked on it some more and finally exclaimed, "Aha—I get it!" The next day in class, Marella was one of only three students to have solved the geometric proof. Ashley got some steps in the proof correct, but her solution was far from complete.

Achievement motivation is the desire to excel at effortful activities. In the opening scenario, it seems that Marella was more motivated to achieve in geometry than was Ashley. Marella displayed interest in solving the proof, persisted at it, was excited when she understood what to do, and solved it correctly.

Achievement motivation has a long history in psychology and education, and for good reason. Motivation to achieve is necessary for all but the simplest tasks. Achievement motivation helps students to learn in school, fuels creative activities, and helps individuals and societies to attain goals.

Despite the intuitive importance of achievement motivation, researchers disagree on its critical components. The next two sections examine the background of achievement motivation and some current perspectives.

2. BACKGROUND

It is difficult to pinpoint the historical onset of the study of achievement motivation because the human desire to achieve has been of interest for ages. The scientific study of achievement motivation received impetus from work by Murray, who included it as one of several human needs that contribute to personality development. Murray also devised the Thematic Apperception Test (TAT) to study personality processes. The TAT is a projective technique in which people view a series of ambiguous pictures (i.e., inkblots) and make up a story or answer questions for each picture.

McClelland and colleagues adapted the TAT to study achievement motivation. People were shown pictures of individuals in ambiguous situations (e.g., a student at a desk holding a pencil and looking into the air) and were asked questions such as the following: “What is happening?,” “What led up to this situation?,” “What is wanted?,” and “What will happen?” Responses were scored and categorized according to strength of achievement motivation. Unfortunately the TAT has some measurement problems, and TAT achievement motivation scores often did not relate well to other measures of achievement. Over the years, researchers have devised other methods for assessing achievement motivation.

Important early work on achievement motivation was done by Atkinson and colleagues. Atkinson drew on work by Lewin and others on the level of aspiration or the goal that people set in a task. Lewin’s research showed that successes raised and failures lowered the level of aspiration, that people felt more successful when they met the goals they had set for themselves than when

they attained objective standards, and that the level of aspiration reflected individual and group differences.

Atkinson’s expectancy–value theory of achievement motivation states that behavior depends on how much people value a particular goal and their expectancy of attaining that goal as a result of performing in a given fashion. Atkinson postulated that achievement behavior involved a conflict between a motive to approach a task (hope for success) and a motive to avoid it (fear of failure). These motives conflict because any achievement task carries with it the possibilities of success and failure. The achievement motivation that results in any situation depends on people’s expectancies of success and failure and their incentive values of success and failure.

The historical research focused on achievement motivation globally, that is, motivation across many situations. But research and everyday observations show that people rarely are motivated to achieve at high levels in every situation. Rather, students typically have greater achievement motivation in some content areas than in others. In the opening scenario, although Marella’s achievement motivation was higher than Ashley’s in geometry, Ashley may strive to excel more than Marella in history. Given that the achievement motive differs depending on the domain (and even depending on the task within the domain), the validity of general achievement motivation is questionable.

3. CURRENT PERSPECTIVES

People who study achievement motivation today believe that it is more situationally specific and is affected by many factors: personal, social, instructional, familial, and cultural (Table I). To understand why students differ in achievement motivation, one must examine the roles of these factors in their lives. Although researchers agree that achievement motivation is complex, they disagree on which factors are the most important.

Personal factors reside within students. Some key personal factors are goals, expectations, values, and attributions. Goals are what one is trying to accomplish. Goals usually are cast in terms of products—Marella and Ashley’s goal was to work the geometry proof—but they also can represent processes. Thus, an academic goal may be to improve one’s skill in comprehending scientific texts. Goals contribute to achievement motivation because people pursuing goals persist and expend effort to succeed. As they work on the tasks, they evaluate their goal processes, and the belief that they are making progress sustains motivation.

TABLE I
Influences on Achievement Motivation

Factors	Sample influences
Personal	Goals, outcome expectations, self-efficacy, values, attributions
Social	Peers, peer models, peer networks
Instructional	Planning, decision making, instructional grouping, interactions, activities, classroom climate
Familial	Socioeconomic status, capital, guidance
Cultural	Educational emphasis, social orientation

But goals actually are less important than their properties: specificity, proximity, and difficulty. Goals may be specific (e.g., read 10 pages) or general (e.g., read some pages), proximal (e.g., read 10 pages tonight) or distant (e.g., read 10 pages by next week), and difficult (e.g., read 400 pages) or easier (e.g., read 50 pages). From a motivational perspective, goals that are specific, proximal, and moderately difficult produce higher achievement motivation than do goals that are general, distant, and either too difficult or too easy. Thus, motivation is not aided when goals denote general outcomes (because nearly any action will satisfy them), are temporally distant (it is easy to put off until tomorrow what does not need to be done today), and too difficult or too easy (people are not motivated to attempt the impossible and may procrastinate completing easy tasks).

Expectations can be of two types. Outcome expectations refer to the expected outcomes of one's actions (e.g., "If I study hard, I should make a high grade on the test," "No matter how hard I study, I probably will fail the test"). Outcome expectations motivate students because the belief that a certain action will lead to a given outcome should lead students to pursue or avoid that action, assuming that they value that outcome or want to avoid it.

A second type of expectation involves beliefs about one's capabilities to learn or perform given actions. Bandura and other researchers termed this "self-efficacy." Self-efficacious students believe that they can study diligently, whereas those lacking efficacy might believe that they cannot. Marella's self-efficacy in geometry likely was higher than Ashley's. Self-efficacy is important because students who believe that they can learn or perform desired actions are more likely to choose to engage in them, expend effort, and persist.

Self-efficacy and outcome expectations often are related, but they need not be. Students who believe that they are capable typically expect to perform well and receive high grades and other rewards. However,

students may believe that diligent studying will lead to good grades (i.e., positive outcome expectation) but also may doubt their ability to study diligently (i.e., low self-efficacy), in which case they might feel demoralized. Positive outcome expectations and strong self-efficacy for learning and performing capably produce high achievement motivation.

The values and/or importance that students ascribe to learning and achievement are central components of motivation. Those who do not value what they are learning are not motivated to improve or perform well. Research shows that value relates positively to persistence, choice, and performance. Students who value learning choose challenging activities, persist at them, and perform well. Thus, students who value history are apt to study diligently for tests, set goals for their learning, monitor their learning progress, use effective learning strategies, and not be daunted by obstacles. Marella likely valued geometry more than did Ashley.

Attributions are perceived causes of outcomes or the factors that people believe are responsible for their successes and failures. In achievement situations, learners may ask themselves questions such as the following: "Why did I get an A on my biology test?" and "Why can't I learn French?"

Weiner and colleagues formulated an attribution theory of achievement motivation that contends that each attribution can be classified along three dimensions: locus, stability, and controllability. The locus dimension refers to whether the attribution is internal or external to the person. The stability dimension denotes how much the attribution varies over time. The controllability dimension involves the extent that the attribution is under the individual's control.

Weiner found that common attributions in achievement settings are ability, luck, task difficulty, and effort; however, there are many others (e.g., fatigue, illness, personal dislike, time available, attitude). Ability is internal, stable, and uncontrollable (although one's ability

can improve over time); luck is external, unstable, and uncontrollable; task difficulty is external, stable (assuming that the task does not change), and uncontrollable; and effort is internal, unstable (although a general effort factor also seems to exist), and controllable.

Students who attribute academic success to high ability and effort are more likely to expect future success than are those who attribute it to task ease and good luck. Students who attribute failure to low ability are less likely to expect future success than are those who attribute it to low effort. The latter finding is especially critical because a low expectation of future success stifles motivation. From the perspective of achievement motivation, it is far better to stress effort than ability because the former has stronger motivational effects. Of course, as skills develop, students do become more able, so the attribution of success to ability is credible. Teachers often have difficulty in motivating students who believe that they lack the ability to succeed and that no amount of effort will help them to be successful.

Social factors are those that are inherent in interactions with others. Peers are a key social group for students. Peer models are especially influential, especially those who are similar to observers in important ways, because they convey that tasks are valuable.

Peer group goals are highly valued by students. Thus, students may want to be liked and approved, develop social and/or intimate relationships, learn to cooperate, win favors, and be sensitive to the needs of others. Students' perceptions of their capabilities also are affected by peers through social comparisons. Observing similar peers succeeding can raise observers' self-efficacy.

Peer networks are large groups of peers with whom students associate. Students in networks tend to be highly similar and, thus, are key models. Students' motivational engagement in school across the school year is predicted by their network membership at the start of the year. Those in more academically inclined networks demonstrate higher academic motivation than do those in low-motivation networks.

Although students may select their peer networks, parents can play a key role by "launching" their children onto particular trajectories. For example, parents who want their children to be academically oriented are likely to involve them in activities and groups that stress academics. Peers with whom children associate reinforce the emphasis on academics.

Instructional factors include teacher planning and decision making, grouping for instruction, teacher-student interactions (including feedback to students), activities, and classroom climate. Teachers can enhance student

motivation by planning interesting activities that maximize student involvement in lessons. Teachers who plan only lectures are less apt to promote student motivation. Teachers also can promote motivation by basing instructional decisions not only on how well students are learning but also on how much the material appeals to students.

Three types of grouping structures are competitive, cooperative, and individualist. Competitive situations are those in which the goals of individuals are linked negatively such that if one attains his or her goal, the chance that others will attain their goals diminishes. Cooperative structures are those in which the goals of the group members are linked positively such that one can attain his or her goal only if others attain their goals. In individualist situations, there is no link among the goals of individuals such that one's goal attainment has no effect on the goal attainment of others. From a motivational perspective, competitive situations highlight differences among students, and lower achievers may become discouraged if they believe that they have no chance to earn rewards. Cooperative situations are better if all students contribute to the project. If only one or two students do most of the work, there is apt to be resentment. In individualist situations, achievement motivation can be developed and sustained when learners focus on their progress or on how much better they are performing now compared with earlier.

Performance feedback provides information on accuracy of work and may include corrective information (e.g., "The first part is correct, but you need to bring down the next number"). Motivational feedback can provide information on progress and competence (e.g., "You've gotten much better at this"), link student performance with one or more attributions (e.g., "You've been working hard"), and inform students about how well they are applying a strategy and how strategy use is improving their work (e.g., "You got it correct because you followed the proper method"). Feedback motivates students when it informs them that they are making progress and becoming more competent.

Classroom climate refers to the atmosphere of the classroom—its social, psychological, and emotional characteristics. Climate is important for motivation because classroom interactions define the climate. Climate often is referred to in terms such as "warm," "cold," "permissive," "democratic," and "autocratic." Research shows that a democratic environment—one based on mutual respect and collaboration—fosters goal attainment by learners without their becoming frustrated or aggressive.

There are many familial factors, but a key one is socioeconomic status, whose link with students'

academic motivation is well established. Children from lower socioeconomic backgrounds typically display lower motivation and achievement, and are at greater risk for school failure and dropout, compared with children from wealthier families. But socioeconomic status is only a descriptive term and does not explain why effects occur. There also are many people who grew up in impoverished environments but became well educated and successful.

A major contributor is a family's capital or resources. Poor families have less financial resources to support their children's learning outside of school than do wealthier families. Socialization in lower class homes often does not match or prepare students for the middle-class orientation of schools and classrooms. Lower socioeconomic students might not understand the full benefits of schooling or comprehend that getting a good education will increase their chances of college acceptance, good jobs, and financial stability. Because of family financial strain, they also might not be able to resist the short-term benefits of working in favor of the long-term benefits of schooling. Such students might have few, if any, educated role models in their environments. Many enter school without the needed social, cognitive, and emotional prerequisites to learn successfully.

Families continue to influence children's motivation throughout childhood and adolescence by steering children in given directions. Families that provide rich resources in the home and guide their children into activities that stress motivation and achievement are apt to develop children higher in achievement motivation.

Cultural factors also affect motivation. Cross-cultural research shows that there are differences in how much cultures emphasize education and motivation for learning. For example, children from Asian cultures often place greater emphasis on effort as a cause of success than do students in the United States. Some cultures are more socially oriented, whereas others place more emphasis on individual accomplishments. Although it is hard to make generalizations about cultures given that not all members of a culture act alike, it does seem that motivational differences stem in part from influences in cultural background.

4. PROMOTING ACHIEVEMENT MOTIVATION

How can parents and educators help to improve students' achievement motivation for academics? First,

they can help students to set challenging but attainable goals. Students must believe that the goals are attainable; they will not be motivated to attempt what they see as impossible. Teachers and parents might need to work with students to ensure that goals are realistic; if students are unaware of the demands of an assignment, they might set an unattainable goal. Challenging and attainable goals help to build self-efficacy as students perceive that they are making progress.

Second, it is important for parents and educators to stress the value of learning. Motivation is enhanced when learners understand how they can use what they are learning and how it will help them in the future. People are not motivated to engage in "busy work." Marella and Ashley's teacher would do well to point out applications of geometry in daily life.

Third, parents and educators should build students' perceptions of their competence or self-efficacy. Self-efficacy is increased when learners believe that they are developing skills, making progress toward their goals, and performing better. Self-efficacy develops through actual performance accomplishments, vicarious (modeled) experiences, and social persuasion. Teachers and parents should ensure that students work at tasks on which they can be successful, observe similar peers succeeding, and receive feedback indicating that they are capable (e.g., "I know you can do this").

Fourth, parents should get involved in children's learning. Parents can be involved in school by assisting in classrooms and at home. Parents serve as models for learning, and they can help to establish a productive study environment. They also can be taught tutoring skills. The importance of parents as motivational models cannot be overemphasized.

Fifth, teachers should use peers effectively to build motivation. Teachers who group students for collaborative project work must ensure that each student has responsibility for part of the task so that the bulk of the work is not done by one or two students. In using models for comparisons, it is imperative that students view the models as similar to themselves. Motivation of lower achieving students might not improve when these students are asked to observe higher achieving students perform.

Finally, parents and educators should use feedback to teach and motivate. Feedback typically informs students whether they are correct or incorrect and what to do to perform better. Feedback motivates when it informs students about their progress—how much better they are performing now than they were previously—and when it links their performances to effort, good strategy use, and enhanced ability.

Academic motivation for academics is important not only for schooling but also for the future. Educators want students to continue to be motivated to learn once they leave their classrooms. This is the essence of “lifelong learning” by which citizens move their societies forward.

GLOSSARY

ability test A procedure designed to measure an examinee's potential for achievement, sometimes also referred to as an aptitude test.

achievement test A procedure designed to measure an examinee's attainment of knowledge or skills.

battery A collection of related subtests, the performance on which can be aggregated to form a composite or "total battery" score on the entire test.

classroom assessments Achievement tests that are developed, administered, and scored for classroom use.

content standards Statements that describe specific knowledge or skills over which examinees are expected to have mastery for a given age/grade and subject area.

criterion-referenced test (CRT) An instrument whose primary purpose is to gauge whether an examinee knows or can do specific things.

high-stakes/low-stakes Terms referring to the severity of the consequences associated with test performance.

inference A reasoned leap, supported by evidence, made whenever observed test scores are interpreted in terms of examinees' underlying standing on a construct or actual level of knowledge or skill.

norm-referenced test (NRT) An instrument whose primary purpose is to describe the relative standing of examinees at a particular age or grade level.

performance standards Prescribed levels of performance representing differential degrees of knowledge or skill with respect to a set of content standards.

reliability The dependability of test scores; because an assignment or test consists only of a sample of questions or tasks, and because both the students who respond and those who score the responses are susceptible to various unpredictabilities in their performance (called random errors), no score can be considered to be a perfectly dependable representation of a student's performance.

standardized A term used to describe any instrument that is developed, administered, and scored under controlled conditions.

standards-referenced test (SRT) An instrument whose primary purpose is to describe examinees' performance with respect to a set of content standards.

validity The degree to which the conclusions yielded by any sample of behavior (e.g., test, quiz, interview) are meaningful, accurate, and useful; in the context of achievement testing, validity is the degree to which students' test scores yield inferences about the students' level of knowledge, skill, or ability that are "correct" or "on target."

Achievement tests are used in diverse contexts to measure the degree to which examinees can demonstrate acquisition of knowledge or skills deemed to be important. The contexts range from teacher-made testing in elementary and secondary school settings to

high-stakes testing for college admission, licensure to practice a profession, or certification. The design of achievement tests varies depending on whether the inference intended to be drawn regarding examinees' performance is the absolute or relative level of mastery of specific knowledge and skills.

1. INTRODUCTION

Achievement testing is a general term used to describe any measurement process or instrument whose purpose is to estimate an examinee's degree of attainment of specified knowledge or skills. Beyond that central purpose, achievement tests differ according to their specific intended inference. Common inferences include either absolute level of performance on the specified content or relative standing vis-à-vis other examinees on the same content. Achievement tests may be group or individually administered. They may consist of differing formats, including multiple-choice items, essays, performance tasks, and portfolios.

Achievement tests are administered in diverse contexts. For example, they are used when the school-related skills of preschool pupils are measured to assess their readiness for kindergarten. During the K–12 school years, students typically take a variety of achievement tests, ranging from teacher-made informal assessments, to commercially prepared achievement batteries, to state-mandated high school graduation tests. Following formal schooling, achievement tests are administered to assess whether examinees have an acceptable level of knowledge or skill for safe and competent practice in a regulated profession for which licensure is required. In other situations, professional organizations establish certification procedures, often including an achievement test, to determine examinees' eligibility to attain a credential or certification of advanced status in a field. Even the ubiquitous requirements to obtain a driver's license involve an achievement testing component.

Although the purposes and contexts may vary, fairly uniform procedures are implemented for developing achievement tests and for evaluating their technical quality. Several sources exist for potential users of achievement tests to ascertain the quality of a particular test and its suitability for their purposes.

In any context where an achievement test is used, consequences for individual persons or groups may follow from test performance. In addition, the context and extent of achievement testing may have broad and

sometimes unforeseen consequences affecting, for example, the security of tests, the formats used for testing, and the relationship between testing and instruction.

2. DEFINITIONS AND EXAMPLES

Achievement testing refers to any procedure or instrument that is used to measure an examinee's attainment of knowledge or skills. Achievement testing can be done informally, as in when a teacher asks a student to perform a skill such as reading aloud or demonstrating correct laboratory technique. More formal, and perhaps more common, achievement tests are routinely administered in educational and occupational settings. Examples of formal achievement testing in education would include spelling tests, chemistry lab reports, end-of-unit tests, homework assignments, and so on.

More formal achievement testing is evident in large-scale, commercially available standardized instruments. The majority of these achievement tests would be referred to as standardized to the extent that the publishers of the instruments develop, administer, and score the tests under uniform, controlled conditions. It is important to note, however, that the term "standardized" is (a) unrelated to test format (although the multiple-choice format is often used for standardized tests, any format may be included) and (b) not synonymous with norm referenced (although sometimes the term "standardized" is used to indicate that a test has norms).

Examples of standardized achievement tests used in K–12 education would include the Iowa Tests of Basic Skills, the 10th edition of the Stanford Achievement Test, and the TerraNova. These tests ordinarily consist of several subtests, measuring achievement in specific narrow areas such as language arts, mathematics, science, and study skills. The composite index formed from these subtests (often referred to as a "complete battery score") provides a more global measure of academic achievement.

The preceding tests are also usually administered in a group setting, although individually administered achievement tests are also available and are designed for administration in a one-on-one setting with individual students, usually of very young age. Examples of individually administered achievement tests include the Woodcock–Johnson III Tests of Achievement, the third edition of the Developmental Indicators for the Assessment of Learning, and the Brigance Comprehensive Inventory of Basic Skills.

Following secondary schooling, achievement testing continues in colleges and universities, primarily in the

form of classroom achievement measures, but would also include standardized in-training examinations and board examinations for persons pursuing professional careers. Achievement testing has a long history in diverse occupational fields. Achievement tests are routinely administered to ascertain levels of knowledge or skills when screening or selecting applicants for positions in business and industry. These tests have traditionally been administered in paper-and-pencil format, although technology has enabled administration via computer or over the Internet to be secure, fast, and accessible. For example, one vendor of computerized achievement tests offers computerized “work sample” achievement tests to assist human resources personnel in selecting applicants for positions in legal offices, food service, information technology, accounting, medical offices, and others. Many state, federal, and private organizations also provide achievement tests for a variety of fields in which licensure or certification is required.

3. TYPES OF ACHIEVEMENT TESTS

In the previous section, it was noted that achievement tests could be categorized according to administration (group or individual) and scale (informal classroom tests or more formal commercially available tests). Another more important distinction focuses on the intended purpose, use, or inference that is to be made from the observed test score.

Less formal classroom achievement tests are usually developed by a teacher to align with an instructional unit, or they may be pre-prepared by publishers of classroom textbooks or related materials. The primary purposes of such tests are for educators’ use in refining instruction and assigning grades as well as for both teacher and pupil use in understanding and responding to individual students’ strengths and weaknesses.

More formal standardized achievement tests can also be categorized according to the inferences they yield. Three such types of tests—criterion-referenced tests (CRTs), standards-referenced tests (SRTs), and norm-referenced tests (NRTs)—are described in this section.

CRTs are designed to measure absolute achievement of fixed objectives comprising a domain of interest. The content of CRTs is narrow, highly specific, and tightly linked to the specific objectives. Importantly, a criterion for judging success on a CRT is specified a priori, and performance is usually reported in terms of pass/fail, number of objectives mastered, or similar terms. Thus, an examinee’s performance or score on a CRT is

interpreted with reference to the criterion. The written driver’s license test is a familiar example of a CRT.

SRTs are similar to CRTs in that they are designed to measure an examinee’s absolute level of achievement vis-à-vis fixed outcomes. These outcomes are narrowly defined and are referred to as content standards. Unlike CRTs, however, interpretation of examinees’ performance is referenced not to a single criterion but rather to descriptions of multiple levels of achievement called performance standards that illustrate what performance at the various levels means. Typical reporting methods for SRTs would consist of performance standard categories such as basic, proficient, and advanced or beginner, novice, intermediate, and expert levels. Familiar examples of SRTs include state-mandated testing for K–12 students in English language arts, mathematics, and so on to the extent that the tests are aligned with the state’s content standards in those subjects. At the national level, the National Assessment of Educational Progress (NAEP) is administered at regular intervals to samples of students across the United States.

NRTs are designed to measure achievement in a relative sense. Although NRTs are also constructed based on a fixed set of objectives, the domain covered by an NRT is usually broader than that covered by a CRT. The important distinction of NRTs is that examinee performance is reported with respect to the performance of one or more comparison groups of other examinees. These comparison groups are called norm groups. Tables showing the correspondence between a student’s performance and the norm group’s performance are called norms. Thus, an examinee’s performance or score on an NRT is interpreted with reference to the norms. Typical reporting methods for NRTs include z scores, percentile ranks, normal curve equivalent scores, grade- or age-equivalent scores, stanines, and other derived scale scores. Familiar examples of NRTs include the Iowa Tests of Basic Skills (ITBS), the Scholastic Assessment Test (SAT), and the Graduate Record Examinations (GRE).

Many publishers of large-scale achievement tests for school students also provide companion ability tests to be administered in conjunction with the achievement batteries. The tests are administered in tandem to derive ability/achievement comparisons that describe the extent to which a student is “underachieving” or “overachieving” in school given his or her measured potential. Examples of these test pairings include the Otis–Lennon School Abilities Test (administered with the Stanford Achievement Test) and the Cognitive Abilities Test (administered with the ITBS).

4. ACHIEVEMENT TEST CONSTRUCTION

Rigorous achievement test development consists of numerous common steps. Achievement test construction differs slightly based on whether the focus of the assessment is classroom use or larger scale. *Table I* provides a sequence listing 18 steps that would be common to most achievement test development.

In both large and smaller contexts, the test maker would begin with specification of a clear purpose for the test or battery and a careful delineation of the domain to be sampled. Following this, the specific standards or objectives to be tested are developed. If it is a classroom achievement test, the objectives may be derived from a textbook, an instructional unit, a school district curriculum guide, content standards, or another source. Larger scale achievement tests (e.g., state mandated, standards referenced) would begin the test development process with reference to adopted state content standards. Standardized norm-referenced instruments would ordinarily be based on large-scale curriculum reviews, based on analysis of content standards adopted in various states, or

promulgated by content area professional associations. Licensure, certification, or other credentialing tests would seek a foundation in job analysis or survey of practitioners in the particular occupation. Regardless of the context, these first steps involving grounding of the test in content standards, curriculum, or professional practice provide an important foundation for the validity of eventual test score interpretations.

Common next steps would include deciding on and developing appropriate items or tasks and related scoring guides to be field tested prior to actual administration of the test. At this stage, test developers pay particular attention to characteristics of items and tasks (e.g., clarity, discriminating power, amenability to dependable scoring) that will promote reliability of eventual scores obtained by examinees on the operational test.

Following item/task tryout in field testing, a database of acceptable items or tasks, called an item bank or item pool, would be created. From this pool, operational test forms would be drawn to match previously decided test specifications. Additional steps would be required, depending on whether the test is to be administered via paper-and-pencil format or computer. Ancillary materials, such as administrator guides and examinee information materials, would also be produced and distributed in advance of test administration. Following test administration, an evaluation of testing procedures and test item/task performance would be conducted. If obtaining scores on the current test form that were comparable to scores from a previous test administration is required, then statistical procedures for equating the two test forms would take place. Once quality assurance procedures have ensured accuracy of test results, scores for examinees would be reported to individual test takers and other groups as appropriate. Finally, documentation of the entire process would be gathered and refinements would be made prior to cycling back through the steps to develop subsequent test forms (Steps 5–18).

TABLE I

Common Steps in Achievement Test Development

-
1. Establish need, purpose
 2. Delineate domain to be tested
 3. Develop specific objectives, content standards
 4. Decide on item and test specifications, formats, length, costs
 5. Develop items, tasks, scoring guides
 6. Conduct item/task review (editorial, appropriateness, alignment, sensitivity)
 7. Pilot/Field test items/tasks/scoring guides
 8. Review item/task performance
 9. Create item bank/pool
 10. Assemble test form(s) according to specifications
 11. Develop test administration guidelines, materials
 12. Establish performance standards
 13. Administer operational test forms
 14. Score test
 15. Evaluate preliminary item/task and examinee performance
 16. Report scores to appropriate audiences
 17. Evaluate test, document test cycle
 18. Update item pool, revise development procedures, develop new items/tasks
-

5. EVALUATING ACHIEVEMENT TESTS

In some contexts, a specific achievement test may be required for use (e.g., state-mandated SRTs). However, in many other contexts, potential users of an achievement test may have a large number of options from which to choose. In such cases, users should be aware of the aids that exist to assist them in making informed choices.

One source of information about achievement tests is the various test publishers. Many publishers have online information available to help users gain a better understanding of the purposes, audiences, and uses of their products. Often, online information is somewhat limited and rather nontechnical. However, in addition to providing online information, many publishers will provide samples of test materials and technical documentation on request to potential users. Frequently, publishers will provide one set of these packets of information, called specimen sets, at no charge for evaluation purposes.

When evaluating an achievement test, it is important to examine many aspects. A number of authorities have provided advice on how to conduct such a review. For example, one textbook for school counselors by Whiston contains a section titled "Selection of an Assessment Instrument" that consists of several pages of advice and a user-friendly checklist. The single authoritative source for such information would likely be the Standards for Educational and Psychological Testing, jointly sponsored by the American Educational Research Association, the American Psychological Association, and the National Council on Measurement in Education.

Finally, a particularly useful framework for evaluating achievement tests was developed by Rudner in 1994. Table II provides a modified version of key points identified by Rudner that should be addressed when choosing an achievement test.

It is likely that some potential users will not have the time or technical expertise necessary to fully evaluate an achievement test independently. A rich source of information exists for such users in the form of published reviews of tests. Two compilations of test reviews are noteworthy: *Mental Measurements Yearbook (MMY)* and *Tests in Print*. These references are available in nearly all academic libraries. In the case of MMY, the editors of these volumes routinely gather test materials and forward those materials to two independent reviewers. The reviewers provide brief (two- to four-page) summaries of the purpose, technical qualities, and administration notes for the test. Along with the summaries, each entry in MMY contains the publication date for the test, information on how to contact the publisher, and cost information for purchasing the test. In these volumes, users can compare several options for an intended use in a relatively short time.

TABLE II
Evaluation Criteria for Achievement Tests

-
1. Is the purpose of the test clearly stated? What achievement construct is claimed? Is the construct or intended content domain clearly delineated?
 2. What are the intended uses of the test? What are the intended audiences for the test results?
 3. For what ages, grade levels, or subject areas is the test intended?
 4. Are the test materials (e.g., booklets, answer sheets) clear, engaging, and appropriate for the age/grade level of the examinees?
 5. What are the costs of the test materials, scoring, training personnel, and time required to administer the test?
 6. Are the procedures for administering the test clear? Is the information provided sufficiently detailed so as to provide consistent administrations across users and contexts?
 7. What are the qualifications of those who participated in the development of the test? What qualifications are required for test administrators?
 8. How were samples selected for developing, pilot testing, norming, estimating reliability, screening out potentially biased items, and gathering validity evidence for the test? Were the samples relevant? Were they representative? Were they collected recently?
 9. Does the test yield scores of acceptable reliability? Were appropriate methods used to compute reliability estimates? If decisions are to be made based in part on test performance, what is the evidence regarding decision consistency?
 10. Is there adequate validity evidence to support the intended inferences, uses, interpretations, or meanings that will be made from test scores? Is there evidence to support the use of the test with various groups (including non-native speakers of English, special needs learners, students in need of testing accommodations, etc.)?
 11. Is the scoring system likely to produce accurate scores? If hand scoring is involved, are scoring keys easy to use and is conversion of raw scores to derived scores facilitated by tables, look-up charts, and the like? If machine scoring is used, are answer documents easy for examinees to use? Are timelines and costs for scoring reasonable?
 12. Do score reports provide a clear, detailed, and comprehensible summary of performance and diagnostic information? Are users appropriately cautioned about likely misinterpretations?
-

GLOSSARY

advertising appeal The central theme or idea behind an advertising message.

collectivism A cultural value system that emphasizes in-group goals such as family integrity, harmonious relationships, and the well-being of the in-group.

horizontal-vertical dimension A cultural distinction within the individualism-collectivism framework; members of horizontal societies value equality and view the self as having the same status as others in society, whereas members of vertical societies view the self as differing from others along a hierarchy, accepting inequality, and believing that rank has its privileges.

independent self-construal A view of the self that focuses on one's own psychological traits, feelings, and actions.

individualism A cultural value system that emphasizes being independent and pursuing individual goals rather than in-group goals.

interdependent self-construal A view of the self that focuses on one's social roles or memberships.

Culture is a crucial concept to the understanding of advertising and consumer behavior because it is the

lens through which people view advertising messages and products. This article reviews and discusses a series of studies on the relations between culture and advertising. The content is organized around different levels of analysis of culture, for example, national level versus individual level. The individualism-collectivism cultural construct and independent-interdependent self-construal construct are given special attention because extensive research has demonstrated the persuasion implications of these variables for advertising content, attitude toward advertisements, and cognitive processing of advertisements.

1. ADVERTISING AND ADVERTISING APPEALS

Advertising has been defined as the nonpersonal communication of information, usually paid for and usually persuasive in nature, about products (goods or services) or ideas by identified sponsors through various media. The central theme or idea behind an advertising message is called the advertising appeal.

2. APPROACHES TO CULTURE IN THE CONTEXT OF ADVERTISING AND CONSUMER BEHAVIOR

Intensified global marketing and advertising activities have given rise in the advertising industry to the

advertising standardization versus specification debate. The standardization proponents believe that people around the world have the same needs and desires and that they would react to advertising messages in the same or a similar way. The specification proponents argue that cultural differences among nations make advertising one of the most difficult marketing elements to standardize.

Culture consists of shared elements that provide the standards for perceiving, believing, evaluating, communicating, and acting among those who share a language, a historical period, and a geographical location. As a psychological construct, culture can be studied at multiple levels—across nations, across individuals within nations, and even within individuals through the priming of cultural values. Regardless of how culture is studied, cultural distinctions have been demonstrated to have important implications for advertising content, advertising persuasion, and consumer response.

2.1. Cultural Differences at the National Level

2.1.1. Individualism and Collectivism

Individualism and collectivism comprise the main cultural distinction that has been explored in studying both advertising content and the persuasiveness of ad appeals. Individualism and collectivism have been conceptualized as two powerful cultural models that represent broad differences among nations. As Hofstede, Triandis, and others have proposed, members of collectivistic cultures endorse in-group goals, such as family integrity, harmonious relationships, and the well-being of the in-group, whereas members of individualistic cultures endorse being independent and pursuing individual goals instead of in-group goals. Extensive cross-cultural (cross-national) data have shown that North American and most European countries, such as the United States, Canada, Germany, and Denmark, are individualistic societies and that most East Asian and Latin American countries, such as China, Korea, Japan, and Mexico, are collectivistic societies.

Past research has indicated that more individualistic and less collectivistic advertising appeals are present in individualistic cultures than in collectivistic cultures. For example, Han and Shavitt's 1994 study found that Korean ads tended to employ appeals emphasizing in-group benefits, harmony, and family integrity, whereas U.S. ads tended to employ appeals emphasizing individual enjoyment, personal success, and independence.

Similarly, in other research, more conformity themes (e.g., respect for collective values and beliefs) and fewer uniqueness themes (e.g., rebelling against collective values and beliefs) were found to be present in Korean ads compared with U.S. ads. In studying humorous appeals, ads from both Korea and Thailand were found to contain more group-oriented situations than those from Germany and the United States.

Existing research has also indicated that culturally matched ad appeals are more likely to be persuasive than are mismatched appeals. U.S. respondents found ads emphasizing individualistic benefits to be more persuasive, and found ads emphasizing family or in-group benefits to be less persuasive, than did Korean respondents. Also, Chinese participants responded more favorably to collective ad appeals (e.g., "share the moments of happiness") than to individualistic appeals (e.g., "the joy of self-expression"), whereas the reverse was true for U.S. participants. In addition, advertisements in Mexico that depict values that are consistent with the local cultural norms and roles (e.g., familial norms and roles in Mexican culture) elicited more favorable attitudes and purchase intentions than did ads that depict inconsistencies.

Product characteristics, such as whether a product is personal or shared (i.e., privately used vs publicly visible), have been found to moderate the effect of culture on the persuasiveness of ad appeals. Only for shared or socially visible products—those purchased or used with in-group members—did strong cultural differences emerge between Americans and Koreans in Han and Shavitt's 1994 study (Fig. 1) as well as between Americans and Chinese in other research.

2.1.2. Horizontal and Vertical Cultural Orientations

Within the individualism–collectivism framework, a distinction between horizontal and vertical societies has recently been introduced. Members of horizontal societies, such as Denmark and Sweden, value equality and view the self as having the same status as others in society. In contrast, members of vertical societies view the self as differing from others along a hierarchy, accepting inequality and believing that rank has its privileges. In comparison with the individualism–collectivism dimension, the horizontal–vertical dimension is less explored. However, recent studies have begun to examine the implications of the horizontal–vertical cultural dimension. In 2002, Nelson and Shavitt found that members of a relatively vertical society (the

FIGURE 1 Persuasiveness of individualistic and collectivistic appeals in the United States and Korea. Bars represent mean standardized scores on an attitude index (the average of standardized scores across three evaluative measures). Adapted from Han and Shavitt (1994), *J. Exp. Soc. Psychol.*, 30, 326–350, Copyright 1994, with permission from Elsevier.

United States) are more likely to endorse achievement values than are members of a horizontal society (Denmark). Moreover, Shavitt and colleagues' 2002 research suggested that vertical collectivism in the United States is associated with a tendency to be persuaded by ad appeals to status and hierarchy.

In 2000, Gurhan-Canli and Maheswaran demonstrated that Japanese consumers tended to favor products from their own country over foreign products, whereas American consumers tended to favor high-quality products regardless of the countries of origin of these products. Mediation analyses indicated that the vertical dimension of individualism and collectivism accounted for the country-of-origin effects in Japan. This is consistent with the cultural orientation in Japan—vertical collectivism—in that Japanese tend to believe in and value the superiority of the in-group over others.

In terms of advertising content, studies examining humor executions in ads have indicated that relationships between the central characters in ads where humor was intended were more often unequal in high power distance cultures (or vertical cultures such as Korea and Thailand) than in low power distance cultures (or horizontal cultures such as Germany); in the latter, these relationships were more often equal. Such unequal relationships in the ads are believed to reflect the hierarchical interpersonal relationships that are more likely to exist in high power distance (or vertical) cultures.

2.2. Self-Construal: Cultural Differences at the Individual Level

In 1991, Markus and Kitayama proposed that individualistic and collectivistic distinctions affect how individuals define or construct themselves in relation to others. According to these authors, the cultural norms of individualism require defining oneself as an individual whose behavior is organized and made meaningful primarily by reference to one's own thoughts, feelings, and actions. This independent self-construal is associated with describing oneself with reference to individual psychological traits such as "I am easygoing." On the other hand, the cultural norms of collectivism require individuals to see themselves as part of harmonious relationships and to recognize that their own behavior should seek benefits to their in-groups. This interdependent self-construal is associated with describing oneself with reference to social roles or memberships such as "I am in the gymnastics club." Recent research has indicated that self-construals account for and moderate cultural-level persuasion effects.

2.2.1. Chronic Self-Construal

Cross-cultural experiments have demonstrated that consumers with a more interdependent self-construal responded favorably to ads with a connected theme (e.g., interdependence, togetherness), whereas consumers with a more independent self-construal responded favorably to ads with a separate theme (e.g., independence, autonomy).

Self-construals have also been found to affect regulatory focus. Regulatory focus is built on the general hedonic notion that people approach pleasure and avoid pain. In 2001, Aaker and Lee found that, for people with an independent self-construal, promotion-focused information (e.g., drinking juice promotes energy or enjoyment of life) led to more positive attitudes toward a juice product. In contrast, for people with an interdependent self-construal, prevention-focused information (e.g., drinking juice helps to prevent disease) led to more positive attitudes.

2.2.2. Salient Self-Construal

Although an individual's cultural orientation may strongly determine the self-construal that is chronically accessible, self-construals may shift in response to other factors such as situational accessibility, motives, and reference points. The effect of temporarily accessible

self-construals on persuasion parallels that of chronic self-construals. For instance, regardless of whether self-construal is measured with the Self-Construal Scale or is situationally activated, studies have shown a consistent effect of independent self-construal versus interdependent self-construal on preference for either promotion-focused information or prevention-focused information.

The persuasion implications of salient self-construals have been further evidenced among bicultural consumers in the United States, that is, individuals who have been equally influenced by East Asian and Western cultural orientations. For example, Lau-Gesk's 2003 study found that an independent self-construal was temporarily activated when bicultural individuals were exposed to an individually focused appeal, and this in turn guided them to respond favorably to the advertised product. On the other hand, an interdependent self-construal was activated when bicultural individuals were exposed to an interpersonally focused appeal, and this in turn guided them to respond favorably to the advertised product. A frame-switching mechanism has been used to explain these findings in that bicultural individuals appear to be capable of shifting between individualistic and collectivistic interpretive frames in response to persuasive cues.

2.3. Culture and Cognitive Processing of Advertising Appeals

Just as psychological research on culture has focused extensively on cognitive process issues, recent research has demonstrated that a consumer's culture or cultural orientation influences the nature of information processing that accompanies a message.

Some studies along this line have focused on examining the effect of cultural orientation on persuasion by application of the Elaboration Likelihood Model/Heuristic-Systematic Model. Individualism and collectivism appear to be associated with different perceptions of cue diagnosticity in the processing of ads, and these in turn result in different patterns of attitudinal outcomes. Because of their individualistic tendencies, Americans are relatively uninterested in others' opinions; conversely, because of their collectivistic tendencies, people in Hong Kong tend to be more affected by the preferences of others. Consequently, among U.S. participants, product attribute information tends to be seen as more diagnostic than do consensus cues. In contrast, in 1997, Aaker and Maheswaran found that among Hong Kong participants, consensus cues are

treated as relatively diagnostic. Moreover, in 2000, Aaker and Sengupta's research demonstrated that individualistic versus collectivistic cultures are also associated with different strategies used in resolving incongruities between a source cue and product attribute information. In an individualistic cultural context, attribute information is perceived as more diagnostic than is a source cue and influences product evaluations. Hence, an attenuation strategy is used in information processing when incongruity between a source cue and attribute information occurs. In a collectivistic cultural context, where source information is relatively important and where there is less of a tendency to choose one type of information over another, the source cue and attribute information jointly influence evaluations. Hence, an additive strategy is applied when there is incongruity between a source cue and attribute information.

Culture also influences the role of affect in processing a message. Ego-focused (e.g., pride, happiness) versus other-focused (e.g., empathy, peacefulness) emotional appeals lead to more favorable attitudes among members of a collectivistic culture, whereas other-focused versus ego-focused emotional appeals lead to more favorable attitudes among members of an individualistic culture. This differs from the standard cultural congruity findings about persuasive effects. That is, relatively novel types of appeals, rather than culturally congruent appeals, elicit more elaboration. Because elaboration involves effortful thinking about the merits of a message as opposed to the use of simple cues, such elaborated thoughts tend to have a relatively large impact on evaluations.

2.4. Factors That Covary with Culture

Race, gender, and economic factors also affect ad content, ad processing, and attitude formation, although these effects are beyond the scope of this article. Very often, these variables will covary with culture, making studies of race, gender, and economic factors in conjunction with cultural ones particularly important.

The standard cultural congruity findings, suggesting that culturally matched ad appeals are more prevalent or are more likely to be persuasive, were reviewed earlier. However, a growing number of studies have indicated that the situation in rapidly transitioning economies may be more complex. For example, Westernized appeals, such as appeals to technology, individuality/

independence, and youth/modernity, have been found to be rather salient in Chinese and Japanese ads and to have been used frequently in current Taiwanese advertising agencies. These cultural incongruity findings could be driven by government policies regarding internal development and modernization, public exposure to Western media, and demographic and geographic contact zones. In addition, consumers in developing countries tend to respond favorably to Western products. For example, in one study of Indian consumers, brands perceived as having nonlocal (Western) countries of origin were favored over brands perceived as local. Moreover, this effect was found to be stronger for consumers who have a greater admiration for the lifestyle in economically developed countries. These cultural incongruity findings are meaningful because, as discussed by Zhang and Shavitt in 2003, they suggest the important role that advertising plays in reshaping cultural values in developing countries that are experiencing rapid economic growth. Rather than reflecting existing cultural values, advertising content in those countries promotes new aspirational values such as individuality and modernity; hence, these new values become acceptable and desirable among consumers.

3. CONCLUSIONS

As the advertising industry has become increasingly globalized, there has been increased research attention given to the role of culture in advertising. Progress in understanding this role has been made on a number of fronts. This article has reviewed empirical research on the effects of a number of cultural variables on advertising-related processes. Distinctions between individualistic and collectivistic cultures have been demonstrated to have important implications for advertising content, advertising persuasion, and consumers' cognitive responses. Parallel effects of culture and self-construal (independent vs interdependent) have been shown as well. In addition, studies on the distinction between horizontal and vertical cultural orientations within individualism–collectivism have begun to show advertising implications.

GLOSSARY

advertising A paid, mass-mediated attempt to inform and/or persuade.

AIDA model The acronym for Awareness, Interest, Desire, Action—a description of the stages by which advertising may have the desired effect on consumers.

attitude A psychological tendency to evaluate something (e.g., a person, an object, an idea) with some degree of favor or disfavor.

balance theory Theory that considers attitudinal relationships among a perceiver, an other, and a target; from the perceiver's perspective, balanced relationships are preferable to unbalanced relationships.

belief A piece of information about a person, an object, or an idea that an individual has in memory.

cognitive consistency A state when attitudes, beliefs, and behaviors are logically harmonious with one another.

cognitive dissonance An unpleasant state aroused by awareness of inconsistent cognitions.

Elaboration Likelihood Model and Heuristic-Systematic Model Dual-process theories of persuasion that posit both high-effort (central or systematic processing) and

low-effort (peripheral or heuristic processing) routes to persuasion.

memory The mental ability to store and recall (intentionally or unintentionally) past experiences.

mere exposure effect Generation of favorable attitudes toward a given stimulus due to repeated (subliminal) exposure to that stimulus.

perception Recognition and interpretation of sensory stimuli.

persuasion The processes by which an individual's attitudes are changed.

priming A technique for increasing the accessibility, and likelihood of use, of some concept.

self-perception A theory suggesting that individuals infer their attitudes based on past behavior, particularly when they are uncertain of their attitudes.

subliminal advertising An attempt to advertise without the awareness of the message recipient.

Principles of psychological science have been applied to advertising practice since both fields were relatively young. The study of information processing, attitudes, and persuasion creates a foundation for advertising psychology because each is an important determinant of achieving advertising's main functions: to inform, persuade, and influence.

1. INTRODUCTION

The *Advertisers Handbook*, published in 1910 by the International Textbook Company, offered a wide range of advice to advertising professionals. According to the

handbook, an advertisement should not be too general, a headline should not be silly or deceptive, and an ad should be arranged logically, be concise, contain a proper amount of matter for the commodity being sold, and so forth. A few pages of the handbook were even devoted to the use of psychology in advertising: "Study of the goods or service to be sold is highly important, but no more important than the study of that wonderful subject, the human mind. The advertiser will do well, in all his work, to give special attention to psychological principles."

The handbook's advice has been heeded. Advertisers have used both psychological theory and method to gain a better understanding of consumers. The study of information processing has been particularly influential as advertisers have sought to gain consumers' attention and ensure that consumers interpret and understand their messages and (hopefully) retain some of the information. The attitude construct has been particularly important in advertising psychology because advertisements are generally intended to create positive attitudes toward some objects and because attitudes are an important determinant of behavior. Thus, an understanding of attitudes is doubly important for advertisers given that attitudes are both desired outcomes and causes of desired behavior. Therefore, the psychological study of attitude change, or persuasion, is another crucial part of advertising psychology. This article reviews important aspects of psychology that also play an important role in advertising.

2. THE PSYCHOLOGICAL STUDY OF ADVERTISING

2.1. Historical Perspectives

The scientific study of psychology is roughly 125 years old, with the first laboratory of psychology being founded in 1879 by Wilhelm Wundt in Leipzig, Germany. Modern advertising is only slightly older than scientific psychology, having appeared in the earliest newspapers circa 1850, reaching a circulation of approximately 1 million readers. The two fields came together in the earliest application of psychological principles to advertising practice in America in 1896. At the University of Minnesota, Harlow Gale conducted systematic studies of the influence of ad placement within a page on attention, the impact of necessary versus superfluous words in headlines, and how various colors used in ads might influence readers' attention.

Gale's research did not receive wide attention, but several years later another researcher, Walter Dill Scott,

wrote a series of articles on psychological aspects of advertising. Scott's research on advertising psychology tended to focus on the concept of suggestion. He believed that advertising was primarily a persuasive tool, rather than an informational device, and that advertising had its effect on consumers in a nearly hypnotic manner. People were thought to be highly susceptible to suggestion, under a wide variety of conditions, so long as the suggestion was the only thought available to them. According to Scott, advertising was most effective when it presented consumers with a specific direct command. "Think Different," a suggestion used by Apple Computer, is a good example of a direct command, but it would not necessarily be an effective advertisement because it does not tell consumers how to think differently. A more effective advertisement might be "Use Apple Computers."

2.2. Contemporary Perspectives

It is interesting to note that the concept of suggestion went out of style for some time among scientific psychologists. It is somewhat unflattering to think of people as automatons who unthinkingly follow whatever instruction is given to them; however, contemporary scientific psychologists have once again embraced the notion that a fair proportion of human behavior is due to influences of which people are entirely unaware. One intriguing line of contemporary research has shown that simply asking people whether they intend to purchase a new car sometime during the next year dramatically increases the chances that they actually do purchase a new car during that year—even if they respond "no" to the initial inquiry. Remarkable as these ideas are, advertising has relied on a number of basic, tried-and-true psychological principles that are covered in the remainder of this article.

One very general model of advertising effects, the AIDA (Attention, Interest, Desire, Action) model, has roots in Scott's writings. In 1913, Scott proposed a model of advertising effects that had three stages: attention, comprehension, and understanding. Over the course of several decades, Scott's model evolved into the AIDA model, which is still in use. According to this model, advertising, or promotions more generally, must first garner the attention of consumers and help them to develop beliefs about the product or service. Second, advertising should create interest or positive feelings about the product/service. Third, advertising or promotions should instill in consumers a desire for the product/service, thereby helping them to form purchase intentions. Finally, consumers must be

convinced to take action, that is, to purchase the product/service. This article covers all of these aspects of advertising psychology and more. It is important to note, however, that the AIDA model represents a strong version of advertising effects.

2.3. Strong and Weak Models of Advertising Effects

Advertising can strongly persuade consumers into immediate buying, or it can have a more subtle effect by reinforcing people's existing propensities to buy certain brands. The psychological processes underlying these two mechanisms also differ. The strong model focuses on consumers' immediate psychological or behavioral reactions where explicit advocacy and rationales of advertising messages are vital. The weak model emphasizes brand awareness where advertising is viewed as a reminder of a brand or source of information. For example, according to the strong model, Mark may decide to go to the shopping mall immediately after viewing a television commercial that says, "40% off any purchase at Macy's." On the other hand, David may buy Coke instead of Pepsi because he has greater familiarity with the Coke brand name, although both brands were initially in his consideration set.

Whether the strong or weak theory provides a better explanation for advertising effects hinges on numerous factors. For example, strong effects are more likely to occur in "high-involvement" situations where advertising directly aims at changing individuals' attitudes. However, when consumers have a predetermined set of alternative brands or are in a "repeat buying" situation where purchase decisions tend to be habitual, weak reinforcement enhances long-term brand awareness, familiarity, salience, and brand associations. In any event, for advertising to have either strong or weak effects, it must first be perceived by prospective consumers.

3. PERCEPTION

The first issue is the process of getting the advertising "into" consumers. The sheer amount of stimuli around people is quite overwhelming. Consider all of the following stimuli to which people are constantly being exposed but are unconsciously "filtering out": the air rushing into their mouths or nostrils as they breathe, the sensation of tightness where their shoes are touching their feet, the color of the walls nearest

them, and so forth. When one considers all of these things, it is remarkable that any advertising makes it into people's consciousness at all. Nevertheless, if advertising is to reach consumers, they must first and foremost be exposed to it.

3.1. Exposure

Exposure is the first stage in perception, and it occurs when people achieve physical proximity to some stimulus. Whenever something activates their sensory receptors, it means they have been exposed to that something. A printed advertisement must activate rods and cones in people's eyes, and a radio advertisement must move the small bones that make up people's inner ears.

This activation of sensory receptors may occur at different threshold levels, with the lower, terminal, and difference thresholds being important to advertisers. The lower threshold is the minimum amount of stimulus that is necessary for people to be aware of a sensation. Images presented very briefly (i.e., a few milliseconds) fall below the lower threshold and are imperceptible to people. The terminal threshold is the point at which additional increases in stimulus intensity produce no awareness of the increase. The difference threshold is the smallest noticeable change in stimulus intensity. These threshold levels have aroused interest among advertisers due to their application to subliminal advertising.

During the late 1950s, Jim Vicary claimed to be able to influence people without them even knowing that they had been exposed to influence attempts. Vicary claimed to have increased soft drink and popcorn sales by subliminally presenting messages to movie viewers. Years later, Vicary confessed to fabricating his claims, but the notion that people could be subliminally influenced took hold somewhere in the popular imagination. Sporadically throughout the next several decades, the question of whether subliminal presentation of persuasive messages could influence consumer behavior was debated. It is now known that subliminal presentation of stimuli can influence attitudes and behavior, but not quite in the way that Vicary suggested.

In 1968, Robert Zajonc discovered that positive attitudes can be induced simply by repeatedly exposing people to a subliminally presented stimulus, a finding that he termed the "mere exposure" effect. Participants in these studies were repeatedly exposed to a set of unfamiliar stimuli (e.g., Chinese ideographs), although the exposures were so fast that participants were unaware of even having seen the stimuli. Yet, when asked to evaluate a variety of similar stimuli, some of

which they had been exposed to and others of which had not been presented to them, they evaluated the stimuli to which they had been previously exposed more positively than they evaluated similar stimuli that had not been presented to them subliminally. Of course, developing favorable attitudes toward something is a long way from actually getting people to buy something; however, it is now known that subliminal presentation of stimuli can also influence behavior.

Individuals can be “primed” by the subliminal (or even supraliminal under certain conditions) presentation of stimuli in essentially the same way that they prime a pump (i.e., by filling it with fluid so that it is ready for immediate use). Following the presentation of a primed concept, individuals are more likely to use that concept given an appropriate opportunity. For example, individuals primed with the concept of elderly were observed to walk slower than individuals primed with neutral concepts. However, priming is a relatively weak influence on behavior and simply could not make people get up in the middle of a movie to go fetch soft drinks and popcorn. There are far more effective ways in which to influence consumer behavior.

3.2. Attention

One of the enduring problems facing advertisers is attracting consumers’ attention. “Zipping and zapping” behavior is extremely common; television viewers record programs and zip (fast-forward) through the commercials or zap (eliminate commercials during recording or change the channel when they appear) them altogether. Drivers change the radio station when advertisements come on, they look away when billboards annoy them, and so forth. Attention is simply the conscious allocation of cognitive resources to some stimulus, but it is hard to grab.

A number of strategies have been used by advertisers to attract consumers’ attention. Theories of human motivation have been popular guidelines for advertisers. For example, Maslow’s hierarchy of needs posits five levels of motives that are common to all people: physiological (e.g., food, sex), safety (e.g., protection from the elements), belongingness (e.g., acceptance by others), esteem (e.g., admiration of others), and self-actualization (e.g., fulfillment of potential). Advertisers have tried to attract attention by positioning their products to fulfill one or more of these needs. Exercise equipment and healthy food appeal to physiological needs, bicycle helmets and smoke alarms appeal to safety needs, mouthwash and acne creams appeal to belongingness needs, designer clothing and luxury automobiles appeal

to esteem needs, and computer software and military service have even been made to appeal to self-actualization needs. One might imagine that nearly any product can be positioned to appeal to nearly any need—all in the name of attracting attention.

Properties of the stimulus can also be manipulated to attract attention. Size, color, intensity, contrast, position, movement, novelty, and so forth all can be used to attract attention.

3.3. Interpretation

Interpretation is the way in which meaning is assigned to stimuli. People exposed to exactly the same stimulus may interpret it very differently. For example, they may perceive a fuzzy kitten as an adorable target for cuddling or as a loathsome beast that causes sneezing and hives. Individual, situational, and stimulus characteristics all can influence the interpretation of stimuli.

At the individual level, consumers’ expectations, motives, and attitudes all can have a profound influence on the way in which they interpret advertisements. When clear cola was introduced, consumers expected it to taste different from the traditional caramel-colored colas; however, clear cola did not taste much different from brown colas, and many consumers were turned off by this. The violation of their expectations may have, at least in part, caused them to ultimately reject the clear cola. Motives and attitudes are particularly likely to have an influence on the interpretation of ambiguous stimuli. Advertisers who do not send clear messages may be opening themselves up to very different, and possibly unflattering, interpretations that reflect consumers’ own motives and attitudes.

At a situational level, the context in which an advertisement appears can have an influence on how it is interpreted. Several years ago, a prominent newspaper put out a Sunday supplement that featured a lengthy article on starvation and drought in Africa, followed immediately by a lengthy pictorial on the coming season’s high-fashion formal wear. The following week, there was a section in the same supplement that was devoted to outraged letters from readers and a formal apology by the newspaper. Rarely are pictorials on fashion the target of so much outrage, but the context made a huge difference.

At a stimulus level, interpretations vary a great deal as well. As noted previously, stimulus ambiguity opens doors for motives and attitudes to have their influence on interpretations. Other stimuli can have vastly different interpretations due to cultural differences.

Different colors and numbers have different culturally laden meanings in different countries. There used to be a brand of cold medicine called “666.” This brand likely did not fare well among conservative Christian consumers; but it might be prized in cultures where the number six has a positive meaning.

4. MEMORY AND LEARNING

Memory is complex; we can remember toys that we wanted as children, yet we sometimes cannot remember what we did the weekend before last. The simple change of a single word (e.g., how fast was the car going when it “bumped” [or “smashed”] into the pedestrian?) can substantially alter our memories. Yet it has been estimated that over the course of a lifetime, the average human stores approximately 500 times the amount of information that is in a full set of encyclopedias. Given these seemingly strange contradictions regarding memory, what hope can advertisers have of getting their products, brands, and ideas into consumers’ memories?

4.1. Encoding, Storage, and Retrieval

Memory involves three main processes: encoding (the process by which information is put into memory), storage (the process by which information is maintained in memory), and retrieval (the process by which information is recovered from memory).

Encoding may be visual, acoustic, or semantic. Visual encoding and acoustic encoding are self-explanatory; they are named for the sensory modality through which they operate. Semantic encoding refers to the general meaning of an event. For example, one might encode a television advertisement in terms of the visuals presented, the sounds that accompany it, or the general idea that there is a sale at the market.

Storage may be short term or long term. Short-term memory, or working memory, is of quite limited capacity and is used to hold information in consciousness for immediate use. Long-term memory is quite vast and can retain information for extremely long periods of time (e.g., some childhood memories last until death).

Retrieval also comes in different forms. Explicit memory is tapped by intentional recall or recognition of items or events. Implicit memory is the unintentional recollection and/or influence of prior experience on a current task. On implicit memory tests,

respondents are unaware that memory is being accessed. Implicit memory is assessed in a variety of ways such as word fragment completion (words seen previously are more likely to be completed than are words not seen previously) and time savings for tasks that have been done before. Advertisers may be particularly interested in explicit memory because the ability to intentionally recall information serves as a good measure of advertising effectiveness.

4.2. Short- and Long-Term Memory

Short-term memory is of relatively little consequence to advertisers because it does not, by definition, have any “staying power.” Short-term memory may be important for direct response advertising, where consumers are asked to call a phone number to order or request additional information. But there is little that an advertiser can do with short-term memory. The primary function of short-term memory is to allow people to perform mental work such as calculating a sum or remembering a telephone number until they can either dial it or write it down. The fairly recent trend of placing advertisements on shopping carts in supermarkets might be a good way for advertisers to keep their products in short-term memory while people are doing their grocery shopping. In general, however, for an advertisement to be effective, it must work its way into long-term memory.

One bright spot for advertisers hoping to etch their work in consumers’ long-term memory is the fact that most theorists believe that long-term memory has nearly unlimited capacity. So, there is always room for more information. But what is the best way in which to achieve storage in long-term memory?

Some information is stored in long-term memory accidentally (i.e., unintentionally), but most information that makes it to long-term memory is encoded semantically. According to one model of memory, information is better remembered when it is thoroughly processed. To the extent that people elaborate on, and think deeply about, a particular piece of information, they are more likely to be able to recall it later. This notion of cognitive elaboration is important in the understanding of persuasion as well. Clearly, advertisers would do well to generate ads that cause people to think deeply or discuss extensively. According to another model of memory, retrieval is enhanced to the extent that learning and retrieval occur under similar conditions. This bodes poorly for advertisers given that the encoding and storage of advertising rarely occur under the same

conditions as the actual buying behavior. Advertisements tend to be absorbed most everywhere except the marketplace.

4.3. Processing Pictures Versus Text

Pictures enhance advertising effectiveness in several ways: They help to get the audience's attention, they provide information about the brand and product use, and they help to create a unique brand image. Because people examine the visual elements before the verbal elements, pictures in advertising are a useful tool as attention grabbers. For example, extensive use of sex appeal and celebrity endorsement in advertising can be understood in this context.

Images and text are processed differently. Pictorial information seems to be processed more holistically, whereas verbal information is processed more sequentially. Information conveyed by pictures is recalled and recognized more easily than is textual information. Therefore, the fact that more than two-thirds of print advertisements today have pictures covering more than half of the available space is not surprising. So, why are pictures more memorable than words?

According to Paivio's dual-coding model, different codes exist in memory for verbal material and pictorial material. Pictures tend to be remembered over verbal information because they activate both verbal codes and pictorial codes spontaneously. This ease of cognitive access leads to the facilitation of memory. In addition, ads with concrete, easily identifiable pictures (e.g., celebrities) or realistic pictures are more memorable than ads with abstract or unidentifiable pictures. Furthermore, consumers exhibit more favorable attitudes when they see identifiable objects (e.g., an Adidas logo, a picture of Michael Jordan) than when they simply view text (e.g., the combination of alphabetical letters P-U-M-A).

Memory effects of text vary depending on how difficult it is for perceivers to comprehend the text. When the text is complex, people engage in more elaborative processing, resulting in a greater number of associations in memory as well as improved memory. Finally, pictures and text interact. Congruency between pictures and ad copy enhances consumers' recall.

4.4. Repetition and Learning

Advertising repetition is generally known to enhance memory by strengthening memory traces because it increases redundancy and provides more encoding opportunities to process the message, leading to higher

levels of brand name recall. Nevertheless, advertising repetition rarely works in such simple ways. For example, varying the interval between message repetitions affects memory of an advertising message. Although not without exceptions, memory for repeated material generally improves as the time between presentations of advertising material increases, particularly when there is a delay between the subsequent presentation of the stimulus and the memory test.

Another explanation of learning through repetition is derived from encoding variability theory, which predicts that presenting a series of ads containing slight variations of a theme enhances memory for the ad material. For example, according to this view, repeated presentation of a bottle of Absolut Vodka in different contexts helps consumers to retain its brand name in their memory.

Attention, recall, and brand awareness initially increase, then level off, and ultimately decline as the number of exposures increases. At least two explanations are available for this "wear-out" effect: inattention and active information processing. With increasing repetition, viewers no longer attend to the message, and this inattention causes forgetting. According to the active information processing perspective, an audience rehearses two kinds of thoughts: thoughts stimulated by the message reflecting message content (i.e., message-related thoughts) and other thoughts based on associations reflecting previous experiences (i.e., people's own thoughts). With the initial exposure to a message, people's thoughts tend to be message related, but at some level of repetition, people's thoughts stem mainly from associations that are only indirectly linked to the message. These thoughts are less positive toward the product than are message-related thoughts, primarily because the latter were selected to be highly positive.

4.5. Low- and High-Involvement Learning

Learning may occur either in a situation where consumers are highly motivated to process the advertising material or in a situation where consumers have little motivation to learn the material. For example, a woman reading an automobile magazine in a dentist's office is less involved than another woman reading the same magazine prior to purchasing a new car. Personal, product, and situational factors jointly affect the level of involvement. A different level of involvement is likely to follow, for example, depending on whether the individual perceives the advertised product as enhancing

self-image (i.e., personal factor) or entailing risk (i.e., product factor). And this whole perception of the product will again be influenced by whether the consumer views the product for personal use or views it as a gift (i.e., situational factor).

High involvement stimulates semantic processing, whereas low involvement is linked to sensory processing. Text-based information is better remembered when viewers are highly involved, whereas graphic-oriented information exerts a greater impact on viewers' memory when they have low involvement. The study of learning and memory is important for understanding how consumers obtain information about a product or service. Another primary goal of advertising is to persuade, so the next section considers the psychological study of attitudes and persuasion.

5. ATTITUDES

The attitude construct has been recognized as one of the most indispensable concepts in psychology. It is similarly crucial in the study of advertising. But what exactly is an attitude? For a psychologist or an advertiser, an attitude refers to an evaluation along a positive–negative continuum. For purposes of this article, an attitude is defined as a psychological tendency to evaluate an object with some degree of favor or disfavor. The target of an attitude is called the attitude object. When an individual says, “This pie is lovely” or “That car is no good at all,” that person is expressing his or her attitudes. When the individual says, “This pie is fattening” or “That car has poor acceleration,” the person is expressing his or her beliefs. Attitudes are different from beliefs, although the latter help to make up the former. Beliefs are units of information that an individual has. Beliefs may be facts or opinion, and they may be positive, negative, or neutral with regard to the target.

5.1. The Structure of Attitudes

Attitudes are generally not thought of as monolithic constructs; they are made up of conceptually and empirically distinct components. At a very basic level of analysis, attitudes have three important components: affective, behavioral, and cognitive. Affect refers to feelings and emotional components of attitudes. Behavior, of course, refers to behavior that an individual takes with regard to a target. Cognition refers to the beliefs or thoughts that an individual has about a target.

Affective, behavioral, and cognitive processes help to form attitudes. The mere exposure effect suggests one way in which positive affect may arise. Classical conditioning and operant conditioning are two additional ways in which affective processes influence people's attitudes. The continuous pairing of some stimulus and a reward (or punishment) creates positive (or negative) affect. In advertising, brands of clothing are nearly always paired with attractive models. The models are intended to create affectively positive feelings, and advertisers hope that people will be conditioned to like their brands of clothing.

Behavior also contributes to the formation of attitudes in that sometimes people infer their attitudes on the basis of their previous behavior. Self-perception theory posits that people infer their attitudes on the basis of their past behavior, particularly when they believe that their behavior has been freely chosen. For example, if someone points out that Jane always wears green, she may infer that she has some affinity for green. But if Jane always wears green because her school has a strict dress code requiring her to wear green, she is unlikely to infer that she has a favorable attitude toward green.

Cognition is another important antecedent of people's attitudes. A cognitively based learning process occurs when people acquire information about attitude objects. People may gain information through direct experience such as when a free trial product is sent in the mail or when a free sample is offered in a store. Or, people may gain information indirectly, for example, when a television commercial shows them the benefits of owning a particular make and model of automobile. People's beliefs about attitude objects have been proposed as a central determinant of attitudes. Indirect learning, or observational learning, is an important tool for advertisers. Consider any advertisement that shows a model using a product to benefit in some way. It is hoped that viewers will develop favorable attitudes toward the product by learning how others have benefited from the product.

So, attitudes generally have affective, behavioral, and cognitive components. However, it is not necessary for all attitudes to have all three components. Some attitudes may be based primarily on affective factors (e.g., attitudes toward tequila), and others may be based primarily on cognitive factors (e.g., most people probably feel mildly positive about photosynthesis due to the important functions performed by the process, but they probably do not have strong emotions about it).

One very influential model of the structure of attitudes is Martin Fishbein's expectancy-value model.

Fishbein proposed that attitudes are a multiplicative function of two things: (a) the beliefs that an individual holds about a particular attitude object and (b) the evaluation of each belief. According to the expectancy-value model, beliefs are represented as the subjective probability that the object has a particular attribute. The model can be expressed as a mathematical function:

$$A_o = \sum_{i=1}^n b_i e_i,$$

where A_o is the attitude toward the object, b_i is a belief about the object, and e_i is the evaluation of that belief. According to Fishbein, people's attitudes are typically based on five to nine salient beliefs. So, if a researcher wanted to know someone's attitude toward a particular brand of clothing, the researcher might ask that person to estimate the likelihood that a particular brand has a variety of attributes (e.g., fashionable, durable, well priced) and how positive or negative each of those attributes is. The researcher could then compute an estimate of the person's attitude by multiplying the pairs of scores and then summing the products.

The expectancy-value model also implies that persuasion is largely a function of message content. That is, favorable attitudes can be produced by making people believe that an object is very likely to have some desirable trait, by making people believe that some trait is very favorable, or by both. For example, an advertiser might endeavor to make people believe that its automobile is very reliable (i.e., influence the subjective probability of beliefs) or to make people believe that its automobile's ability to take turns at very high speeds is highly desirable (i.e., influence the evaluation of a particular attribute).

Although the expectancy-value model seems to be perfectly logical, it may seem surprising to suggest that all attitudes are based on a series of beliefs. Consider, for example, the mere exposure research discussed earlier. According to Zajonc, preferences need no inferences (i.e., people may like something without having any beliefs about it). Under some conditions, attitudes may be formed outside of people's conscious awareness, or attitudes may be directly retrieved from memory rather than "computed" based on a mental review of salient beliefs. However, it is generally accepted that highly elaborated attitudes are more influential than poorly elaborated attitudes. So far, the discussion of attitude structure has considered how different aspects of a single attitude relate to one another. Next, the

discussion considers how different attitudes relate to one another.

One of the most enduring psychological principles developed during the 20th century is the simple notion that people have a desire for cognitive consistency. Cognitive consistency is the simple notion that beliefs and actions should be logically harmonious. If an individual believes that cats make good pets but hates her pet cat, she has beliefs that are inconsistent; if an individual believes that cats make good pets and she loves her cat, she has beliefs that are consistent. For most people, cognitive inconsistency is unpleasant, so they take steps to achieve consistency.

One consistency theory with many advertising-related applications is Heider's balance theory. Balance theory was initially applied to cognitive consistency between dyads (two units) and among triads (three units), but because most research has examined triads, this article focuses on this arrangement. The triad arrangement pertains to the attitudinal relationships among a perceiver (p), an other (o), and an attitude object (x). Consider the example where Cody has recently met an individual named Sam, and Cody likes Sam quite a bit. One afternoon, Cody learns that Sam loves to listen to country music. However, Cody cannot stand country music. How does the fact that Sam loves country music make Cody feel? Probably not very good; the triad of Cody, Sam, and country music is not balanced. However, if Cody loved country music, Cody liked Sam, and Sam loved country music, all would be simpatico. These ideas illustrate the basic tenets of Heider's balance theory. As can be seen in Fig. 1, there are eight possible sets of relationships among the triads: four balanced and four imbalanced. One simple way in which to identify whether a triad is balanced or not is to calculate the product of the three relationships. If the product is positive, the triad is balanced; if the product is negative, the triad is imbalanced.

The efficacy of well-liked, or celebrity, endorsers may be explained at least in part by evoking balance theory. The viewers of the advertisement are expected to have a favorable attitude toward the endorser (e.g., Britney Spears), and the endorser is clearly portrayed as having a positive attitude toward the advertised product (e.g., cola). To maintain balance, viewers also should adopt a positive attitude toward the cola. Alternatively, viewers could decide to dislike the cola and change their attitude toward Spears so as to maintain a balanced triad. Balance theory also helps to explain one way in which consumer trends migrate. People who become friends with one another often adopt attitudes similar to their friends'

FIGURE 1 Eight possible triads proposed by Heider's balance theory. The triads in the top row are balanced, and the triads in the bottom row are imbalanced.

attitudes. A classic study by Theodore Newcomb illustrated this point with women who lived together at college; over time, the women's political attitudes became more and more similar.

Another theory that has roots in cognitive consistency, and has been very influential in advertising and consumer behavior, is cognitive dissonance theory. Leon Festinger proposed cognitive dissonance theory in 1957, and it spurred more research than perhaps any other social psychological theory. Cognitive dissonance has been defined as a feeling of discomfort that arises as a result of one's awareness of holding two or more inconsistent cognitions. Often, dissonance is aroused when one behaves in a manner that is inconsistent with his or her beliefs. For example, Greg may believe that Japanese cars are superior to cars made in America, but if he buys an American car, he will likely experience cognitive dissonance. Because cognitive dissonance is uncomfortable, people are motivated to reduce the feeling of dissonance by changing their behavior, trying to justify their behavior by changing their beliefs, or trying to justify their behavior by adding new beliefs. Having purchased an American car, Greg might try to reduce cognitive dissonance by investing in Japanese auto manufacturers, by changing his belief in the superiority of Japanese cars, or by adding a new belief to help regain consistency, for example, "My car may be American, but many of the engine parts are from Japan."

When people make large-scale purchases, they often experience what is known as postdecisional dissonance. Large expenditures may arouse dissonance because they are inconsistent with the need to save money or make other purchases. Furthermore, making a purchase decision necessarily means giving up some attractive features on the unchosen alternatives (e.g., buying a Sony means

not buying a Samsung). In a decision-making context, dissonance may be reduced by revoking the decision, by bolstering the attractiveness of the chosen alternative or undermining the attractiveness of the unchosen alternative, or by minimizing the differences between or among the alternatives. Another important role that advertising can play is in helping to reduce postdecisional dissonance. Advertising can help to reduce the feeling of discomfort that follows a major purchase by changing beliefs (e.g., "The new MP3 player has state-of-the-art technology") or by adding new beliefs (e.g., "The new MP3 player will make you the envy of your friends") that enable buyers to feel good about their recent major purchases.

5.2. Functions of Attitudes

Why do people have attitudes? Consider, for a moment, what life would be like without attitudes. For example, Tracy might sit down to dinner one day to find a plate of lima beans. She might eat the beans and discover that they taste horrible. The following week, Tracy is once again served lima beans and remembers them from the last time, but she has no attitude toward them. She eats them again and finds out, once again, that they taste quite horrible. For someone without attitudes, the discovery that lima beans are horrible could occur hundreds of separate times over a lifetime. At a most basic level, attitudes help people to navigate their world; they help them to know how to respond to things. Attitudes allow people to approach rewards and avoid punishments. Beyond this basic "object appraisal" function, attitudes have long been thought to serve a number of important functions.

More than 40 years ago, Daniel Katz described four functions of attitudes: ego-defensive, value-expressive,

knowledge, and utilitarian. Some attitudes have an ego-defensive function in that they help protect people from unflattering truths about themselves. People may bolster their own egos by holding negative attitudes about other groups (e.g., Hispanics, homosexuals). The value-expressive function occurs when attitudes allow people to express important values about themselves. For example, people may express a positive attitude toward recycling, suggesting that environmentalism is an important value. The knowledge function of attitudes allows people to better understand the world around them. For example, if a person dislikes politicians, it is easy to understand why politicians always seem to be giving themselves pay raises when the economy is particularly weak. Finally, attitudes may have a utilitarian function. Tracy's attitude toward lima beans helps her to know whether to approach them (because they are delicious) or avoid them (because they taste horrible). As suggested by all of these functions, attitudes also help to guide people's behavior.

5.3. Attitude–Behavior Relations

Indeed, the study of attitudes was at least partly initiated because attitudes seemed to be a logical predictor of behavior. As noted earlier in the article, behavior is an important form of attitudinal expression. For example, if Tara has a positive attitude toward a brand of pants, it follows that she will buy the pants; she will behave in a way that is consistent with her attitudes. Advertisers aim to create positive attitudes toward objects in the hope that consumers will purchase those objects. Unfortunately, the study of attitude–behavior relations has not been quite so simple. The following is only a very brief review of attitude–behavior relations.

A 1969 review of the literature on attitude–behavior relations found that attitudes and behaviors were modestly correlated with one another at best. This lack of attitude–behavior correspondence caused some researchers to suggest abandoning the attitude concept altogether. Fortunately, others rejected this suggestion and worked to better understand attitude–behavior relations. It is now known that attitudes reliably predict behavior under certain conditions. Attitudes and behaviors correlate when the attitude measures and behaviors correspond with regard to their level of specificity. If one wants to reliably predict a specific action, one should assess attitudes toward performing that action, with regard to a particular target, in a given context, and at a specific time. Or, one could enhance attitude–behavior correspondence by broadening the scope of

the behaviors. Knowing someone's attitude toward a particular attitude object (e.g., religion) is not necessarily going to predict whether that person attends church on a given Sunday, but it should reliably predict a variety of religious behaviors over the course of time (e.g., attending religious services over a period of weeks, having a religious text at home, wearing a symbol of religious faith).

Another way in which to enhance the attitude–behavior relationship is to provide people with direct experience with attitude objects. Indirect learning is not as powerful as direct learning, so an advertisement showing people enjoying a frosty beverage is not as persuasive as having people enjoy the frosty beverage in person. Behavioral prediction is enhanced when one also considers the influences of social norms and perceived control on behavior. Finally, attitudes are more predictive of behavior when attitudes are strong or readily accessible.

Attitude strength has been defined and measured in a variety of ways, but it is generally accepted that strong attitudes are resistant to change, persistent over time, and predictive of behavior. Clearly, these are the types of attitudes that advertisers want to inculcate. But given that there are multiple definitions of attitude strength, what is the best way in which to identify and produce strong attitudes? In considering various measures of attitude strength, it may be helpful to think in terms of whether the measures are operative or meta-attitudinal. An operative measure of attitude strength is one that reflects the operation of the attitude (e.g., the accessibility of the attitude can be measured by the speed with which people can provide evaluations of objects), whereas a meta-attitudinal measure of attitude strength is one that requires people to provide a subjective self-report of their own attitudes (e.g., the confidence with which an attitude is held cannot be directly measured but rather must be reported by an individual). One way in which attitudes can be strengthened is through cognitive elaboration. To the extent that people intentionally and carefully think about, and elaborate on, their attitudes, they are engaged in cognitive elaboration.

6. PERSUASION

The study of attitude change has existed since Aristotle's time. However, empirical research on persuasion and attitude change is a much more recent phenomenon. It was not until the mid-20th century that the study of attitude change developed into a thoroughly systematic process.

6.1. Message Learning Approach

Carl Hovland and colleagues, working at Yale University during the 1950s, sought to study persuasion by considering the question, “Who says what to whom with what effect?” That is, they were interested in studying the effects of different variables in the persuasion process. “Who” refers to the source of the persuasive communication, “what” refers to the message that is presented, and “to whom” refers to characteristics of the message recipient. This approach to the study of persuasion was an information-processing, or message-learning, paradigm. According to the message-learning paradigm, persuasive communications could have an effect only to the extent that they commanded attention and were comprehensible. Furthermore, message recipients had to yield to the persuasive communications and retain the information presented in the persuasive communications. If these conditions were met, beliefs, attitudes, and behaviors were liable to change. The following considers some of the critical variables studied by the Yale group.

Holding message, recipient, and channel characteristics constant, how do different characteristics of the source influence persuasion? Hovland and colleagues found that communicator credibility had an effect on persuasion, such that credible sources were more persuasive than noncredible sources. But what exactly is a credible source? Hovland and colleagues examined three characteristics of credible sources: expertise, trustworthiness, and the source’s intent to persuade. An expert source (e.g., a Nobel prize-winning scientist) is more persuasive than a nonexpert source (e.g., the director of a local YMCA). A trustworthy source (e.g., a news anchor) is more persuasive than a nontrustworthy source (e.g., a member of the Liars Club). A source that is known to have a persuasive intent (e.g., an advertisement) is often less persuasive than one delivering the same message but with no persuasive intent (e.g., a friend). Forewarning people of a communicator’s persuasive intent seems to instigate mental counterarguing in the audience. It is also known that physically attractive sources are generally more persuasive than unattractive ones and that similar communicators are usually more persuasive than dissimilar ones. Finally, powerful communicators (i.e., communicators who can administer punishments or rewards to the message recipients) tend to be more persuasive than powerless communicators.

Holding source, recipient, and channel characteristics constant, how do different characteristics of the message influence persuasion? The comprehensibility of a message is (obviously) an important determinant of persuasion; if

people cannot understand the message, it is unlikely that they will be persuaded by it. The number of arguments in a persuasive communication also matters; more arguments are generally better than fewer arguments. Of course, there is a limit to the number of arguments one can present before message recipients become annoyed and lose interest. Presenting a few strong convincing arguments is better than presenting dozens of weak specious arguments. Messages that arouse fear (e.g., “If you do not brush your teeth, you will end up ugly, toothless, and diseased”) can also be persuasive if certain conditions are met. An effective fear appeal must (a) convince the recipients that dire consequences are possible, (b) convince the recipients that the dire consequences will occur if instructions are not followed, and (c) provide strong assurance that the recommended course of action will prevent the dire consequences. One- and two-sided messages are differentially persuasive for different audiences; two-sided messages are generally more effective among knowledgeable audiences, whereas one-sided messages are more effective among less knowledgeable audiences. Two-sided messages can be more effective in general so long as the opposing arguments are effectively countered in the message.

Recipient characteristics also influence the efficacy of persuasive communications. An audience that is highly motivated and able to process information is more apt to be persuaded (provided that strong, rather than weak, arguments are presented) than is an audience that is distracted or apathetic. People who are of lower intelligence are generally easier to persuade than are people of high intelligence, people with moderate levels of self-esteem are generally easier to persuade than are people with either low or high self-esteem, and younger people are more susceptible to persuasive communications than are older people. Some personality traits also have important implications for persuasion. Self-monitoring is a characteristic that varies in the population. High self-monitors are particularly sensitive to situational cues and adjust their behavior accordingly, whereas low self-monitors are guided more by internal cues and tend to behave similarly across various situations. High self-monitors tend to be susceptible to persuasive communications that have image-based appeals, whereas low self-monitors tend to be more susceptible to value or quality-based appeals.

6.2. Dual-Process Theories

The message-learning approach to persuasion obtained a great deal of information about the influence of different

variables on persuasion. However, there were also a lot of apparently contradictory findings. One study might report that attractive sources had a large impact on persuasion, whereas another study would report no impact at all. During the late 1970s, a pair of integrative frameworks for understanding persuasion emerged. The Elaboration Likelihood Model (ELM) and the Heuristic-Systematic Model (HSM) are both dual-process models of persuasion, emphasizing that different variables can have different effects on persuasion. These models are fairly similar to one another and can be used to explain similar findings and make similar predictions, but the language used in describing the two models is different. The focus here is on the ELM because it has spurred the most research in advertising and marketing.

The ELM is based on the proposition that there is a continuum of elaboration likelihood. At one end of the continuum, the amount of cognitive effort that is used to scrutinize persuasive communications is negligible; information processing at this end of the continuum is minimal. This is known as the peripheral route to persuasion. At the other end of the continuum, there is a great deal of cognitive elaboration; people are highly motivated to carefully process information pertaining to the persuasive communications. This is known as the central route to persuasion. One might say that there are two routes to persuasion: central and peripheral. Which route is taken is dependent on message recipients' motivation and ability to process information. According to the ELM, people who are both motivated and able to process persuasive communications will take the central route, whereas people who are lacking either motivation or ability to process information will take the peripheral route.

The central and peripheral routes are metaphors for the amount of cognitive elaboration in which people engage when they are faced with persuasive communications. Central route processing is particularly likely to occur when the persuasive communications are personally relevant to the recipient. If an individual is in the market for a new automobile, automobile advertisements would likely be personally relevant and, therefore, more highly scrutinized. If a person happens to be a home theater enthusiast, he or she would be more motivated to attend to advertisements for televisions and stereo speakers. Of course, all of the motivation in the world cannot cause greater cognitive elaboration if the message recipients do not also have the ability to process the information carefully. Distractions and other

forms of cognitive business would prevent cognitive elaboration.

Persuasion through the central route occurs when the arguments presented are strong and compelling, and attitudes formed through the central route are persistent over time and resistant to change. Persuasion through the peripheral route occurs when there are compelling peripheral cues present (e.g., a long list of arguments, an attractive speaker, a credible source), and attitudes formed through the peripheral route are more temporary and subject to further change. The ELM and HSM can account for a wide variety of persuasion phenomena and have proven to be very robust and useful theories.

The psychology of advertising has come a long way. We now have a greater understanding than ever before of psychological processes crucial to advertising. From attracting attention to understanding how people are persuaded, the advancement of psychological science and that of advertising practice have much to learn from one another. This article has but scratched the surface of advertising psychology. New theories and applications are emerging at a rate that is unparalleled in the history of either advertising or psychology.

GLOSSARY

affirmative action Any measure, beyond a simple termination of discriminatory practice, adopted to correct for past or present discrimination or to prevent discrimination from recurring in the future.

affirmative action plan (AAP) A set of specific and results-oriented procedures designed to eliminate discrimination and enhance opportunities for members of an underrepresented group.

affirmative action plan (AAP) strength The weight given by an AAP to demographic status.

discounting principle In affirmative action, the tendency to derogate the competence of target group individuals who have been selected in the context of an affirmative action plan.

preferential treatment The provision of positive weight to minority status in an affirmative action plan; in weak preferential treatment (WPT), a member of the target group is preferred only if his or her qualifications are equivalent to those of a competing majority individual, whereas in strong preferential treatment (SPT), a member of the target group is preferred even if his or her qualifications are inferior to those of a competing majority individual.

principled conservatism theory The theory that opposition to affirmative action is not due to racial prejudice but rather is due to the inconsistency between affirmative action and conservative principles.

racioethnicity A term that refers to the combination of race and ethnicity that is used to distinguish among groups in affirmative action regulations.

racism The belief that a particular race is superior or inferior to other races.

social dominance orientation (SDO) A person's general approval of either dominance or egalitarian relationships among groups; individuals who are high in social dominance orientation support group-based inequality.

stigmatization In the context of affirmative action, the derogation of the competence or qualifications of an individual who is believed to have been selected on the basis of gender or racioethnicity.

utilization analysis An analysis that compares an organization's workforce (workforce analysis) with the availability of qualified individuals (availability analysis) to determine whether women or racioethnic minority groups are underutilized (i.e., whether there are fewer minorities or women in a particular job group than would reasonably be expected by their availability).

Affirmative action refers to any measure, beyond a simple termination of discriminatory practice, adopted to correct for past or present discrimination or to prevent discrimination from recurring in the future. This controversial social policy has inspired research in

a variety of disciplines. The present article summarizes research on (a) the economic effects of affirmative action on target groups and on organizations, (b) stigmatization of affirmative action target group members by others and by the individuals themselves, and (c) attitudes toward affirmative action.

1. WHAT IS AFFIRMATIVE ACTION?

1.1. Background

Humans have a propensity to distinguish between the in-group and the out-group, a process that often results in prejudice and discrimination toward individuals in the out-group. Consistent with this tendency, most countries have long histories of discrimination toward women and racial/ethnic minorities. During recent decades, many countries have passed antidiscrimination laws, and some have gone further to require that affirmative actions be taken to enhance opportunities for traditionally underrepresented groups. Although affirmative action may apply to university admissions, this article is restricted to affirmative action in the workplace. It summarizes the economic, behavioral, and psychological research on affirmative action that has been published in English. Most of this work has been conducted in the United States or Canada.

1.2. Definitions

What is affirmative action? That question can be answered conceptually, legally, and operationally.

1.2.1. Conceptual Definition

Many conceptual definitions have been offered. For example, the U.S. Civil Rights Commission has defined affirmative action as “a term that in a broad sense encompasses any measure, beyond a simple termination of discriminatory practice, adopted to correct for past or present discrimination or to prevent discrimination [from] recurring in the future.”

1.2.2. Legal Definitions

The legal definitions of affirmative action vary from place to place and change over time. Critical dimensions on which the law varies include which groups are targeted, which actions are required and forbidden, what penalties can be imposed for violations, and

how the law is enforced. In the United States, federal affirmative action law is jointly determined by the U. S. Constitution (5th and 14th amendments), presidential executive orders (e.g., Executive Order 11246 [EO 11246]), legislation (e.g., Civil Rights Acts of 1964 and 1991), implementing regulations promulgated by federal agencies (e.g., Office of Federal Contract Compliance Programs [OFCCP], Equal Employment Opportunity Commission [EEOC]), and court decisions.

Organizations in the United States may be required to establish affirmative action plans (AAPs) for four reasons. First, courts may impose AAPs on organizations that have been convicted of discrimination. Second, to avoid adverse legal decisions, organizations may set up AAPs as required by court-approved consent decrees. Third, EO 11246 and other acts require affirmative action of federal agencies and of most organizations that do business with the government (i.e., federal contractors). Fourth, government “set-aside” programs at the federal, state, and local levels require that some proportion of contracting and procurement expenditures go to designated firms. In addition to these legal bases for affirmative action, some organizations may voluntarily take affirmative actions to diversify their workforces. All AAPs are constrained by the Constitution and by the Civil Rights Acts.

It is not possible to describe here the requirements and constraints of affirmative action in detail. However, because most AAPs in the United States are established by federal contractors as required by EO 11246, some of their key requirements and constraints are described here. First, the organization must not discriminate on the basis of race, color, religion, sex, or national origin. Second, the organization must complete an annual utilization analysis that compares its workforce, in terms of gender and racial/ethnicity, with the available qualified workforce. Third, if underutilization of women or a racial/ethnic minority group is revealed, the organization must generate a plan for eliminating the underutilization. Fourth, the plan should use targeted recruitment, outreach, and other nonpreferential actions that will facilitate target group success. Fifth, the plan must not involve the use of demographic status (i.e., racial/ethnicity, gender) in making selection, promotion, or termination decisions. This last point is important: Preferential treatment of women and racial/ethnic minorities is contrary to EO 11246. Preferences are legal only when they are specifically required by a court order or consent decree to reverse the effects of proven discrimination.

1.2.3. Operational Definitions

For current purposes, we must consider two types of operational definitions: organizational implementation of affirmative action and the descriptions of affirmative action used in behavioral research. Organizational AAPs are complex. They potentially include organizational structures, written reports, proscribed and prescribed processes, and more. Although “best practice” reports exist, the author has never seen a report summarizing the frequencies of typical practices. Importantly, although much of the public equates affirmative action with preferential treatment, the actual frequency of such illegal procedures is unknown. Operationalizations used in behavioral research tend to be brief, simplistic, and (often) illegally strong.

1.3. Public Beliefs

The American public construes affirmative action in many different ways. Some people focus on the role of affirmative action in decreasing discrimination against women and ethnic minorities. Other people believe it involves quotas or preferential treatment. Very few people think of affirmative action in terms of recruitment and outreach, and virtually nobody has a realistic understanding of the law. Beliefs about what the term “affirmative action” means vary with respondent characteristics, such as race/ethnicity and political orientation, and predict support or opposition to affirmative action.

2. ECONOMIC EFFECTS OF AFFIRMATIVE ACTION

There has been a lively debate regarding the economic effects of affirmative action on the targeted groups and on organizations subject to affirmative action regulations. The implicit question is whether the benefits of affirmative action outweigh the costs. That question cannot be answered in the abstract because it depends both on the effects of affirmative action and on the values one assigns to organizational outcomes and to the well-being of the target groups. Although such values are a personal matter, it is possible to study the effects of affirmative action. Both conceptual and empirical studies have been published, and the conclusions are summarized in what follows. However, it is important to acknowledge some unavoidable methodological challenges. Causal conclusions are possible only when the experimenter can randomly assign

experimental units to treatment conditions while holding constant all other potentially relevant factors. That is impossible when dealing with a public policy such as affirmative action, where assignment to “conditions” is determined by the law and by the experimental units (organizations and target groups) themselves.

2.1. Target Groups

Many studies assess the employment status of White women and race/ethnic minorities, vis-à-vis White men, in federal contractors versus noncontractors while controlling for relevant variables such as the type of industry. A positive effect of affirmative action is inferred if the relative outcomes of target groups are better in federal contractors than in noncontractors. This research indicates that affirmative action has had a positive effect on the employment status of White women and race/ethnic minority groups, but the results are complex and some are tentative. At a minimum, the effects have varied across target groups, locations, time, and types of positions. The initial effect of affirmative action was substantial for African Americans and slightly positive for White women. The limited work on Hispanic Americans suggests that they were also helped. The clearest effects were on employment, especially in professional positions, although wages may also have been affected. However, this conclusion must be qualified by effects of region and time. The largest initial impact of affirmative action (and of antidiscrimination law in general) was observed in the South, where the extent of discrimination was most extreme and so there was the greatest room for improvement. In addition, changes were most substantial during the decade from 1965 to 1975. Broad progress stagnated during the 1980s, especially for African Americans, although there is some indication of continuing effects on the status of White women.

Other studies use micro-level employer data drawn from a variety of sources, including the organizations themselves. This work has found that target groups profit more from affirmative action than from passive equal opportunity practices. The effects of affirmative action vary across target groups, locations, industries, implementation procedures, and other factors.

A final indication of the effectiveness of affirmative action is the finding that growth in employment of White women and African Americans within organizations is predicted by organizational AAP goals. Although the relation is positive, the actual growth in employment of these groups is just a fraction of the

goals. This demonstrates that affirmative action goals do not function as strict quotas.

2.2. Organizations

The public debate surrounding affirmative action often centers on the presumed consequences of affirmative action policies for organizations. Critics claim that AAPs adversely affect performance by (a) forcing organizations to expend resources on implementation, (b) constraining organizational decisions, and (c) forcing organizations to hire underqualified individuals. Supporters of affirmative action argue that AAPs improve organizational performance by (a) motivating both White male and other employees and (b) providing organizations with the resources represented by a diverse workforce.

Theoretical models show that whether the net effect of affirmative action on organizations is positive or negative should depend on several factors, including the extent of preexisting discrimination, exactly how the AAP is implemented, and differences in human capital resources of majority and minority groups. Preexisting discrimination would hinder firm performance by limiting access to the resources represented by the victimized groups. If affirmative action decreased this discrimination, the effect on firm performance would be positive. On the other hand, if discrimination were already absent, the constraints on behavior posed by affirmative action could have a negative effect. Similarly, AAPs such as focused recruitment that serve to increase organizational access to human resources should have a positive effect on performance, whereas preferential selection should have a negative effect. Finally, the magnitude of the negative effect of preferential selection should increase with the size of the human capital gap between the majority and minority applicant groups.

As is clear from the preceding, there are logical arguments for both positive and negative effects of affirmative action on organizations. Thus, we turn to the empirical literature. The strongest research has included a wide variety of organizations and has controlled for industry, job level, and other influential variables. The paper qualifications (e.g., education) of minorities and White women appear to be somewhat lower than those of White males in firms with AAPs, particularly when affirmative action is used in hiring rather than when it is used only in recruiting. (The use of affirmative action in hiring does not necessarily imply preferential selection. Instead, it can involve actions such as the use of different screening mechanisms and the insistence that each

set of interviews must include one person who belongs to an underrepresented group. Many organizations reported that affirmative action was involved in hiring processes that resulted in the selection of White males.) Importantly, the minor decrements in educational qualifications are not associated with decrements in performance. Several explanations are offered for this apparent inconsistency, but all relate to the fact that firms that use affirmative action tend to have superior human resources practices. For example, virtually all AAPs include extensive recruitment, and this increases the overall quality of the labor pool. In addition, these organizations tend to use selection procedures that are unusually comprehensive and valid. Their use of comprehensive selection systems enables them to detect high-potential minority applicants whose competence is greater than their education would suggest. The null effect of affirmative action on organizational performance that has been observed in the multi-industry research has been replicated in the few studies that have assessed a single type of organization (e.g., police departments).

3. AFFIRMATIVE ACTION AND STIGMATIZATION

Concerns about stigmatization have been raised by judges rendering decisions in affirmative action cases, by Black and Hispanic intellectuals, and by conservative opponents of affirmative action. Empirical research has addressed several questions, of which three have received the lion's share of attention. Are members of affirmative action target groups stigmatized by others? Do members of affirmative action target groups expect to be stigmatized by others, and if so, what are their reactions? Do affirmative action beneficiaries engage in self-stigmatization? Work in this area draws on concepts from stigma theory and from attribution theory, particularly the principle of discounting.

According to the discounting principle, an individual's confidence regarding a possible cause of some outcome is affected by the presence or absence of plausible alternative causes. For example, if a woman is hired by a firm that has an AAP that targets women, she could have been selected either because she is highly qualified or to help the firm meet its affirmative action goal. In the absence of affirmative action, the only remaining explanation is her qualifications. Thus, a woman hired in the context of an AAP will be

evaluated less positively than a woman hired in the absence of affirmative action or less positively than a man. This reasoning applies both to observers and to the selected individual herself.

Note that the logic of discounting requires the assumption that affirmative action involves preferences. Also note that this reasoning assumes there are only two plausible reasons for an individual's selection—qualifications or affirmative action—and that a White male's selection must necessarily be based on his qualifications. This ignores factors such as traditional gender or racial discrimination, nepotism, personal friendship, similar backgrounds, and the myriad of other factors that are unrelated to merit but nonetheless affect employment decisions.

3.1. Stigmatization by Others

In the prototypical stigmatization experiment, the participant is given information about the background and performance of an employee who is either male or female and, if female, either is or is not an affirmative action hire. The affirmative action condition nearly always involves absolute preferences. The participant is asked to evaluate the employee on competence and other dimensions. Comparisons among the three conditions—male, female, affirmative action female employee—provide the key tests of stigmatization. In a second approach, the male participant believes he is working with a female leader on a one-way communication task, with the leadership role having been assigned on the basis of either test performance or gender. Again, the affirmative action condition involves explicit preferences. After successful or unsuccessful completion of the task, the participant is asked to evaluate his partner.

Consistent with the discounting principle, the affirmative action female is stigmatized. In the scenario research, she is evaluated less positively than either the male or the non-affirmative action female. In the communication research, she is evaluated less positively when selected on the basis of gender than when selected on the basis of test scores. Although the target is usually a White female, a few studies have included racioethnic minority targets. The stigmatization effect generalizes to these targets.

Having established the existence of stigmatization, subsequent research has concentrated on determining its limitations. Key conclusions include the following. First, stigmatization can be eliminated by providing incontrovertible information regarding the employee's competence or successful performance on the job.

Second, ambiguous information about employee success does not eliminate stigmatization. Third, stigmatization occurs when affirmative action is explicitly described as involving preferences and also when it is undefined. The latter finding is consistent with the common assumption that affirmative action involves preferences. Fourth, stigmatization does not occur when affirmative action is explicitly limited to the elimination of discrimination.

Much of this work has assessed the impact of respondent gender and racioethnicity and has sometimes found that stigmatization is most evident among respondents who are not members of the target group. With this exception, there is little research on the potential importance of other individual attributes, such as political ideology, prejudice, and belief in a just world, regarding the extent of stigmatization. In addition, there is little use of attribution theory other than the principle of discounting.

3.2. Target Group Members' Anticipation of Stigmatization

Conceptual and empirical work on self-fulfilling prophecies and stigmas suggests that the anticipation of stigmatization will affect the individual's affective, cognitive, and behavioral reactions. The belief that others consider one to be inferior will usually be distressing. It can stimulate either assumption-confirming or assumption-disconfirming behavior, depending on the situation and the individual. Indeed, concerns about stigmatization have motivated several Black and Hispanic intellectuals to speak out against affirmative action. However, little research directly addresses this issue in the context of affirmative action. The research that exists suggests that many White women and racioethnic minorities expect to be stigmatized by others even in the absence of affirmative action. They anticipate that affirmative action will increase the stigmatization, although they may express less concern about this possibility than do White males. The anticipation of stigmatization, with or without affirmative action, affects their feelings and behavior. One consequence may be a lessening of support for affirmative action. Nonetheless, they apparently believe that the known disadvantages of discrimination outweigh the possible disadvantages of stigmatization because they consistently support nonpreferential versions of affirmative action. A second possible effect could be an increase in stereotype threat. Stereotype threat refers to the fear that one may behave in such a way as to

confirm negative stereotypes of one's group. It is exacerbated by factors that draw attention to the stereotype and to the individual's membership in the devalued group. Although the presence of an AAP may be such a factor, this possibility has not yet been subjected to empirical investigation.

3.3. Self-Stigmatization by Target Group Members

Self-stigmatization refers to doubts regarding one's own competence, subsequent selection of a less demanding task rather than a more demanding task, decreased interest in the position in question, negative affect, and the like. There are two primary reasons to anticipate self-stigmatization as a result of preferential selection. The first relates to the discounting principle mentioned previously. If a woman knows that her selection is based on her gender rather than her qualifications, she may be less confident about her qualifications than she would be if merit were the only plausible reason for her selection. Preferential selection may also lead to self-stigmatization because receiving help can have self-threatening implications. The fact that one is helped suggests that one needed to be helped, and this implies incompetence.

Most research in this area has used the following research procedure. Male and female participants (typically White undergraduates) believe that they are about to partake in a one-way communication task. Assignment to the leader and follower roles is said to be based either on gender or on test performance. In reality, assignment to role is predetermined and the participant is assigned to the leader role. After role assignment, participants are asked about their leadership ability in general, their interest in serving as the leader in the communication task, and the like.

This research reveals consistent evidence of self-stigmatization by preferentially selected White undergraduate women. This effect is clearer for judgments of competence than for reports of motivation or task interest. However, when the AAP involves selection among comparable candidates, self-stigmatization is eliminated. Research on people of color is very sparse, but the work that exists has failed to observe self-stigmatization. This null effect likely stems from the belief by people of color that they are hurt more by discrimination than they are helped by affirmative action. Similarly, virtually all of this research has studied undergraduates; the limited work on employed adults has obtained no evidence of self-stigmatization. Several

studies failed to replicate the effect with White male respondents. This is consistent with the general lack of concern about self-stigmatization among White males, who have profited from traditional race and sex discrimination for centuries. These results suggest that initial self-confidence plays a critical role in reactions to preferential selection, and there is some empirical support for that perspective. Finally, psychological processes such as self-protective and egocentric biases would work against the development of self-stigmatization.

3.4. Summary

One observation applies to all of the work that has been discussed in this section: Negative effects are limited to situations in which affirmative action is operationalized as preferential treatment or is assumed to involve preferences. Preferential selection causes observers to question the competence of the selected individual and causes selected White women to doubt their own competence. These effects are eliminated or sharply reduced when affirmative action involves preferences among comparable candidates, and these effects are fully eliminated when affirmative action is restricted to the elimination of discrimination and opportunity enhancement efforts such as targeted recruitment.

4. ATTITUDES TOWARD AFFIRMATIVE ACTION

By far the largest body of research on affirmative action deals with the variables that predict attitudes. Support for affirmative action is frequently assessed in large surveys, and many dozens of questionnaire studies have been published.

Although many attitudinal predictors have been studied, this article is limited to the variables that have received substantial empirical attention. These predictors can be divided into three categories: structural aspects of the AAP, characteristics of the respondents, and psychological mediators. The structural factors include AAP strength, identity of the target group, and justification. The individual difference variables fall into two categories: demographic characteristics and opinion variables. Finally, the respondent's personal and collective self-interest and the perception of affirmative action fairness are presumed to mediate the relationship between the individual difference predictors and attitudes.

4.1. Structural Factors

The structural factors include details of the AAP. Real AAPs are complex. They include utilization analyses that compare the employer's workforce with the corresponding qualified labor market as well as organizational structures that assign responsibilities for maintaining equity. If target groups are underrepresented, the AAP includes goals for target group employment and a set of processes for implementation of the change. In contrast to this complexity, few research descriptions of AAPs exceed a single paragraph. In addition, much of this research includes AAPs that would be illegal if actually implemented.

4.1.1. Affirmative Action Plan Strength

The structural factor that has received the most attention is the manner in which the AAP attends to demographic status. This is typically referred to as AAP strength. The most common AAPs used in research, from weakest to strongest, include (a) the elimination of discrimination against the target group; (b) opportunity enhancement activities such as focused recruitment of the target group and the provision of training; (c) a tie-break procedure (often referred to as weak or soft preferential treatment) in which members of the target group are preferred if, and only if, their qualifications are equivalent to those of nontarget applicants; and (d) a preferential procedure (typically referred to as strong or hard preferential treatment) in which members of the target group are preferred even if their qualifications are inferior to those of nontarget applicants. Quotas would also qualify as strong preferential treatment. Although strong preferential treatment is normally illegal, this is the version most frequently used in behavioral research. Note that these four procedures confound the weighting of demographic status with the relevant phase(s) of the employment process.

Most research has found a negative effect of AAP strength on attitudes. The elimination of discrimination receives strong support. Opportunity enhancement procedures receive somewhat weaker support. Preferences are opposed, with most studies finding greater opposition to strong preferential treatment than to weak preferential treatment.

However, the preceding conclusions must be qualified. To a great extent, they are drawn from research on White respondents. When the effect of AAP strength on attitudes is studied within racioethnic minority groups, the negative monotonic effect observed

among Whites is not always observed. Although all groups express opposition to strong preferences, racioethnic minorities make less of a distinction than do Whites among the weaker versions of affirmative action. Indeed, two studies on minority respondents have found greater support for recruitment than for the elimination of discrimination or any other AAP. Very few studies have included multiple racioethnic groups and AAPs of varying strength, so this conclusion is tentative.

4.1.2. Identity of Target Group

A few studies have manipulated the identity of the target group. There is a tendency for White respondents' attitudes to be less positive when the AAP targets minorities (especially African Americans) than when it targets White women or individuals with disabilities. Explanations for this effect could include racial prejudice (which would lower evaluations when the AAP targets racial minorities) and inclusion of the target group in the respondents' scope of justice (which would raise evaluations when the AAP targets White women or individuals with disabilities). However, there is such little work in this area that these conclusions must be tentative. One would expect the impact of target group status on attitudes to vary with demographic status of the respondents, but this interaction has received too little attention to permit any conclusion.

4.1.3. Justification

A number of studies have assessed the effects of explicit justification on attitudes. This work has found a modest positive effect of justifying the AAP on the basis of fairness (it is needed to remedy past discrimination) or economic value (it increases diversity, which has a positive impact on the organization's success). Justifying the AAP by stating that the target group is underrepresented appears to have a neutral or very small positive effect.

4.2. Individual Difference Variables

Dozens of studies have correlated affirmative action attitudes with a host of individual difference variables. The conclusions drawn in what follows are largely based on a meta-analysis of this research that was presented by David A. Harrison, David A. Kravitz, and Dalit Lev-Arey at the 2001 meeting of the Academy of Management.

4.2.1. Demographic Variables

Two demographic variables, race/ethnicity and gender, have received the bulk of the attention, although there is also enough research on education to permit conclusions. Other variables such as age, income, and religion have occasionally been studied, but they have typically been included as controls rather than as variables of central interest. It is important to emphasize that demographic variables cannot serve an explanatory role. If one finds an effect of gender, for example, then one must ask why the effect occurred. The answer necessarily lies in the opinion variables that covary with gender and with the psychological mediators, as detailed in what follows.

4.2.1.1. Race/ethnicity One of the most consistent and powerful predictors of affirmative action attitudes is the respondent's race/ethnicity. African Americans are the most supportive, Whites are the least supportive, and Hispanic Americans usually fall between the other two groups. The very limited work on Asian Americans suggests that their attitudes are usually more favorable toward affirmative action than those of Whites but are less favorable than those of other minorities. Despite these mean differences, it is important to note that disagreement exists within each of the groups. Many White Americans support affirmative action, and many African Americans oppose it. Also, as mentioned previously, attitudes vary with the interaction of race/ethnicity by AAP strength. There is a large effect of race/ethnicity in evaluations of strong preferential treatment, a weaker effect in evaluations of weak preferential treatment and opportunity enhancement plans, and no effect in evaluations of the elimination of discrimination.

Why is the effect of race/ethnicity so consistent and substantial, at least in reactions to the stronger AAPs? One simple explanation is that attitudes are a function of self-interest, and affirmative action has different implications for the interests of the various groups. There is no doubt some truth to this explanation, but it is much too simple. For historical and cultural reasons, individuals in the various race/ethnic groups see the world in different ways, and these differences affect their affirmative action attitudes. If we consider Blacks and Whites in the United States, for example, we find that African Americans are more likely than Whites to be politically liberal and to identify with the Democratic party. They are more likely than Whites to have experienced racial discrimination and to believe

that it is an ongoing problem. They are less likely than Whites to be racially prejudiced against Blacks and to believe that affirmative action involves preferences. Each of these differences is associated with attitudes toward affirmative action.

4.2.1.2. Gender Numerous studies have assessed gender differences in attitudes toward affirmative action. In general, women are more supportive than men. However, this conclusion must be qualified. First, it is not clear whether it applies equally to all racial groups. It is only among Whites that gender determines target group membership, so self-interest considerations would suggest that the gender effect should be larger among Whites than among other race/ethnic groups. At least one study has reported a reverse effect of gender among African Americans. Second, the author's reading of the literature suggests that the gender effect has shrunk over the past 20 years or so. However, the correlation between effect size and year of publication has not yet been reported, so this supposition is tentative.

4.2.1.3. Education The third demographic variable that has received the most attention is education. Some of the most significant work on education has used it as a moderator of other predictors in the context of tests between competing theories. When the main effect of education has been assessed, the effect has varied with respondent race. The relation between education and support for affirmative action is usually positive among African Americans and is usually nonsignificant or negative among Whites. This latter result is anomalous because education is also associated with decreased racial prejudice and increased political liberalism, both of which predict support for affirmative action. This relationship between education and support for affirmative action among Whites merits closer investigation.

4.2.2. Opinion Variables

The two theoretical perspectives that have received the most research attention emphasize the importance of political ideology and prejudice. Distinguishing between these two approaches is complicated by the positive correlation between political conservatism and most measures of prejudice. A third theory posits that prejudice and political orientation serve as mediators between a desire for group dominance and affirmative action attitudes. Each of these three perspectives is described in what follows.

4.2.2.1. Prejudice Research indicates that prejudice is among the most powerful predictors of White Americans' attitudes toward affirmative action. However, the effect of racial prejudice varies with the measure used. The correlation is larger when racial prejudice is assessed with a measure of contemporary racism than when it is assessed with a measure of old-fashioned racism, and it is smaller yet when it is assessed as pure anti-Black affect. Because of a dearth of research, comparable distinctions among measures of sexism cannot be made.

The distinction between contemporary racism and old-fashioned racism requires some explanation. The core of old-fashioned racial prejudice, which prevailed among Whites until the past few decades, is the assumption of inherent inferiority of non-White racial groups. Blacks, in particular, were assumed to be inferior in intelligence and other characteristics. This belief was accompanied with support for racial segregation and for discrimination. Such beliefs have become relatively uncommon. Instead, many scholars argue, such old-fashioned racism has been replaced with contemporary forms of racism. The author uses the term "contemporary racism" to represent several different but related concepts, including ambivalent racism, aversive racism, laissez-faire racism, modern racism, racial resentment, subtle racism, and symbolic racism. These various conceptualizations differ in important ways, but most incorporate the following components. First, they assume that contemporary racists have underlying anti-Black feelings. Second, they assume that contemporary racists do not accept old-fashioned racist beliefs in inherent inferiority, segregation, and discrimination. Instead, contemporary racists believe that African Americans violate American values such as individualism and self-reliance. Third, contemporary racists acknowledge that racial discrimination existed in the past but believe that it is no longer a problem. Thus, they conclude that any economic disadvantages experienced by Blacks are due to their cultural inferiority. Finally, contemporary racists reject racism and any suggestion that their own beliefs are racist. One implication of this is that they feel most free to express their prejudice when some non-prejudicial reason for their action can be offered.

Given this distinction between old-fashioned racism and contemporary racism, one can understand why the latter predicts opposition to affirmative action more strongly than does the former. The anti-Black affect assumed by contemporary racism predisposes individuals to oppose affirmative action. The assistance that

affirmative action offers to target group members decreases the importance of self-reliance. In addition, affirmative action is designed to eliminate the effects of discrimination that contemporary racists do not believe exists. Finally, because they can justify their opposition to affirmative action by arguing about the importance of self-reliance and the lack of ongoing discrimination, contemporary racists feel free to oppose it. On the other hand, old-fashioned racists who genuinely believe that Blacks are genetically inferior may conclude that African Americans need the assistance offered by affirmative action and so lessen their opposition. In addition, the ideological argument for individualism that is at the center of the contemporary approaches, and that is a core reason for opposition to affirmative action, is not central to old-fashioned racism. When both old-fashioned racism and symbolic racism are included as predictors of affirmative action attitudes, the latter is appreciably more important and typically explains incremental variance beyond the former.

One problem with the contemporary racism approach is that it overlaps conceptually and (in some cases) empirically with political conservatism. Thus, an individual who espouses a conservative ideology but genuinely lacks any prejudice toward Blacks would score relatively high on most measures of contemporary racism.

4.2.2.2. Political Orientation Beliefs associated with respondents' political orientation consistently predict attitudes toward affirmative action. Specifically, numerous studies have found that support for affirmative action is greater among Democrats than among Republicans and is greater among liberals than among conservatives.

From the beginning of the modern civil rights era during the 1950s, the major political parties in the United States have taken opposing positions on many racial issues. This divergence was solidified in the 1964 presidential race, when the Republican party nominated Barry Goldwater to run against President Lyndon Johnson. The civil rights movement played a central role in that election, and this established a pattern of Republican opposition to, and Democratic support for, government policies designed to assist racioethnic minorities. Indeed, in recent national elections, opposition to affirmative action, in particular, has been a formal or informal plank in the Republican party platform. Republican politicians typically refer to affirmative action as "preferential treatment" or "quotas" and argue

for its elimination. With this history, it is no surprise that party identification predicts public attitudes toward affirmative action.

Political conservatism is an even stronger predictor of affirmative action attitudes than is political party identification. Political conservatism includes several beliefs that engender opposition to affirmative action. First, conservatism posits that government should not intervene in the marketplace. Affirmative action is a federally mandated policy that constrains business actions. Second, conservatism is associated with support for self-reliance and individualism in both its normative and descriptive meanings. Normatively, individualism argues that individuals should take responsibility for their own success and should not rely on assistance from others (e.g., the government). Descriptively, individualism argues that success in the United States actually is determined by individual actions rather than structural forces. Affirmative action, with its underlying assumption that success is affected by structural factors and its targeted assistance to women and minorities, is contrary to individualism. A related point is that conservatives would support actions designed to ensure equality of opportunity but not those designed to ensure equality of outcomes. For these and associated reasons, conservatism is a strong predictor of opposition to affirmative action, particularly when it is construed as involving preferences.

The past decade has seen the development of a principled conservatism theory of affirmative action attitudes. The argument is that opposition to affirmative action is largely a function of race-neutral conservative principles rather than of racial prejudice. These scholars do not deny the importance of prejudice, but they argue that it is more important among the less educated than among the more educated, who are better able to behave in a manner consistent with their principles. One important point made by some principled conservatism scholars is that members of the public may be less than candid in their responses to survey questions regarding sensitive racial issues. When these researchers use both overt and covert measures of anger about affirmative action, they find the usual effect of political ideology on the overt measures, but this effect is greatly reduced or entirely eliminated on the covert measures. The effect of political orientation decreases because liberals express more anger on the covert measures than they do on the overt measures. A related point is that the effect of prejudice on affirmative action attitudes was stronger among liberals than among conservatives.

4.2.2.3. Social Dominance Theory A number of scholars have developed models that emphasize the role of group conflict in motivating attitudes toward affirmative action. These approaches assume that societies are organized as hierarchies, with some social groups being dominant and others being subordinate. To maintain its position, the dominant group creates an ideology that legitimizes the status quo. In the current case, this ideology incorporates meritocracy, political conservatism, classical racism, and a belief in the cultural inferiority of racial minority groups. These beliefs serve as legitimizing myths; they legitimize the differences in status between the dominant and subordinate groups. They also legitimize opposition to affirmative action, which threatens the status hierarchy. This theory explains the correlation between prejudice and political conservatism, both of which serve as legitimizing myths, as well as the correlations of each with opposition to affirmative action.

Social dominance theory differs from some other conflict-based theories in its assumption that people vary in the extent to which they have internalized this perspective. This personality trait is called social dominance orientation. Supporting social dominance theory, there is a consistent correlation between social dominance orientation and affirmative action attitudes.

4.2.2.4. Comparison among Theories There has been a rigorous debate within the affirmative action area among scholars who espouse the prejudice, principled conservatism, and social dominance perspectives. The resulting literature is quite complex and cannot be summarized briefly. In addition, much of it suffers from a significant limitation, that is, the equating of affirmative action with preferential treatment. As mentioned previously, attitudes toward affirmative action are strongly affected by AAP strength. More importantly, there is evidence that the importance of certain predictors varies with AAP strength. For example, research suggests that principled conservatism may be especially important in predicting reactions to strong forms of affirmative action that run counter to the basic principles of conservatism. On the other hand, racial prejudice seems to be most important in predicting opposition to weaker forms of affirmative action that are less inconsistent with conservative principles. To the author's knowledge, no research has assessed the relative importance of social dominance orientation across AAP strength.

The consistent correlation between measures of prejudice and opposition to affirmative action supports

both the prejudice and social dominance approaches. However, it is important to emphasize that the racism literature is complex and that the strength of the racism–attitude correlation varies with the conceptualization and measure of racism. The correlation is most substantial in studies that employ measures of contemporary racism that often overlap with measures of political conservatism. A limitation of the prejudice approach is that it does not explain attitudes of target group members.

Much of the research designed to competitively test these theories assesses the impact of potential moderators. For example, research has found that correlations between affirmative action attitudes and all three predictors increase with respondent education and political sophistication. This is fully consistent with the logic of social dominance theory, but the principled conservatism approach would predict a negative effect of education on the correlation between affirmative action attitudes and racism. Also contrary to the principled conservatism approach, the correlation between racism and political conservatism increases with education. However, these results are based on overt measures of racism and affirmative action attitudes. As mentioned previously, the principled conservatism scholars have demonstrated that the use of covert measures can profoundly affect results.

Some results supportive of social dominance theory were mentioned previously. In addition, research has shown that the significant correlation between racism and conservatism disappears when social dominance orientation is controlled. This result is consistent with the assumption that racism and conservatism are merely legitimizing myths that render the dominance hierarchy acceptable. Other supportive research has involved the use of structural equation modeling analyses of the social dominance and principled conservatism theories.

Finally, at least one study found that all three concepts—racism, conservatism, and social dominance orientation—contributed unique variance to the prediction of affirmative action attitudes. It is not now possible to say that one of these approaches is right and the others are wrong; it is likely that each is at least partly correct. It is also likely that the validity of these approaches varies with the operationalization of affirmative action. Unfortunately, little can be said about the moderating effect of AAP strength because, as noted previously, the vast majority of studies in the principled conservatism and social dominance areas have equated affirmative action with preferential treatment.

4.2.2.5. *Beliefs About the Extent of Discrimination*

More than 20 studies have correlated beliefs about the extent of target group discrimination with affirmative action attitudes. The result is clear: Support for affirmative action increases with the perception that the target group has suffered from discrimination. There are at least two reasons for this relationship. First, most people support equality of opportunity for all racial groups and actions designed to ensure such opportunity. Consistent with this reasoning, the association of perceived discrimination with support for affirmative action appears to be most substantial for the strongest AAPs. The second reason for this correlation is that perceptions of target group discrimination are associated with other predictors of affirmative action attitudes. For example, political liberals generally believe that discrimination is still a major problem, whereas conservatives tend to believe that discrimination is now uncommon. Along the same lines, social dominance theory would argue that disbelief in discrimination serves as a legitimizing myth.

4.2.3. *Psychological Mediators*

Finally, research has focused on the psychological mediators of affirmative action attitudes. Precisely how do AAP strength, race/ethnicity, political orientation, and other variables affect attitudes? The two answers that have received the most attention are that they affect the respondent's perceptions regarding (a) the impact of the AAP on his or her interests and (b) the fairness of the AAP.

4.2.3.1. *Self-Interest (Personal and Collective)*

Assumptions regarding self-interest underlie the conflict theories, such as social dominance theory, mentioned previously. Self-interest has been assessed both indirectly and directly. An example of an indirect approach would be to use respondent age as an indicator of economic self-interest, assuming that younger workers are more strongly affected by affirmative action policies than are older workers. The direct approach asks the respondent to rate the likely impact of the AAP on his or her outcomes. Each of these approaches is flawed. The indirect measures suffer greatly from construct contamination and deficiency, whereas the direct measures suffer from common method variance and experimental demands. Research using indirect measures of self-interest finds that it is only weakly related to affirmative action attitudes, whereas work employing direct measures finds a strong relation.

Furthermore, research using direct measures finds that self-interest partly mediates the impact of other predictors such as gender and race/ethnicity.

Self-interest has been studied at both the personal and collective levels. Personal self-interest refers to the impact of the AAP on the respondent's own outcomes. Collective self-interest refers to the impact of the AAP on the respondent's demographic group, which is typically defined in terms of race/ethnicity and perhaps gender. The few studies that have included both predictors have found that they correlate similarly with affirmative action attitudes.

4.2.3.2. Perceived Fairness Attitudes toward affirmative action are more closely related to perceived fairness of affirmative action than they are to any other variable. Indeed, research on evaluative reactions to affirmative action has often used measures of fairness rather than attitudes as the dependent variable. People report positive attitudes toward AAPs they consider fair and report negative attitudes toward AAPs they consider unfair.

Fairness perceptions mediate many of the effects described previously. Strong AAPs that provide rewards on the basis of demographic characteristics rather than merit are disliked because they are seen as unfair. That is a central argument of the principled conservatism perspective. Justifications affect attitudes in part because they affect the respondent's beliefs about the fairness of the AAP. In short, support for affirmative action is strongly predicted by beliefs about its fairness.

4.3. Complications and Limitations

As detailed previously, attitudes toward affirmative action are affected by actual or perceived details of the AAP, by the target group, and by justification for the plan. Attitudes are also associated with various demographic factors and opinion variables. Many of these effects are mediated by judgments of AAP fairness and self-interest implications. Most scholars would acknowledge the importance of all these predictors. There is disagreement, however, regarding their interrelationships and their relative importance. Unfortunately, most studies include relatively few predictors. In these cases, one cannot know how important the predictors would be in the context of additional variables. A related issue is that many of the most important predictors are individual difference variables that are intercorrelated and over which the experimenter has no control. This exacerbates the "missing variables" problem and also

means that causal conclusions cannot be drawn from the results. Of perhaps greater significance, not enough is known about how the predictors interact. We know that the relative importance of race/ethnicity varies with AAP strength, but because of a dearth of research, it is impossible to draw strong conclusions about other interactions. This limitation is due in part to an unfortunate tendency for research to include only a single AAP.

The operationalizations of affirmative action have tended to be brief, simplistic, and (often) illegally strong. In many studies, affirmative action is not even defined. Instead, the stimulus is simply the term "affirmative action." In such situations, responses are determined by the participant's beliefs about what affirmative action entails, and these beliefs are rarely assessed. In addition, this work relies on respondent self-reports. Self-reports on controversial issues may be less than candid, especially if the research procedures do not guarantee anonymity. Furthermore, much of this research has used only White respondents. Even more disturbing, a few studies pool data across all race/ethnic groups, and many studies pool results across minority groups. There is evidence that the minority groups differ in their attitudes. Of greater importance, it appears that minority groups may also differ in the factors that predict those attitudes.

Affirmative action is a complex social policy, and the determination of attitudes toward it is complex. Theories and research designs must be similarly complex if we are to obtain a fuller understanding of attitudes toward affirmative action. There is ample room for progress in this area.

5. CONCLUSIONS

One common thread weaves throughout the tapestry of research on affirmative action: Many negative effects are associated with the use of strong preferences but not with weak forms of affirmative action. Negative effects of affirmative action on organizational performance should be limited to situations in which the organization gives preference to underqualified target individuals. Stigmatization of target group individuals by others and by the individuals themselves occurs when affirmative action involves (or is believed to involve) preferences but not when preferences are known to be absent. Opposition to affirmative action and the resulting conflict exist primarily in response to preferences and quotas. The good news is that such

strong preferences are illegal, at least in the United States. The bad news is that a substantial segment of the population equates affirmative action with preferences. A major challenge for the future is to craft affirmative action procedures that are widely perceived to be fair and legitimate and that improve employment opportunities for traditionally underrepresented groups. Furthermore, the nonpreferential nature of these plans must be publicized, and the tendency to equate affirmative action with preferences should be eliminated in public discourse and academic research. Such actions should decrease social conflict while leading to a more equitable society.

GLOSSARY

biopsychosocial model A framework for understanding human behavior, health, and well-being across the life span; it incorporates the biological, psychological, and social perspectives on the etiology, understanding, and treatment of illness and disease.

formal care Paid care received from private or government social service agencies or organizations.

informal care Unpaid care received from family, friends, neighbors, or religious organizations.

receiving care Help with impairments in activities of daily living (ADLs), such as eating, walking, using the toilet,

bathing, and getting in and out of bed, or help with limitations in instrumental activities of daily living (IADLs), such as cooking, cleaning, and shopping.

reciprocity The exchanges of goods, services, and support of equal value among members of a social network.

sense of control The degree to which people believe that they can deliberately bring about desired outcomes and avoid undesirable ones in their environment.

In contrast to just a few years ago, more research on the psychological and social gerontology of racial and ethnic minority groups is being included within the general investigation of ethnicity and cultural factors in aging and human development. The existence of large national data sets and more powerful analytical techniques is increasing the quality and quantity of aging research on these groups in many areas of psychological interest. National longitudinal data collection efforts are improving the available data on the aging experience of minority Americans. Although better data are always needed, the improvement in a relatively few short years has been impressive. Similarly, the approach to research on the ethnic minority elderly has also seen a greater recognition of the heterogeneity among and within these groups. Research is now more focused on the role of culture, socioeconomic status, and gender as important markers of potential process differences within and among aging

groups of color, especially Black Americans. Recent ethnogerontology research is reversing historical trends, and generalizable high-quality findings are emerging concerning health, socioeconomic status, work and retirement, social support, well-being, and especially family patterns of caregiving and care receiving. This article reviews some implications of this work for the applied psychology of aging, with a special focus on issues related to perceptions of control, family caregiving, and care receiving among racial and ethnic minority populations.

1. INTRODUCTION

Research on racial and ethnic minority populations has propelled significant interest in the development of life course models and frameworks that assume an important role of race and ethnicity, culture, acculturation, and national origin in how various groups in the United States traverse the individual life course and age. The growth of racial and ethnic groups in the United States, and the relative deprivation of these groups in material, social, and health resources, demands greater attention if we are concerned about characterizing them appropriately and providing effective and adequate services as they age.

The growing internationalization of research on aging demands that we move beyond singular cultural perspectives. Fortunately, the United States is culturally heterogeneous, and comparative research on racial and ethnic groups yields excellent models relevant to understanding basic processes in aging in larger cross-national contexts. Important processes, such as stress and coping, may be more sharply defined in environmentally pressured groups (e.g., Blacks, Latinos, Native Americans). Racial and ethnic group boundaries may provide a personal and group coalescing of culture/environment and biological differences. For example, recent research supports degrees of assimilation and acculturation as important variables for understanding basic processes in mental health and mental disorder outcomes.

2. THE CHANGING NATURE OF AGING IN AMERICA

America has always been a nation of immigrants. Several factors will change the face of America in

the future. The population will age dramatically. The racial and ethnic composition of the country will change significantly. Earlier waves of migration came from Europe, China, and Africa, whereas new waves are coming from Central and Latin America, the Middle East, and Southeastern Asia. Although the country is aging rapidly, the rate of aging is faster among the racial and ethnic minority "new" immigrant groups, especially Latinos, Asians, and (to a lesser extent) African Americans and other Black immigrant groups.

This changing racial and ethnic minority population will represent culturally unique groups of aging individuals. As culture has affected their lifetime experiences, it will also influence the nature of their aging experiences. Elements of the biopsychosocial model of aging are fundamentally affected by the cultural experiences of aging individuals, both cumulatively and contemporaneously. Immigrant groups in the United States have unique histories. For example, Cuban immigrants fled Castro and arrived in the United States feeling forcibly expelled from their homeland. They came to the United States, which was largely anti-Castro and sympathetic to their plight. Middle Easterners escaped dictators, war, and oppression, but (at least currently) they are aging in a considerably less sympathetic, if not hostile, United States. Asians (e.g., Koreans) also fled a homeland torn by war and remain embedded in communities with specific cultural values that guide their expectations about aging. The life span experiences of these individuals may include immigrating as children and spending 60 years in the United States, learning another language, living in urban versus rural communities, and being among a minority versus majority culture. Some immigrants left a higher standard of living, whereas others came to the United States to seek a higher standard of living. But particularly relevant to the aging experience is the fact that all immigrants have been influenced by their biological and physical characteristics, their family and friendship relationships, and the communities within which they live (i.e., their biopsychosocial development). Although this article focuses on minority racial and ethnic minority groups in the United States, these biopsychosocial influences are no less important for the majority group. In this case, recognizing the significant influences on racial and ethnic minority groups only serves to highlight the role of these factors for aging among all individuals.

3. A LIFE COURSE FRAMEWORK FOR AGING IN RACIAL AND ETHNIC GROUPS

As changing demographics require increased focus on older ages, lessons learned from the life span model of development are particularly germane. A life span framework is needed to explore how environmental stressors influence and interact with group and personal resources to both impede and facilitate the quality of life of successive cohorts of racial and ethnic minorities over the group life course and in the nature of their individual human development and aging experiences. Research on socioecological predictors of health in African American and Caucasian residents of a large midwestern city exemplifies the need for the life course approach. Findings have demonstrated relationships between socioecological factors (e.g., high crime rates, family dysfunction, high noise levels, social isolation) and negative health factors (e.g., hypertension) among minority residents. These factors can affect all members of the minority families and community, thereby possibly initiating poorer health among both younger and older individuals. It is the premise of a life course perspective that current and aging cohorts of ethnic minorities have been exposed to the conditions that will profoundly influence their social, psychological, and health statuses as they reach older ages during the years and decades to come.

Recent work on the incomplete ontogeny of human development and the recognition of the influence of culture in human development represents an important extension of the original work. In this latest consideration of life span developmental theory, the concepts of selection, optimization, and compensation are illustrative of the adaptive strategies that people use to maximize their competency. With the challenges of age, one has an increased need to select, optimize, and compensate to achieve designated goals. At the same time, it is noteworthy that culture is infused in every element of this process. What one selects, how one chooses to optimize, and what one considers appropriate forms of compensation all are culturally influenced if not culturally determined. As one ages, this influence accumulates and appears to have ever-increasing effects on the experiences of aging. The greater emphasis on culture in this life course modeling is very important in understanding the experiences of racial and ethnic minority groups. In fact, some have suggested that although culture becomes increasingly important

with age, its actual influence on development decreases with age. Thus, biological and physical development are said to dominate during childhood when culture has minimal impact. Within most Western cultures, this appears to be true. But of course, one might imagine a culture where one group is disfavored (e.g., girls) and, thus, is provided only very limited access (e.g., to nutritional resources), thereby limiting the biological or physical development that might otherwise dominate. Similarly, among older people, what one values and how one copes with biological or physical losses might also be influenced by culture.

The current authors believe that it is necessary to incorporate both the life span model and the role of culture, especially a view of culture nuanced by racial and ethnic differences, into life course biopsychosocial models, especially as they apply to aging.

4. RESOURCE DEPENDENCY: WORK, ASSET ACCUMULATION, AND RETIREMENT

4.1. Socioeconomic Status

Many minority elderly individuals continue to lag behind Whites in social and economic status. For example, indicators of income, education, and health status document the deprived position of Blacks relative to Whites. Some argued that this was a cohort effect, but the lingering poor relative position of Blacks refutes this; new cohorts of the Black elderly are not faring significantly better than prior ones. For example, there is a continuing disadvantage of middle-aged and younger Blacks (and increasingly Hispanic groups), relative to Whites, in housing, income, occupation, health, and education. Recent reports on the circumstances of Blacks across the entire life course continue to show the presence of relatively poorer circumstances, especially wealth, suggesting that new cohorts of elderly Blacks will continue to experience relative disadvantage in comparison with other groups.

On the other hand, even though approximately one-third of the Black elderly continue to live below the poverty level, today's Black elderly are better fed, better housed, and in better health than were those during earlier eras. Most of this improvement is attributable to government assistance programs, which is still the prime support of many black Americans and increasingly among other older age groups as well. Unfortunately,

because of histories of poor occupational opportunities, lack of wealth, and private retirement funds, a large proportion of Blacks are heavily dependent on these government programs. It is still unclear whether future cohorts of older Blacks will enjoy what may be the relative luxury of today's elderly. Recent diminution of federal programs, a change in the economy favoring job creation in "high-tech" and specialized educational intensive sectors of the economy (e.g., computers, communications), and simultaneous growth in low-paying service positions (e.g., fast-food restaurants) provide little room for today's Black adult and middle-aged cohorts, many of whom lacked basic educational opportunities during their formative years. It is now predictable that future cohorts of older Blacks may not be as well off as their White counterparts, and it is still unlikely that they will be as well off as today's cohort of Black elders, many of whom worked in union-intensive industries.

4.2. Health Morbidity and Mortality

At nearly every point from birth to death, African Americans and other minority groups (e.g., Native Americans) have poorer morbidity and mortality rates than do Whites. It is also well documented that there is increased longevity among Blacks (and some suggest that this is also true among Hispanics) who live to approximately 84 years of age. Many have suggested a possible selection bias favoring the long-term survival of particularly robust and hardy individuals (e.g., immigration) or differential rates of aging within Black, Asian, Hispanic, Native American, and White populations. Others have claimed that this crossover is only an artifact of faulty reporting and exaggerated age claims. The effect has been firmly established, although there is still no widely accepted explanation. The racial mortality crossover appears to be a real phenomenon—one that may involve some type of "survival of the fittest."

Recent research on the "oldest old" continues to document the heterogeneity of the social and psychological health of very old Blacks. This type of data provides strong support for a thesis that views the mortality crossover as involving the survival of hardier old Blacks and not a methodological artifact. Similarly, other work reveals some evidence for greater functional health among older elderly Blacks in comparison with Whites, although the effect seems highly dependent on educational status.

Recent research points to differences between ethnic minority groups and Whites in the nature of self-

reported health. Early in the past decade, it was found that the largest differences were in the validity of the subjective interpretations of health state. These findings challenge traditional thinking and research regarding possible race differences in health. At this point, whether there are differences in the structure of health, the processes of health, or the influence of service use on experienced health problems remain open questions. What is clear is that changing health policies may have increasing negative effects on the ability of Black and many other minority elderly to receive adequate health care in the new century.

4.3. Psychological Well-Being

Research on psychological well-being has shown an increasing sophistication over the past few years. Structural factors, such as income and education, tend to show small but positive relationships to well-being. Some recent work suggests that psychological well-being may be strongly tied to family and health satisfaction. Some recent evidence also suggests that younger ethnic minority cohorts may be less satisfied than older cohorts at comparable periods during the life span. This is in sharp contrast to Whites, who have shown the opposite pattern. This lowered satisfaction and happiness in younger Blacks may be related to rising expectations and structural constraints that are likely to persist into older age.

4.4. Work and Retirement

Little empirical research had been devoted to the study of work and retirement among ethnic and minority elderly individuals. Some earlier work had speculated that the entire retirement process, viewed within a life span context, may be very different for Blacks and other disadvantaged ethnic minorities. For example, Blacks and other groups, such as Native Americans and some Latino groups, often have long histories of dead end jobs with poor benefits and bleak expectations, thereby lowering any advantages of retirement. Thus, inadequate income, poor housing, and uncertain futures may confront these older groups at retirement age. Faced with limited retirement resources, many older ethnic minorities may continue to work past customary retirement ages out of desperation. Some research indicates that these individuals are physically, psychologically, and socially worse off than their retired counterparts. As suggested earlier, even the relatively poor but stable government retirement

support (if these individuals are fortunate enough to qualify for such support) may, in contrast, be better than sporadic and poor jobs in the regular labor market. Thus, retirement may provide a small but secure government income, leading to increased psychological and social well-being.

4.5. Family and Social Support

Historically, research on minority family and social support networks has been based predominantly on anecdotal data. Two myths have dominated this area. The first is a view of older minorities being cared for by loving and extended family members and fictive kin. The other is a view of impoverished, lonely, older minority elderly individuals being abandoned by a disorganized and incompetent family system. National and other large social surveys indicate a reality somewhere in between, documenting the existence of extended family forms but also demonstrating that much of the assistance is reciprocal; that is, ethnic minority elderly individuals often provide help to younger family members and neighbors. Recent research supports the importance of community institutions, such as churches, as sources of physical and emotional support for older Blacks. This work points to the considerable obstacles faced by many ethnic minority Americans in providing services to physically disabled and/or demented (and mentally ill) relatives.

5. IMPORTANCE OF FORMAL AND INFORMAL CARE

5.1. Benefits of Support/Informal Care

Research has provided impressive evidence of the importance of social support throughout the life span, particularly to the elderly. Social support has salutatory effects on physical and mental health of older adults. Support reduces the negative effects of health problems, helps in coping with stressful life events, and buffers the impact of psychological distress. A lack of social support from family and friends is associated with poor psychological well-being (e.g., depression). The most important social support usually involves long-lasting, significant, and close relationships with a network of family, friends, and church members. The quality, rather than the quantity, of the support relationship has been shown to contribute most

significantly to health and well-being. In ethnic minority families, informal support has served to counteract the overall deleterious effects of adverse environmental, social, and economic conditions.

5.2. Sources and Types of Informal Support/Care

Studies that examine the beneficial effects that care networks have on health and well-being find that support derives from many sources, including spouse, children, siblings, and friends. Racial and ethnic minority families, in comparison with White families, tend to have larger multigenerational households. On the one hand, investigators report that generations live together out of economic necessity due to low socioeconomic status, poverty, and generally few resources and opportunities available to ethnic minorities. On the other hand, some researchers assert that intergenerational households may be more the product of cultural norms such as familism, filial piety, and familial obligation. In any case, the large family provides a functional, mutually beneficial network from which to give and receive care. Common characteristics of ethnic minority families are the importance of strong family bonds, exchanging of resources, and caring for the elderly.

As they age, many elderly individuals perceive that family and friends can be relied on to help with increasing needs. Family, friends, neighbors, and fictive kin play an important role in the care of ethnic minority elders. Mutual assistance, exchanges, and reciprocity involving informal and formal exchanges characterize the support patterns. A variety of tangible and emotional resources are exchanged within racial and ethnic minority populations, including goods and services as well as financial, emotional, and affective support. Instrumental aid (e.g., food, money, transportation) and emotional support (e.g., advice, counseling, visiting, companionship) are exchanged throughout the life course. These exchanges allow elderly individuals to remain viable and independent in their communities.

The elderly prefer assistance in a manner depending on need. Members of helping networks provide different types of support. Some members may give emotional support, such as listening and advice, whereas others may provide instrumental support, such as sick care and financial help. Family assistance may be more appropriate for long-term care, addressing impairments in activities of daily living (ADLs) and limitations in instrumental activities of daily living

(IADLs). Friends and neighbors, in close proximity to elders, may help with daily or short-term needs. Friends may also be a source of companionship and emotional support.

Research provides a wealth of information concerning formal and informal church support. The special role of church support is separate from its religious role for Black elderly individuals. Black churches have proven to be responsive to the needs of communities that have limited access to general societal support systems. Church members exchange instrumental, financial, emotional, and spiritual assistance with each other. This support includes food, clothing, and sick care as well as advice, encouragement, and information.

5.3. Reciprocity

Overall, older individuals are more satisfied with their relationships and have increased well-being if they are involved in reciprocal relationships. The nature of reciprocity exchanges is dependent on the nature of the relationships. Some relationships require immediate and in-kind or equivalent value return of services or goods. Other more intimate or lifelong relationships have more mutually satisfying exchanges over time and less immediacy to the exchanges. For example, receiving more aid than giving aid can result in feelings of guilt and indebtedness. One theory that addresses this issue is Antonucci's notion of a support bank or support reserves. The concept explains how many elderly individuals are able to maintain positive psychological well-being when they are in need of support but are unable to reciprocate. To illustrate, older minorities usually have fewer resources than do younger network members. By participating in years of giving and mutual exchanges, it becomes psychologically acceptable for the elderly to receive care without giving something in return. There is also evidence that some elderly individuals may reduce the size of their social exchange networks so as not to feel indebted to too many people. It is important to keep in mind that the elderly are not necessarily unable to render some type of reciprocity. For example, they might provide child-rearing assistance, including child care and advice, to younger parents in their networks.

5.4. Formal Care

At times, the elderly may need more professional care than family and friends can provide. When necessary,

family, friends, and church members are instrumental in providing referrals to formal services such as professional home care providers. Ethnic minority elders also use formal services in the absence of spouses, children, or other informal helpers. Traditionally, the minority elderly have had few links to formal service. In the past, service delivery organizations rarely acknowledged cultural or family generational lifestyles differences, thereby perhaps contributing to mistrust of formal service organizations.

In general, the ethnic minority elderly are involved in long-term associations involving reciprocal support and care exchanges. More information is needed, however, about how societal changes affect these relationships. For example, younger people who become more educated and economically successful might need to move farther away from their family homes, thereby affecting the availability of care for elderly family members. Furthermore, people are living longer and having fewer children, and more middle-aged adult daughters are working outside the home. These changes also may contribute to a decrease in the number of people available for caring for elderly family members. Among recent immigrants, assimilation and acculturation issues also may complicate familial and friend relationships. The degree of assimilation varies and has effects on the provision of care. Despite histories of disadvantage, including poverty and poor medical care, ethnic minority groups have been creative at developing resources and effective coping strategies to alleviate these deleterious situations. Consequently, they have high levels of satisfaction with life, even in circumstances of relatively poorer health than that of Whites.

6. RECEIVING CARE

Although it has been noted that ethnic minority elderly have viable support systems, the helping literature suggests that receiving aid may have negative psychological consequences for care recipients who have health limitations. The logistical differences between receiving social support in general and receiving care for functional limitations are vague. Past research indicates that older Blacks have varied social support networks consisting of family as well as friends. But little research has examined the adequacy, satisfaction, or psychological implications of transitioning from self-sufficiency to dependency among older Blacks. The psychological effects of actual dependency differ from the psychological benefits of participating in

social support exchanges. Studies have focused on the psychological and physical effects of providing care to functionally limited elders, but little is known about care recipients' perceptions of the caregiving relationship.

It is often implicitly assumed that if care recipients with IADL limitations and ADL impairments have caregivers who adequately meet their physical needs, they are likely to be functioning satisfactorily both physically and mentally. In general, giving help is beneficial and should be encouraged; however, it is also complex and multifaceted.

Responses to aid depend on many factors, including the relationship and history of the donor with the recipient, the characteristics of the donor and the recipient (e.g., age, race, socioeconomic status, gender), and the appropriateness of aid to the needs of recipients (e.g., the context in which the aid is given). Research indicates that all of these factors can affect the recipient's sense of control. For example, if the help is threatening to feelings of personal control, it can lead to negative psychological outcomes for the recipient. However, if the help is supportive and appropriate to the needs of the recipient, it may reduce any threat to the recipient's concerns about control. Having some sense of control over who provides care and how much is provided may help to limit psychological distress.

Sense of control is a psychological resource that is effective in helping people to overcome environmental threats. Believing that one has control over negative events reduces possible adverse effects and promotes positive psychological outcomes. Control is indicative of psychological resilience and is effective in buffering the effects of stress. Perceptions of control have beneficial effects on individuals, whereas diminished control over undesirable events induces stress and anxiety and may lead to learned helplessness and depression. A sense of not being in control reduces motivation and adversely affects coping strategies, adaptation, and problem solving.

Some studies show an increase in control with age, whereas others demonstrate a decrease in control with age. The elderly usually encounter more loss and negative life events than do younger individuals. Events such as loss of one's spouse, physical limitations, and increased contact with health care providers are often associated with a decrease in control and adverse psychological outcomes. However, it is important to examine control within a specific context. Individuals do not feel the same extent of control over all sectors of their lives; degree of control varies from one aspect of

life to another. For example, control over career and social relations increases with age, whereas control over health and physical functioning decreases with age. How older people adapt to a new care-receiving situation may depend on caregiving factors noted earlier and control beliefs. Successful adjustment means better mental health outcomes. Believing that one has control over challenges and difficulties results in positive outcomes in various domains, such as psychological adjustment. Research has determined that the perception that an individual has control over his or her life is a stronger predictor of psychological well-being than is actual control. Thus, threats to perceived control in important domains of life may have particularly salient effects on overall health and well-being.

7. IMPORTANCE OF PERCEIVED CONTROL TO PHYSICAL AND MENTAL HEALTH OUTCOMES

Control has been studied in relation to a number of psychological constructs and has been found to be a strong predictor of physical and mental well-being. These constructs include life satisfaction, coping, depression, mortality, and morbidity. There is a strong relationship between helplessness (i.e., the opposite of control) and depression. Sense of control over both good and bad outcomes is associated with low levels of depression. Studies also indicate that people with a high sense of control are more satisfied with life and are more willing to face challenges than are those with a low sense of control. Attributing control to luck or chance fosters uncertainty and anxiety and may lead to depression. When people believe that they have a low or no degree of control, they become passive and withdrawn. People who believe that they have a higher level of control develop habits to solve and prevent problems.

Feelings of control are especially important for vulnerable populations. Sense of control not only affects psychological functioning but also affects the actions that people pursue as well as people's cognitions and emotions. For example, control influences how people characterize an event. Those who have low control expectations will attribute declining health to the aging process and, thus, do little to change or prevent further problems. Those with a higher sense of control will participate in intervention and prevention activities to improve their health. Elders receiving care due to physical impairments or health problems may be

feeling particularly susceptible to concerns about loss of control. Sense of control is an important construct in predicting adjustment among the elderly, particularly those with ADL impairments, such as problems with cooking, housework, shopping, and walking.

The infirm elderly may find themselves with care providers who prefer compliant care recipients who easily relinquish control in exchange for care. There may be expectations that care recipients should accept decisions made for them about who provides care and how much care is provided. These uncontrollable stressors, including physical limitations and problems in caregiving, may magnify the sense of loss of control and lead to depressive symptoms for elderly individuals receiving care. To illustrate, research suggests that when older people move into their children's homes, they often experience feelings of depression and increased helplessness and dependency, a diminished sense of personal control over their environment, and a loss of control over their destinies. However, when elderly people in care-receiving situations are given responsibility for some of their daily activities, they experience higher levels of control and fewer symptoms of depression and less dependency. Elderly people experience less psychological distress when they are able to control the course of events in their lives.

For people in poor health, a high sense of control is usually associated with high levels of psychological well-being. However, it should be noted that high perceptions of control have also been linked to poorer psychological well-being in people with health problems. This may be because people with a high sense of control and health problems may feel as though they are losing their independence. Specifically in the caregiving context, recipients with physical impairments may consider the assistance they receive to be intrusive. Nevertheless, the caregiving assistance is needed. Therefore, those who are impaired and have a high sense of control may be at greater risk for depressive symptoms than are those without a high sense of control. Traditionally, people with a low sense of control depend on others for help, whereas a high sense of control is related to greater motivation for making the decisions that affect people's own lives. Care receivers with a low sense of control may be better at adapting to relinquishing control of their daily lives to their caregivers. This relinquishing of control may result in positive psychological outcomes for care recipients as well as feelings of satisfaction with their relationships with caregivers. On the other hand, people with a high sense of control might feel more independent

and perceive themselves as not giving up their autonomy and self-sufficiency in exchange for care. Consequently, these individuals might be at risk for poor care or, worse, for no care providers, eventually resulting in institutionalization.

Levels of sense of control may have unique effects on psychological well-being for ethnic minorities. Research suggests that because of past histories of discrimination, ethnic minorities might interpret some negative life events as uncontrollable. However, these interpretations are often associated with positive outcomes of psychological well-being. Racial and ethnic minorities may be well adapted to dealing with stressful negative life events and to acknowledging and accepting when they are unable to control or change the course of those events. When opportunities and resources are low, or when advantages are few, it may be healthier and more prudent to assume a low sense of control. Usually, an external sense of control is associated with unhealthy physical and mental health outcomes, but for the ethnic minority elderly, an external view may serve as a buffer to the effects of uncontrollable negative life events.

8. RECEIVING CARE, SENSE OF CONTROL, AND PSYCHOLOGICAL WELL-BEING

8.1. Caregivers

8.1.1. Burden, Stress, Depression as a Result of Providing Care

The caregiving literature reveals that spouses are the first choice for providing care. Spouses are willing and committed to helping each other, but often the outcome for caregiving spouses is depressive symptoms, anxiety, stress, and physical impairment. Spouses in caregiving situations may be at advanced ages with limited physical strength and stamina for the tasks of caregiving and sole responsibility of performing household tasks and home maintenance that were previously shared. The added responsibilities may lead to burden, stress, and depressive symptoms for caregiving spouses.

Adult children are also preferred over other nonrelative care providers. However, caregiving adult children usually have other obligations, including the needs of their spouses, children, and career goals. These other demands can be negatively affected by providing care to elderly parents. Some adult children providing care for parents often forfeit or delay career advancements due

to the responsibilities of caregiving. Furthermore, adult children may experience role reversal due to caring for their parents. Role exchange, career delay, and multirole responsibilities can have negative psychological consequences, such as role strain, depression, and poor physical health, for caregivers.

Studies comparing caregivers' psychological well-being indicate that Black caregivers report better psychological well-being and less negative psychological consequences of caregiving than do White caregivers. Investigators attribute these differences to cultural norms and beliefs and to patterns of living. For example, some studies show that Black caregivers report lower levels of caregiver burden and stress, and greater levels of caregiving mastery and satisfaction, than do White caregivers. Furthermore, ethnic minority caregivers often have less social and high-status career obligations to relinquish when assuming caregiver responsibilities than do Whites. As a result, they usually have less to lose economically than do their White counterparts.

8.2. Care Recipients

8.2.1. Effects of Caregiving on Care Recipients' Psychological Well-Being

Care recipients who must learn to master a new environment due to physical limitations or some other transition in their lives find that they would rather have the freedom to choose who helps, when they need help, or when they would rather do tasks themselves. When help is needed, recipients of aid are usually more willing to receive help from family and friends than from strangers. The more intimate the relationship with the helper, the better for the care recipient. Receiving help from family and friends permits care recipients to use little or no formal services and to remain in the community.

Although care recipients rely heavily on family, they also weigh the costs of time and effort to their caregivers. If the cost to the caregiver is low, the care recipient may be more comfortable in asking for or receiving help. If the caregiver is a spouse, it may be less costly than it would be for an adult child who has a family and other job and career responsibilities. However, some research has found that recipients' psychological well-being sometimes is negatively affected in caregiving contexts with both spouses and adult children. Other work has found that the elderly prefer to have less control, particularly during major

health-related difficulties. Giving up control to family or health care professionals can often be a relief if control is not possible. In most day-to-day living circumstances, the elderly desire to have a routine schedule, to be independent, and to make decisions for themselves.

The literature suggests that care recipients with spouses or other family care providers feel dependent on caregivers and depressed. In his research on receiving help, Newsom reported that recipients often have negative cognitive and emotional reactions to receiving care, including feelings of dependency, indebtedness, incompetence, and worthlessness. Furthermore, having family caregivers sometimes exacerbates those perceptions, especially if recipients perceive that family members are burdened, stressed, and depressed by providing care or if care is not appropriate for the IADL limitations (i.e., too much or too little).

8.2.2. Spouse Caregiver

The caregiving literature indicates that spousal care is less costly in terms of time constraints than is care from others. On the other hand, recipients with spouse caregivers report being more worried, depressed, and dependent than do recipients with younger relative caregivers. These negative effects can be attributed to concerns about overtaxing the elder caregiving spouse with additional responsibilities and tasks. The spouse receiving care may harbor a sense of guilt, realizing that he or she can no longer share the responsibilities of housekeeping tasks and other marital obligations and that the extra burden of caregiving and added household responsibilities could jeopardize the health of the caregiving spouse. In addition, research indicates that the quality of marital relations affects caregiving perceptions and psychological well-being for both spouses. Poorer quality relationships are exacerbated by caregiver burden and stress. These effects on the caregiving spouse may be manifested in the quality of care given and contribute to increased depressive symptoms for recipients with either a low or high sense of control.

Research shows that the quality of spousal care has a strong influence on care recipients' psychological well-being. However, the literature also presents evidence that even spousal care is not always helpful. Unhelpful care can lead to negative self-perceptions and to negative perceptions about caregivers. Spouse caregivers who over- or underestimate the abilities of care recipients can inadvertently criticize recipients'

recovery efforts. These criticisms erode self-esteem, decrease sense of control, and contribute to increased depressive symptoms in recipients. In general, spousal caregivers provide appropriate care; however, the effect of poor-quality care is more detrimental to mental health than high-quality care is beneficial to mental health. Inappropriate help can, at times, reduce the actual and perceived capabilities of recipients. Help implicitly threatens the sense of control of recipients, depending on the nature of the need and the help given.

8.2.3. Adult Children

Most care recipients have good relationships with their adult children caregivers; however, there are elderly individuals with adult children caregivers who perceive themselves as burdensome to their children. In a review of the caregiving literature within Hispanic communities, it was concluded that familial support systems for the impaired elderly could have detrimental consequences for both care recipients and adult child caregivers. The more dependent elders were on their children, the more depressive symptoms the elders reported. Depressive symptoms and dependency can be a result of role reversal and of the feeling of being a burden on children. Receiving support for shopping, cooking, and household tasks from children indicates that individuals are no longer self-sufficient, causing care recipients to feel as though they are losing control of their lives and their independence. Most elderly individuals would prefer to live independently from their adult children and to receive emotional support rather than instrumental support. Care recipients fear burdening their children and experience more psychological problems receiving help when adult children have to adjust their lives, including work schedules, to provide any type of support.

In addition, with family members performing chores and tasks for care recipients, time for social interactions with recipients may be reduced. After completing caregiving tasks, adult children may lack the time or energy to show affection or emotional support, resulting in elder recipients feeling lonely as well as burdensome to their children. Lack of affection can cause negative psychological consequences for recipients, particularly if the stress and burden that family members feel as a result of providing care is manifested in their behaviors, attitudes, and quality of care toward recipients. The elderly desire to continue familial relationships, but they also want to live independently.

8.2.4. Other Relatives, Friends, and Church Members

The literature indicates that the ethnic minority elderly in the community without family often have several sources of support. Studies have examined the similarities and difference in the structure, demographics, and living arrangements of elderly Black and White social and caregiving networks and found that elderly Blacks are more likely to have nonfamily and unpaid caregivers than are elderly Whites. Many elderly individuals may feel less of a burden to other relatives and friend caregivers than to spouses and adult children care providers. Nonfamily members may be providing care out of kindness and genuine concern, but the care might not be consistent, steady, or dependable. For example, neighbors or friends going to the market may offer to purchase groceries or prepare extra food, and church friends may provide emotional support and transportation. However, providing care on a daily basis, such as for bathing, dressing, and taking medication, might require more commitment than friends and neighbors are able to give. If help is required too often, care recipients may begin to feel burdensome to nonfamily members. Receiving help from nonfamily members may be distressing but necessary to overcome care needs. The familiarity found in families is usually not present with nonfamily caregivers. In addition, nonfamily members may begin to feel beset by too many requests for assistance.

Because of the need for help with physical limitations, such as eating, bathing, and walking, recipients with nonfamily caregivers might need more professional help than spouses or family members can possibly offer. Some daily tasks are more appropriate for trained formal caregivers. Having physical or medical needs met, however, does not guarantee that recipients are comfortable with the caregiving situations or with the caregivers. Elderly individuals who are reluctant to voice disapproval or who have no control (whether actual or perceived) over ineffective or excessive care are at risk for depression.

9. RACIAL AND ETHNIC MINORITY ELDERLY AS A RESOURCE

The information in this article is important for practitioners dealing with elderly care recipients. Frequently, psychological well-being, such as depressive symptoms in the elderly, are ignored or misdiagnosed, resulting in early morbidity and mortality among older persons

receiving care. Research indicates that some health care professionals believe that the symptoms of depression are inevitable in the elderly and focus more on physical and medical problems. This article suggests that elderly care recipients' psychological needs are also important and that certain aspects of the caregiving relationship are related, for example, to an increase in depressive symptoms. Unfortunately, most care recipients often feel that they should be appreciative of any help they receive and will not complain, even when the help is inappropriate and causes poor psychological well-being.

Consideration should be given to elder care recipients as a resource. The elderly often possess valuable knowledge, skills, and insights that they can share with others. The elderly generally have more positive perceptions about the quality of their lives when their relationships with family and friends are of a reciprocal or interdependent nature than when they are simply receiving help from others. Elderly individuals receiving care are not necessarily unable to reciprocate in the caregiving relationship. Elderly parents are more satisfied if they can exchange support with care providers. For example, care recipients often provide emotional and financial support to caregivers, serve as confidants and sources of advice, and provide child care and sick care. The relationships between caregivers and care recipients are found to be supportive and reciprocal for both parties when recipients are given some responsibilities. Recipients can help with child care for their adult children who work and provide caregiving. The elderly can also share their skills and knowledge with family caregivers and grandchildren. They can help teach younger children to read and write, and care recipients who have hobbies (e.g., knitting) can teach skills to younger generations, further helping adult children and strengthening family intergenerational bonds. The elderly often help to relate and preserve family heritage and serve as socialization agents. Moreover, although frail or disabled older adults may be dependent on family members for care and support, there is some indication that various caregivers are dependent on care recipients for economic and housing assistance. For example, when adult children are in the divorce process or are experiencing temporary unemployment, parents are usually their first source of help.

Caregivers should also be aware of the importance of the emotional needs of care recipients and how to provide necessary care in a nonintrusive way. Care recipients should have as much control as possible over who provides care. Caregivers should allow care recipients to become involved in the planning of their daily care. For

example, recipients may help to create grocery lists to purchase foods of their liking and help to prepare meals of their choice. The literature indicates that when care recipients are allowed to make decisions about their routines and are given some responsibility for their well-being and the important events in their lives, their emotional and physical well-being improves. Recipients who must learn to master a new environment due to disabilities need the freedom to choose when they need help or which tasks they would rather perform themselves. Their perceptions of their needs may be different from their actual needs, but it should be possible to provide care in a way that is not perceived as intrusive, overwhelming, or useless. To provide the best possible experiences for both receivers and caregivers, practitioners should assess and evaluate emotional and psychological aspects, and not only physical and medical aspects, of caregiving situations.

9.1. Implications

One of the major implications of the literature in the area of caregiving and care receiving is that recipients can have poor psychological health even when caregivers are providing for their physical needs and IADL limitations. Recipients' psychological health is an important factor to consider when examining the caregiving environment.

As noted previously, research that has investigated care recipients and caregivers has largely addressed the medical and physical limitations of care recipients. It is erroneously assumed that if caregivers are available to help with those limitations, recipients are functioning satisfactorily. Contrary to expectations, being cared for by family for some limitations and by nonfamily members for others might not always be beneficial to recipients' psychological well-being. Sense of control may be related to decreased psychological well-being, such as depressive symptoms, and there is compelling evidence that receiving and giving care is multifaceted and complex, especially among racial and ethnic minority elders. The authors believe that more research is needed on recipients' psychological well-being, especially sense of control, within the caregiving relationship.

10. CONCLUSIONS

This article has reviewed some implications of research findings in the areas of socioeconomic status, social support systems, well-being, and family patterns,

focusing specifically on perceptions of control and family caregiving and care receiving. It discussed how these findings are important for an applied psychology of aging, particularly within a biopsychosocial model of human development and aging. As indicated at the beginning of the article, the population of the United States continues to grow, especially in racial and ethnic diversity. Along with this complex demographic growth are social, health, and well-being considerations that affect the structure and functioning of the entire society. A clearer understanding of the influence of ethnic, racial, and cultural dimensions on social and psychological processes of aging and human development is necessary to address this complicated change in the size, diversity, and needs of the expanding older population.

GLOSSARY

aggression Acts of coercive control perceived as illegitimate for the social context in which they were enacted.

coercive control Influence applied to another person or group that harms the person's or group's physical, material, or social interests.

culture Ecological–social contexts that promote or restrain acts of interpersonal or intergroup control.

holocultural studies Research that treats a social unit, such as the nation, as the unit of analysis and that spans as much of the world as possible.

retaliation Application of coercive control against a person or group deemed to have attacked oneself or one's group unjustly.

This article conceptualizes aggression as coercive forms of social control, perceived as being applied illegitimately. Mundane social control is exercised through role prescriptions and is routinely met with compliance. Whenever social control is perceived to be exercised illegitimately, however, victims and their representatives respond to restore interpersonal and

social order. That response may be retaliatory coercion. The type of response elicited will be shaped by personal factors such as the emotionality of the victim and the hedonic relevance of the anti-normative action; target factors such as the gender, status, and ethnicity of the perpetrator; social factors such as the degree of interpersonal support for retaliation or harmonizing; historical factors such as the strength of antagonistic ideologies among ethnic groups; economic factors such as the degree of relative inequality between the actors and between their social groups; and cultural factors such as the presence of honor or restraint codes. For the purpose of understanding aggression, culture may be understood as that complex set of external conditions that sustains or retards the development of those social psychological conditions that predispose toward interpersonal violence. This article elaborates these societal conditions and their psychological imprints on social actors.

1. CULTURE AND AGGRESSION: CONTEXTS FOR EXERCISING COERCIVE CONTROL

Cultures may be construed as ecological–social contexts that promote or restrain acts of interpersonal or intergroup control. These acts function to influence other persons or the groups they constitute to provide resources desired by the influencing agent while minimizing the costs required for their acquisition. The party being influenced is also acting to maximize benefits and

minimize costs while engaged in this dance of interdependencies. So long as this exchange of influence proceeds within normatively accepted guidelines, the process is regarded as an acceptable negotiation. Once one of the parties violates the other's norms of acceptable procedure or outcome, the other's influence attempts may shift and become more coercive.

Coercion in influence is characterized by the use of punishments or by the withholding of rewards from the target as a consequence of his or her behavior. It is these tactics of contingent control that are closely monitored in society because their use may violate social norms for exercising social influence over another's interests. Any escalation in the strength of influence tactics will typically be construed as intended by the other party but unethical, illegitimate, unjustified, savage, immoral, or wrong and will typically be met with a counterattack. One party triumphs, at least in the short term, leaving the other party subjugated and resentful, immobilized and hopeless, or dead and past harboring plans for revenge.

Harmony or at least a working truce may be restored between these interdependent parties. If that harmony has not been restored in ways that satisfy the aggrieved parties, however, memories of unrequited abuse will fester, motivating acts of revenge for past wrongdoings. These acts of retaliation may erupt if the social calculus shifts through changes in the balance of power, economic recession, environmental degradation, and the like.

In the course of this familiar drama, the label "aggressive" will often be deployed to describe anti-normative tactics of influence exercised by the other party. In general, such acts result in physical or material harm to the other party, such as wounding or removal of possessions, but can also include symbolic impositions, such as insults or threats. However, these same acts are generally not construed as aggressive by those who perform them. Such dramatically different accounts of hurtful acts given by perpetrators and by victims have been well documented. Instead, if called to account by an accepted authority, "aggressors" will justify their use of coercive control in terms of self-defense, doing their job, retaliating for past injustices—that is, getting even; serving their group, organization, or nation; protecting the social order; and the like. Aggression, then, is not a characteristic of the action itself but rather a labeling process arising out of the social context within which it occurs. That label constitutes a disapproving judgment passed on the process by which social influence over another person is exercised. Homicide, robbery, rape, and assault are

universally regarded as acts of aggression. Defending oneself against attack, performing painful surgery, executing a convicted rapist, and spanking a disobedient child are generally not so regarded because those acts are often socially approved.

Of course, the exercise of illegitimate tactics of control does not always result in retaliation by the aggrieved party. The target may instead undertake proxy control, influencing third parties—be they friends, family, or social authorities—to restrain, distract, or attack the "aggressor." Or recipients of such resented manipulation may withdraw from the relationship if an exit option is possible and if alternative relationships providing the same desired goals are available. Alternatively, they may accept such "altercasting" into a subordinate status, thereby acceding to a relationship in which the dominant party may exercise such tactics of control.

The use of any such response to counternormative control depends on the skills and resources available to the target. The target must be aware of alternative responses because not everyone has the social training and intelligence to appreciate alternatives other than retaliation. The target must be willing to use the alternative responses because some may be proscribed by socialization or normatively sanctioned by proximal social groups. The target must be able to mobilize the personal resources and the social agents necessary to exercise that form of influence because not everyone commands the required talents, time, energy, resources, and social credits with others to motivate their intervention.

2. CULTURE AS CONTEXTS FOR INFLUENCE

Culture is a polysemous construct of kaleidoscopic richness, variously defined by practitioners of different social sciences. It may be defined for purposes of doing psychology as a set of ecological-social constraints and affordances potentiating some behaviors, retarding others, or even rendering them irrelevant. This general psychological definition culture was elaborated by Bond as

a shared system of beliefs (what is true), values (what is important), expectations, especially about scripted behavioral sequences, and behavior meanings (what is implied by engaging in a given action) developed by a group over time to provide the requirements of living (food and water, protection against the elements, security, belonging, social appreciation, and the exercise of one's skills) in a particular geographical niche. This shared system

enhances communication of meaning and coordination of actions among a culture's members by reducing uncertainty and anxiety through making its members' behavior predictable, understandable, and valuable.

This definition focuses on the socialized psychological "software" constituting the operating system for functional membership in a group setting. That group may be any social unit—a family, a work group, an organization, a profession, a caste, a social class, a political state, and the like. The preceding definition is silent about the characteristics of those social units that predispose toward the development of different types and levels of the shared software called culture. Nor does this definition focus on the types and levels of behavior likely to characterize that social unit and its members. It is precisely those contexts and consequences of culture that need to be elaborated whenever one addresses the link between culture and any behavioral outcome such as aggression.

The cultural factors relevant for explaining differences in aggressive behavior will depend on how aggression has been conceptualized. These factors would then be linked to mediating processes responsible for driving aggressive behaviors. Given the preceding discussion, relevant considerations for a cultural analysis would include institutional supports enforcing procedural norms for coordinating action and for dividing resources; norms about the legitimacy of claims made by outsiders or different others on one's resources, including ideologies of antagonism and social representations of a group's history, focused on specific out-groups and their members; direct or indirect socialization for coercive responses to particular targets (e.g., women, the disabled, other lower status persons); training provisions and social support for conflict resolution strategies other than retaliation; the goals that social group members hold about desirable material and social outcomes and the procedures for achieving those outcomes (i.e., their instrumental and terminal values); attitudes held by citizens about the proper place of out-groups (i.e., social dominance orientation); and beliefs about the efficacy of various influence tactics, citizen neuroticism, and emotionality affecting impulse regulation. Each of these mediators is made salient in the issue of culture's relation to aggression by its hypothesized role in eliciting coercive tactics of interpersonal and social control. Whether a person or group using such coercive violent means of social control would be perceived as behaving aggressively would depend on the position of the actor and the target in the social order of their culture.

3. HOLOCULTURAL STUDIES OF AGGRESSION

Dramatic and universally accepted acts of aggression, such as homicide and political violence, can be studied only at the level of larger social units, such as societies and nations, because their incidence is either rare or group encompassing. Such studies are called "holocultural" because they involve social units sampled from the whole range of the earth's cultures. Aggression-relevant data on larger social units are easier to obtain than are individual-level data on cross-cultural comparisons of coercive control. Perhaps this is one reason why there is so little comparative psychological work on aggression despite its social importance. The problem with holocultural studies, however, is that it is more difficult to extract defensible social psychological explanations for their results.

3.1. Waging War and Internal Political Violence

In 1994, Ember and Ember examined the ethnographic atlas for clues about the causes of war in 186 societies. They concluded that societies wage war due to recurrent natural disasters that rendered them vulnerable to food shortages: "Fear of such unpredictable shortages will motivate people to go to war to take resources from others in order to protect against resource uncertainty." The societies they studied were smaller than current nation-states, which are enmeshed in relations of trade interdependence and protected by mutual defense pacts. These state-level connections act to restrain war, although the driving force of resource acquisition remains a powerful incentive for waging war. Looming environmental disasters, with their potential for reducing current national resources such as arable land and potable water, argue for carefully coordinated international programs of disaster relief and foreign aid. In their absence, pressures for waging war will mount as some nations suffer reversals of fortune.

In 1988, Rummel assessed war making during the course of the 20th century. He concluded that the historical record shows that democratic political systems—that is, "those that maximize and guarantee individual freedom"—are less likely to engage in war. Rummel argued that "there is a consistent and significant, but low, negative correlation between democracies and collective violence" and further that "when two

nations are stable democracies, no wars occur between them.” Rummel argued that this relationship is causal and not merely correlational, stating that a democracy “promotes a social field, cross-pressures, and political responsibility; it promotes pluralism, diversity, and groups that have a stake in peace.” Institutional pressures and supports in a democracy, from the opportunity to vote anonymously to legal supports for human rights, lead to the development of psychological processes, such as egalitarian values and trust in others, that prevent political leaders from mobilizing the mass support required for waging war. The same argument applies to restraining internal political violence. In this regard, Rummel provided this sobering reminder:

War is not the most deadly form of violence. Indeed, while 36 million people have been killed in battle in all foreign and domestic wars in our century, at least 119 million more have been killed by government genocide, massacres, and other mass killing. And about 115 million of these were killed by totalitarian governments (as many as 95 million by communist ones).

He hastened to point out that during the 20th century “there is no case of democracies killing en masse their own citizens.”

The preceding discussion suggests that if the big picture on aggression is considered, concerted efforts toward educating populaces for effective democratic citizenship would be the most powerful prophylactic against violence and investment in social capital that the leaders of a nation could make. Of course, the courage and insight required for nondemocratically installed leaders to commit the resources necessary for this task and imperil their own power basis will be hard to find without external political influence being engaged.

3.2. Homicide

The most reliable data on levels of homicide in a social unit are provided by the standardized measures collected by the World Health Organization, although judgments of homicide levels in a society have also been taken from the anthropological record provided by the Human Relations Area Files. These homicide levels are typically correlated with societal factors to provide insights about characteristics of social systems that predispose members of their citizenry toward lethal aggression against one another. Such findings are springboards for some social psychological explanation of violence by citizens against fellow citizens. Occasionally, empirical data are

provided to support such speculations about social psychological processes mediating these acts of violence.

3.2.1. Societal Factors

Most research in this area is bivariate, where one societal predictor, such as national wealth, is correlated with the rate of national homicide. Over time, a number of societal factors have been advanced as “causing” higher levels of internal murder. Theory is then advanced to explain each variable’s avenue of influence. One problem with this piecemeal approach is that many of these factors are interrelated and their avenues of influence are overlapping or perhaps identical. Understanding the full range of societal relations to homicide rate requires multivariate studies where a host of potential societal predictors is deployed, so that their separate influences may be assessed. Such studies could then confirm many of the past findings, integrating theorizing around key processes such as social trust. It could also add new predictors to the societal equation, suggesting further lines of theoretical development.

It is possible to use these fewer multivariate studies to integrate the results from the various studies that have been conducted on homicide rates over the past 40 years. Using this approach, the following societal variables have been linked to homicide rate: a society’s recent history of waging war, its level of wealth (negatively), its degree of economic inequality, its percentage of male unemployment, its strength of human rights observance (negative), and a measure of male dominance themes in its national system (labeled “female purity”). More studies have been conducted using the readily available economic indexes, so one can be more confident in their robustness of impact, especially that of relative inequality. The other variables are new entrants in the predictive arena, emerging as more national indicators become available for use by social scientists during the 21st century.

3.2.2. Social Psychological Mechanisms

Investigators of societal variables related to homicide have often used their empirical results to support the probable operation of certain social psychological processes in potentiating homicide. So, for example, Wilkinson argued in 1996 that relative economic inequality predisposes the “have-nots” in a social system to feel routinely status deprived and inferior. The social stress so induced increases the likelihood of violent behavior in everyday social exchanges. Taking a complementary approach, Fukuyama argued in 1995 that the

higher levels of incivility, including homicide, in poorer societies arise through lower levels of social trust held by citizens in such polities. This higher ambient trust among a society's members may be sustained by greater equality in resource distribution because the two features of a social system are highly correlated.

In their 1994 analysis, Ember and Ember did more than speculate on the social psychological processes involved in homicide; they empirically demonstrated that the societal link between a recent history of warfare and a society's internal homicide rate is mediated by the stronger socialization of males for aggression in such societies. This demonstration is accomplished by using regression techniques that enable the interrelatedness of societal and social psychological variables as predictors of homicide to be assessed within the same data set. The richness of the linkages so revealed, however, depends on the types of social psychological variables included in the data set and their overlap with the nations whose homicide rates are being studied. Because these data sets consist of nation scores, considerable data collection must be undertaken to provide the necessary number of "citizen" averages on the social psychological predictors. This multicultural database is becoming more and more available with the increasing activity in cross-cultural psychology, so the linking of societal factors

to psychological dispositions of a citizenry to national rates of violent outcomes is becoming possible.

Using one such database, Lim and colleagues found that national rates of homicide across 56 nations were jointly predicted by a nation's level of economic inequality, its gross national product (GNP) growth over a decade (negative), and its emphasis on female purity (Fig. 1). This finding confirmed the results of many previous studies of economic inequality and homicide but extended them to include additional societal predictors of internal violence. Lim and colleagues also found that citizen scores on the psychological constructs of belief in fate control and the length of typical emotional experiences predicted national rates of homicide. Using regression techniques, they concluded that the effect of female purity was mediated by citizen endorsement of fate control, that is, the belief that one's outcomes were shaped by one's predetermined destiny. This linkage led to speculation that in societies characterized by social divisions and rigidity of social structure, parents typically socialize their children for responsiveness to external control rather than for internal self-regulation. Lacking strategies for internally generated self-control, citizens in such societies are more likely to respond with homicide to the universal frustrations arising out of mundane interpersonal interdependencies.

FIGURE 1 Homicide rates in 56 countries.

In nations where citizens routinely experience emotions for longer periods of time, there would be a persistence of emotionality into more of one's daily interactions with others. This wider reach of emotionality would amplify whatever dominant tendencies characterized a particular exchange. It is easy to understand how, if that exchange involved coercive control or resistance to its imposition, the frequency of homicide as one extreme outcome would be higher in such countries.

Such conclusions are speculative because they are drawn from correlations of national-level scores. In the case of homicide, however, there is little choice but to use data from large social units. The plausibility of the conclusions drawn will depend on their connectability to theory and empirical data derived from analyses of individual behaviors related to homicide. For example, a person's capacity for self-regulation has been linked longitudinally to lower frequencies of antisocial acting out. So, it is plausible that belief in control by fate is part of a personality constellation related to poor impulse control. Psychological studies of individuals differing in their beliefs about fate control will be necessary, however, to strengthen the plausibility that citizen differences in fate control link to national homicide rates through the agency of impulse regulation.

4. CULTURE AND STUDIES OF AGGRESSION IN INDIVIDUALS

The holocultural studies discussed previously alert social scientists to the need for validated theories about the psychological mechanisms involved in generating violent behavior against others. These mechanisms must be measurable across cultural systems, and their role in potentiating harm to others must be demonstrated empirically. This is the mandate for cross-cultural psychology, but its offerings are remarkably scanty. In part, this shortfall arises due to the definitional problems noted earlier (e.g., what behaviors other than homicide, rape, or physical assault constitute aggression?) There are a plethora of American laboratory studies, for example, that use paradigms such as the teacher-learner shock scenario to examine aggression. In such a setup, the participant-teacher trains her confederate-student under various experimental conditions hypothesized to provoke higher levels of hostility (e.g., ambient temperature, expectation of future interaction, prior insult by the confederate-student). This procedure, however, fails to engage the dynamics of aggression as anti-normative

behavior because the experimenter has explicitly legitimized the delivery of noxious stimuli to the student as an educational exercise. Other experimental scenarios for studying aggression and its facilitating conditions likewise encounter the same problem of its implicit legitimation by the experimenter.

A related problem for the cross-cultural laboratory study of aggression involves the meaning of the exchange between the two parties created by the experimenter. In the teacher-learner scenario, one could imagine that in more hierarchical cultures with a tradition of corporal punishment in classrooms, the legitimation of hurtful behavior by the experimenter would appear to be more acceptable to the participant-teacher. The confederate-student would then receive even higher levels of shock for a given set of experimental conditions. One could not, however, conclude that persons of this hierarchical culture were more aggressive given that local understanding of the shock-behavior is so different in the new culture.

Given these conceptual problems, two ways forward have been tried. One approach across cultural groups involves the use of scenario studies where cultural informants are presented with descriptions of behavioral exchanges between persons and are asked to make judgments about these exchanges and the persons involved. Knowledge about the cultures can then be used to predict the outcomes of these judgments. So, for example, Bond argued that in a more hierarchical culture, a direct coercive tactic of influence in a business meeting would be construed differently than it would in an egalitarian culture, depending on its source. As predicted, a superior insulting a subordinate was less sanctioned in Chinese culture than in American culture, and a subordinate in Chinese culture was more strongly sanctioned for insulting a superior than was a subordinate in American culture for insulting a superior. Similarly, knowledge about cultural dynamics can be used to predict the frequency and judged effectiveness of direct coercive tactics of influence, depending on their source and their relationship with the target. In such studies, the behavior being judged is the same, and its different meaning is examined in light of different cultural dynamics. The perceived aggressiveness of the behavior and the sanctions it receives vary as a function of these dynamics.

The second approach involves observation of hostile behavior in common settings such as prisons and schools. These observational studies are time-consuming and require agreement on what behaviors to measure. There has been considerable debate across participants

in the European Union, for example, as to what behaviors constitute “bullying,” so that cross-national comparisons can proceed. Typically, a “least common denominator” position that includes only physical or verbal provocation between perpetrator and victim is adopted. Other indirect forms of bullying, such as gossiping and cliquing against others, are excluded. This happens in part because persons from different cultural traditions might not regard these behaviors as bullying, but also because the indirect behaviors are extremely difficult to measure reliably. Given all of these concerns, few cross-cultural studies involving *in situ* measures of behavior have been conducted to date.

Less conceptual and measurement difficulty is encountered when behaviors are measured by asking knowledgeable observers, such as parents and teachers, to rate the frequency with which their charges engage in aggressive behaviors. Chang, for example, employed a 7-item scale measure of aggressive behaviors such as hitting, teasing, and shoving others. The scale forms a coherent single measure of aggressiveness, and independent observers of a given pupil rate that pupil’s aggressiveness with high degrees of agreement. It would be easy to examine this measure in other cultural contexts for its equivalence, adding or subtracting behaviors until a comparable measure of pupil aggressiveness is achieved. Cultural groups could then be compared for their levels of aggressiveness.

There is a slowly growing body of cross-cultural research using the scenario and behavior-reporting approaches. The problem with this work is that it is often only descriptive, reporting the cultural differences and perhaps speculating why they occur. There is little theory-driven work that measures the processes hypothesized to drive the aggressive behavior in the cultural groups studied. One exception is a recent study by Chow and colleagues using recollections by cultural informants of upsetting interpersonal events. They argued that everyday aggressive behavior often emerges out of social exchanges where one party harms another party, resulting in retaliation from the aggrieved party. Self-reports of behaviors undertaken by the victim after the harm doing indicated an equivalent cluster of assertive or aggressive behaviors in both Japanese and American informants. This assertive counterattack is driven by psychological factors uniting to generate a motive to retaliate and by social factors relevant to the relationship such as the gender of the two parties and their degree of familiarity.

Chow and colleagues found that both internal psychological and external social factors contributed toward

assertive counterattack in both Japanese and American cultures but that psychological factors weighed more heavily than social factors for the Americans than for the Japanese. This finding confirmed theoretical speculation that collectivists, such as Japanese, are more responsive to external forces, whereas individualists, such as Americans, are more responsive to internal forces. This reasoning was supported by personality measures of individualism that predicted the tendency to emphasize psychological factors more than social factors in directing one’s retaliation against the harm doer. Controlling for the level of harm experienced, the investigators found that Americans were more likely to counterattack assertively because their motivation to retaliate was greater than was the Japanese motivation.

The next step in such research on culture and aggression is to examine why the motivation of any cultural group to counter any harm with coercive retaliation is greater than that of another cultural group. One strong possibility is the experience of harsh parenting. Punitive parents model coercive strategies of control as they manage their children, indirectly teaching children to respond to interpersonal frustration with confrontational assertiveness. This linkage between harsh parenting and children’s aggressiveness has been confirmed in other settings such as school. Such studies have provided the inspiration for successful intervention studies that reduce the level of child aggression through programs teaching parents to intervene nonviolently.

Chang further discovered that some of the linkage between harsh parenting and child aggression is mediated by lower levels of affect regulation characterizing those pupils who act out. Such internal dispositions may be higher in citizens of some cultural groups than in citizens of other cultural groups due to differential socialization styles and procedures. The different strengths of these aggression-related attributes could then account for observed cultural differences in aggressive responding. Other possible internal mediators include well-studied psychological dispositions such as self-regulatory efficacy, sociopathy, and state anger. Social psychological factors varying across cultures could include orientation toward confrontation, honor sensitivity among males, degree of ethnic identification, social support for retributive as opposed to restorative procedures of justice, and socialization into ideologies of antagonism and indebtedness.

Higher cultural levels of these psychological and relational dispositions may be the legacy of cultural circumstances (e.g., a history of war, tribal conflict, or colonialism), a herding economy, slavery, or internal political violence, any of which may lead parents to

socialize their children to inflict harm on others as a way of solving problems in interpersonal and intergroup coordination. As indicated earlier in the discussion of holocultural studies, psychologists have some ideas about what these cultural circumstances might be. But they need to conduct the sort of theory-driven and empirically validated research necessary to substantiate their speculations about how culture operates to affect aggression. Psychologists must instrument the hypothesized dispositions, measure them in persons, and then observe their behavior when dealing with interpersonal and intergroup relationships. Who chooses cooperation and consensus? Who chooses confrontation and conflict? How then can life be enhanced by encouraging social systems to socialize their citizens for the former rather than for the latter?

GLOSSARY

autonomy A concept in biomedical ethics that refers to an individual's right to self-determination and to make decisions and choices concerning one's own life.

beneficence An ethical principle important to consider in guardianship issues that refers to the obligation to intervene to positively benefit another individual and prevent harm.

capacity Another word for competency referring to the ability to receive and evaluate information and to make and communicate decisions.

competency A legal status presumed for all adults—as opposed to incompetency, wherein a person with a clinically diagnosed condition is unable to receive and evaluate information or to make and communicate decisions to such an extent that he or she lacks the ability to meet essential requirements for health, safety, and self-care; judicial determinations of incompetency are not necessarily permanent and may be revoked if and when the ward's mental status changes.

conservatorship A legal mechanism established by a court after a hearing that empowers one party to make financial decisions (e.g., management of assets, businesses, contracts, wills, and gifts) for another party.

durable power of attorney (DPA) An alternative to guardianship in which a competent individual designates another person to manage his or her affairs (medical and/or financial) in the event of incapacity.

guardianship A legal mechanism established by a court that designates a party to make decisions (e.g., health, financial, residence) for another (incompetent) individual.

health care proxy Any person appointed by another competent individual to have the authority to make health care decisions if and when he or she becomes incapable of making such decisions; the proxy's authority may be unspecified (to make all decisions in accordance with the principal's best interests) or may be specified (to make decisions in accordance with advance directives).

representative payee An individual appointed by a benefit provider (e.g., veterans disability, social security disability) when the provider questions the benefit recipient's ability to manage the funds; the payee receives and has responsibility for only the funds distributed by that provider.

Many people use the concept of competency in clinical settings, although there continues to be confusion about what it means, when it is relevant, and how it should be assessed. All adults are presumed to be legally competent unless otherwise determined in a court of law. An adult's competency may be questioned when a family member or other interested party files a petition for guardianship of that individual. If incompetency is found in a court hearing, a guardian or conservator may be appointed. In most states, a guardian is responsible for decisions regarding the care of the individual's "person" (e.g.,

day-to-day issues of care, residence, and activities), whereas a conservator is responsible for decisions regarding the care of the “estate” (i.e., management of assets).

individual strengths and weaknesses or functional capacities rather than the all-or-none notion of incompetency.

1. CLINICAL VERSUS LEGAL COMPETENCY

Although clinicians may question a patient’s competency status and may request other clinicians to evaluate the patient’s competency, a clinical finding of incompetency should not be confused with a judicial determination of incompetency. The clinical use of the term “competency” refers to a clinical opinion regarding the patient’s decisional capacities. Such an opinion may be used to activate a durable power of attorney or health care proxy if one exists. However, clinical statements about capacities should not be equated with court-determined findings of incompetency.

2. COMPETENCY VERSUS CAPACITY

Increasingly, the term “capacity” is preferred to competency. The use of capacity recognizes the possibility of

3. LEGAL FRAMEWORKS FOR AGING AND COMPETENCY

In the United States, most statutory definitions of incapacity to care for one’s person or estate include four parts, as shown in Fig. 1. This four-part definition means that a diagnosis is a necessary, but not a sufficient, component of incompetency. Rather, information must be provided as to how the disease affects attention, memory, information processing, and so forth as well as, in turn, how these symptoms affect the person’s ability to do certain things or make specific decisions. The ability level should be considered within the context of the environmental demands and resources as well as specific situational risks and benefits. For example, the threshold for the capacity to reasonably manage a small amount of day-to-day cash spending would be different from the capacity to manage a complex portfolio of investments, and the abilities needed for the capacity to consent to a relatively harmless medical intervention (e.g., a flu shot) would be much lower than those needed to consent to a more risky medical intervention (e.g., heart bypass surgery).

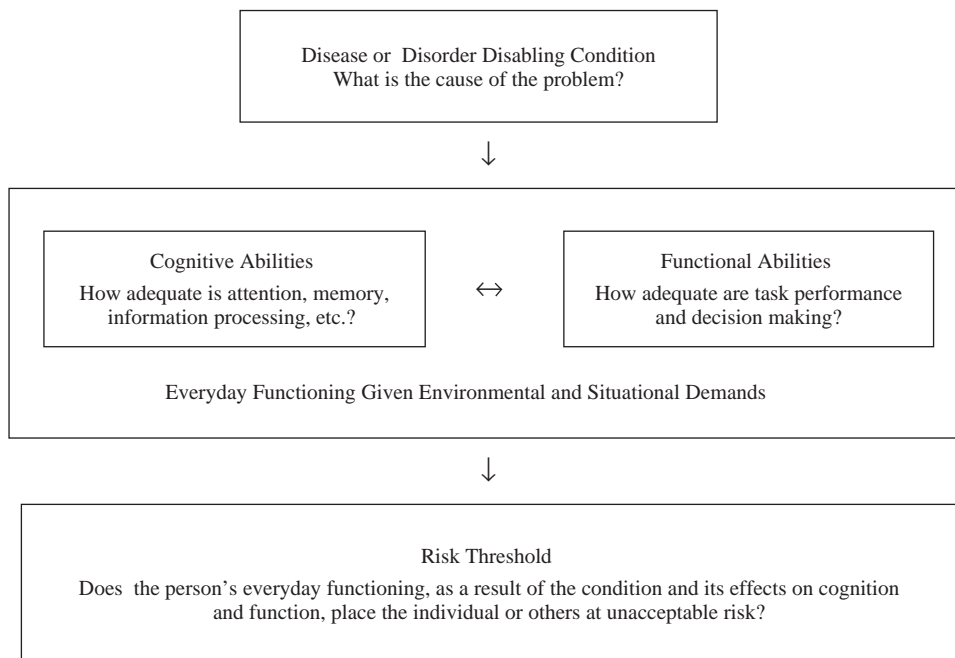

FIGURE 1 Four components of most U.S. statutory definitions of competency.

4. DECISION-MAKING ABILITIES IN COMPETENCY

Much U.S. case law about competency to consent to treatment refers to four decision-making abilities, as shown in Table I. Case law typically refers to these abilities individually as independent legal standards. Together, they form a useful framework for evaluating decisional processes.

5. CLINICAL EVALUATIONS OF CAPACITIES

5.1. Competency and Older Adults

Although the large majority of guardianships concern elderly individuals with psychiatric or neurological diagnoses, it is clear that advancing age or physical frailty themselves are not grounds for guardianship. Competency questions are increasing for older adults due to the age-associated increase in prevalence of dementia that can affect competency during the later stages of the disease.

TABLE I
Four Decision-Making Abilities Important for Legally Competency

Capacity	Definition
Understanding	The ability to comprehend diagnostic and treatment-related information and to demonstrate that comprehension
Appreciation	The ability to determine the significance of treatment information relative to one's own situation, focusing on beliefs about the actual presence of the diagnosis and the possibility that treatment would be beneficial
Reasoning	The process of comparing alternatives in light of consequences through integrating, analyzing, and manipulating information; also defined as providing "rational reasons"
Expressing a choice	The ability to communicate a decision about treatment that applies to individuals who cannot express a choice and also to those who are consistently ambivalent

5.2. Competency Assessment

In the past, most clinical evaluations of competency relied on a physician's interview or knowledge of the patient. However, such approaches can be unreliable. A more objective evaluation of competency, particularly important in more complicated cases, involves three parts, as shown in Table II.

5.3. Ethical Issues

5.3.1. Consequences of Guardianship

Many adults who receive guardianship experience benefit from the arrangement. In the best case, the

TABLE II
Components of Competency Assessment

Component	Definition
Clinical interview	
Who	Patient and relevant informants
What	Patient's values, goals, and preferences Situational factors Mental health conditions Symptoms of other illness
How	Open-ended interview Psychiatric rating scales

Performance based assessment of the specific capacity in question	
Who	Patient
What	Capacity to do the task or make the decision being questioned
How	Activities of daily living and instrumental activities of daily living instruments Capacity assessment tools

individual receives needed care, supervision, and advocacy in accordance with his or her wishes. In the worst case, guardians may take advantage of the individual's assets. In either case, removal of competency results in the loss of the right to make choices about residency, health care, medication, relationships, marriage, contracts, voting, driving, use of leisure time, and how one's own money is spent. Such losses in autonomy may affect the individual's emotional well-being. These potential rights deprivations and personal consequences of incompetency underscore the special care that should be taken in competency assessments and the extra attention that should be devoted to ethical concerns.

5.3.2. Informed Consent

An individual who is the subject of a competency evaluation needs to be informed of the nature of the evaluation and the potential consequences. Obtaining informed consent for the evaluation of competency from a person whose decision-making capacity is in question requires special care. Clinicians should fully disclose information about the evaluation and its risks and benefits in clear and direct language and then should assess the individual's ability to understand, appreciate, and reason through the information and options.

5.3.3. Individual and Cultural Differences

Persons from different ethnic or age backgrounds may have different cultural and cohort preferences for medical care, finances, living situations, relationships, and so forth. Evaluators must be sensitive so that individual and cultural differences are not misconstrued as incompetent decisional processes. This also applies to the use of standardized tests because some do not have adequate normative data concerning cultural, cohort, and educational influences on test performance, especially in older populations. Test instruments should be given in the primary language of the person being assessed.

6. CATEGORIES OF CAPACITIES

6.1. Financial Management

As shown in Table III, one important category of competency is the capacity to manage finances, including managing assets and how one spends money, managing debts and how one pays bills, and managing specific issues of contracts, disposition of property, and wills. Such financial capacities may involve knowledge of facts (e.g., where one's bank account is), financial skills (e.g., counting change), and financial judgment (e.g., avoiding

TABLE III
Categories of Competency

Category	Possible tasks	Potential services
Finances	Managing assets	Bill-paying services
	Paying bills	Money management services
	Writing will	
Health	Medical decision making	Visiting nurse
	Health care management (including medications)	Pill box and pill-dispensing systems Telephone reminder systems
Independent living	Household cleaning and maintenance	Homemaker services
	Laundry	Meals on wheels
	Meal shopping and preparation	Emergency call systems
	Communication	Home health aide
	Personal hygiene	Care management Adult protective services Assisted living
Transportation	Driving	Adult foster care
	Use of public transit	Skill training classes
		Rides to appointments and services Assisted public transportation

fraud). As indicated in the table, services can sometimes provide alternatives to guardianship.

6.2. Health Care

Another category of competency focuses on health care, especially the capacity to consent to treatment. Health care capacities may also cover managing day-to-day health such as nutrition, wound care, and medications.

6.3. Independent Living

A third and more broad category of competency concerns the capacity to live independently. Tasks in this category include household cleaning and maintenance, laundry, meal shopping and preparation, and communication (telephone and mail). Senior service agencies have a wealth of services to assist vulnerable adults in living independently, including homemaker services to clean, do laundry, and prepare meals; “chore” services to tackle larger tasks such as lawn care and snow removal; and meal delivery programs. Communication aids, including large-button telephones, assistive devices, and animals for the deaf and hard of hearing, may also promote independent living. Medical alert systems can be installed for seniors to enact in the event of a disabling emergency.

6.4. Transportation

A more narrow category of functional abilities concerns transportation and the capacity to drive a motor vehicle. This question may arise outside of other competency concerns when an adult with a disabling psychiatric or neurological condition has a series of motor vehicle accidents.

GLOSSARY

aging Becoming old and showing the effects or the characteristics of increasing age.

culture The totality of socially transmitted behavior patterns, norms, beliefs, institutions, and all other products of human work and thought.

demographics The statistical characteristics of human population.

families All members of a biologically or legally related group usually living in one household.

health The condition of being sound in body, mind, and/or spirit; it especially refers to freedom from physical disease and pain.

immigration Entering and settling in a country or region to which one is not native.

life course The interval of time between birth and death.

Although the world population has been aging at an unprecedented rate, the speed of change is considerably

different depending on national history and life circumstances. The association between age and culture can be best understood in the light of the life span perspective and the family. Different cultural backgrounds affect individuals' aging experiences contemporaneously and cumulatively. Family is both the conveyer and interpreter of culture. The life span attachment model and the convoy model emphasize that close relationships accumulate over time and differentially affect the aging process and, consequently, the physical and psychological well-being of individuals who live in different cultural milieus.

1. INTRODUCTION

The study of aging has a long and ancient history, with notable comments having come from historical luminaries such as Aristotle, Socrates, and Plato. Despite the increasingly youth-oriented society, the modern study of aging has garnered increased attention during recent years for many reasons, not the least of which is recognition of the significantly changing world demography. This article first presents a brief overview of these changes. It then considers the association between aging and culture, noting the role of family and cultural diversity as well as the implications of both family and culture for health and well-being among the elderly. The article closes with a consideration

of how culture shapes aging and health in the United States as well as around the world.

2. AGING AND DEMOGRAPHICS

Changing world demographics are nowhere as dramatic as they are with respect to the age structure of the world population. According to the UN Populations Division and the U.S. Census, the world is graying at an unprecedented rate. For example, comparison of the percentages of people who will be age 60 years or over in the years 2005 and 2030 indicates that approximately 20% of the European population will be at least 60 years old in 2005 and that 30% of the population will share that status by 2030. The situation in the United States is not quite as dramatic, but the increase is still noteworthy. In 2005, 17% of the U.S. population will be age 60 years or over, and in the year 2030, one-quarter of the U.S. population will be in that age bracket. The figures are much smaller for Latin America, where 9 and 15% of the population are expected to be at least 60 years old in 2005 and 2030, respectively. The lowest figures are for Africa, where only 5% of the population is currently age 60 years or over and a mere 7% is expected to reach that age bracket by 2030. The AIDS epidemic is actually reducing the life expectancy in some African countries. These differences make it clear that the age distribution of the world is changing differently, depending on national history and current life circumstances. Interestingly, and perhaps contrary to the assumptions of most people, the United States ranks only 28th in "aging" among the oldest countries of the world, with most European countries and Japan reporting older populations. Although these changing age structures reflect increased longevity, this longevity is due mostly to changes at the other end of the life span. That is, fewer children are dying in childbirth, thereby increasing the numbers of people who will live to old age, and fewer children are being born, thereby reducing the proportion of a population of young people and naturally increasing the proportion of older people in each society. The decline in fertility has reached critical proportions in many countries, including Italy, Greece, Sweden, Japan, and Spain. Although fertility has been declining in the United States, it has not reached the crisis levels being experienced in other parts of the world.

3. AGING, CULTURE, AND FAMILIES

The effort to understand the association between age and culture must include consideration of both the life span perspective and the family. The life span perspective incorporates a long-term view of the growth and maturity of individuals throughout their lifetimes on multiple dimensions. Development on these dimensions is influenced by previous developmental periods that can manifest through stability or change as well as through continuity or discontinuity. Consequently, individuals become more different from each other as they develop over time. This is noteworthy because life span development both affects and is affected by the cultural milieu within which individuals live. During recent times, those cultural milieus have been changing in unprecedented ways in the United States as well as around the world. Examples of cultural milieus include specific individual experiences (e.g., ethnic identity) as well as more universal experiences (e.g., the unprecedented advances in technology experienced during recent years).

Although the life span perspective focuses on the individual, any effort to understand the aging experience must also include the families within which most people age. The family usually surrounds an individual with a protective convoy that nourishes and supports the individual as he or she faces the challenges of life. The family also is often the embodiment of the cultural perspective that the individual values. Just as each individual emerges as an older person who has evolved throughout his or her lifetime, so too does the individual bring that lifetime of growth and development to the family. At the same time, the family also evolves. A family might begin as a young couple who are the parents of a small child and evolve to a family composed of an adult child with aging parents and later to a family that includes grandparents with adult children and grandchildren. The family can be thought of as the vessel within which the individual experiences culture. Although people experience culture at multiple levels—as an individual, as a family member, and as a member of society—it is the family that most often is both the conveyor and interpreter of the culture. The United States may not be the oldest country in today's industrialized world, but the increased longevity of Americans means that most individuals will at some point be members of three-, four-, or even five-generation families. Hence, the role of the older person as a

family member in both promoting and maintaining culture has been steadily increasing.

4. CULTURAL DIVERSITY AND AGING

The United States has, at least ostensibly, always embraced a commitment to the blending of many cultures. This phenomenon is perhaps best exemplified in the term “melting pot.” This term was used to refer to the blending of many cultures, but these cultures were mostly Western European. Although immigrants also came from China (e.g., to work on the railroads) and from Africa (e.g., to work as slaves), those immigrants were generally not among the “blended.” An important new development in the cultural influences on aging in the United States is the recent immigration from different parts of the world, namely, Central and Latin America, the Middle East, and Southeast Asia. The nature of this immigration is important not only because it represents different cultural influences but also because the immigration patterns are affecting how the United States ages. As noted earlier, the country is aging rapidly, but particularly important is the fact that among certain ethnic and racial minority groups (i.e., the “new” immigrant groups), aging is taking place at an even more rapid pace because more older people are immigrating to be with their children. Hence, as the U.S. population ages, it is also becoming more diverse both racially and ethnically. This will pose a challenge as different immigrant groups seek to maintain their identities while at the same time embracing the American culture.

Several kinds of aging experiences that will be directly influenced by cultural background and perspective can be identified. For example, some older people came to the United States as young immigrants and are now aging. Having arrived during childhood or early adulthood, they are familiar with the American culture and understand it, often while maintaining some “old world” values. At the same time, their children and grandchildren were most likely born in the United States and have embraced only American values. Some problems may arise if, as these individuals age, they identify more strongly with their cultures of origin, especially in terms of their expectations about the role of families and the experience of aging.

Potentially even more problematic is the phenomenon of immigrating in old age. Some people came to

the United States to join their children, who had immigrated earlier and settled in the country. The motivation could be emotional ties (i.e., a desire to be close to their children as they age), or it could be based on pragmatic need (i.e., the expectation that children will care for their aging parents). The potential for conflict in such families is even greater because the elderly immigrants are less likely to have embraced American values; therefore, the situation may exist where parents and their adult children have fundamentally different expectations about the aging experience.

It is clear that people, whether they recognize it or not, experience age through a cultural lens. Thus, the changing racial and ethnic population of the United States represents a unique group of individuals. These different cultural backgrounds affected their individual lifetime experiences as children, adolescents, and adults. It will, of course, also affect their aging experiences both cumulatively and contemporaneously. Each cultural group has a unique history. For example, consider the case of Cuban immigrants in Miami, Florida, who fled Fidel Castro’s dictatorship and arrived in the United States feeling forcibly expelled from their homeland. When they arrived in the country, they found very sympathetic Americans who believed that Castro was an evil and unjust dictator who was treating Cuban people unfairly. On the other hand, Middle Easterners also have come to the United States to escape an unpopular dictator, but during recent times, Americans have become more hostile, rather than less hostile, toward people from the Middle East. In addition, despite the fact that Middle Easterners also came to escape an unjust dictator, war, and oppression, they are currently viewed with suspicion, unkindness, and resentment. But another current example indicates that these more recent reactions are not ubiquitous. Interestingly, although the United States is experiencing increased hostilities with North Korea, this hostility does not seem to extend to Koreans in this country. They also fled a homeland torn by war, but somehow Americans are more accepting of their presence and their culture. The attitudes of the American public certainly influence the aging experience of both early and later immigrants.

Although these comments have addressed the general concept of culture, there are culture-specific expectations and beliefs concerning health and aging. The next section briefly considers the health implications of culture on aging persons and their family.

5. AGE, CULTURE, AND SOCIAL RELATIONS

Individuals age within families, communities, and society. They interact with these organized structures most frequently through social relations. Social scientists have studied social relations extensively, and it is increasingly understood that social relations affect both the psychological health and physical health of people of all ages. This is evident in models emerging from the childhood literature, such as the life span attachment model, as well as in those emerging from the adult literature, such as the convoy model of social relations. Both of these models emphasize that social relations accumulate over time and influence both contemporaneous and longitudinal choices. These literatures have identified several elements of social relations that influence both morbidity and mortality. In the convoy model, as well as in other adult social relations models, these elements include structural characteristics such as the number, age, gender, role relationship, and years known of network members; support exchanged with network members such as love, tangible aid, and advice; and evaluation of these relationships, that is, whether one feels that they are positive or negative and whether one is satisfied and/or happy with them. Although some elements of social relations transcend age and culture, other aspects of social relations are fundamentally influenced by culture and age. For example, most people of all ages have close social relations with their parents, spouses, and children. Europeans tend to include more extended family members among their close social relations, whereas this is less true among Americans, who are more likely to include friends.

Social relations involve the exchange of social support in all cultures. How often these supports are exchanged, as well as who exchanges them, what supports are exchanged, and when the supports are exchanged, often varies by age and cultural expectations. Although it is common across cultures to expect that parents will provide for their children when their children are young, the degree to which parents continue to do so when those children become adults, or the way in which the expectation might reverse such that parents expect support from their adult children, varies by culture and country. In a recent Italian court case, parents were sued by their employed, 35-year-old son because he was reluctant to accede to his parents' wishes that he move out and live on his own. The

Italian court ruled in favor of the son, requiring the parents to continue providing room and board for as long as the son so desired. A similar case would be unheard of in the United States because it is non-normative for an able adult son to live with his parents and because no court would sustain such a petition. Similarly, in the United States, it is common for parents to attempt to provide for their adult children, for example, through gifts, favors, and loans. But in Japan, the culture assumes the opposite; that is, no matter what age, children are understood to be in a state of indebtedness to their parents and, thus, are expected to be constantly in the position of providing to their parents rather than receiving from them.

There are many factors that influence how social relations are evaluated. There are objective characteristics that influence this evaluation, but a solid accumulation of empirical evidence indicates that significant subjective characteristics influence this evaluation as well. Subjective evaluation could be considerably different depending on the age and culture within which the social relations are embedded. The Italian son just described would rate his parental support received as poor, whereas an American son would not. An adult American son might be dissatisfied and unhappy if his parents did not provide a college fund or a downpayment on a house, whereas the lack of either of these in another culture would generate no parallel dissatisfaction or unhappiness. For older family members, it is clear that their expectations vary depending on both age and culture. Interestingly, in the United States, some evidence indicates that younger people expect to provide more support than their elders expect to receive, whereas in other countries, parents report rather high expectations of what their children should provide. Regardless of the cultural convention regarding who is in an individual's social network or an objective assessment of what is exchanged, evaluation of social relations varies considerably. This variation, although influenced by many factors, has been well documented in the influence of culture on health and well-being.

6. CULTURAL INFLUENCES ON THE HEALTH OF AGING PEOPLE

Different cultural experiences, traditions, and values have direct implications for the expectations of both elders and their families. These expectations range from minor

considerations (e.g., concerning customs around favorite foods or holiday traditions) to more significant ones (e.g., concerning family roles and responsibilities).

There is clear evidence that culture influences health. Some examples are illustrative. It has been documented that elderly Japanese living in Japan are much more likely to die of a stroke than are elderly Japanese living in the United States, where the leading cause of death has been cardiovascular disease. This difference has been traced to dietary differences in ethnically Japanese people living in Japan versus those living in the United States. Similarly, hypertension is a major health problem among people of African descent living in the United States but is relatively rare among Africans living in Africa. Researchers have suggested that this difference is caused by the stressful life circumstances of racial discrimination experienced in the United States. Another interesting example is menopause. Research in medicine, epidemiology, and anthropology has consistently documented that women in many countries (e.g., Japan) experience fewer and/or lighter menopause symptoms (e.g., hot flash, insomnia, depression) than do American women. Although a consensus explanation has not yet been reached, these differences have been attributed to diet (e.g., soybeans) and cultural attitude toward (e.g., acceptance of) the physical and physiological changes associated with aging. A final and compelling argument for the influence of culture on health is that, regardless of the health differences evident among people of different countries, by the third generation all immigrants exhibit patterns more similar to other Americans than to people from their countries of origin.

Cultural expectations of family roles and responsibilities are critical when they have a direct impact on an older person's health and expectations concerning health care. Some simple examples are illuminating. In some countries (e.g., Japan), it is much more common for older people to live with their adult children. The differences in customs have both positive and negative implications. In Japan, older people often live in their own home, and an adult child—often the eldest son—continues to live at home with his wife and children. Although this is a traditional custom that has been changing in modern Japan, it does mean that traditionally a live-in relative attended to the health care needs of a family's oldest members. This live-in relative was most often not the eldest son but rather his wife, that is, the daughter-in-law. Much has been made of the advantages of coresidence for the elderly in terms of meeting their health care and other needs as they get older. However, social scientists have increasingly

documented that not all such arrangements are ideal. There is often tension between the daughter-in-law and her parents-in-law as well as between the son and his parents. This coresidential custom is much less common in the United States, and when it does occur, it is often the case that a parent moves in with an adult child, although the opposite may be the case when the adult child is impoverished or experiencing a life crisis such as divorce or job loss. Under the coresidential condition where the elder moves in with a child, the power dynamics are reversed in terms of the traditional American family dynamics as well as the situation just described in Japan. Tension can arise in this case as well, although health care needs and expectations are also more likely to be met. Certainly, these examples provide persuasive testimony concerning the influence of culture on the health experience of aging people.

7. SUMMARY AND CONCLUSIONS

With the radically changing world demographics leading to a significant increase in the number of older people, it is critical to attend to those factors that positively or negatively affect the experience of aging. Although culture is an important influence, one should be aware that there are also other factors that influence aging and family relations such as socioeconomic status, race, and industrialization. Therefore, culture should be neither overlooked nor overestimated. It remains for researchers and clinicians to identify when culture is a primary factor and when it is not and to determine at what point one should seek to optimize the experience of aging both within and across cultures.

GLOSSARY

external memory strategies Actions undertaken to support prospective memory whereby the physical environment is changed (e.g., the use of lists, notes, calendars, and pillboxes).

internal memory strategies Mental actions undertaken to support prospective memory (e.g., linking planned activity with daily events).

medication nonadherence Failure to take medications as prescribed; this can include taking too few or too many doses, taking medication at incorrect times or in incorrect quantities, or not following special instructions related to the medication (e.g., regarding food or beverages).

prospective memory Memory for actions to be performed in the future (e.g., remembering to take prescriptions at a prescribed time).

reality monitoring The ability to distinguish between actions that were planned and actions that were actually carried out.

retrospective memory Memory for events that occurred in the past (e.g., remembering the instructions received for when and how to take medication).

Medication adherence is increasingly recognized as a complex task involving many cognitive abilities, and adherence errors are common in both younger and older adults. Patients must integrate often complicated instructions on how to take medication into their daily routines, remember to take the medication at the appropriate time, and remember that the medication has been taken. Although age-related declines in many cognitive abilities are clear, older adults manage familiar tasks such as medication taking quite well, at least until very late age. Many mnemonic supports have been found to function quite effectively to remind patients to take their medication. However, more and more, researchers and health care providers are focusing on multifaceted interventions that are tailored to the specific needs, abilities, and beliefs of older patients.

1. EXTENT AND COST OF MEDICATION NONADHERENCE IN THE ELDERLY

Individuals over 65 years of age make up an increasingly large percentage of the population in industrialized

countries around the world, and the trend is expected to continue for many decades to come. Indeed, the World Health Organization has projected that the percentage of older adults in developed countries will increase from 14.3% in 2000 to 19.2% by 2020. The majority of older adults suffer from at least one chronic illness; consequently, older adults are the largest consumers of medications of any age group. Many of the illnesses that afflict older adults can be treated or at least controlled quite successfully through the use of prescription medication—if medications are taken as prescribed. Unfortunately, rates of adherence to medication regimens are believed to be quite low. It is quite difficult to establish adherence rates precisely, but in general, as few as 50% of patients treated for chronic conditions are believed to take their medications as prescribed. Rates of adherence are also thought to be particularly low in asymptomatic conditions such as hypertension that afflict many older adults. Surprisingly, most studies have not found evidence that older adults in general are more nonadherent to medication than are middle-aged or younger adults. Recent work by Park and colleagues even indicated that older adults, between 65 and 74 years of age, made the fewest number of adherence errors of any age group, although adults over 75 years of age made the most.

The risks of nonadherence are numerous and serious. Up to 40% of hospital admissions in adults over 65 years of age are due directly to medication errors. Even though older adults do not seem to be more nonadherent than younger adults, they are more likely to experience serious health consequences because their bodies are less tolerant of medication errors and drug interactions. When treatment regimens are not followed, the risk of toxicity is heightened, medical conditions are likely to worsen, and expensive and often invasive treatments become necessary. Clearly, enhancing medication adherence is a priority for the effective treatment of chronic diseases, for enhancing the well-being of elderly individuals, and for reducing health care costs.

2. TYPES OF NONADHERENCE

Medical nonadherence occurs when patients do not carry out medical regimens as prescribed and includes any of the following: (a) not taking the medication at all, (b) taking smaller or larger doses than prescribed, (c) taking fewer or more doses than prescribed, or (d) not following recommendations regarding food or beverages while medicated. Such behaviors can be either intentional (i.e., the patient chooses not to take

the medication as prescribed) or unintentional (i.e., the patient intends to take the medication correctly but does not). In general, unintentional overuse or underuse of medication is due to cognitive variables such as forgetfulness and misinterpretation of instructions. Intentional noncompliance, on the other hand, can be seen as relatively more complex and is linked to either external circumstances or motivational issues. External circumstances include factors such as not being able to pay for the medication, not being able to reach the pharmacy to get the prescription filled, and not being able to open resistant packaging (e.g., childproof bottle tops) due to physical handicaps. Motivational issues refer to the fact that many individuals, both young and old, hold views about their illness and their medication that are incompatible with adherence.

3. ADHERENCE: A COMPLEX COGNITIVE TASK

In the past, medication adherence has been presented as an example of a simple everyday prospective memory task, where prospective memory is defined as remembering to do things in the future. Recently, however, there is a clear consensus emerging that medication adherence is a complex process involving a host of variables. Although many of these factors are clearly cognitive, others (e.g., motivation to adhere to the medication regimen) involve the interplay between cognitive and social factors.

From a cognitive standpoint, the patient must understand the instructions for how to take the medication. These instructions are often complex, especially when multiple medications, each with its own regimen of doses and times, are presented. Thus, combining the information across multiple medications, and integrating all of this information with daily activities to form a plan of action, can be quite challenging. Once the plan of action is created, the patient must remember to take the medication at the correct time and must remember what dose and what medication to take. Moreover, the patient must keep track of whether or not the medication was taken so that extra doses are not taken inadvertently (i.e., reality monitoring). Reality monitoring can be particularly challenging when a medication for a chronic condition has been taken at the same time of day for months or years. Finally, the patient should monitor his or her health for a range of possible side effects from the medication, including symptoms such as confusion and forgetfulness.

4. PROSPECTIVE MEMORY AND EPISODIC MEMORY: AGE-RELATED CHANGES AND EFFECTS ON ADHERENCE

Clearly, cognitive factors such as language comprehension (e.g., understanding the medication instructions), long-term memory (e.g., remembering what to do), working memory (e.g., juggling the competing demands of everyday tasks and medication taking), problem solving (e.g., integrating complex medication instructions with the daily routine), prospective memory (e.g., remembering to take the medication at the correct time), and metamemory (e.g., monitoring memory performance and judging whether external support is needed for adequate adherence) all are involved in determining whether correct adherence will occur. Although age-related losses in many of these areas have been clearly established, many older adults are able to maintain high levels of performance, especially on everyday tasks such as medication taking.

Many language abilities are maintained into very old age. However, the comprehension of complex medication instructions may depend heavily on working memory capacity as well as language abilities. Age-related losses in working memory and problem solving are well documented. It is clear that if information is presented quickly or is presented using an unfamiliar or disorganized format, many older adults will have difficulty in comprehending and recalling the information. Many studies have shown that older adults are at a distinct disadvantage, compared with younger adults, when asked to combine complex medication instructions into a plan of action, especially if the instructions require inferences. Such problems have also been found when older adults are asked to transfer medication into weekly pillboxes, especially if the pillboxes do not contain multiple compartments for each day.

To take medications correctly, the patient not only must understand the instructions when they are given but also must remember these instructions over the days and weeks following the meeting with the physician. In general, age-related losses are also observed when the ability to recall verbal information after a relatively long interval (i.e., hours or days) is measured. However, age differences can be greatly reduced, at least for relatively healthy older adults, if environmental supports for recall are present. For example, if information is presented clearly, if multiple formats are used (e.g., written and verbal presentation), if recall is based on habitual or

familiar activities, if cues for recall are present in the environment, and if the person is not distracted by competing stimuli at time of recall, age differences in episodic memory are greatly reduced or even eliminated.

Although it is well documented that there are age-related losses in working memory, problem solving, and long-term memory, prospective memory does not show the same rates of decline with age. For example, when asked to make a telephone call or mail a postcard at a certain time, older adults attain performance levels similar or superior to those of younger adults through the use of memory strategies. This may help to explain why older adults do not make more medication errors than do younger adults. Park and colleagues have speculated that adults in their 60s and 70s may have few adherence errors because (a) they are sufficiently focused on their health to adopt mnemonic strategies for medication (unlike middle-aged adults) and (b) they have the cognitive ability to adopt and use mnemonic strategies (unlike much older adults).

In laboratory-based studies of prospective memory, it has been suggested that prospective memory tasks can be divided into time-based and event-based tasks. In a time-based task, the individual must accomplish the task at a certain time (e.g., "Take your pill at 8 AM"), whereas in an event-based task, the individual must accomplish the task when cued by a specific event (e.g., "Take your pill before breakfast"). Computer-based simulations of prospective memory tasks have shown that event-based tasks are easier for older adults to accomplish, especially if the accompanying background task is not particularly difficult. This may also explain why many older adults report that the main strategy they use to remember their medication is to mentally link the medication with routine daily activities. It may also explain why some studies have found that tailoring medication regimens to patients' routines enhances adherence significantly.

5. KNOWLEDGE, BELIEFS, AND COMMUNICATION: AGE-RELATED CHANGES AND EFFECTS ON ADHERENCE

At least three major foci in the research on the motivational factors of adherence in old age can be identified. First, the beliefs and attitudes that the patient has about his or her illness have been shown to predict adherence. Some people may deny that they are ill or might not believe that their conditions have serious consequences.

Patients who are more knowledgeable about their conditions are more likely to follow recommended medication regimens. This may also explain why social support has been found to predict adherence. It may be that significant others play a role in motivating an individual to adhere. Providing cues or reminders to follow the prescription also may play a role.

A second factor concerns the beliefs that the patient holds about his or her treatment. Beliefs about the effectiveness of the medication, about whether the regimen prescribed is appropriate, about whether medications cause uncomfortable side effects, and about how important it is to adhere to medication regimens as prescribed have been shown to contribute to treatment adherence. Thus, some older adults may simply not believe that their medication is helpful. Others may choose underadherence to avoid side effects or may overmedicate because they believe that the prescribed dose is ineffective. (It should be noted that because many health care professionals lack extensive knowledge about the effects of medications—especially multiple medications—on the older body, partial adherence may be beneficial in at least some cases.)

Finally, a third set of factors revolves around the relationship with the health care provider. This relationship is critical in many ways. Medication adherence can be seen as the outcome of a process that begins before the physician and patient even meet. Namely, the attitudes and beliefs that each holds about the other are likely to affect patient–physician interactions in at least two ways. First, the quality of the interaction and the satisfaction that the patient feels with his or her health care are very important predictors of motivation to adhere to a medication regimen. Second, the relationship may also affect the quantity and quality of the information that is exchanged during the patient–physician encounter. For adherence to occur, the patient must be told how to take the medication in detail and must be informed about his or her condition and its associated risks. Unfortunately, many studies suggest that health care providers are less likely to provide this information to older patients than to younger ones, and older patients are also less likely to question their physicians. Thus, even though older adults are likely to be taking more medications and to have more complex regimens, they are also likely to receive less information about their medications. Finally, the relationship between the health care provider and the patient also affects the quality of the information that the patient provides. In other words, the patient is more likely to provide accurate and detailed information about his or her symptoms and adherence

to existing medications when the patient perceives the health care provider to be caring and approachable. Such accurate information is key for the health care provider to be able to make accurate diagnoses and treatment decisions.

In conclusion, even though the relationship between the health care provider and the patient is commonly addressed from a social psychology perspective, this relationship has important cognitive repercussions as well. The patient's knowledge about the illness and medication and his or her beliefs about the importance of adherence are often highly dependent on how well and how comfortably the patient communicates with the health care provider.

6. MEASURING ADHERENCE: A DIFFICULT CHALLENGE

The difficulty of measuring medication adherence is well established and often discussed in the literature. Both technical and nontechnical approaches have been used. One technical approach has been the evaluation of body fluids (e.g., blood, urine) for the presence of the prescribed medication. However, this technique only recognizes drugs ingested during the recent past and does not indicate whether the patient has taken the medication regularly. Pharmacy refill rates and pill counts have also been used; however, with these methods, flawed data are obtained if the patient is using multiple pharmacies, disposing of pills, hoarding pills, and/or sharing pills with others. The most accurate data come from a specially designed pill bottle with a lid containing a microchip that records every time the bottle is opened. However, even this system still does not provide an accurate measure of whether the drugs were actually taken when the pill bottle was opened and does not verify whether the correct doses were taken. Although these special pill bottles are useful for research purposes, their general use remains limited because they are very costly.

The most convenient and the most often used means of assessing adherence is self-reports. However, it is clear that self-reports underestimate medication errors. Patients are likely to overestimate their adherence levels, not only because they do not recall errors but also because they hope to avoid confrontations and/or embarrassment. Cognitive factors also contribute to the accuracy of self-reports. When asked to recall the frequency of a behavior, respondents are likely to reduce their efforts

by estimating rather than counting, and this is especially true of older adults. Moreover, with older adults, memory complaints are often not predictive of objective memory performance. Thus, the older adults who complain about having bad memories might not be the ones who make adherence errors due to forgetting. Despite the potential pitfalls of self-reports, recent work by Hertzog and colleagues suggests that when older patients are asked specific questions about memory problems relating to medication adherence rather than general memory performance, self-reports can be quite useful.

7. INTERVENTIONS: HOW COGNITIVE PSYCHOLOGY CAN HELP

Much of the intervention research has focused exclusively on compensating for either cognitive or motivational deficits. Many studies have focused on providing older adults with external mnemonic strategies. Such strategies involve effecting changes in the environment so that it provides prospective memory cues. Many studies have been carried out to investigate the effectiveness of aids such as pillboxes and pill bottle alarms, memory training, voice mail reminders, and organizational charts. Most of these studies found such memory aids to be at least somewhat effective in enhancing medication adherence. However, many of these studies were conducted over a short period of time, and neither young nor older adults are likely to continue using memory strategies assigned to them after the training period has ended. It is also interesting to note that the few studies that examine what strategies older adults use spontaneously tend to find that internal strategies (i.e., using mental actions to help encode or retrieve information) are reported quite often. However, very little is known about the effectiveness of internal strategies for routinized, long-term prospective tasks such as medication adherence. Also, little is known about what drives the process of determining that a mnemonic strategy is necessary, deciding which one to use, and evaluating its effectiveness.

One external strategy that is being adopted by many older adults is the use of pillboxes with daily compartments. However, as noted previously, at least some older adults have difficulty in transferring pills to the container correctly, at least when the smaller versions are used (i.e., only one compartment per day), and the larger containers have the disadvantage of being bulky and might not be practical unless patients are

housebound. Recently, attempts to reduce adherence errors have focused on using technological advances in how medication is presented to patients. Some have speculated that as pharmaceutical science continues to advance, medications will be released into the body in a controlled fashion (e.g., slow-release pills), thereby making frequent doses and complex regimens unnecessary. More immediately, the use of individualized packaging is becoming more affordable and common. For example, when blister packs are used, the time to take the medication can be listed on the package, and monitoring whether the medication has been taken becomes much easier. However, when patients must take many different medications, each in its own blister pack, the packaging may increase rather than decrease the confusion (and be large and bulky to transport as well). Finally, increases in adherence levels have also been obtained in studies that addressed motivational factors. These studies focused on improving the relationship between the physician and the patient or tried to educate the patient as to the seriousness of the illness or the importance of the medication.

In conclusion, many different interventions can be useful, but there is a growing recognition that the intervention applied must be tailored to the characteristics of the patient. Clearly, it is not helpful to provide mnemonic strategies to someone who is nonadherent by choice, and neither is it helpful to convince someone of the importance of medications if the person cannot remember to take them. Thus, cognitive psychologists today are working in collaboration with health care providers to develop exciting multifaceted approaches that tailor cognitive and motivational interventions to the needs, abilities, and beliefs of individual older adults.

GLOSSARY

effortful control The ability to suppress a dominant response for a subdominant response (e.g., the ability to cope with frustration).

knowledgeable others Peers, teachers, parents, and others who know the person being evaluated.

latent variable An underlying system.

personality dimension A set of related traits.

Agreeableness is a personality dimension (or set of related traits) that describes a class of individual differences that generally have to do with being pleasant, likable, and harmonious in relations with others. Empirical research finds that Agreeableness as a dimension hangs together consistently (persons who are “kind” also tend to be “considerate”), is relatively stable and enduring over time, and is related to many kinds of human activity.

1. DESCRIBING AGREEABLENESS: WHAT IS IT?

Agreeableness has become the label most frequently used for this personality dimension, but it is only one of many such labels. Some of the other labels used to describe the dimension (or closely related dimensions) are tendermindedness, friendly compliance versus hostile noncompliance, love versus hate, likability, communion, and conformity. It has been argued that none of these labels, including Agreeableness, adequately captures either the breadth or the substantive content of this dimension of personality. As a label, Agreeableness has been criticized specifically for being too narrow and perhaps for overemphasizing acquiescence. Theorists have suggested that it may be more appropriate to refer to the dimension either with numerals (the Roman numeral II has been used in the past) or simply with the letter A (for agreeableness, altruism, and affection).

At a theoretical level, Agreeableness describes an underlying system (latent variable) of individual differences. It is one of five broad personality dimensions that appear in all versions of the five-factor approach to personality (i.e., the Five-Factor Model). The five-factor approach describes personality at perhaps its broadest and most abstract (decontextualized) level. Trait adjectives that are positively associated with Agreeableness include kind, warm, cooperative, unselfish, polite, trustful, generous, flexible, considerate, and agreeable. Trait adjectives that are negatively associated with

Agreeableness include cold, unkind, uncooperative, selfish, rude, distrustful, stingy, stubborn, and inconsiderate. Overall, Agreeableness describes a broad, but related, set of individual differences in how a person relates to others. Specifically, Agreeableness appears to describe differences in being predominantly prosocial or other-oriented versus antisocial or self-oriented in social interactions.

Self-report measures of Agreeableness are those most frequently used for assessment. The use of ratings of Agreeableness by knowledgeable others (e.g., peers, teachers, parents) in addition to self-ratings is desirable from a psychometric standpoint but is less common due to the increased demands associated with collecting this information. Currently, there are several measures available to assess Agreeableness within the framework of the five-factor approach to personality. The three most frequently used measures in research are Goldberg's adjective markers, the questionnaire-format Big Five Inventory (BFI) developed by John, and the Neuroticism Extraversion Openness Personality Inventory-Revised (NEO) developed by McCrae and Costa. These measures vary in their construction, length, and content, yet empirical research shows that the five-factor dimensions assessed by these measures, including Agreeableness, are nearly identical across measures. Focusing on Agreeableness, there is some discrepancy between the NEO and the other two measures. The main difference is that the NEO includes warmth as a facet of Extraversion, whereas in the other two measures warmth is associated with Agreeableness. Overall, however, outcomes of studies using different measures of Agreeableness show convergence. For most purposes, the various measures of Agreeableness are functionally equivalent.

2. EXTERNAL CORRELATES: WHAT IS AGREEABLENESS RELATED TO?

Over the past decade or so, cross-cultural research has uncovered the same or similar five-factor personality structure in many cultures with many different languages and in both adults and children. In all cultures studied, Agreeableness has been seen as a major dimension of personality. At a minimum, this research indicates that Agreeableness describes a set of individual differences that are of interest worldwide. The dimension is not an artifact of the English language, college-age participants, or Western cultural norms. Recent

research also suggests that despite the clear preference that most groups have for persons with agreeable qualities over persons with disagreeable qualities, Agreeableness differences are also not an artifact of social desirability, self-presentation, or self-deception, nor are they merely a characteristic of observers' evaluations. Instead, research suggests that Agreeableness describes a stable enduring set of qualities in individuals that is related to important social outcomes.

Agreeableness differences can be studied in many different ways. One of the most common ways is to bring persons who differ on Agreeableness into a laboratory, where their behaviors can be assessed in various kinds of social situations. Typically, these persons are college students. In laboratory studies of group processes, Agreeableness is related to lower within-group conflict and to positive within-group evaluations. For example, more agreeable people like their fellow group members more and are liked more in return. Research also shows that Agreeableness is negatively related to competitiveness in group interactions and is positively related to expectations of enjoying group interactions. These findings suggest that Agreeableness may contribute to group cohesion and may serve as a protective factor against group dissolution. These findings also provide empirical support for the notion that Agreeableness can be mapped onto the social motives described by communion.

In some circumstances, being a more cooperative and generally more prosocial group member may contribute positively to group and individual functioning. In these circumstances, one would expect that Agreeableness is related to both group- and individual-level performance. In some situations, however, being considerate, trusting, and compassionate may undermine a group's performance or an individual's performance. In these situations, Agreeableness may be unrelated, or even negatively related, to performance. One meta-analysis found that Agreeableness was negatively related to job performance for managers but also found that Agreeableness was positively related to job performance for professionals and skilled laborers. A later meta-analysis found that in most studies, Agreeableness was unrelated to job performance but was positively related to teamwork. In a competitive business environment, Agreeableness may be a more desirable quality for group members than for managers or business leaders. To a certain extent, goals and tasks that emphasize competition, profits, and self-gain may run contrary to the selflessness and positive social orientation associated with Agreeableness. This may, in part, explain findings that, across the life span, Agreeableness is negatively related

to extrinsic success (e.g., salary) and career satisfaction. Perhaps more agreeable individuals would find more satisfaction, if not more success, in helping professions or public service than in corporate job environments.

Other research (some laboratory and some field studies) has examined Agreeableness and dyadic relationship processes and outcomes. One area of interest has been the resolution of dyadic conflicts. If more agreeable individuals are more motivated to maintain positive social relations with others than are their less agreeable peers, one would expect more positive patterns of attributions and behaviors from agreeable individuals than from their peers when they have disagreements with others. We might also expect that a concern for others would lead to less disagreement or conflict with others in general. Research outcomes have shown that in both adolescents and adults, Agreeableness is positively related to constructive conflict resolution tactics (e.g., negotiation) and is negatively related to destructive conflict resolution tactics (e.g., physical force). Agreeableness is also negatively related to the number of daily conflicts that individuals report in daily diary records. After a conflict has occurred, agreeable individuals say that they are more upset by the conflict but are less likely to have vengeful attitudes about the conflict or to use vengeance as a problem-solving tactic.

In general, more agreeable individuals appear to behave in ways that are constructive rather than destructive to their relationships with others. This suggests that Agreeableness should be positively related to relationship quality (e.g., fewer conflicts, more satisfaction) and perhaps to relationship quantity (e.g., more friends, more robust social networks). Agreeable individuals may incur costs in maintaining their relationships, but they should also gain the benefits associated with having a strong social network. During adolescence, research found that Agreeableness was positively related to the quality of teacher and peer relations as well as to peer social status. In adults, research on social support showed that Agreeableness was positively related to the perceived support satisfaction, and negatively related to the frequency, of negative social exchanges.

These positive relationships with others may either stem from or contribute to a positive relation between Agreeableness and evaluations of the self. As discussed previously, agreeable individuals view others favorably and are viewed favorably by others. Research also shows that agreeable individuals view themselves favorably. During adolescence, Agreeableness and self-esteem are positively related in both self-ratings and teacher ratings. In adults, Agreeableness is positively related to

happiness and subjective well-being. Agreeableness is negatively related to anger, hostility, and (indirectly) depression in both daily and general dispositional self-reports. In general, agreeable individuals earn higher scores on measures of adjustment than do their less agreeable peers. Conversely, research shows that less agreeable individuals are more likely to exhibit various kinds of externalizing problems during both adolescence and adulthood.

3. ETIOLOGY/ANTECEDENTS: WHERE DOES AGREEABLENESS COME FROM?

In considering the development of individual differences in Agreeableness, researchers have taken two distinct but related approaches. The first approach is to examine the specific contribution of genes to individual differences in Agreeableness. Over the years, behavioral genetic studies have attempted to determine the contribution of both genetic and environmental (shared and nonshared) influences on personality. Results have varied, with at least one study suggesting that among the Big Five dimensions, Agreeableness is the most susceptible to environmental influences. However, most of the behavioral genetic studies do not find that Agreeableness is any less heritable than the other Big Five dimensions. Some theorists suggest that all of the Big Five dimensions, including Agreeableness, represent entirely genetically driven, biologically based dispositions. Supporting this claim are a variety of studies showing that constructs related to Agreeableness, such as altruism, prosocial behavior, and empathy, also show moderate to high heritabilities.

The second approach to identifying the root of individual differences in Agreeableness has been to link adult personality to infant and child temperament. One problem is that the individual differences identified through modern temperament approaches rarely map directly onto adult personality traits. Agreeableness, in particular, has no clear antecedent among temperament constructs. This may, in part, have to do with the emphasis of Agreeableness on the quality of peer relations and other-oriented responsiveness. During infancy, it may be difficult to detect individual differences in the concern for the quality of relationships with others given that infants have a comparatively limited repertoire of both behaviors and communication abilities. In addition, in comparison with other personality

dimensions such as Extraversion and Neuroticism, if Agreeableness is already present as a disposition, it may require the development of more elaborate cognitive processes (e.g., perspective taking, theory of mind) before it can be observed.

Among the temperament traits that have been observed, theorists have suggested that individual differences in effortful or executive control may be an antecedent of individual differences in Agreeableness. Effortful control refers to the ability to suppress a dominant response for a subdominant response. In particular, effortful control is related to the ability to cope with frustration and respond adaptively to goal blockage. More generally, researchers have proposed that effortful control is linked to both cognitive (e.g., attention) and emotional self-regulatory capabilities. In this light, individual differences in Agreeableness may reflect differences in the ability to monitor and control a variety of self-centered or even antisocial impulses in social situations. For example, in daily interactions, less agreeable individuals report feeling (and probably exhibit) more anger and hostility than do their more agreeable peers. These feelings of anger and hostility may stem from an underlying inability to regulate or suppress emotions to avoid damaging relationships.

Even if there were large heritable or temperamental contributors to Agreeableness, it would still be necessary to know how social learning histories and life experiences shape these tendencies into adult individual differences. There is good evidence that cultures differ in the values they assign to Agreeableness; accordingly, we might expect average differences in Agreeableness among children reared in different cultures. Nevertheless, differences within cultures remain. Agents of socialization may leave their marks, but persons enter the socialization environment with something more complicated than blank slates. Some individuals will be receptive to agents of socialization, absorbing and internalizing cultural values, whereas other individuals will resist. In this approach, then, socialization can produce large effects on Agreeableness, yet adult differences in Agreeableness within cultures are the end-state products of Person \times Socialization interactions.

Consistent with this line of reasoning, recent research has demonstrated complex links between childhood self-regulation and adult Agreeableness. Childhood self-regulation has, in turn, been linked both to the quality of child-rearing practices and to temperamental characteristics. It is possible that temperamental characteristics and socialization experiences may interact in

a variety of ways to produce individual differences in Agreeableness. For example, temperamental characteristics may contribute to the selection of particular social ecologies that restrict the range of socialization experiences available to any given individual. Children who lack self-control and are easily frustrated may make for poor relationship partners and may subsequently be rejected by their peers. Consequently, these children might miss important socialization experiences provided by peer relationships. Temperament may interact with parent-child relationships to affect socialization experiences in a similar way. As children get older, they may also consciously choose to place themselves in particular environments that are consonant with their temperamental predispositions. Similarly, as adult personality characteristics emerge, they may interact with situations to reinforce underlying predispositions. For example, if given a choice, highly agreeable children may choose to avoid highly competitive situations. If forced into competitive situations, highly agreeable children may attempt to convert the situation into a more cooperative one or otherwise adapt to the social norms associated with highly competitive interactions.

4. CONCLUSION

Agreeableness is a dimension of personality associated with motives for maintaining positive relations with others. It is a superordinate descriptor for a system of lower order affective, behavioral, and cognitive tendencies. Cultures may differ in the emphasis they put on socializing children into seeking harmonious relations with others, but differences remain within cultures. Agreeableness differences in people seem to be relatively stable over time and across settings. Agreeableness may have developmental origins in temperament and in skills in coping with frustration. These differences are associated with corresponding tendencies in dealing with conflict, emotional responsiveness to others, group interaction, interpersonal relationships, and self-evaluation. For many life events, Agreeableness is associated with positive outcomes such as good social relations, friendships, better adjustment, and social recognition (with the exception of external rewards, e.g., salary). There is some suggestion that agreeable persons are less effective as managers, but there is no evidence (at least so far) for claims that agreeable persons are less attractive, more conforming, more compliant, or more submissive than their peers.

 9. Prevention of Alcohol Use and Problems
- Further Reading

Practically everyone has consumed alcohol in his or her lifetime. Fully 90% of the U.S. population has had at least one alcohol-containing beverage. In addition, 30% of the population drinks regularly with adverse consequences (15% develops alcohol dependence and another 15% drinks heavily). Costs due to problems from alcohol use and dependence reach \$100 billion annually in the United States. Despite the available knowledge about the etiology and course of alcohol consumption, the costs from adverse consequences continue to rise each year for a wide range of age groups (including children, adults, and the elderly), most ethnicities and cultures, and both genders.

GLOSSARY

anhedonia Lack of pleasure or satisfaction in experiences that are normally pleasant or satisfying.

delirium tremens A kind of alcohol withdrawal occurring during abstinence or reduced alcohol use after excessive long-term alcohol consumption; symptoms include delirium and hallucinations.

DSM-IV-R Abbreviation for *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, revised (published January 2000).

DSM-IV-TR Abbreviation for *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision (published June 2000).

gateway drug A substance that, when abused, is known to lead to the abuse of other substances.

phylogenetic Relating to evolutionary relationships within and between groups.

1. WHO BECOMES ALCOHOLIC?

The best predictor of who will become an alcoholic is a positive family history of alcoholism. Family history studies of alcoholism show that alcoholism is common among families of alcoholics and that a given alcoholic is likely to have a family history for alcoholism. Moreover, family history, rather than environmental factors, is associated with the development of alcoholism. Contrary to popular belief, histories of deprivation and poverty do not predict alcoholism nearly as well as do biological factors. Furthermore, although mental illness is commonly associated with alcoholism, most alcoholics do not have a mental illness beyond their alcoholism.

Adoption studies reveal that the biological parents, and not the adoptive parents, predict alcoholism in the offspring. Thus, it is the relationship of sons and daughters to parents through blood linkage, and not who raised them or their environment, that predicts the onset of alcoholism. In addition, identical twins who share the same genes (DNA) have a greater prevalence of alcoholism than do fraternal twins who share half of the same genes (DNA), again implicating the biological origin of alcoholism. Importantly, although the prevalence of alcohol dependence typically has been greater in males, studies have shown that the biological risk for developing alcohol dependence is the same among women as among men.

When children are asked for reasons for initiating alcohol (and drug) use, peer influences and exposure to alcohol are the best predictors. Those children who associate with other children who consume alcohol are more likely to try alcohol and use it more often. Other factors, such as poverty and social deprivation, do not predict alcohol use; in fact, certain racial populations such as black males are negatively correlated with onset of alcohol dependence (i.e., they have lower rates of alcoholism). Thus, we can predict alcohol use and onset of dependence with a family history and exposure to alcohol, particularly if an individual is biologically related and exposed to alcohol by peers. Physicians can do well in assessing the risk for onset of alcohol dependence, and who might actually be alcoholic, by inquiring about patients' family histories of alcoholism and patients' association with other drinkers.

2. OTHER DRUG USE ASSOCIATED WITH ALCOHOL DEPENDENCE

Other drug use is commonly associated with alcohol use and dependence. For instance, more than half of those identified as alcoholic will have at least one other drug dependence. This is somewhat age dependent; younger alcoholics are more likely to have another drug dependence. At least 80% of alcoholics are dependent on nicotine, with the vast majority smoking cigarettes. Conversely, 30% of those with nicotine dependence are dependent on alcohol. Cannabis (marijuana) dependence is probably the next most common drug dependence among alcoholics, particularly among younger alcoholics. Most cocaine addicts use alcohol, and many qualify for alcohol dependence, as do most heroin addicts.

Longitudinal studies tend to demonstrate alcohol as a gateway drug, followed by nicotine, for those who go on to develop other drug addictions such as cocaine and heroin. Surveys of high school-age students show that 80 to 90% of students have consumed alcohol during the past year and that 5 to 10% drink daily. Also, the mean age of onset of alcoholism in the U.S. population is 21 years in males and 24 years in females, indicating that alcoholism is a youthful disorder that begins to be prevalent during the teenage years. Initiation of other drug use also occurs during these vulnerable developmental years, when biological and especially peer factors are operative.

3. DEPENDENCE SYNDROME AND SCREENING INSTRUMENTS

3.1. Syndromes

The dependence syndrome, as described in the fourth edition (text revised) of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR), defines a maladaptive pattern of alcohol use leading to clinically significant impairment or distress, as manifested by three or more of the following occurring at any time during the same 12-month period:

- Tolerance (need for increase in dose or loss of effect)
- Withdrawal (typical of alcohol withdrawal: anxiety, dysphonic mood, muscle aches, insomnia, nausea, vomiting)
- Use of larger amounts for longer periods of time than intended
- Persistent desire or unsuccessful attempts to cut down or control alcohol use
- Preoccupation with acquiring alcohol (e.g., frequently in the presence of alcohol; giving up or reducing important social, occupational, or recreational activities due to alcohol use)
- Alcohol use despite knowledge of adverse physical or psychological problems caused or exacerbated by alcohol (e.g., depression; anxiety; restricted options in daily living; pursuit of drugs to the exclusion of social, occupational, and normal interpersonal relationships; poor motivation to solve pain problems through evaluation and treatment; resistance to alternative resolutions to life problems)

Pervasive to these criteria is a loss of control over the use of alcohol, whether an inability to resist initiating alcohol use or an inability to modulate the amount

used during a given episode of alcohol consumption. Accordingly, the dependence syndrome mirrors the following basic definition of behavioral addiction:

- Preoccupation with acquiring alcohol
- Compulsive use of alcohol (continued use despite adverse consequences)
- Pattern of relapse to alcohol use despite adverse consequence

The neuropharmacological basis for behavioral addiction or dependence on alcohol lies in the phylogenetically ancient portion of the brain in the limbic system, which is responsible for instinctual drive states and emotions. The brain center responsible for behavioral addictive use (and dependence) lies in the mesolimbic pathway, which extends from the ventral tegmentum in the midbrain to the nucleus accumbens in the limbic forebrain. Scientific studies show that stimulation of the mesolimbic pathway with alcohol and other drugs reinforces compulsive use of alcohol that closely resembles the out-of-control addictive use seen in patients.

3.2. The CAGE and MAST

As screening instruments, the CAGE (Cutting down, Annoyance by criticism, Guilty feeling, and Eye-openers) and MAST (Michigan Alcohol Screening Test) are useful in identifying problematic use of alcohol and probable alcohol dependence in individuals. In the CAGE, individuals are asked whether they find it hard to cut down, whether others are annoyed by their alcohol use, whether they feel guilty about drinking, and whether they use alcohol as an eye-opener in the morning or early in the day to relieve distress (usually symptoms of withdrawal from alcohol). A positive answer to one question means a possible diagnosis of alcohol dependence, and a positive answer to two questions means a probable diagnosis. However, the CAGE is a screening instrument that requires a follow-up clinical assessment for a revised DSM (DSM-IV-R) or similar objective diagnostic scheme for definitive diagnosis.

The MAST is a self-administered questionnaire that comes in various lengths (e.g., brief, standard), depending on the number of questions indicating a diagnosable alcohol dependence according to the number of positive answers. As with the CAGE, the MAST requires a follow-up clinical interview to confirm the diagnosis of alcohol dependence.

4. ALCOHOLISM TREATMENT: PHARMACOLOGICAL APPROACHES

We know well that pharmacological treatment of withdrawal from alcohol or medical detoxification reduces morbidity and mortality from chronic alcohol use. The mortality from untreated delirium tremens ranges between 20 and 50%, and untreated alcohol withdrawal can complicate other conditions associated with alcohol withdrawal such as cardiovascular problems (e.g., abnormal heart rhythm, hypertension).

The reliable and commonly used medications to treat alcohol withdrawal are from the benzodiazepine class and include diazepam (Valium) and lorazepam (Ativan). Benzodiazepines share cross-tolerance and dependence with alcohol and are effective in suppressing signs and symptoms of withdrawal from alcohol in the brain at the gamma amino butyric acid (GABA) receptors on nerve cells. These are particularly effective medications to treat withdrawal when used in the short term under clinical supervision for alcohol withdrawal.

Moreover, pharmacological management of alcohol withdrawal improves compliance with behavioral approaches to alcohol dependence in promoting abstinence from alcohol. Alleviation of the noxious symptoms of withdrawal, such as anxiety, depression, malaise, and intense cravings for more alcohol, will reduce the risk for continuous alcohol consumption and provide a transition to the abstinent state. Behavioral management is typically not effective in the setting of active alcohol use due to the poor insight and judgment and the reduced motivation in the intoxicated and withdrawal states from alcohol use.

5. PSYCHIATRIC AND MEDICAL COMPLICATIONS

Alcohol regularly induces or causes a plethora of psychiatric symptoms in varying degrees of severity. Depression and anxiety can be expected to occur in virtually any chronic drinker (e.g., daily or weekly consumption). Correspondingly, these symptoms usually subside within a few days following cessation and during abstinence from alcohol. Predictably, chronic drinkers experience sadness, loss of energy, anhedonia, hopelessness, and helplessness that reaches degrees equivalent to those of major depression. In addition, suicidal thinking is common among drinkers; alcoholism is the most common diagnosis among those attempting or completing

suicide. Moreover, 25% of alcoholics commit suicide. Often, these suicidal thoughts subside within days of abstinence from alcohol.

Anxiety is a prominent state during alcohol withdrawal, and most chronic drinkers spend some portion of the day in withdrawal as the blood alcohol level drops. Also, tolerance to alcohol diminishes with chronic intake, such that greater symptoms of anxiety and depression reflect increasing dependence on alcohol. Usually, anxiety and depression subside with abstinence within a few days.

Occasionally, visual and auditory hallucinations, as well as delusions (mostly paranoid in type), can occur in chronic drinkers. Typically, these subside with abstinence, although short-term treatment with antipsychotic medications may be required.

Importantly, 50% of those with significant psychiatric diagnoses will use alcohol and often qualify for an alcohol dependence diagnosis. Although a presumptive dual diagnosis can be made on the basis of history and mental status examination, abstinence from alcohol over time is often required to make a definitive diagnosis to exclude the alcohol-induced effects on mood and thought.

6. ALCOHOLISM TREATMENT: BEHAVIORAL APPROACHES

Although there are many studies on a variety of behavioral approaches for alcohol problems, these methods are not designed for “typical” alcoholics as defined in the DSM-IV-R. Consequently, brief interventions do not work well in individuals who have actual alcohol dependence with the concomitant loss of control over alcohol use. Moreover, studies of behavioral management approaches typically do not provide long-term follow-up of their effectiveness beyond a few months. These approaches have a variety of names, such as relapse prevention and motivational enhancement, but most are derived from cognitive behavioral techniques. However, one approach termed “12-step facilitation” shows long-term positive results principally due to referral to 12-step groups such as Alcoholics Anonymous (AA).

An approach called “controlled drinking” is a misnomer and has caused substantial confusion, and ultimately harm, to those who suffer from alcohol dependence. In studies on controlled drinking, abstinence was the best predictor of those who experienced the fewest adverse consequences from alcohol use

following controlled drinking exercises. Moreover, the mortality from these controlled drinking techniques during follow-up was high among the study participants. Carefully constructed studies of actual alcoholics revealed that once loss of control over alcohol use manifested itself, the return to controlled drinking was not possible. Thus, abstinence is required to prevent adverse consequences from alcohol once alcohol dependence is established in individuals.

Importantly, behavioral approaches that employ the 12-step approach to the treatment of alcohol dependence show significant abstinence rates from alcohol. These approaches incorporate cognitive behavioral management with a focus on alcoholism as an independent disease that responds to treatment and recovery methods over time. Typically, treatment of alcoholism occurs in inpatient and outpatient settings following detoxification from alcohol and concentrates on increasing the individual's ability to refrain from relapse to alcohol and to maintain the abstinent state.

Outcome studies show that following a treatment experience in a structured inpatient or outpatient treatment program, 60% of patients achieve abstinence at 1 year no matter what follow-up care they may receive. However, they achieve abstinence rates of 70% if they attend continuing care in the treatment program (20–30%) or attend 12-step groups regularly (50% attended at least one AA meeting per week). In addition, they improve their abstinence rates to 80% if they both receive continuing care and attend AA meetings.

7. LONG-TERM RECOVERY FROM ALCOHOLISM

Although spontaneous recovery from alcoholism occurs, the only assurance of long-term abstinence supported by empirical data and clinical experience is continuous attendance in AA. Surveys of its members reveal an 83% probability of abstinence for the next year if an individual is abstinent between 1 and 5 years with regular attendance of at least one AA meeting per week and a 91% probability of an additional year if the individual is abstinent in AA for more than 5 years.

Clinical experience shows that relapse to alcohol use is very uncommon for someone who attends AA meetings regularly, particularly after being abstinent in AA for more than a year. However, for those who relapse, their attendance at AA meetings had ceased for a substantial period prior to the relapse, typically years

before the actual relapse to alcohol use. Also, use of other addicting drugs, such as cocaine, cannabis, heroin, and nicotine, and/or use of addicting medications, such as opiate analgesics and benzodiazepines, render continuous abstinence difficult and reliably predict relapse to alcohol.

8. BENEFICIAL VERSUS HARMFUL EFFECTS OF ALCOHOL

Some studies have indicated a modest but positive effect of reducing the risk of cardiovascular disease or heart attacks in those who regularly consume one to two drinks of alcohol per day. These studies are featured in influential medical journals, implicating alcohol as a therapeutic agent. Despite the overwhelming evidence of the harmful effects of alcohol on health, these studies advocate the use of alcohol without instructing individuals about its untoward or adverse effects.

For instance, studies show that the same amount of alcohol that is described to be beneficial (one or two drinks per day) will significantly reduce intelligence quotients (IQs), resulting in poor attention, poor concentration, and impaired short-term memory. Studies of alcoholics show that chronic alcohol use causes reduced cognitive capacities that tend to reverse with abstinence from alcohol. Importantly, the reduced IQs correlated with the age of the drinker; thus, the intended audience for putative efficacy on incidence of heart disease is those who are at high risk for the dementing properties of alcohol—namely older adults.

9. PREVENTION OF ALCOHOL USE AND PROBLEMS

Currently, our public health policy and controls for alcohol consumption are archaic and counterproductive. The example of advocating alcohol to reduce heart disease in high-risk populations is indicative. Thus, alcohol abuse is not commonly thought of as a

health issue but rather is regarded as a legal and moral issue. The policies usually do not support educating young people and adults on the responsible use and the potential pitfalls and risks of alcohol use, particularly by those at high risk. Most discussions focus on the legal age for drinking and the legal limit of intoxication. Not well discussed are that 80% of homicides occur in the setting of alcohol and that alcohol use and dependence is the leading risk factor for suicide at any age.

Despite these well-established adverse consequences and firm knowledge that onset of alcohol use and alcohol problems occur at young ages, there is blatant advertising clearly and convincingly targeted to these high-risk populations. Our controls over exposure to alcohol for vulnerable populations, and our education in elementary, middle, and high schools, are woefully lacking if we are to protect these vulnerable and at-risk populations. Currently, we do not hold producers of alcohol accountable for the high rate of alcohol-related consequences (in the billions of dollars) due to our lack of policy to protect the public against adverse consequences from alcohol use.

GLOSSARY

anterograde amnesia The inability to learn and recall events and facts following the onset of amnesia.

declarative memory Memory for concepts, facts, and personal events; declarative memories are accessible to consciousness and can be retrieved at will.

episodic memory A component of declarative memory; it refers to memories of personally experienced events, placed in specific spatial and temporal contexts.

nondeclarative memory A collection of unconscious forms of memory, including procedural memory, simple forms of conditioning, and priming.

priming A component of nondeclarative memory referring to the facilitation in processing information as a consequence of prior exposure to that information or to related information.

procedural memory A component of nondeclarative memory referring to the acquisition of skills and habits through repeated practice.

retrograde amnesia The inability to retrieve information about facts and events known prior to the onset of amnesia.

semantic memory A component of declarative memory referring to one's fund of knowledge of facts, concepts, and word meanings; these memories are impersonal and contain no reference to the time and place in which they were formed.

Through the study of amnesic patients, cognitive neuroscience has advanced our understanding of the processes that underlie learning and remembering. Memory is now understood to be a collection of functional systems, with each contributing uniquely to the storage and retrieval of information. The study of neurological populations with lesions that interfere with the function of specific components of memory has revealed distinct roles for these memory systems. This understanding has provided the theoretical foundation for evidence-based treatment approaches.

1. INTRODUCTION

In 1606, Shakespeare's Lady Macbeth described memory as "the warder of the brain," as a function that somehow stands apart from the brain's other cognitions while bearing witness to them. She made this reference while planning to induce a temporary amnesia in the king's attendants by getting them drunk. Her aim in doing so was to ensure that the attendants would not recall the events surrounding her husband's intended murder of the king. She knew that after the

deed was done and their alcohol-induced stupor passed off, they would be left witness to a blank, to a discontinuity in their experience, and not to the murder. For memory to be capable of keeping an account of the swift interplay of sensations, perceptions, and thoughts that make up events and thereby give experience its continuity, memory must itself have an underlying continuity. If it did not, there would be nothing for people to “go back to” that would allow them to witness an earlier event again, and Lady Macbeth would have had nothing to fear from any witnesses to her husband’s intended crime. Now, four centuries later, modern cognitive neuroscience is going beyond description. It investigates how memory enables people to actively bring the past into the present moment, thereby allowing them to experience their personal persistence through time.

The fact that memory can fail has been known for millennia, but its failure was not specifically called “amnesia” (from the Greek for forgetfulness) until relatively recently in 1786. In current common use, amnesia refers loosely and interchangeably to either one of two quite different states or to both of them. First, it refers to a state in which memories that were available for recall in the past have been lost and are no longer available in the present. Second, it refers to a state in which current experiences are not being kept account of and duly recorded, with the result that they will not be available for recall in the future. The first usage is reflected in the Oxford English dictionary definition of amnesia as “loss of memory” and roughly coincides with retrograde amnesia, whereas the second usage is reflected in the Merriam–Webster dictionary definition as “forgetfulness” and roughly coincides with anterograde amnesia. The loss of previously consolidated memories, on the one hand, and the inability to create and retain new memories, on the other, are states that can occur separately. However, more often than not, both occur together in the same individual following a single event, hence the tendency to refer to either or both of them without distinction by means of the same term “amnesia.”

In addition to its common meaning, the term “amnesia” has both a general sense and a specific sense in current scientific literature. In general, it refers to any pathological loss of the ability to acquire or recall information. In that sense, it encompasses psychogenic amnesia, posttraumatic amnesia following closed head injury, memory loss that occurs along with other major cognitive impairments in progressive degenerative neurological disorders such as Alzheimer’s disease,

and isolated global memory loss that characterizes the amnesic syndromes. In its more restricted use, it refers specifically to these latter syndromes, and it is in this sense that the term is used in what follows.

Early investigation of the amnesic syndromes proceeded both by means of clinical case descriptions and through the correlation of lesion analyses with deficits found through neuropsychological investigations. The most widely known of the early case studies was of the patient “H.M.,” and it is through studies of his memory function that the current understanding of amnesia began to unfold.

2. THE CONTRIBUTION OF PATIENT H.M.

At 9 years of age, H.M. suffered a head injury followed by seizures that became more frequent and more severe over the subsequent 18 years. In 1953, as a treatment of last resort, he underwent an experimental neurosurgical operation in which a large portion of the medial temporal region of his brain was removed bilaterally. That extensive resection was successful in reducing his seizures, but it left him with an unexpected devastating memory loss.

One striking finding that came to light in the early studies of H.M.’s memory loss was that his profound forgetfulness and loss of personal memories had occurred without any damage to his general intellectual ability, attention, and language. This discovery established that normal medial temporal lobe functioning is necessary for the accumulation of memories. However, the fact that its dysfunction does not interfere with the attention, thoughts, and perceptions that give rise to experiences in the first place suggests that memory is specifically linked to the function of the medial temporal lobe. Further studies of H.M.’s memory impairment led to the current understanding of the characteristics of hippocampal amnesia. They also revealed that memory, rather than being a unitary capacity, is composed of several functional systems, not all of which are impaired in amnesia. Those systems fall into two major classes. The first group involves nondeclarative memory, that is, the form of memory that functions without awareness. The second group involves declarative memory, that is, the form of memory that supports conscious retrieval of experiences. It is the latter form of memory that is impaired in amnesia.

3. IMPAIRED MEMORY IN AMNESIA: DECLARATIVE MEMORY

After H.M.'s operation, it became apparent that he had suffered damage to the memory system that supports the conscious (intentional) retrieval of experiences. Not only did he fail to remember the events of his then current day-to-day life, but he also could not recall memories he had accumulated over much of his life prior to the onset of his amnesia. This clinical profile of severe anterograde amnesia together with an extensive retrograde memory impairment is typical of hippocampal amnesia.

3.1. Retrograde Amnesia

H.M.'s inability to recall memories that he had formed prior to the onset of his amnesia extended back approximately 11 years. The density of his retrograde amnesia followed Ribot's law, a semiquantitative description offered in 1881 that states that the "loss of memory is . . . inversely [related to] the time that has elapsed between any given incident and the fall (injury). . . . The new dies before the old." H.M. showed just such a temporal gradient. His inability to recall autobiographical and public events from shortly before his operation was total, but his amnesia was found to be less dense as testing probed further back in time and he was able to remember more and more.

Investigation of patients with a variety of amnesic syndromes has demonstrated that such a temporally graded retrograde amnesia is common and that its severity and duration tend to vary with the size of the brain lesion. Retrograde amnesia can affect both the recall of autobiographical and public events (episodic memory) and the retrieval of facts and concepts (semantic memory) that were known before the onset of amnesia. However, episodic and semantic memory are differentially affected across syndromes. For example, some patients have severe retrograde amnesia for events together with relatively preserved memory for facts and concepts, whereas others show the opposite pattern with severely impaired semantic memory but relatively preserved episodic remote memory.

The finding of a graded decrease in the density of memory loss as probing moves backward through time starting from the onset of amnesia establishes two important facts regarding how memories are stored and retrieved. First, it establishes that a

functional medial temporal region is required for permanent learning of new information. Second, it indicates that the medial temporal lobe is not the ultimate repository of long-term memories given that long-established memories can survive and be available for recall despite the presence of medial temporal damage. It has since been found that long-term memories are stored in the neocortex, specifically in the lateral temporal regions. This is confirmed by the fact that in patients with lesions in these areas, even old memories can be permanently lost, so that their retrograde amnesia is not temporally graded. Thus, the medial temporal lobes and neocortical areas make unique contributions to information storage. When an event is originally experienced, separate aspects of the event, such as its perceptual characteristics, emotional connotations, and associated thoughts, are processed in initially unconnected sites throughout the cortex, as determined by the functional specialization of various parts of the brain. The medial temporal lobes, and especially the hippocampus, provide the glue that allows these diverse aspects to be linked together into a single representation. When a part of any event is recalled again, the hippocampus is engaged, and it simultaneously reactivates the spatially separated cortical traces that together make up the brain's representation of the whole event. With repeated activation over time, links are established among the involved neocortical sites. Eventually, these separate neocortical sites that collectively represent a single event become interlinked to the extent that hippocampal activation is no longer necessary for recall of the event as a whole. It is at that point that the consolidated memory can survive medial temporal lobe damage.

3.2. Anterograde Amnesia

The nature of the impact of H.M.'s neurosurgery on his cognition gradually became apparent when it was noticed that H.M. consistently failed to recall having eaten a meal and that he failed to develop any ability to get to know the people who provided his daily care. This anterograde amnesia was so pervasive that he could hold onto new information for only a few seconds and then only if there was no distraction. If his attention was diverted, the information faded away and was not available for recall. As was noted earlier, the normal functioning of the hippocampus and surrounding medial temporal lobe structures is crucial for forming and storing new memories. In general, the severity of anterograde amnesia is proportional to the extent of

damage to medial temporal structures. Furthermore, because the hippocampus receives input from a variety of neocortical regions that process information in the various sensory modalities, such anterograde loss is invariably global; that is, it involves both verbal and nonverbal information in all possible modalities of presentation. Such dense global anterograde memory impairment is the hallmark of medial temporal lobe amnesia.

Anterograde amnesia is evaluated in the clinic through tasks that measure recall and recognition of information to which the individual is exposed during a testing session. Recall tasks require that recently learned information be consciously and deliberately retrieved in response to a question, whereas recognition tasks require that previously encountered information be distinguished from, and so recognized among, foils. The recognition format is generally easier for normal individuals because it requires less retrieval effort than does recall. Recognition is thought to be easier for individuals with intact memories because recall depends on conscious and effortful recollection, whereas recognition can be supported not only by recollection but also by familiarity. Familiarity refers to the sense of knowing that arises when a stimulus is processed with ease. Recollection and familiarity can be distinguished from one another experientially. For example, consider the situation where a man hears his name being called out while he is in a crowd. He turns and sees the woman who called his name and has a short conversation with her. The woman is familiar to the man, but he cannot recall any context that accounts for that familiarity. Several days later, the man receives a telephone call from the woman in which she identifies her place of work and, at that moment, he knows who she is and is flooded with memories of details and events. Sudden recollection replaces felt familiarity. In the laboratory, patients with amnesia secondary to medial temporal lobe damage generally show impairments on both recall and recognition tasks, suggesting that familiarity and recollection both are impaired. However, some amnesic patients show relatively preserved recognition memory, and this may reflect their residual ability to use familiarity as a basis for remembering.

Patients with lesions involving the frontal lobes, either directly or indirectly, can also have severe deficits in memory. However, although their performance is impaired on tasks of free recall, they show normal performance on tasks that require the recognition of previously learned information. This performance disparity between recall and recognition is

due to the distinct roles of the medial temporal lobes and the frontal lobes. The medial temporal lobes contribute to the encoding, storage, and retention of newly learned information, whereas the frontal lobes support the organizational and strategic aspects of memory necessary for developing encoding and retrieval strategies, monitoring and verifying memory output, and setting order within the recalled memories.

4. PRESERVED ASPECTS OF MEMORY IN AMNESIA: NONDECLARATIVE MEMORY

H.M.'s severe amnesia notwithstanding, some aspects of his memory functioning were found to be intact following his surgery. In contrast to his inability to consciously retrieve information acquired before and after onset of his amnesia, it was found that H.M. showed evidence of learning on tasks that did not require his awareness of the learning episode.

4.1. Procedural Memory

Careful experimental study brought to light that H.M. was able to acquire specific perceptual–motor skills as well as do normal individuals. One such motor task involved his tracing the outline of a star with a stylus while gaining feedback of his ongoing performance through the reflection of his performance in a mirror. H.M. improved with repetition exactly as did normal individuals. But for him, each trial was experienced as if it were his first trial, despite his steady improvement. He had no way of knowing that he was getting better at it, as normal people did. This finding was one of the first to show that procedural memory (i.e., the ability to know how) is distinct from declarative memory (i.e., the ability to know that something occurred). It also established that procedural memory does not depend on the integrity of the medial temporal lobes. Procedural memory develops gradually through repetition without any requisite awareness that the skill is being learned.

4.2. Repetition Priming

Priming is another form of learning that occurs without conscious awareness. It is defined as a bias or facilitation in identifying or responding to certain information to which one has been exposed previously. In contrast

to procedural learning, the effect of priming can be seen following a single exposure. In a typical priming task, an individual is asked to view a list of words or pictures. The individual is then asked to perform a seemingly unrelated task such as naming words or identifying degraded pictures. Unbeknownst to the individual, some of the stimuli in the second task were part of the list of stimuli that were seen in the first task, whereas others are presented for the first time. Priming is in evidence when naming or identification of previously seen stimuli occurs faster or more accurately than does identification of stimuli not seen previously. Amnesic patients show intact priming across a broad variety of tasks. Sometimes priming reflects facilitation of the processes that support the perception of stimuli, whereas other times priming reflects the facilitation of processes that support conceptual analysis (i.e., meaningful interpretation) of stimuli. Both perceptual priming and conceptual priming are independent of medial temporal structures, and both depend on distinct neocortical regions.

5. AMNESIC SYNDROMES

Amnesia can result from a variety of etiologies that cause damage to various regions of the brain. For example, diencephalic amnesia, the memory disorder of patients with Korsakoff's syndrome, arises from damage to structures that make up the diencephalon, particularly the mammillary bodies, the anterior thalamic nuclei, and the medial dorsal thalamic nucleus. Basal forebrain amnesia, in contrast, arises in patients with a history of rupture and repair of an anterior communicating artery (ACoA) aneurysm and is caused by damage to structures of the basal forebrain, the septum, and frontal brain regions. The following is an overview of the clinical characteristics of five of the more common amnesic syndromes.

5.1. Herpes Simplex Encephalitis

Herpes simplex encephalitis (HSE) is an acute inflammation of the brain caused by a herpes simplex virus infection. Some patients recover fully following infection, but most are left with a cluster of cognitive deficits that include a memory disorder. The heterogeneous pattern of these cognitive impairments reflects the extent and variability of damage to the brain. Among those patients who recover, a small number are left with a circumscribed amnesic syndrome similar to that of H.M. The fact that these two forms of amnesia share a clinical

profile is not surprising given that the herpes simplex virus preferentially affects medial temporal brain structures, including the hippocampus and adjacent entorhinal, perirhinal, and parahippocampal cortices. In all postencephalitic patients, the extent of any anterograde memory impairment is proportional to the amount of damage to the medial temporal lobes. Although some patients are incapable of any new learning, others can learn and can benefit from increased study time, external cues, and/or repeated exposure. Because the herpes virus can affect the brain asymmetrically, the pattern of anterograde memory loss will also depend on the laterality of damage. The greater the damage to the right temporal region, the greater the difficulty in performing nonverbal/visual memory tasks (e.g., memory for faces), whereas the greater the damage to the left temporal region, the greater the deficit in verbal memory.

Postencephalitic patients with damage extending to the lateral temporal lobes, the region where memories are permanently stored, will have dense retrograde amnesia for autobiographical and public information with little or no temporal gradient. Damage to the right anterior temporal region interferes primarily with retrieval of autobiographical memories, whereas damage to the left temporal cortex impairs semantic memory.

5.2. Anoxia

Amnesia can result from damage to, or death of, brain tissue due to a lack of oxygen supply to the brain. This can be caused either by reduced blood flow, such as in cardiac arrest or strangulation, or by normal perfusion with hypoxic blood secondary to respiratory distress or carbon monoxide poisoning. When the oxygen supply to brain tissue is disrupted, compensatory mechanisms that maintain cerebral homeostasis are triggered immediately. These protective autoregulatory mechanisms, although effective in adjusting for sudden short-lived changes, will eventually fail in the face of sustained oxygen deprivation. Oxygen deprivation for 3 to 8 minutes will trigger the release of excitatory neurotransmitters that can result in damage to the hippocampus. Shorter events may also damage regions that are perfused by terminal vascular branches or that lie in the watershed regions because these areas are deprived of oxygen early on. Longer lasting events will result in neuronal damage that extends to the cerebellum, the basal ganglia, the thalamus, and neocortical areas. The outcome following an anoxic event depends on many factors, including the cause and duration of the event as well as the age and health status of the individual.

Therefore, it is not surprising to find variability in the clinical profiles associated with anoxic events.

Most individuals who have suffered an anoxic brain injury experience a memory disorder along with other cognitive impairments. On occasion, an isolated amnesic syndrome is documented secondary to a lesion in the hippocampus. When the lesion is limited to the CA1 area of the hippocampus, there is moderately severe anterograde amnesia together with very mild retrograde loss. When the lesion extends beyond the CA1 area of the hippocampus but remains limited to the hippocampal formation, there is severe anterograde memory impairment and more robust retrograde memory impairment that can extend back more than 15 years. More commonly, however, anoxic patients have a memory impairment that is akin to that seen in patients with damage to the frontal brain region due to disruption of frontal–subcortical circuits as a result of damage to watershed zones in the cerebral cortex. Rather than encoding, storage, and retention deficits, these patients demonstrate impairments at the level of the organizational and strategic aspects of memory.

5.2.1. Anterior Communicating Artery Aneurysm

Memory deficits, along with associated behavioral disorders, frequently follow rupture and surgical repair of an ACoA aneurysm. Such deficits vary from a very mild impairment to a severe amnesic disorder called basal forebrain amnesia. This wide variability reflects the fact that the ACoA perfuses a broad anatomical brain region, all of which is vulnerable in the event of rupture to damage from infarction, either directly or secondary to subarachnoid hemorrhage, vasospasm, or hematoma formation. Basal forebrain amnesia is usually due to damage to the septal nucleus and the subcallosal area. Disruption of hippocampal functioning may play a role in the amnesia of at least some patients with ACoA aneurysm because several basal forebrain nuclei contain a large number of cholinergic neurons that innervate the hippocampus as well as large neocortical regions. Disruption of frontal network systems can occur and may also contribute to the quality of the memory deficit seen in some ACoA aneurysm-related forms of amnesia.

The severe deficit in recall found in basal forebrain amnesia shares superficial similarities with the anterograde memory impairment that characterizes medial temporal lobe amnesia. However, the deficit in basal forebrain amnesia is due to inefficient encoding and not to the failure of consolidation that characterizes

medial temporal amnesia. As a result, ACoA patients will benefit from the use of encoding strategies, whereas patients with medial temporal lobe damage will not. Another difference is found in the performance of ACoA patients on recognition tasks, where they are found to succeed more often than their medial temporal lobe counterparts. This recall–recognition disparity is attributed to the frontal executive component of the amnesia that follows ACoA aneurysm, particularly the disruption of strategic effortful search processes that give access to information stored in memory. Another executive contribution to the disorder is the tendency of some ACoA patients to score many false positives on recognition tasks, a finding that suggests an additional impairment in the ability to monitor the outcome of a memory search. Retrograde memory is nearly always impaired in amnesia secondary to ACoA aneurysm, and it invariably shows a temporal gradient. However, patients do appear to benefit substantially more from cueing than do other amnesic groups, suggesting that impaired retrieval efficiency contributes to both the anterograde and retrograde aspects of their amnesia.

5.2.2. Stroke

Amnesia is a common consequence of infarction of the posterior cerebral artery (PCA). It results from neural tissue damage caused by the interruption of blood flow to a large part of the medial temporal lobes, particularly the posterior two-thirds of the hippocampus, the parahippocampal gyrus, and other critical pathways that connect the hippocampus to surrounding brain areas. A more posterior extension of the lesion will result in other neuropsychological deficits in addition to the memory disturbance, for example, visual field defects and other visual disturbances that may affect reading and cause problems with color identification, space perception, and/or object naming. The typical memory disturbance associated with bilateral PCA infarction is an inability to establish new memories in the presence of preserved intelligence and attention. Retrograde memory problems are also often present. There have been several reported cases of bilateral PCA infarction that spared the medial temporal lobes proper but that involved the occipital lobes bilaterally as well as the deep white matter of both the occipital and temporal lobes. These patients present with a visual amnesic syndrome that results from the disconnection between occipital cortices involved in visual processing and temporal brain regions supporting memory. There have been other reported cases in which the PCA

infarction was unilateral. Patients with infarction of the left PCA present with a selective verbal memory deficit, whereas patients with infarction of the right PCA have preserved verbal memory but impaired visual processing skills and impaired visual memory.

Amnesia can also be caused by thalamic infarction. In such cases, the severity of the memory impairment is related to the site of damage within the thalamus. Lesions that damage the mammillo–thalamic tract, in particular, have been associated with severe anterograde amnesia. Infarction of the medial dorsal thalamic nuclei has also been associated with memory impairments, but it appears that the damage must extend beyond the medial dorsal nucleus to include the mammillo–thalamic tract or anterior nucleus for the development of a severe amnesic disorder. Because the thalamus has rich connections with the frontal lobes, this anterograde amnesia is also accompanied by an increased sensitivity to interference and by impairments in executive functioning. As with other amnesic syndromes, left-sided lesions result in impairments on tasks of verbal learning, whereas right-sided lesions result in nonverbal/visual memory impairments. Retrograde memory deficits following thalamic infarction are variable; some patients are found to have little impairment in remote memory, whereas others demonstrate severe long-term memory impairments.

5.2.3. Wernicke–Korsakoff Syndrome

Wernicke–Korsakoff syndrome (WKS) is seen in patients with a history of long-term alcohol abuse in association with poor nutrition and a lack of Vitamin B1 (thiamine). In acute Wernicke's encephalopathy, patients exhibit confusion, a gait disorder (ataxia), and abnormal eye movements (oculomotor palsy). Treatment with large doses of thiamine may result in improvement in, or even reversal of, some of these symptoms. However, most patients are left with a permanent dense amnesic disorder referred to as Korsakoff's syndrome. This amnesic syndrome arises from damage to the thalamic nuclei, the mammillary bodies, and the frontal system.

Patients with WKS suffer from both anterograde and retrograde amnesia. Several explanations have been proposed to account for their episodic memory impairment. Although early models emphasized their superficial and deficient encoding strategies or their failure to inhibit competition from irrelevant material at the time of retrieval, current views agree that an explanation of their learning deficits is best accounted for by a theory that integrates both encoding and retrieval processes.

The retrograde amnesia in WKS has a steeper temporal gradient than that found in medial temporal lobe amnesia. The concomitant presence of frontal dysfunction in Korsakoff's patients is believed to account for their poorer performance on remote memory tests. Intelligence is usually preserved in Korsakoff's patients, but there are often associated cognitive and neurobehavioral deficits that are unique to this patient population. In particular, some combination of impaired planning and initiation, passivity, apathy, confabulation, and limited insight is nearly always found. These symptoms are thought to arise from associated frontal dysfunction.

6. NEUROPATHOLOGY OF AMNESIA

For centuries, any lapse in the functioning of the warden of the brain's cognitions was described, and eventually defined, as simple forgetfulness. During the first half of the 20th century, it was thought that memory, as the cognition that keeps account of other cognitions, was not dependent on the activity of a circumscribed brain region (as are those other cognitions) but rather was directly dependent on the functioning of the whole brain. There also emerged an opposing view that held that memory function was localized in the brain. There was no conclusive experimental evidence for either view until, at midcentury, the consequences of H.M.'s surgical resection decided the matter in favor of a localized brain representation for declarative memory. Later evidence similarly established distinct localizations for priming and procedural learning, two forms of nondeclarative memory. Cognitive neuroscience has since clarified the nature of those localizations in substantial detail.

6.1. Declarative Memory

Declarative memory is mediated by a group of interconnected structures that are part of the extended limbic system. Within the limbic system, two interacting memory circuits can be identified: the Papez circuit and the basolateral circuit. The Papez circuit is composed of the hippocampus, the fornix, mammillary bodies, the anterior thalamus, and the posterior cingulate gyrus (with additional connections to the basal forebrain via the fornix). The basolateral circuit is composed of the amygdala and surrounding perirhinal cortex, the dorsomedial thalamus, and the prefrontal cortex. Although damage to any part of either circuit in isolation will impair memory

function, damage to both circuits will result in a profound amnesic disorder. The contribution that each circuit makes to memory function remains a matter of active debate. On one side of the discussion are those who believe that both circuits are involved in all aspects of declarative memory. Lesions affecting both circuits would, therefore, be expected to result in more severe amnesia simply because more of the relevant neural tissue would be dysfunctional. Others suggest that the two circuits make qualitatively different contributions to memory. In particular, they suggest that the hippocampus and related structures in the Papez circuit support the recollection of episodic information, whereas the perirhinal cortices and related structures in the dorso-lateral circuit support judgments of familiarity. In this case, damage to both circuits would impair more functions than would damage to either circuit alone and, therefore, would explain current clinical findings. Future studies of patients who present with selective lesions will be needed to resolve this debate.

The finding of temporally graded retrograde amnesia in association with damage to the medial temporal lobe reveals that this brain region plays a critical role in the establishment of memory and also suggests a subsequent slow transfer of memory to other brain regions. The finding that old memories, both autobiographical and semantic, are left untouched by damage limited to the hippocampus suggests that memories are not stored there. Long-term storage takes place in neural networks in the neocortex.

6.2. Nondeclarative Memory

Nondeclarative memory systems are supported by widely varying brain regions, depending on which sensory mode is involved in a given task and whether or not performance of the task involves higher associative functions. For example, evidence from neuroimaging studies, together with clinical data from individuals who have suffered focal cortical damage, has established that priming finds its substrate in the neocortex. Specifically, the substrate for perceptual priming is the relevant unimodal cortex (i.e., visual priming in the occipital visual cortex, auditory priming in the auditory cortex), whereas the substrate for conceptual priming is located in multimodal association cortices. The same brain regions that are involved in the initial processing of information are also involved in the more fluent processing that follows repetition, and priming is accompanied by a reduction in neural activity in these regions.

Although priming manifests after a single exposure to a stimulus, procedural memory requires a series of repetitions for its manifestation. Consequently, the involvement of relevant brain regions and their changes over time is more complex for procedural memory. The initial acquisition of motor skills engages the motor/prefrontal cortices, basal ganglia, and the cerebellum. Over time, however, two opposite tendencies are evident. On the one hand, as procedural learning develops and a skill can be performed with less effort, the prefrontal cortex and cerebellum gradually become less activated. This repetition suppression effect mirrors that seen in the neural substrate for priming. On the other hand, repetition leading to increased skill engages the higher order motor cortex more than it had initially been engaged. This latter finding indicates expanded cortical involvement in the retention of procedural memory for motor tasks that mirrors the increased neocortical involvement in the long-term retention of declarative memories.

7. APPROACHES TO TREATMENT OF AMNESIC DISORDERS

The treatment of memory disorders aims at enhancing day-to-day memory functioning and routine so as to increase an individual's level of independence. The choice of treatment will depend on both cognitive and noncognitive factors. Noncognitive factors to be considered include psychosocial context (e.g., family situation, educational background, lifestyle habits) and emotional factors (e.g., level of insight, motivation, neuropsychiatric symptoms). Of critical importance among these factors are level of insight and motivation. Research has shown that interventions are unsuccessful in patients who fail to appreciate that their memory is impaired and/or who are unmotivated. In these patients, efforts should initially focus on increasing level of insight and/or motivation. Cognitive factors that must be taken into account include premorbid abilities and skills and postmorbid neuropsychological deficits, including a clear delineation of those areas of memory that are impaired and preserved. Within the context of a holistic individualized approach, a memory remediation program can be developed based on current understanding of the processes that support learning and memory.

Several treatment approaches for densely amnesic patients capitalize on nondeclarative memory

processes because this form of memory remains intact in most patients. The “vanishing cues” technique is an example of a treatment method that recruits preserved implicit perceptual memory processes to teach patients domain-specific facts or concepts. The technique takes advantage of patients’ preserved ability to complete studied items in response to word fragment cues. In a typical vanishing cue paradigm, patients are given a definition and are then presented with as many letters as is necessary to produce the target word. With training, the letter cues are gradually reduced until the patients can spontaneously generate the sought after information. Success has been achieved using this technique in teaching patients computer-related vocabulary, business-related terms, and novel concepts. Learning by means of this technique is slow and laborious but can lead to surprisingly good retention, particularly if the information to be learned uses a knowledge base that is already familiar to the individual. However, a caveat arises from the inherent reliance of the vanishing cues method on the perceptual cues given during learning. As a result, generalization has often been limited, and benefits have been found to be best when the information is used in situations similar to those where learning occurred.

Attention to training contexts may be important when using techniques that take advantage of preserved implicit memory processes. Because amnesic patients have no recollection of the learning episodes, they fail to remember their mistakes and consequently fail to benefit from ongoing error correction. Instead, incorrect responses made during learning are often unconsciously repeated, leading to errors becoming primed and more likely being repeated subsequently. To avoid the perpetuation of errors through priming, some investigators have emphasized the importance of “errorless learning” for patients who have explicit memory impairments. In errorless learning, the possibility of making errors is eliminated by using cues and prompts or by providing the correct answer. The approach has met with some success in teaching memory-impaired patients both new skills (e.g., use of a memory book, programming of an electronic organizer) and new knowledge (e.g., learning of new words). Errorless learning is thought to operate by strengthening residual explicit memory, either alone or together with implicit memory. Its applicability as a method to facilitate learning appears to be broad and promising because errorless learning principles can be applied to a variety of remediation methods.

Other treatment approaches capitalize on preserved procedural learning. Through repetition, skills and habits that are important for activities of daily living or occupation can be taught. Such skills can range from simple assembly tasks to more complex multistep tasks such as learning to type. A variety of compensatory aids (e.g., notebooks, scheduling books, diaries, alarms) and augmentative technologies (e.g., computers, personal digital assistants, paging systems) rely on procedural memory. The notebook is an example of a low-tech aid. It is usually created at the early stage of rehabilitation and contains sections aimed at drilling overlearned personal information (e.g., date of birth, age, address), information about immediate family members (including their telephone numbers), daily schedules, and a daily record of activities. The book is tailored to the individual and can be gradually increased in complexity. Electronic organizers, the most favored external memory aid among normal individuals, are now also being used by memory-impaired patients. Training in the use of such technology requires lengthy practice sessions, within and outside the rehabilitation environment, to foster generalization. Because the acquisition of new skills is time-consuming for everyone involved, careful consideration needs to be given as to whether an electronic device is appropriate for an individual before investing the time and effort. Factors that would argue against it include dense amnesia associated with poor insight, lack of initiative, impaired visual attention, poor motor control, and limited problem-solving skills. Patients who are good candidates for this technology are generally younger, have experience in using electronic devices, and have achieved higher educational levels. Devices used premorbidly are preferable because familiarity increases the likelihood that they will be used effectively outside the clinic.

The preceding examples illustrate approaches that focus on preserved memory systems to teach new skills and habits. Another approach focuses on enhancing impaired forms of memory to improve day-to-day episodic memory by means of internal strategies. Internal strategies require awareness of the learning method and recall of the strategy itself; therefore, they are of limited use to patients who are moderately or densely amnesic. However, they are useful for patients who have mild memory deficits secondary to impaired effortful encoding or retrieval, who have good awareness of their deficits, and who have adequate motivation. These patients are more likely to generalize their training to situations that go beyond the clinic setting.

Examples of internal strategies include mental retracing, feature–name association, and verbal elaboration by means of a story or an association—all of which are skills that promote the use of imagery. The choice of technique will depend on the memory process that is targeted for remediation. For example, techniques that focus on strengthening encoding, and therefore storage, are effective at remediating consolidation problems. Story elaboration is effective in linking together a list of unrelated words through the development of a scenario that features the target words. The use of verbal associations is often effective in recalling a surname. In all of these instances, repeated use of the strategy is important and spaced repetitions, at different times and in different contexts, generally increases the likelihood that information will be learned and become conceptually integrated within a matrix of old memories. Strategies that are most effective when the deficit is at the level of strategic processes that enhance encoding are those that increase the organizational structure of incoming information. For example, learning how to “chunk” incoming information is helpful in streamlining and organizing that information. Organizing information according to themes or categories can also structure learning so that a thematic cue can serve to trigger recall when necessary.

These remediation methods are guided by knowledge regarding the cognitive processes that support learning and memory. More than 50 years ago, the early clinical findings with H.M. and other patients informed the theoretical understanding of the functional systems that comprise human memory. Current cognitive neuroscience has evolved from those early findings and now, in turn, can inform clinical approaches to remediation that enable amnesics to function more effectively in their daily lives.

GLOSSARY

anxiety An emotion consisting of unpleasant thoughts and sensations as well as physical changes; it is a response to a situation or stimulus perceived to be threatening or dangerous.

arousal Traditionally defined as a generalized and undifferentiated physiological response to a stressor that is closely associated with negative emotions such as anxiety; research indicates, however, that the physiological responses to standardized stressors can differ significantly across individuals and are often unrelated to negative emotions such as anxiety.

Of all the psychological variables implicated in sport performance, anxiety is regarded to have the greatest impact. Putative explanations for why anxiety can degrade sport performance include diminished cognitive resources, a narrowing of the visual field, diminished motivation, and excessive muscle contraction or

co-contraction of opposing muscle groups that impairs coordination or results in physical injury. As a consequence, a wide variety of techniques have been used to assist athletes in controlling or reducing anxiety. Yet in spite of the general consensus within the field of sport psychology that anxiety harms sport performance, there are major disputes as to which theory best describes this relationship and as to what the most appropriate means are to measure anxiety in athletes. This article presents an overview of anxiety and sport performance literature. Limitations of traditional theoretical explanations are described, as are more recent sport-specific theories based on the premise of individual differences in the responses of athletes, with particular emphasis on the Individual Zones of Optimal Functioning (IZOF) model.

1. INTRODUCTION

Anxiety has been defined as an emotion consisting of dysphoric thoughts, unpleasant sensations, and physical changes that occur in response to a situation or stimulus perceived to be threatening or dangerous. According to most theories, anxiety consists of state and trait components. State anxiety indicates the intensity of anxiety experienced at a given moment and can fluctuate widely in intensity over a short time span.

Trait anxiety is a more stable factor that assesses the general tendency of an individual to experience elevations in state anxiety when exposed to stressors such as sport competition. Persons scoring high in trait anxiety should experience greater increases in state anxiety when exposed to a stressor than should persons scoring low in trait anxiety. The experience of anxiety as a response to a stressor such as sport competition is contingent on both an individual's perception of the stimulus and his or her ability to effectively cope with it. Because of this, sport competition may be perceived as threatening to some individuals, neutral to others, and enjoyable to still others.

1.1. Assessment of Anxiety

In sport psychology research, a variety of approaches have been used to quantify anxiety, including the observation of overt behavior, biological activity (e.g., galvanic skin activity, heart rate, stress hormones), and self-reports. No single method is entirely reliable. Assessments of behaviors implicated in anxiety (e.g., pacing) may be an anxiety-reducing strategy for some individuals or may be entirely unrelated to anxiety in other instances. Physiological variables that have been used as biological correlates of anxiety (e.g., electromyogram [EMG]) may be difficult to assess prior to competition, or they may provoke an increase in anxiety in some cases (e.g., sampling blood to assess stress hormones).

Because of these problems, anxiety is most commonly determined by means of self-report questionnaires. In sport research, the most frequently used general measure of anxiety has been the State-Trait Anxiety Inventory (STAI), a 40-item questionnaire that assesses both state and trait anxiety. Despite its proven validity, the efficacy of the STAI and other general measures of anxiety in the context of athletics has been questioned, leading to the creation of more than 30 sport-specific anxiety scales. Among these, the most widely used is the Competitive State Anxiety Inventory-2 (CSAI-2), a multidimensional anxiety measure that assesses self-confidence, somatic anxiety, and cognitive anxiety.

Despite advantages such as the ease of administration and interpretation, self-report measures are not without limitations. The validity and reliability of self-reports are delimited by verbal ability and self-awareness of emotional states. Administering questionnaires near the time of competition can be impractical or disruptive and might even result in increased anxiety by directing attention to internal emotional states. A more serious problem is response distortion, which occurs when

individuals respond falsely to questionnaires for reasons such as social desirability, the demand characteristics of the experiment, and personal expectations. Response distortion can be detected through the use of lie scales, but this form of control is rarely used in sport psychology research.

2. TRADITIONAL THEORETICAL PERSPECTIVES ON THE ANXIETY-PERFORMANCE RELATIONSHIP

It has been a long-standing belief in sport psychology that high levels of anxiety experienced during competition are harmful for performance and, if unabated, may even result in some athletes quitting their sport. A variety of interventions have been employed by sport psychology practitioners to reduce anxiety, including hypnosis, progressive relaxation, visualization, biofeedback, autogenic training, meditation, negative thought stopping, and confidence enhancement. However, it also has been posited that anxiety can facilitate performance under particular conditions. This perspective originally stemmed from drive theory, otherwise known as Hullian theory. According to Hullian theory, performance is a function of drive (i.e., physiological arousal or anxiety) and habit strength (i.e., skill). High levels of anxiety should increase the likelihood of correct behavior for well-learned skills, as would be the case for an emotional pep talk presented to a group of talented athletes. Evidence for drive theory in sport settings is lacking, however, and the theory currently has little status in the field of sport psychology.

Theoretical explanations in which high anxiety adversely influences performance have a higher standing in sport psychology, none more so than the Yerkes-Dodson law, familiarly known as the inverted-U hypothesis. The hypothesis stems from the classic work by Yerkes and Dodson, who in 1908 examined the influence of stimulus intensity on habit formation in experiments where mice were timed in maze running. Discrete levels of difficulty were created by manipulating the level of illumination of the maze and subjecting the mice to several intensities of stimulation via electrical shocks. The highest intensity shocks were found to slow learning under the most difficult (i.e., dimmest) maze trial, suggesting that moderate stimulation was best for such conditions. These results have since been widely reported in both general psychology and sport psychology textbooks, and they have been generalized to

a number of constructs such as drive, motivation, learning, arousal, and anxiety.

In sport psychology, the hypothesis is presented as a relationship between athletic performance and either arousal or, more commonly, anxiety. Optimal performance should occur when anxiety is within a moderate range of intensity, whereas deviations above or below this range should result in progressively worsened performance. Hence, anxiety and performance exhibit a relationship describing the shape of an inverted U. In basic terms, optimal performance is most likely to occur when anxiety is neither too high nor too low, but because of the stressful nature of sport competition, it is assumed that it is far more likely for athletes to experience too much anxiety.

2.1. Sport Modifications

The inverted-U hypothesis has been adapted to account for sports with different physical requirements (e.g., fine motor skill vs gross motor skill) and the expertise of the athlete performing the task. Sport tasks that require precise motor control and minimal physical effort (e.g., putting in golf) are posited to benefit when anxiety or physiological arousal is low prior to and during the tasks. As tasks require greater physical effort but less fine motor control (e.g., tackling in football), progressively higher anxiety intensities should enhance performance. The second modification predicts that as expertise and talent in sport tasks increase, the optimal range of anxiety will also be higher compared with athletes who are either beginners or intermediate in skill. It is assumed that more talented athletes possess the necessary motor skills and coping strategies to harness higher anxiety, whereas less skilled or experienced individuals should exhibit worsened performance at the same anxiety intensity. Given information about sport and skill level for a given athlete, it should then be possible to establish an inverted-U function for the individual.

Despite the continued popularity of the inverted-U hypothesis, reviews of the literature in general psychology and sport psychology have concluded that its empirical support is weak or even entirely absent. It has been concluded that much of the research supporting the hypothesis has little bearing on sport because it was conducted in laboratory environments rather than realistic sport settings or because it used nonathletes as test participants. Studies of the inverted-U hypothesis have also failed to support the propositions that optimal anxiety is altered by the motor skills required for

a sporting event or that comparably skilled athletes competing in the same sport benefit from similar anxiety levels.

Another concern expressed in reviews of the inverted-U hypothesis literature and other traditional theories is the assumption that arousal and anxiety are closely related or synonymous constructs. Arousal was originally defined as a global physiological response to a stressor that is closely associated with negative emotions such as anxiety. Subsequent research, however, has shown arousal to be a far more complex phenomenon. Standardized stressors evoke physiological responses that often exhibit little or no intercorrelation, and the pattern of physiological activation can vary considerably across individuals and situations. Physiological variables commonly employed as indicators of arousal (e.g., heart rate, respiration rate) are only weakly associated with self-report measures of anxiety, and this also is true for sport-specific measures of perceived arousal or somatic anxiety. Despite these findings, the conceptualization of arousal as an undifferentiated physiological response closely associated with anxiety persists, particularly within the field of sport psychology.

Finally, reviews of both the general and sport literature conclude that the inverted-U hypothesis and other traditional explanations indicate that athletes should respond uniformly to anxiety. They do not allow for the occurrence of interindividual differences to anxiety despite the fact that it has long been recognized that some athletes perform optimally under high intensities. In 1929, for example, the pioneering U.S. sport psychology researcher Coleman Griffith wrote, "Some of the most distressing cases of anxiety and fear in the dressing room have led to outstanding achievements during the game."

3. SPORT-SPECIFIC THEORIES OF ANXIETY AND PERFORMANCE

3.1. The IZOF Model

The lack of efficacy of traditional anxiety-performance theories, as well as the acknowledgment that individual differences contribute to this relationship, has spurred the development of sport-specific theories that incorporate this concept. Among these theoretical explanations, the Individual Zones of Optimal Functioning (IZOF) model is believed to have the strongest empirical basis. The IZOF model was developed by the Russian psychologist Yuri Hanin from studies of athletes in a wide variety of sports and competitive settings where anxiety was

TABLE I
Basic Tenets of the IZOF Model of Anxiety and Athletic Performance

-
1. Each athlete possesses an anxiety zone that is associated with optimal sport performance.
 2. The optimal anxiety zone may exist anywhere on the continuum of anxiety intensity, from low to extremely high.
 3. The optimal anxiety zone is not systematically influenced by either the nature of the sporting event or the skill and expertise of the athlete.
-

assessed using the Russian-language version of the STAI. The results of Hanin's research supported an ideographic explanation, in which anxiety was associated with performance at the level of the individual athlete, rather than a nomothetic explanation, in which an entire team would respond similarly to anxiety. According to the IZOF model, each athlete possesses an optimal anxiety zone or range that is beneficial for performance. This optimal range may exist anywhere within the continuum of anxiety, from as low to as high as is measurable. When anxiety values fall outside the optimal zone, performance should decrease. The IZOF model further posits that the intensity of the optimal anxiety zone is not predictably influenced by either the type of sporting event or the skill of the individual athlete. As a result, an alternative method is needed to identify a more appropriate required anxiety level for an athlete than has been employed in traditional theories where the responses of athletes to anxiety are assumed to be more uniform (Table I).

3.2. Determining Optimal Anxiety

Two techniques have been developed to identify the optimal anxiety zone of an athlete: the direct method and the indirect method. For the direct method, state anxiety is assessed shortly before competitions until an athlete achieves a personal best performance. The optimal anxiety zone is then created by adding and subtracting 4 units to this anxiety score, which is approximately one-half standard deviation based on the STAI. The span of the optimal anxiety zone was established from initial research, but more recent studies have demonstrated that it can vary in width across athletes, indicating that some individuals can tolerate a wide range of anxiety intensity before experiencing a decline in performance. Unfortunately, the direct technique requires measuring anxiety prior to competitions

until the athlete achieves an outstanding or personal best performance, a process that may require months or even years and that is compounded when dealing with large teams consisting of many athletes.

As a more efficient alternative, Hanin developed an indirect method based on retrospection of past competitions. With the indirect method, athletes complete the state portion of the STAI according to how they recall feeling prior to their own best past performances or prior to performances judged to be optimal. Again, 4 anxiety units are added and subtracted from this "recalled best" anxiety score to establish the optimal zone. The accuracy of the indirect method has been tested by correlating recalled anxiety scores with anxiety values actually obtained at the time of the recalled events, and effect sizes ranging from .60 to .80 have been reported consistently. Research indicates that the levels of accuracy in recalling anxiety are comparable in athletes who performed either better or worse than expected despite concerns that performance outcome could bias accuracy. Although the effect size for recalled and actual precompetition anxiety supports the use of the indirect method for determining optimal anxiety ranges, occasional reports of inaccurate recall have been noted in the literature. In such instances, the direct method should be used.

3.3. Interindividual Variability in Optimal Anxiety

The IZOF model predicts not only that athletes of a similar caliber in a given sport will differ in the intensity of optimal anxiety but also that a significant proportion will benefit from high anxiety. The findings from studies of athletes in a number of sports and different levels are consistent with these propositions, indicating that between 25 and 50% report that best performances occur when anxiety levels are elevated. As predicted by the IZOF model, the proportion of athletes who perform best at high anxiety intensities is not related to skill or even age. For example, in studies of elite U.S. distance runners, it was found that 30% of female runners reported that best performances were most likely when anxiety was significantly elevated, but percentages as high as 51% have been noted in nonelite college track and field athletes. Even in track and field athletes as young as 9 to 12 years, more than one in four indicated that they performed best with high anxiety. These results and other findings provide support for the IZOF model, but they are not consistent with group-based explanations of anxiety and performance. For example, according to both

drive theory and the inverted-U hypothesis, the proportion of individuals who benefit from high anxiety should consistently be higher for elite athletes than for less talented competitors.

The evidence of wide-ranging variability in precompetition and optimal anxiety complicates the use of intervention strategies designed to regulate anxiety. Group-based interventions, in which an entire team of athletes receives a single treatment such as relaxation, are easily administered but would be ineffective or counterproductive for those athletes who perform best at moderate or high anxiety intensities. On the other hand, it can be time-consuming to use IZOF procedures to assess anxiety at the time of competition and then compare these values with each athlete's optimal zone to determine who will be in need of some form of intervention.

3.4. Predicting Precompetition Anxiety

In an effort to provide a means for coaches and psychologists to efficiently identify those athletes who will require anxiety intervention, as well as to determine the appropriate direction of the intervention (e.g., increase or decrease anxiety), IZOF studies have tested the ability of athletes to anticipate the intensity they will experience prior to actual competition. In this research, athletes completed the state portion of the STAI several days prior to a competition with instructions to respond according to how they anticipated they would feel immediately before the competition. Athletes then completed the STAI again just before the competition under the standard instructional set (i.e., "right now"), and that score was then compared with the predicted anxiety score. To minimize intrusiveness, the questionnaires were sometimes completed at a prescribed time before competition (e.g., 60 minutes). The results of this work reveal that predicted anxiety scores correlate quite closely with actual values. Correlations between predicted and actual precompetition anxiety range between .60 and .80, with higher coefficients occurring for difficult or important competitions.

Predicted precompetition anxiety scores are useful in situations where it would be difficult or impossible to assess anxiety just prior to the actual competition. The discrepancy between predicted precompetition anxiety and IZOF values can be contrasted to identify athletes who are likely to be too relaxed or too anxious, and this can be done several days before the competition.

From a practical perspective, the extent to which anxiety deviates from the optimal zone can help dictate how much anxiety must be increased or decreased to reach the optimal zone. Simple techniques that are easily implemented by the coaching staff can be an expeditious means to manipulate anxiety. These include emphasizing or deemphasizing the importance of the competition or the expectations of an athlete's performance.

3.5. Impact of Optimal Anxiety on Performance

Research based on IZOF procedures indicates that deviations in precompetition anxiety from the optimal zone have a significant impact on performance. Studies of athletes in sports such as swimming, rhythmic gymnastics, and ice skating indicate that precompetition anxiety of successful performers is closer to their own optimal anxiety values than is the case with their less successful teammates. In most cases, performance differences are evident only in difficult competitions, and it has been speculated that optimal anxiety is not necessary to achieve adequate performance in easy or unimportant competitions. In research that has examined the net impact of anxiety on sport performance, it has been found that performances were approximately 2% worse on average in cases where precompetition anxiety fell outside the IZOF and that the decrement was approximately equal whether anxiety was lower or higher than optimal.

Despite evidence that supports the major tenets of the IZOF model, the model has been criticized on a number of grounds. One primary concern is that the IZOF model does not indicate what variables contribute to the differences in optimal anxiety observed in homogenous groups of athletes. To date, studies of the factors contributing to interindividual variability in optimal anxiety have been rare, and the bulk of IZOF research has focused on examining the validity of the major tenets of the model. A second line of criticism contends that IZOF research based on the STAI or other nonspecific and general measures of anxiety is inadequate, whereas more complete results would be yielded by employing a sport-specific measure assessing multiple aspects of anxiety, particularly the CSAI-2. However, the results of CSAI-2 research on the IZOF model have been less consistent than research based on the STAI, and the IZOF model has been found to be less accurate than the STAI in assessing both recalled and predicted precompetition anxiety.

4. OTHER IDEOGRAPHIC THEORIES

Two other major theories of anxiety and sport performance have been adopted recently for sport: reversal theory and catastrophe theory. Although the concept of individual differences are not central to these theories, like the IZOF model, they acknowledge that anxiety can either facilitate or harm sport performance. Unlike the IZOF model, both reversal and catastrophe theories incorporate specific anxiety or perceived arousal scales.

Reversal theory predicts that self-reported arousal is important to performance despite a lack of evidence that self-reports can provide an objective indication of physiological activity. Arousal is interpreted on the basis of an individual's current emotional state that results from the interaction of oppositional high-arousal preferring (paratelic) and low-arousal preferring (telic) states that are also assessed via self-reports.

Catastrophe theory uses an arousal-related measure referred to as somatic anxiety, which is assumed to exhibit an inverted-U relationship with performance. In addition, measures of self-confidence and cognitive anxiety are assessed using a modified version of the CSAI-2 that assesses facilitative and debilitating anxiety. Cognitive anxiety is posited to be negatively related to performance, whereas self-confidence exhibits a positive relationship. When these dimensions are considered collectively, they form a complex three-dimensional figure referred to as a butterfly or catastrophe cusp. Reviews of the efficacy of reversal and catastrophe theories have been mixed, and this may stem in part from the challenges of validating these complex theories empirically.

5. SUMMARY

The growing realization that traditional theoretical explanations of anxiety and performance fair poorly when applied to sport has led to the development of several models and theories of anxiety specific to athletes. Further research is needed before definitive judgments can be made about the relative efficacy of these theoretical explanations, but they all indicate that influence of anxiety on sport performance is more complex than is predicted by traditional explanations such as the inverted-U hypothesis. In particular, the results of IZOF model research reveal that the anxiety intensity associated with optimal sport performance varies considerably across athletes, even for those competing in the same competition. This research also indicates that a

substantial percentage of athletes actually benefit from elevated anxiety and that in these cases, interventions aimed at reducing anxiety may be counterproductive.

GLOSSARY

cognitive behavior therapy A collaborative form of psychotherapy that involves facilitating patients' changing their belief system via a Socratic dialogue focusing on those distressing thoughts that exacerbate negative emotions and maladaptive behaviors.

ego-syntonic/ego-dystonic obsessions Terms typically used in describing whether obsessions are congruent or incongruent with one's beliefs; an ego-dystonic obsession may include the belief that washing one's hands for 15 minutes will prevent cancer with the understanding that, despite the persistence of the thought, it is illogical.

epidemiology A branch of medical science that deals with the incidence/prevalence, distribution, and prevention of a disease or condition as well as the identification of at-risk populations.

Likert scale A means of assigning a numerical intensity rating that is anchored by descriptive terms to a construct (e.g., I would describe my worry as 1 = *very mild*, 2 = *mild*, 3 = *average*, 4 = *excessive*, 5 = *very excessive*).

Recent epidemiological studies have underscored the ubiquitous nature of anxiety disorders, with

approximately 25% of adults being affected over the course of their lifetimes. Furthermore, the economic burden of these disorders has been estimated at \$42.3 billion, comprising 31% of psychiatric treatment costs. Given the prevalence of anxiety disorders, it is not surprising that an increasing amount of attention has been given to investigating the prevalence and treatment of these conditions. What is surprising, however, is how little attention has been given to anxiety disorders in what is the fastest growing segment of the population, namely the elderly. This article summarizes how the existing research literature informs us with respect to the epidemiology of anxiety disorders in the elderly and then examines the treatment outcome literature with regard to the individual anxiety disorders.

1. EPIDEMIOLOGY OF ANXIETY DISORDERS IN OLDER ADULTS

The United States is aging. The U.S. Census Bureau predicts that more than 72 million adults will be age 65 years or over by the year 2030. Recent epidemiological studies underscore that anxiety disorders are the most prominent of the psychiatric conditions, with lifetime estimates nearing 25%. Despite the widespread prevalence and extensive cost to society of anxiety disorders, there is currently little data on the rate and phenomenology of anxiety disorders in the elderly population.

1.1. General Prevalence Data

It is generally believed that anxiety disorders occur less frequently in the elderly population than in younger adults. However, there have been only a small number of epidemiological studies that have tested this contention directly. A recent epidemiological study in the United States that included persons over 65 years of age is the Epidemiological Catchment Area (ECA) study, which included more than 18,000 noninstitutionalized adults. The ECA study systematically examined the rate of anxiety disorders at five sites across the country. Fully 30% of the ECA subjects were age 65 years or over. It was ascertained that the 1-month prevalence rate of anxiety disorders in the elderly was approximately 5.5%, lower than the 7.3% estimate for all adults surveyed. Furthermore, elderly women were nearly twice as likely to have anxiety disorders as were elderly men. The percentage of elderly adults with anxiety disorders was higher than that with any other psychiatric illness, including cognitive impairment, underscoring the need for appropriate identification and treatment in this population. Furthermore, rates of anxiety disorders were much higher than the 2.5% prevalence rate of affective disorders in this population. Other reviews of smaller scale epidemiological studies found that rates of anxiety disorders ranged between 0.7 and 19.0%. Similar 6-month prevalence rates of 3.5% have been found in Europe.

1.2. Epidemiology of Individual Anxiety Disorders

Rates for specific anxiety disorders also vary across studies and differ between elderly males and females. Data from the ECA study suggest that phobias are the most frequently experienced anxiety disorder in the elderly, affecting an estimated 4.8% of older adults. Panic disorder (PD) and obsessive-compulsive disorder (OCD) in the elderly population are expected to occur only infrequently. Rates for PD are estimated to not exceed 0.3%, and when panic does occur in elderly adults, it tends to be in women. Similarly, rates of OCD among the elderly are low, with prevalence estimates being 3.5% at a maximum and with elderly adults residing in institutional settings accounting for the upper end of these prevalence estimates.

Data regarding the prevalence of generalized anxiety disorder (GAD) suggest that it has a much more variable occurrence in the elderly population, ranging between 0.7 and 7.1%. It is important to note that data on

the prevalence of GAD are not included in the ECA data and that other studies that find higher prevalence rates of GAD may be due to differences in their respective methodologies, for example, the decision rules applied in rendering a diagnosis.

1.3. Reliability of Epidemiological Studies

There are several potential explanations for the wide variability of estimates of anxiety disorder prevalence in the elderly. The existing epidemiological studies use different methodologies, and this often makes it difficult to compare prevalence rates across individual studies. Some of the studies include institutionalized elderly adults, whereas others survey community-dwelling residents only. In addition, measures of anxiety symptoms validated on younger adults might not be applicable to older adults given that the experience and expression of anxiety may change with age. Likewise, the instruments used to assess anxiety in older adults might not have norms or other psychometric data that are established for older adults, let alone for very old adults. Further research is needed to delineate factors that contribute to the difference in prevalence estimates and to clarify the nature of anxiety in the elderly. Until then, estimates of prevalence rates of anxiety disorders in the elderly should be considered preliminary.

1.4. Comorbidity

It is well known in the literature that anxiety disorders often co-occur with other diagnoses, including depression and other anxiety disorders. However, it is important to examine whether this is true for elderly persons as well. Research is beginning to shed light on the co-occurrence of anxiety and other psychiatric disorders in older adults. As with younger adults, depression most frequently co-occurs with anxiety disorders among elderly patients. In addition, when depression is the primary diagnosis in elderly adults, anxiety frequently co-occurs. In general, the delineation between depression and anxiety is not clear, and research suggests that it might be even less clear for older adults.

Unlike anxiety or depression, the incidence of cognitive impairment increases with age. Research examining the relationship between anxiety and dementia in older adults typically finds that these syndromes often coexist. Symptoms of anxiety often occur in the

context of dementia as well as in nondemented older adults.

In summary, although the frequency with which anxiety disorders are present in older adults is lower than that in younger adults, these data may be confounded by methodological problems such as differences in diagnostic classification, commonalities between anxiety and depression in this population, and the frequent occurrence of anxiety symptoms accompanying medical conditions.

2. ASSESSMENT AND TREATMENT OF ANXIETY DISORDERS

2.1. Generalized Anxiety Disorder

2.1.1. Assessment

Diagnostic criteria for GAD have undergone considerable revision over the past 20 years or so. The most recent version of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) emphasizes chronic uncontrollable worry that causes significant distress or impairment as the hallmark symptom of the disorder. In adults of all ages, GAD is most often comorbid with other affective and anxiety disorders and is sometimes viewed as a vulnerability factor for the development of additional psychiatric problems. GAD is often secondary to depressive disorders in older adults.

As noted by Carmin and colleagues in 1999, the only clinician-rated diagnostic interviews that have been found to yield reliable diagnoses with elderly patients are the Structured Clinical Interview Diagnostic (SCID) and the Anxiety Disorders Interview Schedule (ADIS-IV). Low interrater reliability estimates were reported during the 1980s for GAD; however, better estimates have been found using DSM-IV criteria. A recent investigation using the SCID and the ADIS yielded substantial diagnostic agreement for all of the anxiety disorders in an older treatment-seeking sample. Interrater reliability for GAD with the ADIS was similarly found to be excellent.

Two additional clinician-rated measures have been used to determine anxiety severity in the elderly. The Hamilton Anxiety Rating Scale (HARS) is a 14-item scale tapping anxiety symptoms in somatic, psychic, and affective domains. In 1997, Beck and Stanley found that the HARS distinguished older adults with GAD from normal controls, providing some preliminary support for the measure. The FEAR is a relatively

new instrument developed to measure GAD in older adults in the primary care setting. The FEAR, a 4-item version of the 11-item Anxiety Disorder Scale, is meant to be administered verbally during routine medical exams or in the waiting room. The FEAR demonstrated very good sensitivity and specificity in an initial administration to 88 older medical patients, 27% of whom were diagnosed with GAD. Additional psychometric properties of the measure await investigation.

There are only a few self-report measures that are recommended for use with late-life GAD patients. The Worry Scale (WS) is a 35-item, self-report questionnaire tapping three subscales of worry domains of importance to older adults—finances, health, social issues—using a 5-point Likert scale. The primary utility of the measure is the assessment of GAD. However, the use of the measure with a sample of older adults with GAD yielded poor convergent validity, with low correlations with other measures of anxiety. The internal reliability estimate was .93, but test–retest reliability was not reported. In a second study by Beck and Stanley in 1997, the measure showed adequate internal reliability and convergent validity. Currently, the properties of this measure seem to be better established in healthy controls than in patient samples.

The Penn State Worry Questionnaire (PSWQ) consists of 16 items on a 4-point Likert scale designed to tap the generality, intensity, and uncontrollability of worry. The measure has demonstrated good psychometric properties (e.g., internal consistency, convergent validity) in several studies of older adults with GAD. However, the PSWQ failed to discriminate between older adults with GAD and PD and has shown inadequate test–retest reliability in older GAD patients over a variable period with a mean of 70 days. Stanley and colleagues found that the PSWQ showed good divergent validity with measures of depression. Because late-life GAD is also comorbid with depressive disorders, this is one appealing feature of the measure.

The trait scale of the State–Trait Anxiety Inventory (STAI) assesses the tendency to experience frequent anxiety and nervousness. The measure has 20 items on a 4-point Likert scale and is one of the most frequently used self-report questionnaires in studies of anxiety. In heterogeneous older adult samples, the trait scale has shown adequate psychometric properties, and there are ample normative data. In 1996, Stanley, Beck, and Zebb found low to moderate correlations between the STAI and other anxiety and worry measures in older GAD patients but found good internal consistency of .88 for the trait scale. Test–retest

reliability estimates were not given for the GAD sample but were good in a sample of healthy older adults. A more recent investigation showed good internal consistency but low test–retest reliability (.58) in a sample of 57 older adults with GAD. Mohlman, deJesus, and colleagues found that scores on the measure were very similar in older adults with GAD and PD, suggesting that it taps a nonspecific construct in older samples.

2.1.2. Psychosocial Treatment of Late-Life Generalized Anxiety Disorder

Two early studies by Stanley and colleagues indicated that supportive group therapy was beneficial for late-life GAD treatment. The 14-week intervention focused on the discussion of symptoms and experiences and providing support for group members.

Investigations of individual format cognitive behavior therapy (CBT) have suggested that this treatment is effective in older adults with GAD. However, it is notable that most of these studies have included nonstandard augmentations to the therapy such as concurrent medication and weekly meetings with a physician, treatment conducted in primary care or in patients' own homes, and the use of learning aids. The only investigation of standard individual CBT delivered in a mental health clinic indicated very modest efficacy as compared with a wait list condition. Currently, the efficacy of individual CBT is not well supported.

Several studies assessing the efficacy of group CBT for late-life GAD indicate that the treatment is typically more effective than wait list control conditions; however, it is not significantly better than other control conditions. Thus, it is possible that nonspecific elements of the group format (e.g., increased social interaction, mitigation of loneliness), rather than elements specific to CBT, led to improvement. Studies comparing group format CBT with individual format CBT should help to clarify this issue.

2.2. Panic Disorder and Agoraphobia

2.2.1. Assessment

Notably, very few studies have addressed the psychometric properties of measures of panic and related symptoms in older patient samples. Two studies, one using a nonclinical community sample and the other using patients drawn from a medical clinic, studied the properties of the Beck Anxiety Inventory (BAI), a well-known

measure of anxiety and panic symptoms and found that the scale had good discriminant validity and internal consistency. The latter study also demonstrated the BAI four-factor solution with autonomic, neuromotor, cognitive, and panic subscales, suggesting that anxiety symptom clusters are slightly different from those found among younger adults.

The Anxiety Sensitivity Index (ASI) is a 16-item measure tapping the fear of anxiety sensations, which is known to be a risk factor for the development of panic. In 2000, Mohlman and Zinbarg tested the structure and validity of the ASI in 322 healthy older adults (mean age 75 years). The ASI showed strong internal consistency and moderate correlations with measures of related constructs. Confirmatory factor analysis indicated a hierarchical structure with three group factors—physical concerns, mental incapacitation concerns, and social concerns—as well as a general factor, consistent with previous investigations of the ASI in younger adults. In 1998, Deer and Calamari found that 49% of their older sample (mean age 81 years) reported panic symptoms and that 27% reported a panic attack during the past year. Anxiety sensations predicted unique variance in panic symptomatology and may function as a risk factor for the development of late-life panic.

2.2.2. Psychosocial Treatment of Late-Life Panic Disorder

Trials of psychosocial treatments in older samples with PD, panic disorder with agoraphobia (PDA), or agoraphobia without history of panic disorder (AWOHPD) are limited to case studies and three small pilot studies. One study found that principles of reality therapy, which focuses on an individual's situation and worldview, were effective when used by a neighbor to mitigate an older adult's paranoia and agoraphobia.

Early investigations of behavioral treatments conducted during the 1970s included relaxation, imagery, and exposure. In 1996, Rathus and Sanderson used CBT with two older panic patients: one 70-year-old male and one 69-year-old female. Treatment components were education, cognitive restructuring, interoceptive and situational exposure, and diaphragmatic breathing. Both participants achieved panic-free status and decreased depression following 4 to 5 months of therapy.

In 1991, King and Barrowclough tested CBT for panic and anxiety in a small sample of adults ages 66 to 78 years. Of the 10 participants, 8 had primary diagnoses of PDA. After treatment, 7 were free of

panic and 2 showed decreased symptom severity. Six months later, 8 of the remaining 9 participants were panic free and 6 showed improvement on depression.

In 1996, Swales and colleagues tested 10 90-minute sessions of CBT in 15 adults ages 55 to 80 years. Participants experienced decreased severity and frequency of panic attacks, depression, avoidance, and role impairment, and this was apparent at both post-treatment and 3-month follow-up. A reanalysis of Gorenstein and colleagues by Mohlman indicated that CBT plus medication management ($n = 5$) was somewhat more effective than medication management alone ($n = 5$) in assisting older adults with PD to decrease anxiety while tapering off anxiolytic medication. The use of interoceptive exposure was believed to facilitate habituation to sensations related to PD and medication withdrawal simultaneously.

2.3. Social Anxiety Disorder

Although the social anxiety literature has grown tremendously during the past several years, there is still a relative dearth of empirical research examining the assessment and treatment of social anxiety in older adults. This may be due in part to the fact that in epidemiological studies, social phobia is a relatively rare disorder among the elderly population. In addition, social anxiety as a distinct diagnostic category did not appear until the third edition of the DSM was published.

2.3.1. Assessment

As noted previously, the SCID and the ADIS-IV are the only two clinician-administered diagnostic instruments with published data on older adults. In 1993, Segal and colleagues reported interrater reliabilities ranging from good to excellent across anxiety disorder diagnoses with use of the SCID.

The ADIS-IV is considered the gold standard for diagnosing anxiety disorders in adults. In 2001, Brown and colleagues found the interrater reliability of the lifetime version of this instrument to be excellent for social anxiety on a population of younger adults. Its reliability for diagnosing social phobia in older adults has not yet been established.

There are currently a number of self-report measures available for assessing social anxiety in younger adults. Unfortunately, none of the measures that has been used with younger cohorts has norms or other psychometric data supporting its use with older adults.

2.3.2. Treatment

In contrast to the abundant literature examining psychological and pharmacological treatment of social anxiety disorder in adults, there are no published studies examining the efficacy or effectiveness of treatments for socially anxious older adults. In 2001, Fedoroff and Taylor conducted a meta-analysis of 108 studies. These researchers compared pharmacological treatments, including selective serotonin reuptake inhibitors (SSRIs), benzodiazepines (BZDs), and monoamine oxidase inhibitors (MAOIs), with components of CBT, including exposure and cognitive restructuring. Studies were included in the analysis if they consisted of at least four patients diagnosed with social anxiety using clinical interviews and consisted of standard treatments of social anxiety. The ages of the patients included in the meta-analysis were not provided, although all studies consisted of adults. Results of the analysis suggested that pharmacotherapies were superior to CBT at posttreatment and that both were superior to controls. BZDs were significantly more effective than both CBT and controls but did not significantly differ from SSRIs. Long-term maintenance of gains was not as well established because many of the studies did not contain sufficient information for estimating this variable. Although these results may have applicability to older adults, the use of BZDs is ventured very cautiously given that this class of medication can cause difficulties with dizziness, respiration, and cognitive functioning.

In summary, the literature is scarce regarding effective treatments for social anxiety in older adults. Although both CBT and pharmacotherapy have been proven to be effective treatments, extrapolation to older adults is premature. More research is needed in this area before conclusions can be made concerning best practice treatments of social anxiety treatment in older adults.

2.4. Assessment and Treatment of Obsessive–Compulsive Disorder

The observation made by McCarthy and colleagues more than a decade ago, that there is a paucity of research evaluating the efficacy of treatments for older adults diagnosed with OCD, still remains true today. The limited literature that exists has focused primarily either on a variation of CBT called exposure and response/ritual prevention (ERP) or on pharmacological treatment.

2.4.1. Assessment

The assessment literature, with regard to OCD in older adults, offers few recommendations other than the Padua Inventory, which was used with older adults diagnosed with GAD. Some authors have suggested that certain presentations of OCD, such as obsessions and compulsions related to fear of forgetting names and pronounced ego-syntonic scrupulosity, are more likely to occur in the elderly. Besides these case reports, there is little evidence that particular constellations of obsessions and compulsions are unique to older adults. Typical presentations of OCD, such as contamination fears with washing rituals and fears of harming others accompanied by checking compulsions, are also commonly found in the elderly. DSM-IV criteria appear to be appropriate for use with older adults, but more research is needed using structured diagnostic instruments such as the ADIS-IV to better characterize the presentation of OCD in the elderly.

2.4.2. Treatment

Two early uncontrolled case studies of elderly OCD patients reported significant reductions in OCD symptoms following ERP, whereas one anecdotal report documented unsuccessful combined ERP and medication treatments in a 74-year-old woman with OCD and a learning disability. Several controlled outcome studies of ERP using single-case designs yielded similarly successful results. The one study that directly compared treatment responses of older patients with those of younger patients examined the effectiveness of inpatient ERP administered to 10 severely impaired OCD patients age 60 years or over and 10 younger OCD patients matched for gender and clinical severity. No significant differences in response to treatment were found between the older adults and their younger counterparts, with the majorities of both groups being classified as treatment responders at posttreatment. This finding is particularly noteworthy given that the older patients reported having been symptomatic for more than twice as long as the younger adult cohort.

In a recent controlled case comparison, Carmin and Wiegartz described two older men with OCD. One experienced a successful outcome and the other experienced an unsuccessful outcome when intensive inpatient ERP was the treatment modality. These authors concluded that the duration of the illness, comorbidity of other psychiatric disorders as well as medical conditions, and the availability of social support can have an effect on treatment outcome.

Cognitive decline can exacerbate or mimic symptoms of OCD, and medical difficulties, such as cerebrovascular accidents (e.g., basal ganglia infarcts), are more prevalent in the elderly and have been noted to produce OCD symptoms in previously healthy patients. Such observations raise the question of whether individuals who have experienced neurological insults that result in OCD can benefit from psychological treatment. Of considerable importance is that ERP and pharmacological treatment were found to be effective in treating a 65-year-old man whose OCD was related to recent basal ganglia infarcts.

In comparison with the previously noted studies that used ERP, a follow-up study of medication and supportive psychotherapy that was offered to residents of an old-age home suggested that these methods can have a positive effect on treatment of anxiety disorders, including OCD and panic. One limitation of this study was that this was a diagnostically heterogeneous group, and no details were provided about what medications were used or what supportive psychotherapy entailed.

Studies focusing on CBT for late-life OCD have consisted of relatively small patient samples, thereby limiting generalizability. Preliminary findings, however, suggest that late-life OCD is treatable. Even if subsequent research finds lower success rates for the elderly than rates typically reported for the general adult population, there is sufficient evidence to conclude that at least some, if not most, older adults respond to ERP.

2.5. Assessment and Treatment of Posttraumatic Stress Disorder

Much of the literature pertaining to posttraumatic stress disorder (PTSD) in the elderly focuses on holocaust and natural disaster victims and combat veterans. Given the vulnerability of older adults to physical violence, there is limited research that examines symptom presentations of elderly crime victims and treatment.

Typically, PTSD symptoms in older adults reflect a chronic waxing and waning of symptoms, with exacerbations linked to the expected stressors of advancing age. Despite early studies suggesting a level of resiliency in older adult disaster victims, this resiliency may reflect an underreporting of symptoms by PTSD sufferers, an underdiagnosis by clinicians, or an attribution of anxiety-related somatic symptoms to the normal frailties associated with old age by clinicians, thereby making the accurate diagnosis of this disorder difficult.

2.5.1. Assessment

There are several measures that have been used to assess PTSD symptoms in the elderly. The Clinician-Administered PTSD Scale (CAPS) is a clinician-administered semistructured interview that has been used extensively with older individuals who have typically been exposed to war-related trauma. In addition, the CAPS has been used as a process and outcome measure for those experiencing non-combat-related PTSD. These studies suggest that the CAPS is recommended for use with older PTSD sufferers.

Although a number of self-report measures have been used to assess PTSD in older adult samples, these studies typically provide descriptive rather than psychometric data. Although the Impact of Events Scale (IES) has provided psychometric data, the findings are equivocal with respect to its use with elders, suggesting that the type of traumatic event may be more important than symptomatology in older samples than in younger samples. The combat and civilian forms of the Mississippi PTSD Scales (MISS) have been significantly correlated with diagnostic measures of PTSD; however, the combat version appears to be the most accurate measure of PTSD severity in a small sample of elderly former prisoners of war.

2.5.2. Treatment

There are two reports of PTSD treatment in older adults. In 1998, Bonwick described a 16-week group day hospital treatment for veterans. The program included elements of psychoeducation, symptom management, relaxation, group therapy, and physical exercise. No outcome data were reported, but the author noted that those receiving treatment reported a greater understanding of PTSD, improved coping skills, and an enhanced quality of life. A recent conceptual review of PTSD in older adults indicates that a better understanding of the issues related to risk and vulnerability to trauma, such as the availability of social support networks, the use of coping strategies, and perceptions of the meaning related to the traumatic event, may allow for a better understanding of how to construct better treatment interventions.

2.6. Assessment and Treatment of Specific Phobias

2.6.1. Assessment

There is surprisingly little information with respect to the assessment and treatment of specific fears in older

adults given that specific phobias is the most prevalent anxiety disorder in this age group. Of the measures available that assess for the gamut of phobias, the Fear Survey Schedules (FSS-II and FSS-III) have been used with older adults and are promising screening measures for identifying specific fears. Kogan and Edelstein revised this measure specifically for use with older adults (FSS-OA). Their preliminary results are encouraging but not conclusive. One measure, the Falls Efficacy Scale (FES), appears to have good reliability and validity. However, additional psychometric evaluations (e.g., convergent and discriminatory validity) still need to be done before this self-report measure can be used independently of a comprehensive anxiety assessment battery in older persons with somatic symptoms of dizziness or balance disturbances.

2.6.2. Treatment

There is one randomized controlled study comparing CBT with an educational control group in more than 400 individuals (average age of 77 years) experiencing fears of falling. The CBT patients demonstrated posttreatment gains in mobility control and increased activity, but these gains were lost over a 6-month follow-up period. At 1 year follow-up, the CBT patients showed increased improvement in different areas (e.g., mobility range, social functioning). The authors of this study noted that only 63.4% of their patients attended more than five of the eight offered treatment sessions, thereby highlighting problems with compliance and attrition.

2.7. Issues Related to Anxiety Secondary to a Medical Condition

There is considerable overlap between many symptoms diagnostic of an anxiety disorder and symptoms that can be attributed to a medical illness. Medical illnesses such as cardiovascular disease, pulmonary dysfunction, stroke, hyperthyroidism, sensory impairments, and dementia can mimic, exacerbate, antedate, and/or accompany symptoms of anxiety. For example, symptoms of panic may overlap with certain symptoms related to angina, congestive heart failure, or emphysema, causing the diagnosis of panic to be overlooked. Alternatively, the normal developmental changes associated with aging can be mistaken for an anxiety disorder. Individuals who have sensory or mobility impairments may repeatedly check for where a hearing

aid or walker is located or ask for frequent reassurance, resulting in clinicians mistakenly suggesting a diagnosis of OCD. Clearly, differentiating between anxiety disorders and medical illness in older adults is a complicated task. There are no studies that address the treatment of comorbid anxiety and medical illness.

3. CONCLUSIONS

Enormous strides have been made in the area of the psychopathology, assessment, and treatment of anxiety disorders in adults. Unfortunately, in the area of geriatric anxiety, a tremendous amount of research still needs to be done.

There are significant questions as to whether the fundamental nature of anxiety disorders in adults is the same as that during their later years. A further complication arises in that neurobiological changes across the life span were found to cause an age-related decreased cortisol response to an experimental stressor. These findings suggest a decrease in reactivity to stress with advancing years. It has likewise been hypothesized that age-related changes in hypothalamic–pituitary–adrenal (HPA) activity, as indicated by cortisol level, are markers for central nervous system dysfunction. If this is indeed true, anxiety may be a link between central nervous system instability and the increases in cognitive impairment that are often found in aging and may explain the decreased prevalence of anxiety disorders in older adults.

As noted previously, epidemiological studies are confounded by their method of sampling. Cohort effects relevant to the stigma attached to mental illness have a greater influence on older adults. Thus, fewer elderly individuals may be willing to endorse anxiety symptoms in the course of an epidemiological study. Likewise, where samples are drawn from may influence prevalence data.

Finally, it would appear that both psychosocial and pharmacological treatments appear to aid in the reduction of anxiety symptoms in elderly samples. The prevailing form of psychotherapy that has been studied has been CBT. However, there is not firmly conclusive data that would allow one to unequivocally endorse CBT or a particular medication for use in treating a given anxiety disorder. Clearly, far more research is needed. One optimistic note is that the participants in existing longitudinal studies, such as the Harvard/Brown Anxiety Research Program (HARP), are aging. Data such as those generated by this study will allow

for the close examination of how anxiety disorders progress over adulthood and into later life and, hopefully, will provide answers to many of the questions that remain regarding geriatric anxiety.

GLOSSARY

anxiety A negative emotional state generally expressed as worry and apprehension and accompanied by heightened arousal.

arousal The body's degree of activation from low to high; it is reflected in hormone levels and other physiological reactivity that is mediated by thoughts and feelings.

stress The body's reaction to perceived threat by an individual; the reaction is typically increased anxiety and arousal.

Arousal in sport and exercise is a human condition that ranges along a continuum from sleep to high excitation and is expressed physiologically, cognitively, and behaviorally. Three prominent theories of arousal in sport are drive theory, the inverted-U hypothesis, and reversal theory. Each has unique insights for the discussion of an athlete's ability to perform at optimal levels on the playing field or court and can guide an astute coach, counselor, or psychologist in his or her work. Lastly, the application of cognitive, behavioral,

and cognitive-behavioral interventions for arousal regulation are discussed.

1. INTRODUCTION

The coach gathers the team moments before the championship game for a pep talk laden with fire, brimstone, and proclamations of victory. The professional basketball player sits on the training room table, tattoos lining his arms, bobbing his head rhythmically to the music on his headphones. The sprinter takes a few quick strides, bounds up and down a couple of times, and takes two good deep breaths before assuming her position in the starting blocks. The stock car racer says a short prayer and finds a brief moment of silence before sliding into his car and heading out to the starting line. Excellent athletic accomplishments require the athlete's body to be appropriately energized, with physiological and psychological resources prepared for the stresses and physical demands of competition.

The preceding instances describe the concept of arousal and its regulation in sport. The term "arousal" has been a part of the English language for more than 400 years. The *Oxford English Dictionary* defines "arouse" as "to raise up from sleep or inactivity, to excite." James, in his classical work *Principles of Psychology*, used the term "arousal" to describe "activation." Arousal, as it is used in sport, describes a condition of controlled or uncontrolled preparedness and

manifests itself in varying levels of mental activity, emotional display, physical energy, and concomitant physiological reactivity.

2. CONCEPTUAL CONFUSION SURROUNDING AROUSAL

Besides the historical reference of exciting one to action, being aroused typically refers to physiological responses. That is, aroused individuals demonstrate high heart rates, increased sweat response, increased brain activity, and (typically) increased intensity of physical effort.

A perusal of the general psychology and sport psychology research over the past five decades shows that arousal is often used interchangeably with terms such as anxiety, activation, emotion, motivation, and psychic energy. This understandably has resulted in conceptual confusion. The early researchers of arousal, such as Cannon, Duffy, Hebb, and Malmo, treated arousal as a unidimensional physiological construct. Today, arousal is viewed as a multidimensional construct that includes a physiological dimension paired/grouped with cognitive, affective, and/or behavioral dimensions. For example, an ice hockey player who is optimally aroused would have an elevated heart rate, increased beta waves, increased respiration, and increased adrenalin. In addition, thought processes would be alert and focused, such that the player is able to read and react to on-ice situations quickly and accurately. The optimally aroused athlete would also be in control of essential affective states and would demonstrate “passion” or intensity in play.

The physiological component of arousal can be represented in a number of ways such as through muscle tension, cortical activity, electrodermal activity, respiration, and biochemical markers (e.g., epinephrine, cortisol). The cognitive interpretation appraisal component can influence the physiological component. Furthermore, the affective component can also interact

with thoughts to influence physiological responses and athletic performance (Fig. 1).

3. NEUROPSYCHOLOGY OF AROUSAL

During recent years, much has been learned about the neurological and biochemical mechanisms involved in human arousal. Preparation for competition, as well as competition itself, sets off a chain of events in the central nervous system and autonomic nervous system that results in arousal. Table I provides a summary of nervous system structures involved in arousal as well as the locations and functions of the structures.

4. AROUSAL THEORIES

A number of theories have been proposed to explain the relationship between arousal and athletic performance. Following is an analysis of the major perspectives.

4.1. Drive Theory

The drive theory of arousal states that arousal has a positive correlation with athletic performance, particularly in cases of skills that are well learned (Fig. 2). The theory is based on the classical work of Hull, who stated that drive (or arousal) multiplied by habit strength (amount of prior learning) determines an individual's level of performance:

$$\text{Performance} = \text{Drive} \times \text{Habit Strength.}$$

As emotions and excitement increase, so does an athlete's performance.

Mediating the role of anxiety on an athlete's performance is habit strength. Habit strength speaks to how well an individual has learned particular skills. The better learned a skill (or the more skilled the athlete), the more likely arousal is to enhance athletic performance. Some researchers have even gone so far as to suggest that the play of novice athletes (low in habit strength) is inhibited by increasing arousal levels.

Although this theory has many merits and has been closely associated with the concept of social facilitation, some have questioned whether the arousal-performance relationship depicted exists in all motor activities required in sport. The hypothesis is

FIGURE 1 Arousal and performance.

TABLE I
Nervous System Structures Involved in Arousal

<i>Structure</i>	<i>Location</i>	<i>Function</i>
Reticular formation	Part of brain stem that continues out of medulla and pons	Involved in sleep, waking, alertness, and optimal brain arousal
Hypothalamus	Between the thalamus and midbrain	Involved in appetitive and sexual behavior, regulation of sympathetic nervous system and pituitary gland
Limbic system	Series of structures, including the hippocampus and amygdala, located near the border between the cerebral hemisphere and the brain stem; the hypothalamus is sometimes considered part of the limbic system	Primarily concerned with emotional behavior; amygdala appears to be involved in aggression
Cerebral cortex	Convolutated outer layer of the human brain	Highest center involved in learning, remembering, planning, and performing motor acts
Sympathetic nervous system	A branch of the autonomic nervous system with nerve fibers originating in thoracic and lumbar regions of the spinal cord	Activates glands and smooth muscles during arousal
Parasympathetic nervous system	A branch of the autonomic nervous system with nerve fibers originating in the brainstem and sacral regions of the spinal cord	Maintains appropriate internal states during times of relaxation
Adrenal cortex	Outer layer of two small endocrine glands just above the kidneys	Secretes cortisol that regulates metabolism and stress response
Adrenal medulla	Inner layer of two small endocrine glands just above the kidneys	Secretes adrenaline (epinephrine) and noradrenalin (norepinephrine); both are involved in increased activation of the body
Pituitary gland	Deep inside brain, just below hypothalamus	Releases adrenocorticotrophic hormone that stimulates adrenal cortex to release cortisol

FIGURE 2 Drive theory.

well accepted for gross motor tasks requiring strength and speed, but it is less well accepted for tasks requiring balance, accuracy, and fine motor skills (e.g., putting a golf ball).

Drive theory is most beneficial to practitioners in understanding the link between skill level and optimal arousal. It is unlikely that an excellent athlete facing an easy task will garner sufficient emotional and physiological motivation to perform at his or her best. In such a situation, it benefits that athlete to set challenging process goals for the task at hand, in essence increasing the perceived challenge of the task. Conversely, regardless of the potential benefits of arousal to explosive movements and strength, a novice athlete will not reap great rewards from achieving exceptional arousal levels. Such an athlete should be counseled to find a state of calm that allows him or her to feel comfortable on the playing field or court.

4.2. Inverted-U Hypothesis

The inverted-U hypothesis states that moderate levels of arousal are ideal for optimal athletic performance

(Fig. 3). Performance gradually improves as a competitor goes from underarousal to the alert state of moderate arousal, after which point performance declines as the individual becomes overaroused.

Unlike drive theory, the inverted-U hypothesis does state that there is a point of arousal that exceeds what is needed for excellence on the playing field. Yet since the original model posed in 1908 by Yerkes and Dodson, it has been suggested that one must account for task difficulty, unique sporting demands, ability level of athletes, and individual differences when employing the inverted-U hypothesis. For example, it has been suggested that the peak of a golfer's inverted U ought to be at relatively lower levels of arousal, whereas a sprinter's inverted U will exist at high levels of arousal. In both instances, too little arousal or too much arousal is debilitating, yet the midranges of arousal differ due to sporting demands. Therefore, it is suggested that although the arousal-performance relationship is that of an inverted U, the placement of this inverted U on the arousal continuum ought to vary due to sport demands and individual differences.

The inverted-U hypothesis is perhaps most readily embraced by those in sport psychology practice. This is due in part to the fact that its simplicity (a unidimensional model as opposed to a theory that considers arousal and anxiety or multiple forms of anxiety) makes it easily understood by athletes and coaches. An athlete's ability to move into and out of ideal performance states is clear by drawing an upside down U on a piece of paper. This theory is also appreciated by practitioners because it recognizes the possibility of overarousal. This further illuminates the challenges posed by a "one size fits all" fire and brimstone pep talk.

FIGURE 3 Inverted-U hypothesis.

4.3. Reversal Theory

Unlike other theories, the foundation of reversal theory is an athlete's interpretation of arousal rather than how high or low the energizing state is. Individual differences in perception determine how facilitative or debilitating arousal levels are. Depending on the situation that the athlete faces, arousal levels might be interpreted as "anxiety" or "excitement." For example, high levels of arousal might be interpreted by one athlete as lack of preparedness, whereas the same elevated arousal could be perceived as the appropriate energy for athletic success by another. Furthermore, at the root of this theory is the ability to change (i.e., reverse) one's interpretation of arousal. The reversal of interpretation might lie in improved skill levels (through practice), realization that tasks are not as challenging as thought previously, or support of coaches or teammates. Ultimately, according to this model, optimal performance is achieved when a player's preferred arousal level is in harmony with his or her actual arousal levels.

Sport psychology coaches who understand the reversal theory often see the importance of cognitive restructuring. The fact that perceptions of threats and opportunities on the playing field can change the facilitative nature of arousal makes an athlete's beliefs and thought processes essential for success. Regardless of the situation, an athlete nearly always has an opportunity to find his or her ideal arousal level. For example, a loud and hostile crowd could be perceived as an "extra player" for the home team, reducing the visiting team members' good feelings and confidence (i.e., debilitating perceptions). Conversely, the visiting team members could see and hear the hostile crowd and think, "We must be good! This crowd is worried and needs to help their team" (i.e., a facilitative perception). Drawing from the teachings of cognitive and/or rational-emotive therapies can be very useful to a practitioner who appreciates the reversible nature of arousal's effects on athletic performance.

4.4. Newer Theories

Other theories related to arousal in sport performance are the Individual Zones of Optimal Functioning (IZOF), the multidimensional anxiety theory, and the Cusp Catastrophe Model. Hanin suggested that in the IZOF, each individual has a certain level of emotion where he or she competes optimally. This "zone" of emotion can be high, low, or somewhere in between, depending on each person's unique

cognitive, physiological, and technical resources. The multidimensional anxiety theory suggests that cognitive anxiety (i.e., thoughts/worries) has an inverse linear relationship with performance, whereas somatic anxiety (i.e., physiological) displays an inverted-U relationship with performance. Lastly, the Cusp Catastrophe Model states that one must consider cognitive anxiety, physiological arousal, and performance demands simultaneously. In this theory, the relationship between anxiety/arousal and performance is not a neat linear one but rather one that can be filled with great peaks and valleys. In particular, one can achieve the greatest performances under high cognitive stress and arousal but, at the same time, can experience the greatest performance decline when things go awry.

5. EFFECTS OF AROUSAL ON ATHLETIC PERFORMANCE

Arousal levels directly influence physiological, cognitive, and motor modalities necessary for excellence on the playing field (Table II). Understanding these modalities

can help in the identification and management of underarousal and overarousal. Physiologically, modalities measurable through psychophysiological monitoring, such as brain waves, skin conductance, heart rate, blood pressure, and muscle tension, all are elevated when an individual is aroused. Although these modalities are directly related to somatic arousal, each must be carefully measured because most are automatically increased during physical exertion. Perhaps the speed of recovery to "normal" levels between points and after play is when the goodness of one's arousal level is most apparent.

Arousal level also influences one's cognitive functioning. It is suggested that an athlete beyond his or her optimal arousal level is likely to suffer from poor decision making, impaired memory, and rushed thinking. Nideffer posited that in sport, heightened arousal levels also impair an athlete's ability to focus on the task at hand. Contrary to the lay assumption that overaroused athletes think too much, it is suggested that being outside one's optimal arousal zone leads to thinking about the wrong things at the wrong time. In particular, Nideffer suggested that one begins to concentrate on thoughts, emotions, and feelings (specifically fear and worry). There is little to suggest that underarousal significantly influences one's cognitive

TABLE II
Effects of Arousal on Athletic Performance

Modality	Low arousal	High arousal
Brain wave (electroencephalography)	Increased alpha waves or theta Good performance on fine motor skills	Increased beta waves Good performance on gross motor skills
Skin conductance	Lack of perspiration Good for a sport like golf	Increased perspiration, increased conductance Good for high-energy sports
Heart rate	Decreased heart rate Ability to compete over long periods of time	Increased heart rate Ability to perform skills with speed and power
Blood pressure	Decreased blood pressure Effects uncertain	Increased blood pressure Effects uncertain
Muscle tension (electromyography)	Muscles relaxed Fluid technique, potential poor form	Increased muscle tension Good strength and stability, potential for rigid movements
Focus	May be inattentive	Attention narrows, ultimately leading to focus on fears and worries
Memory	No deficit	Difficulty in remembering large chunks of information and complex tasks
Anaerobic power	Impaired strength and speed	Increased strength and speed
Fine motor control	Improved dexterity	Impaired

abilities, yet at low arousal levels few athletes are able to garner the necessary energy and alertness to succeed at the physical tasks of sport.

6. MANAGING AROUSAL LEVELS

There are many psychological techniques that allow one to effectively manage arousal levels. Understanding that arousal, anxiety, concentration, confidence, and physiological modalities all are inherently linked, it is clear that there are many approaches to help athletes find and maintain facilitative levels of arousal. Interventions can be broken down into three categories: cognitive, behavioral, and cognitive-behavioral. (Although dividing interventions into these categories is useful in understanding the practice of sport psychology, it is important to recognize that the mind and body are inherently linked. This reminds one that these categories are not mutually exclusive.)

6.1. Cognitive Interventions

Increasing an athlete's awareness about his or her optimal arousal levels is the foundation of an intervention. Developing awareness might be achieved through successive postperformance reflections that examine levels of excitement, concentration, emotions, and confidence during a competition. Similarly, a retrospective comparison of "best performances" versus "worst performances" can paint a powerful picture of an athlete's optimal arousal state.

Setting realistic and motivating goals gives an athlete the ability to energize while maintaining appropriate focus. It is appropriate to have a "mission" or goal for one's career and season as well as for each practice and competition. Goals direct an athlete (i.e., energizing) and clarify purpose (i.e., minimizing stress and relaxing).

Cognitive restructuring and self-talk can appropriately energize an athlete and calm him or her down when necessary. Cognitive restructuring fits nicely with the reversal theory of arousal, suggesting that modifying one's perspective and thoughts will help the athlete to find appropriate activation levels. Self-talk or the use of cue words can energize (i.e., "quick feet") or calm down (i.e., "slow and smooth") an athlete when necessary. Thought stoppage allows an athlete to catch himself or herself when he or she begins to focus on task-irrelevant cues.

Mental imagery, another cognitive intervention, is popular in the field of sport psychology. A good

imagery session in which the body is relaxed and all of the senses are incorporated can be used to relax or energize an individual. Accessing one's memory bank of sporting highlights can serve as very motivational imagery, hence increasing arousal levels. Conversely, imagery can be used to escape from the stresses of competition, consequently reducing arousal.

6.2. Behavioral Interventions

There are a variety of relaxation techniques that can benefit an athlete who is overaroused. The following are a few techniques that are used regularly by sport psychology practitioners: controlled breathing, progressive muscle relaxation, meditation, relaxation response, and biofeedback. A few of these interventions can also be used by an athlete to energize, specifically quick shallow breathing and gaining understanding of excited physiological levels through biofeedback. Actions such as quick sprints, jumping rope, and dynamic stretching also serve to energize the underaroused athlete.

6.3. Cognitive-Behavioral Interventions

Both cognitive and behavioral techniques are combined during preperformance preparation and competitive routines. Prior to a competition, successful athletes commonly engage in activities such as setting goals, listening to music, using mental imagery, and physically warming up so as to have optimal arousal at the start of the competition. Similarly, while in the midst of play, athletes often use competitive routines to relax and refocus. Using a physical cue to put a prior play in the past, engaging in mental planning, and taking a good breath or two to help focus attention are often elements of such a routine. Routines are commonly used in sports where the flow of play is intermittent such as tennis, baseball, and golf.

GLOSSARY

assessment contexts The fields in which psychological assessment is applied.

assessment process Series of tasks ordered in a specific sequence conducted by the assessor for solving the client/subject demand.

assessment targets Specific psychological characteristics (intelligence, cognitive skills, personality dimensions, behavioral responses, defense mechanisms, environmental conditions, etc.).

interview The interaction between two people in which one person (the interviewer) asks for and collects information with a given purpose or demand, and the other person (the interviewee, client, or subject) responds or answers questions.

observational method A set of procedures for collecting data, including a protocol with a pre-defined set of behavioral categories in which the subject's behavior is coded or registered.

projective methods Instruments containing relatively structure-free stimuli, considered especially sensitive to covert or unconscious aspects of behavior, that encourage a wide variety of idiographic subject responses with a

minimum of subject awareness concerning the purpose of the test.

psychological assessment The discipline of scientific psychology devoted to the study of a given human subject (or group of subjects in a scientific applied field—clinical, educational, work, etc.), by means of scientific tools (tests and other measurement instruments), with the purpose of answering clients' demands that require scientific operations such as describing, diagnosing, predicting, explaining or changing the behavior of that subject.

psychological testing The process of administering, scoring, and evaluating tests or standard methods.

psychometrics The principles, theories, and techniques of test construction.

self-report A method for collecting data whose source is the subject's verbal message about him- or herself.

standard methods or tests Tests that have a standard set of stimuli, standard administration procedures, and a standard form of measuring subjects' responses, which can be transformed into standard scores.

1. INTRODUCTION

1.1. Concept

Psychological assessment is the discipline of scientific psychology devoted to the study of a given human subject (or group of subjects) in a scientific applied field—clinical, educational, work, etc., by means of scientific tools (tests and other measurement instruments), with

the purpose of answering client's demands that require scientific operations such as describing, diagnosing, predicting, explaining or changing the behavior of that subject. —Fernández-Ballesteros *et al.*, 2001.

Throughout the history of applied psychology, psychological assessment has been a key discipline, often to the extent of being confused with psychology itself and of constituting the public face of psychology. As several empirical studies have pointed out, assessment tasks are an ever-present element in all psychological work, from the scientific laboratory to applied settings. Thus, all types of psychological work involve assessment at some stage and to some extent, whether it be through the use of sophisticated data collection equipment, structured interviews, or qualitative observations, or by means of complex measures obtained through the administration of tests.

1.2. Brief History

Psychological assessment in some form or another can be found throughout the history of human thinking, in the Bible, in ancient China, and even in the works of Socrates, Plato, and Aristotle or those of the ancient physicians Hippocrates and Galen. Nevertheless, it is not until the late 19th century that we find scientific events related to psychological assessment. [Table I](#) offers an overview of the most important contributions to psychological assessment from the starting point of scientific psychology—the founding of Wundt's Psychology Laboratory in Leipzig in 1878—until 1950.

As can be seen in [Table I](#), psychological assessment is a sub-discipline developed at the same time as experimental psychology. While psychology is devoted to the study of the principles of mind, consciousness, and behavior, psychological assessment is devoted to the study of how, or to what extent, these principles are fulfilled in a specific subject or group of subjects. For the study of a particular subject (or group of subjects), psychological assessment requires methods for data collection. Thus, psychological assessment is closely related to psychometrics and to psychological testing. Methodological advances in psychometric theory are important because all measurement devices are developed and evaluated using psychometric criteria; psychological testing and psychological assessment have even been confused. But psychological assessment cannot be reduced to either psychometrics or the processes of administering tests. Rather, as referred to in the above definition, psychological assessment always

involves a process of problem-solving and decision-making in which measurement devices and other procedures for collecting data are administered for testing hypotheses about a subject (or group of subjects), with the specific purpose of answering relevant questions asked by the client or the subject. The client and subject may be the same person or unit, or the client may be another professional or relative (e.g., a psychiatrist, an educator or a judge) who asks for the assessment of a third person or group of persons with a given purpose (description, classification, diagnosis, prediction, prognosis, selection, change, treatment, or evaluation).

1.3. Objectives and Contexts

But these applied questions require scientific objectives, of which the following are the most common: description, classification, prediction, explanation, control, and evaluation. By way of example: when a psychiatrist asks a psychologist for a diagnosis of a given patient, the psychologist should proceed to the description and classification of the patient; when a client asks a psychologist who is the best candidate for a job, the psychologist must predict the candidate who is likely to perform best; when a couple or a family asks for counseling, the psychologist should analyze the situation before intervening; when a pupil has a learning problem, the psychologist must analyze the case and hypothesize about the circumstances that explain or cause the problem, manipulate its cause(s), and evaluate the extent to which it has been solved.

As can be seen from the examples, these various objectives emerge from different applied settings, the three most common assessment contexts being clinical psychology, educational psychology, and work and industrial psychology.

Finally, the relevant events listed in [Table I](#) emerge from different models of scientific psychology, are related to specific psychological content or targets (intelligence, aptitudes, personality characteristics, etc.), and imply a variety of methods (interview, self-reports, projective techniques, etc.).

2. THEORETICAL PERSPECTIVES

Like psychology in general, psychological assessment developed in association with different models or theoretical frameworks, which have given rise to different theoretical formulations, targets, methods, and objectives. [Table II](#) shows the psychological models that have had

TABLE I
Principal Contributions in the History of Psychological Assessment from 1880 to 1950

<i>Year</i>	<i>Author(s)</i>	<i>Contribution</i>
1884	Francis Galton (1822–1911)	At London's South Kensington Museum, British scientist Galton set up the "Anthropometric Laboratory" for the assessment of physical and psychological characteristics (reaction time, visual acuity, discriminative speed and other sensory, perceptive, and motor measures).
1890	McKeen Cattell (1860–1944)	Working on his doctoral dissertation at Wundt's laboratory in Leipzig, the American Cattell developed the first definition of "mental test" as the measurement tool for higher mental processes.
1894	Emil Kraepelin (1856–1926)	One of Wundt's first pupils, Kraepelin proposed a comprehensive system for classifying psychopathology, taking into consideration mental states, memory, etc.
1896	Hermann Ebbinghaus (1850–1909)	Ebbinghaus defined intelligence as the ability to interrelate and combine correctly. He developed the first group intelligence test, the Completion test, consisting of a series of texts with words and parts of words omitted. Subjects (in a group) had to fill in as many blanks as possible in 5 minutes.
1896	Karl Pearson (1857–1936)	The Briton Pearson developed the mathematical method of correlation, a fundamental tool for the development of tests.
1898	E. L. Thorndike (1874–1949)	Thorndike reported the use of mazes and puzzles to measure the intelligence of cats. In 1904, he wrote <i>An Introduction to the Theory of Mental and Social Measurements</i> .
1904	Charles Spearman (1863–1945)	Two important developments can be attributed to this British scientist (who worked for several years in Germany): the development of reliability (<i>The Proof and Measurement of Association between Two Things</i>), and a theory of intelligence that led to the development of methods for locating a general factor underlying a group of tests.
1905	Alfred Binet (1857–1911)	Working on intelligence in an attempt to select students for compulsory education in France, Binet and his colleague Simon developed a set of situations that constituted the first test of intelligence.
1906	Karl Jung (1875–1961)	Jung introduced the first word association method for diagnosing psychopathology, using a list of 100 words, to each of which the subject was asked to respond as quickly as possible with the first word that came to mind.
1914	Robert S. Woodworth (1869–1962)	The first personality questionnaire was developed by Woodworth, intended as a screening process to identify those unfit for active service in World War I. The personal data sheet consisted of a set of self-reported items selected from psychiatric interviews.
1917	Arthur S. Otis (1886–1964) and Robert M. Yerkes (1876–1956)	Developed the "Army Alpha and Beta," general intelligence tests for the assessment and selection of American recruits for service in World War I.
1920	Kurt Goldstein (1878–1965)	Scientific neuropsychological assessment emerged in Germany after World War I from research on the concomitants of brain damage. After concluding that individuals with critical injuries display loss of ability for abstract thinking and that their behavior involves less generalization, Goldstein (in collaboration with Scheerer) developed several tests of abstract and concrete thinking.

Continues

Continued

Year	Author(s)	Contribution
1921	Hermann Rorschach (1884–1922)	The first projective assessment methods were developed by the Swiss Rorschach and published in his <i>Psychodiagnostik</i> . The method used 10 inkblots, to which subjects have to respond by saying what they “could be, or looked like.” This method was designed to assess personality and psychopathology.
1934	Lev Vygotsky (1896–1934)	From the perspective of “Soviet psychology,” the Russian Vygostky, in his <i>Thinking and Language</i> , developed the concept of the assessment of proximal development, which constitutes the roots of cognitive strategies of assessment.
1938	Henry A. Murray (1893–1988)	In the book <i>Exploration in Personality</i> , Murray (with Morgan) presented the thematic apperception test. Consisting of a set of ambiguous pictures with human figures, this test requires subjects to make up a story. The main objective of this method is to assess personality.
1943	Office of Strategic Services (United States)	Using methods first employed in Germany, but later developed in Britain, an important program for the global assessment of individuals, “Assessment of Man,” was consolidated. As Dubois (1970) stated, “Instead of attempting to measure rather limited aspects of behavior as had been the case with the most psychometric and clinical devices up to that time, a program was designed to describe the way the individual was able to act in a wide variety of situations” (p. 110).
1950	Monty B. Shapiro (1951–)	At a meeting of the British Society of Psychology, Shapiro presented an important work developed in the Maudsley Hospital, “Experimental Approach to Diagnosis and Psychological Testing,” which would serve as the basis for behavioral assessment and other idiographic developments.

most repercussion in psychological assessment: trait, medical, dynamic, behavioral, cognitive, and constructivist.

2.1. Trait

As human beings display wide variability in the way they think, feel, and behave, one of the objects of inquiry in psychology has been individual differences in human characteristics related to intelligence or mental aptitudes, affect and emotions (aggressiveness, hostility, etc.), personality (extraversion, flexibility, etc.), psychopathology (depression, anxiety, etc.). All of these have constituted important targets for assessment.

The trait approach uses several data collection techniques, from questionnaires or standardized tasks to rating scales. It is, therefore, the trait approach that has inspired the most well known psychometric tests. The main objective of this approach is to find the true score of a given subject in a specific trait or his or her true position in relation to a normative or standard group. In practical terms, these comparisons allow psychologists to describe and classify subjects with regard to a set of

traits or medical conditions and to predict their future behaviors. The explanation objective would not be applicable to the trait model, for reasons of tautology.

2.2. Medical

Historically, the development of psychological assessment has been closely related to clinical settings. Therefore, from the outset a medical model emerged, focusing principally on mental disorders. Several classification systems have been developed, the most well known being the American Psychiatric Association’s *Diagnostic and Statistical Manual of Mental Disorders* (currently the *DSM IV-R*) and the World Health Organization’s *Classification of Mental and Behavioral Disorders* (currently the *ICD-10*), both of which constitute descriptive category systems with no etiological bases (neuropsychological illness and assessment are not included in this medical approach).

The purpose of these classification systems is to provide clear descriptions of diagnostic categories of mental disorders in order to aid clinicians in diagnosing

TABLE II
Theoretical Approaches in Assessment: Model, Targets, Methods, Contexts, and Goals

<i>Theoretical approach</i>	<i>Targets</i>	<i>Methods</i>	<i>Goals</i>
Trait	Trait	Questionnaires	Description
	Factor	Intelligence tests	Classification
	Dimension	Rating scales	Prediction, prognosis, or selection
	Characteristic Syndrome		
Medical	Mental and behavioral disorders	Classification systems Psychopathological tests	Description Classification and diagnosis
Psychodynamic	Unconscious mental process	Projective techniques	Description
	Conflicts	Completion methods (words, phrases, stories, etc.)	Classification Diagnosis
	Defense mechanisms		Prediction Explanation
Behavioral	Behaviors:	Observation	Description
	Motor	Self-observations	Prediction
	Physiological	Self-reports	Functional
	Cognitive	Physiological measures	explanation
	Environment:

	Social		
	Cognitive processes	Performance on cognitive tasks and cognitive equipment	Description Prediction
	Cognitive strategies	Thinking aloud	Explanation
	Mental representations	Self-reports	Evaluation
Constructivism	Other cognitive constructs		
	Emotions verbally expressed		
	Constructed knowledge	Narrative assessment	Description
	Personal constructs, personal plans, meanings, etc.	Autobiography REP-Grid Personal documents Content analysis	

and referring to these disorders. From this perspective, and with the aim of establishing objective procedures for assessing mental and behavioral disorders, several tests have been developed (e.g., the Multiphasic Minnesota Personality Inventory). In sum, description and classification are the two main objectives of the medical model.

2.3. Psychodynamic

Included under the title of psychodynamic are a series of relevant targets: unconscious mental processes, conflicting attitudes generating anxiety, defensive mechanisms, and interpersonal patterns governed by developmental experience. As stated by Weiner (2003),

the psychodynamic approach serves the purpose of elucidating “aspects of personality structure and personality dynamics in way that clarify the role of drives, conflict and defense, and object representations in shaping people are likely to think, feel and act” (p. 1012).

Throughout the history of psychological assessment, several instruments have been developed from a psychodynamic perspective. Perhaps the most well known are projective techniques using semi-structured visual materials (such as the Rorschach tests or the thematic apperception test), drawing a specific object (draw-a-person, draw-a-tree, draw-a-family), and finally, approaches using verbal material (words, sentences, stories, etc.). The goals of the dynamic model

include description and diagnosis as well as prediction and explanation.

2.4. Behavioral

The behavioral assessment approach has been defined in several ways throughout the 20th century, but three fundamental pillars of these definitions can be identified and reduced to the following: (1) human behavior can be explained by the interaction between the person (from a biological and psychological point of view) and the environment; (2) there are three different modes or systems: motor, cognitive, and psychophysiological; and (3) psychological problems have multiple causes, essentially environmental. Thus, as Table II shows, targets in behavioral assessment are motor, cognitive, and physiological responses, in addition to environmental conditions.

A methodological condition of behavioral assessment is that all targets should be assessed through the multimethod approach. Thus, assessment of behavioral and environmental conditions and their respective interactions takes place through observation (direct observation as well as observations by relatives), self-observation, self-report, and psychophysiological techniques. Finally, because behavioral assessment emerges from a clinical perspective, its objectives are description, prediction, functional explanation (need for treatment), and treatment evaluation. The main goals of the behavioral psychologist are related to the environmental or personal conditions that can be functionally linked to target behaviors and provide indications for the planning of treatment.

2.5. Cognitive

The cognitive model refers to two theoretical perspectives, the first related to the study of cognitive processes and the second associated mainly with therapy and treatment, under the assumption that cognitive processes or structures (or verbal expression of emotions) are causal aspects to be taken into account if the intention is to change behavior.

Table II shows the most important targets for the cognitive model: cognitive processes (such as attention, perception, learning and memory, language, and imagery), mental representations (e.g., visuospatial representations, automatic thinking), cognitive structures (cognitive abilities), and other cognitive constructs or forms of emotional expression. These processes, strategies or structures are assessed mainly through subjects' performance in cognitive tasks. For example, attention

can be measured by asking the subject to find a specific letter (e.g., "m") in a text, or to press a button when a specific cue appears on a screen (testing reaction time).

Cognitive processes or strategies can also be measured using meta-components. Thus, the subject may be asked to "think aloud" while solving a given task. The cognitive model also considers the meta-component of emotions, so that subjects may be asked to self-report what they feel in a particular situation. Finally, the objectives of the cognitive model—in the same line as those of the behavioral model—are the following: description (how the subject can be described on the basis of these processes and structures), prediction (what the subject can be expected to do on the basis of these processes), explanation (which processes may be controlling targets, so that they can be manipulated in order to change targets), and evaluation (to what extent treatment has produced the expected changes).

2.6. Constructivist

The constructivist theoretical approach to psychology stresses conceptual, epistemological, methodological, and ontological characteristics, as opposed to an objective and realistic view of the science. From this approach, all knowledge is considered as a social product, so that there cannot be any universal law or principles: subjective aspects and local custom or practices dictate. Therefore, targets must be selected for each individual and his or her specific way of constructing social reality, the meaning of life, or personal plans, or of producing personal constructs. Methods are idiographic rather than standard. Finally, utility is the most important characteristic of any assessment, as opposed to validity. Table II shows these idiographic targets making up the basic personal knowledge developed across the subject's life span.

Several methods have been developed within the constructivist approach, all of which attempt to capture the essence of the person in question. Perhaps the most well known is the repertoire grid technique. Originally developed by Kelly in the 1950s, several different versions have appeared over the last half-century, all with the basic purpose of assessing the subject's personal constructs. Other methods involve the use of narratives developed by different authors, through which a sense of identity, coherence, meaning of life, and other personal phenomena can be assessed. With these narrative-based methods, the use of autobiography is an essential element for assessing these constructs. Finally, the data from these methods is analyzed through content analysis, which is

essential to constructivist methodology, because hermeneutics is, basically, a system for discovering targets.

3. METHODS AND TECHNIQUES

Marx and Hillix made a distinction between scientific method, methods, and techniques (methodic techniques or instruments). While the scientific method is the basic strategy for the advancement of science (e.g., the hypothetico-deductive method), methods are general data collection procedures, and techniques can be defined as those specific instruments or tests developed for collecting data in a particular field.

An important body of knowledge within psychological assessment is the set of methodic techniques for data collection. However, before going on to describe these methods, it is necessary to first identify some general conditions of psychological assessment methods.

1. Methods, techniques, and instruments should not be confused with psychological assessment. As stated previously, methods and tests constitute the tools for data collection and testing hypotheses, while psychological assessment is a lengthy process of problem-solving and decision-making.

2. There are standard and non-standard methods. All techniques and instruments have a set of stimuli (questions, tasks, etc.), a set of administration procedures, and a set of responses; finally, subjects' responses can be transformed into scores. Standard methods or tests are those that have a standard set of stimuli, standard administration procedures, and standard forms of obtaining subjects' responses—responses that can be transformed into standard scores. Standard methods usually have sound scientific properties and present psychometric guarantees. These standard methods, which allow between-subject comparisons, are known as psychometric tests. But not all data collected in psychological assessment derive from standard methods.

3. As described above, assessment targets are specific psychological characteristics (intelligence, cognitive skills, personality dimensions, behavioral responses, defense mechanisms, environmental conditions, etc.) with several degrees of inference. That is, the majority of these targets are psychological concepts that are operationalized by means of a given method, technique, or measurement device. Thus, all methods in psychology can be considered procedures for operationalizing a given psychological construct or target for assessment. Because each method has its own source

of error, the best way to conduct a rigorous assessment is to use several methodic techniques, tests, or measures or, in other words, to triangulate a given concept through multimethod. For example, if in assessing a particular personality construct (e.g., extroversion) the subject can be administered a standardized self-report, he or she can be given a list of adjectives, and his or her behavior can be observed in an analogue situation or by administering a projective technique.

With these three general conditions in mind, consider the broad categories in which psychological assessment methods can be classified: interview, observation, self-reports, and projective techniques. It should be borne in mind, however, that these four categories can themselves be divided into more specific sub-categories.

3.1. Interview

Interviewing is the most commonly used method in psychological assessment in all basic and applied fields: clinical, educational, work and organizations, forensic, laboratory, and so on. It has the broadest scope, so it can be used for assessing any psychological event (subjective or objective, motor, cognitive or physiological).

For assessment purposes, an interview is basically an interactional process between two people in which one person (the interviewer) elicits and collects information with a given purpose or demand, and the other person (the interviewee, client, or subject) responds or answers questions. The information collected can refer to the interviewee (motor, cognitive, or emotional responses) or to relevant others. Thus, the interview can be thought of as a self-report or as a report to or by another.

Because the interview is an interpersonal process, it has the following several phases:

1. Interview preparation: Before starting an interview, the psychological assessor should plan the interview. What are the purposes of the interview? What are the subject's characteristics? What format will the interview take? How long will the interview last?

2. Interview starting point: A brief presentation by the interviewer about the purpose of the interview, what the interviewer is expecting, and the plans for the assessment process.

3. Body of the interview: The interview is always led not only by the purpose of the assessment but also by the theoretical approach of the interviewer. These two principal conditions influence the content (what type of

question) and the format (amount of structure in questions and answers) of the interview. By way of example, the main common and shared areas of an interview are as follows: sociodemographics, interview purpose or demand, family and social condition, education, work, interest and hobbies, health, beliefs, and values.

4. Closing the interview: The interviewer closes the interview by briefly summarizing the data collected and describing the subsequent steps or actions.

There are several typologies of the interview depending on: (1) the structure of the questions and answers (structured, semi-structured, non-structured), (2) the context in which the interview takes place (clinical, personnel selection, counseling, forensic, etc.), (3) interviewer style (directive, non-directive), (4) theoretical perspective (dynamic or psychoanalytic, behavioral, phenomenological, etc.), and (5) number of subjects assessed (individual, group, family, team group, etc.).

The interview as an assessment method has several advantages and limitations, such as the following:

1. It offers a situation in which subjects can act and interact with several verbal stimuli (or questions) and can be observed. Also, in this situation several interpersonal emotional relationships (interviewer–interviewee) develop that are highly relevant to forthcoming psychological actions.

2. The interview is a broad technique for collecting data; that is, any condition or purpose (past or present; internal or external; descriptive, classificatory, or explanatory, etc.) can be assessed. Also, this flexibility of the interview allows psychologists to clarify a given situation or action of the subject.

3. However, information collected in interviews may present considerable bias and error deriving from the interviewee, the interviewer, and the situation. Inter-interviewer agreement and test-retest reliability is relatively low, and validity depends on the construct assessed.

4. Finally, as emphasized by Meyer et al., although most types of psychological testing—including the interview—show evidence of their predictive validity, the use of multimethods is essential in order to gain a complete understanding of each case.

3.2. Observational Methods

All psychological assessment contains observations. Indeed, as Anastasi (1988) stated: “a psychological test is essentially an objective and standardized measure of a sample of behavior” (p. 23). Thus,

observation is one of the broadest categories in psychological assessment. Common intelligence tests (such as the Wechsler Intelligence scales), as well as cognitive or psychophysiological measurement using special equipment, can be used as observational procedures. In brief, an observational method consists of a set of data collection procedures containing a protocol with a predefined set of behavioral categories in which subjects’ behaviors are coded or registered. These behaviors are external, motor events observed in natural, analogue, or test situations; observation may sometimes involve the use of sophisticated equipment such as tachistoscopes, polyreactographs, or psychophysiological instruments that allow response amplification.

Observational methods have been classified depending on the following: (1) the observer: participant versus non-participant observer; (2) the target or observed event: overt event (motor response or stimuli parameter) versus subject’s attribute or molar characteristic of the observed situation; (3) the situation in which observations take place: natural versus artificial or standardized situations (or even with equipment amplifying the target); and (4) the protocol: coding system versus open description of the continuum of behavior. Table III shows examples of this classification system.

Observer, subjects and targets, and observational protocol are sources of bias of the observational assessment method. Below is a summary of how to maximize the accuracy of observational methods:

1. *Observer.* Observational methods in psychology should maximize objectivity through the assessment of overt (observable) events, ongoing observer training, use of several observers, and checking of inter-observer agreement.

2. *Subject observed.* One of the most important biases of observational methods is subject reactivity. Reactivity can be minimized in various ways, such as use of natural settings, subjects being unaware, and long habituation periods.

3. *Observational systems.* Coding or registration systems require well-defined targets and procedures, a small number of observation categories, and standard data about psychometric soundness.

3.3. Self-reports

As defined elsewhere, the self-report is a method for collecting data whose source is the subject’s verbal message about him- or herself. Self-reports are the most

TABLE III
Type of Observational Methods and Examples of Observational Techniques

<i>Observer</i>	<i>Target</i>	<i>Situation</i>	<i>Protocol</i>	<i>Example</i>
Nonparticipant Expert observes target behaviors or attributes	Motor behaviors Product of behavior Attributes	Natural situation registered through video, film, two-way mirror, etc.	Continuum of observed behavior Category system Behavior checklist Rating scales	Standardized observational code (SOC-III) (Cerezo <i>et al.</i> , 1991)
Participant but expert	Motor behavior Product of behavior (dimensions) Verbal behaviors Attributes	Standardized/Non-standardized situations	Category system Behavior checklist (occurrence, frequency accuracy, reaction time, duration, etc.) Rating Scales (Likert-type scales)	WAIS III (Wechsler, 2000)
Participant and/or relatives	Dimensions of motor and verbal behavior Attributes	Natural situation Non-standardized	Behavior checklist Rating scales	Eyberg behavioral inventory (Eyberg & Ross, 1978)

common assessment procedures for collecting data in psychology and psychological assessment. Self-reports provide information about thousands of targets—from historical events to motor behaviors in the present situation, even subjects' future plans. In fact, human beings can report on their private, unobservable, subjective world, their thoughts, and their emotions, as well as public observable events. This means that, in answering a verbal question, subjects may carry out certain mental operations (from remembering what they did a few minutes previously to inferring why they acted in a certain way a long time ago). Such operations interfere with the fidelity of self-reports.

Also, when a self-report or a set of self-reports is collected, psychologists can either take them as they are (from an isomorphic perspective) or make inferences from them after carrying out statistical manipulations (e.g., item aggregation or item anchoring in new scales). In other words, in order to test theoretical hypotheses, psychologists interpret the self-reports as indices of internal structures or processes, such as attitudes, personality characteristics, motives, and other intrapsychic concepts developed from trait theory, medical models, cognitive psychology, and/or dynamic theories. Thus, since the very beginning of scientific psychology, aggregates of self-reports assessed via questionnaires through inter-subject designs (subject aggregates) have been

used as one of the main assessment methods for describing, classifying, predicting, and even (tautologically) explaining human behavior.

In psychological assessment, clients' self-reports are collected in different formats. As already mentioned, interviews frequently represent the starting point and conclusion of a professional relationship in clinical, educational, and work settings. When self-reports are used as formal procedures for data collection, they imply a broad methodological category: interviews always involve self-reports, and self-observation and self-monitoring also require self-reports. Finally, self-reports can be obtained through questionnaires, inventories, or scales containing a set of relevant verbal statements and a variety of response formats (true or false options, checklists, scaled responses, etc.).

As emphasized elsewhere, self-reports have several sources of bias. Whatever the type of event reported—from objective events to subjective ones—several internal and external conditions, such as length of the question, formulation of the question, type of answer and response requested, and subject's characteristics, strongly affect the fidelity of self-reports. Table IV shows examples of general issues related to self-reports.

In summary, human beings are able to report on a myriad of events and are an important source of information; several assessment methods (such as interviews

TABLE IV
Examples of General Issues in Self-Reports^a

<i>Targets</i>	<i>Subject mental operations</i>	<i>Psychologist inferences</i>	<i>Response format</i>	<i>Type of self-report</i>
Motor response, external events	Accessibility to the target	Self-report as data vs	Open	Interview
Cognitive behavior	Level of inference of required transformation	Self-reports as sign	YES/NO, multiple choice, rating-scale	Questionnaire, inventory, scales
Subjective appraisal Psychophysiological responses	Time: Past, present, future		Latency, occurrence, frequency, amplitude, etc.	Self-observation, self-monitoring

^aModified from Fernández-Ballesteros & Márquez, 2003.

and self-observation, self-monitoring, questionnaires, inventories or scales) are based on self-reports. Even though self-reports have important sources of errors, so that self-report accuracy is threatened by several types of response distortions (positive and negative impression management, faking, acquiescence, and social desirability, among others), these can, at least partially, be measured and controlled. Finally, it is commonly accepted that self-report questionnaires can be optimized through various strategies, and that their accuracy can be maximized. When self-reports are taken as a source of behavioral information, the level of inference should be as low as possible, items should be as direct as possible, questions should be specific and with situational reference, the level of transformation of the information requested should be as low as possible, and finally, the information requested should refer, preferably, to the present.

3.4. Projective Techniques

According to Pervin (1975), a projective technique “is an instrument that is considered especially sensitive to covert or unconscious aspects of behavior, permits or encourages a wide variety of subject responses, is highly multidimensional, and evokes unusually rich or profuse response data with a minimum of subject awareness concerning the purpose of the test” (p. 33).

The basic assumptions of projective techniques are closely related to the psychodynamic model and psychoanalytic theory: (1) they involve the presentation of stimuli relatively free of structure or cultural meaning, consisting of inkblots, pictures, incomplete verbal sentences or stories, or performance tasks; (2) these

materials allow subjects to express idiosyncratic and holistic aspects of their personalities, and allow the assessment of dynamic constructs as well as defense mechanisms against anxiety, and conscious as well as unconscious processes and structures; and (3) subjects are not aware of the purpose of the test and the meaning of their responses to the test. Table V shows four main categories of projective techniques that can be identified depending on the material used and the task involved.

Although projective methods have been widely used, they have received considerable criticism, and continue to cause controversy. In fact, all the characteristics of projective methods—ill-defined stimuli, idiographic responses, non-standardized procedures, and subjective evaluation—have contributed to a lack of psychometric soundness. In sum, much more research is required for projective methods to be used as scientific tools. Nevertheless, there is an exception, as Weiner (2001) has emphasized: “the Rorschach Inkblot Method has been standardized, normed, made reliable, and validated in ways that exemplify sound scientific principles for developing an assessment instrument” (p. 423).

4. THE PROCESS OF ASSESSMENT, TREATMENT, AND EVALUATION

As mentioned previously, assessment should not be confused with its methods and tests, nor with a specific applied setting (such as the clinical one). It begins when a client makes a specific demand of a psychologist in a given context. This demand triggers a long process of problem-solving and decision-making that requires a series of tasks ordered in a specific sequence. This sequence

TABLE V
Types and Examples of Projective Techniques Depending on Materials Used and Task

Type of technique	Material	Task	Examples
Structural	Inkblots	Describe what it looks like	Rorschach Inkblots test (Rorschach, 1929)
Thematic	Pictures	Tell a story	Thematic apperception test (TAT) (Murray, 1936)
Expressive	White paper and pencil	Draw a picture	Machover Draw-a-Person test (Machover, 1948)
Associative	Words, incomplete sentences or stories	Complete the sentences or stories	Free association test (Rapaport, 1965)
Performance	Constructional elements (houses, trees, fences, etc.)	Build a town	Town test (Arthur, 1949)

is dictated by the objectives the psychologist must fulfill: description, classification/diagnoses, prediction/prognosis, explanation, and control. When the demand is for control, implying the need for an intervention, evaluation is an operation to be performed for appraising the treatment, or testing the extent to which the targets have changed in the expected direction. Thus, when assessment is conducted in order to produce change and is followed by treatment, evaluation should be the final step in the assessment process.

After 30 years of research into the assessment process, guidelines for the assessment process (GAP) have been set up in order to formalize it and published so that they can be discussed by the scientific community. The GAPs have been developed with the following purposes: (1) to assist psychological assessors in their efforts to optimize the quality of their work; (2) to assist the client coming from outside psychology in evaluating assessment tasks by allowing quality control; and (3) to facilitate the teaching of assessment, the standardization of practical considerations, and the design of advanced professional training programs.

Table VI presents the general framework of the assessment process. As it can be seen, the assessment, treatment, and evaluation process has four main steps: (1) analyzing the case; (2) organizing and reporting results; (3) planning the intervention; and (4) evaluation and follow-up. The two first phases deal with case formulation as well as with integrating, reporting, and discussing the case, and therefore refer to all assessment contexts (clinical, educational, work and industry, etc.), because description, classification/diagnosis, and prediction/prognosis are the assessment objectives in all cases. The third and fourth phases refer to those cases

demanding control and change and requiring explanatory assumptions, experimental designs, and, finally, treatment evaluation. Each step has several substeps, and from the substeps a set of 96 guidelines has been developed. The GAPs are procedural suggestions and should be taken as recommendations for helping assessors to cope with the complexities and demands of assessment processes in various applied contexts.

5. CONCLUSIONS

Psychological assessment is a subdiscipline of scientific psychology devoted to the study of a given subject with different purposes (describing, diagnosing, predicting, etc.) and in different settings (clinical, educational, etc.). Psychological assessment should not be confused with its methods or tests, since it involves a lengthy and complex process of decision-making and problem-solving that begins with the client's demands. There are several theoretical models proposing specific targets, methods, and assessment objectives.

Psychological assessment uses a variety of methods: interview, observation, self-reports, and projective techniques. Some of these have standard sets of stimuli, administration procedures, and ways of measuring subjects' responses and transforming them into standard scores; these methods are the well-known psychometric tests, but they are not the only means of collecting data in assessment. All assessment methods have particular sources of error, and all can be considered as fallible. The use of multimethod is highly recommended. Through the complex process of decision-making and problem-solving involved in

TABLE VI
Assessment Process: Basic Framework and Steps

START OF PROCESS: Process begins when a person/institution (client) asks an assessor to answer a question or give professional advice about a subject/single case.

PRECONDITIONS: Assessor examines whether he/she is qualified to satisfy the demand and whether the demand is in line with ethical criteria.

0. GENERAL PRINCIPLES

1. ANALYZING THE CASE (DESCRIPTIVE ASSESSMENT)

1.1 ANALYZING DEMANDS, COMPLAINTS, AND/OR GOALS: Gathering general information about client's and/or subject's referral question.

1.1.1 Investigating and evaluating client's and/or subject's questions.

1.1.2 Synthesizing client's demands and aspects of the general problem situation.

1.1.3 Formal agreement.

1.2 FORMULATING TESTABLE ASSESSMENT HYPOTHESES ABOUT THE CASE: Converting demands, complaints, and/or goals into testable hypotheses.

1.2.1 Formulating questions in technical terms, based on information gathered.

1.2.2 Operationalizing technical terms by means of assessment procedures.

1.3 COLLECTING INFORMATION: Gathering information relevant to the questions.

1.3.1 Planning administration of assessment procedures.

1.3.2 Applying assessment procedures.

1.3.3 Evaluating the application of assessment procedures.

1.4 INFORMATION PROCESSING, RELATING DATA COLLECTED TO THE ASSESSMENT QUESTIONS

1.4.1 Analyzing data.

1.4.2 Drawing assessment conclusions.

2. ORGANIZING AND REPORTING RESULTS: Technical preparation of results and reporting to client/subject.

2.1 INTEGRATING RESULTS: Answering the client's/subject's questions as completely as possible.

2.1.1 Combining results into a comprehensive case formulation.

2.1.2 Formulating conclusions with respect to client's/subject's demands.

2.2 REPORTING: Written and/or oral presentation of reports.

2.2.1 Requirements for report generation.

2.2.2 Including relevant information in the report

2.2.3 Making report understandable.

2.3 DISCUSSING AND DECIDING

2.3.1 Discussing report with client, subject, and/or relevant others.

2.3.2 Analyzing whether general circumstances warrant stop, re-start, or moving on to an intervention.

3. PLANNING THE INTERVENTION: If the assessor considers that an intervention is required, several assessment operations are necessary before treatment administration.

3.1 SELECTING AND TESTING SPECIFIC INTERVENTION HYPOTHESES:

3.1.1 Selecting and operationalizing intervention and outcomes variables.

3.1.2 Reviewing and deciding on intervention procedures that best fit the single case.

3.1.3 Selecting and assessing relevant variables for monitoring.

4. EVALUATION AND FOLLOW-UP: If an intervention has been carried out, several assessment operations should be conducted.

4.1 COLLECTING DATA ABOUT EFFECTS OF INTERVENTION:

4.1.1 Inspecting already-available data.

4.1.2 Collecting post-intervention data.

4.2 ANALYZING INTERVENTION OUTCOMES:

4.2.1 Drawing conclusions from data gathered on the effects of the intervention.

4.2.2 Reporting results to client, subject, and/or relevant others.

4.2.3 If necessary, written report to client, subject, and/or relevant others.

Continues

Continued

4.3 FOLLOW-UP:

- 4.3.1 Planning follow-up in agreement with client and/or subject.
- 4.3.2 Assessing subject according to the established plan.
- 4.3.3 Analyzing results.
- 4.3.4 Discussing results with client, subject, and/or relevant others.
- 4.3.5 If necessary, written report to client, subject, or relevant other.

END OF PROCESS: The assessment process comes to an end, if the assessor terminates the professional relationship with the person/institution (client) and subject/single case with respect to the assessment tasks.

psychological assessment, psychologists test hypotheses about the case, achieve assessment objectives, and draw certain conclusions in an attempt to respond to the demands of the client.

GLOSSARY

applied sport psychology The application of psychology, typically toward the improvement of performance, gained through the study of the psychological factors that affect and are affected by participation and performance in sport.

consensual validation The process of confirming, through interview and behavioral observation, the existence of certain psychological qualities previously identified through formal assessment.

response set A situation-specific approach employed by an individual undergoing a psychological assessment to manipulate resulting assessment data (e.g., faking good).

response style An approach that reflects cross-situational, core personality characteristics and that can have an equally strong impact on assessment results (e.g., pessimism).

sport psychological assessment The systematic attempt to measure those psychological characteristics that influence performance and behavior in sport contexts.

sport psychology professional (SPP) An individual with appropriate academic credentials and experience who

applies this expertise responsibly in sport settings; SPPs are interested in helping individuals to improve performance, appreciate the overall sporting experience, and enhance personal development and well-being.

sport-specific measures Inventories that attempt to elicit responses directly relevant to performance in sport generally or in one sport specifically.

trait A relatively enduring characteristic or habit.

state An occurrent characteristic (i.e., situationally dependent).

Assessment enables sport psychology professionals (SPPs) to obtain crucial performance-relevant information. The principal aim is to help athletes perform at an optimal level. To this end, both formal and informal methods are employed. These include interviews, behavioral observation, psychological testing, surveys, and inventories. Effective assessment requires sensitivity to test validity and reliability, response sets and styles, consensual validation, and ethical requirements. This article includes a brief history and a discussion of future directions.

1. INTRODUCTION

At its most basic level, assessment involves information gathering, interpretation, and evaluation. We all constantly engage in one form of assessment or another. It is how we make sense of the world. Sport psychology assessment is the systematic attempt to measure

psychological characteristics with the aim of improving sport experience and performance. Within the field of applied sport psychology, the method of assessment typically depends on the context (e.g., purpose, clients, time constraints). Although most sport psychology professionals (SPPs) associate assessment with more formal approaches (typically paper-and-pencil questionnaires and now online questionnaires), there are a variety of ways in which information can be collected and distilled. This article focuses on the practical applications of assessment and its use in applied settings. It also provides general information on selected assessment methods and a number of widely used instruments and tests.

2. ROLE OF ASSESSMENT

SPPs use assessment to gain crucial information about the people with whom they work. The aim is to help each of these individuals reach the level of performance desired, whether this is the level of a professional or Olympic athlete, an amateur competing in organized club competition, or a purely recreational sport enthusiast. But what exactly does an SPP need to understand about an individual to help? The answer to this question is controversial. Some SPPs believe that a clinical understanding of the client is necessary. Most SPPs focus on gaining more direct performance-relevant information (e.g., how the athlete pays attention, under what situations performance breaks down). Even if there were agreement on exactly what should be assessed, it would be difficult to get agreement on assessment methods. This difficulty increases where there is no agreement on which factors are most important.

There are four primary applications of applied sport assessment:

- Performance enhancement (individual and team)
- Athlete selection and screening
- Injury recovery
- Sport enjoyment

Some SPPs believe that all applications can be subsumed under the primary category of performance enhancement. Others emphasize the importance of having a positive sporting experience regardless of performance issues. Most people choose to work with SPPs because they want to be better at their sport. The presenting issue may be “recovering quickly from an injury,” “resolving conflicts among team members,” or “identifying mental strengths and liabilities,” but the bottom-line concern is with performance (Table I).

TABLE I
Common Reasons for the Use of Assessment

-
1. To measure variables that are important to performance, sport enjoyment, and a variety of other factors that contribute to the quality of the sport experience.
Examples include the following:
 - a. To determine current mental skill ability
 - b. To determine presence of factors associated with overtraining
 - c. To monitor anxiety
 - d. To assist in the presence of clinical issues
 2. To reduce the amount of time it would ordinarily take to collect this relevant information through other means (e.g., observation)
 3. To use a repeatable method for gaining critical information to help athletes
 4. To quantify relevant information for analysis over time or between populations
 5. To determine whether new factors or groups of factors are more or less important contributors to desired outcomes, states, or behaviors
-

3. METHODS OF ASSESSMENT

SPPs apply a variety of assessment methods to understand, predict, and modify behavior, including the following:

- Interviews
- Behavioral observation (including video review)
- Psychological testing, surveys, and inventories
- Third-party anecdotal data collection (from parents, coaches, teammates, etc.)

Typically, context will help to determine the most appropriate methods to employ. In most situations, SPPs will gather information using more than one of these methods.

3.1. Interviews

The most common form of assessment takes place through the process of formal and informal interviewing. There are typically three purposes for conducting an interview: to identify performance issues, to determine ways in which to intervene, and to validate inventory and questionnaire data. The interview itself can be structured by a set of preestablished questions and topics, or it can be free-flowing with a more open and dynamic feel. Topics and lines of inquiry depend on many factors, including the type of SPP–athlete relationship, the phase of the intervention/program, the severity

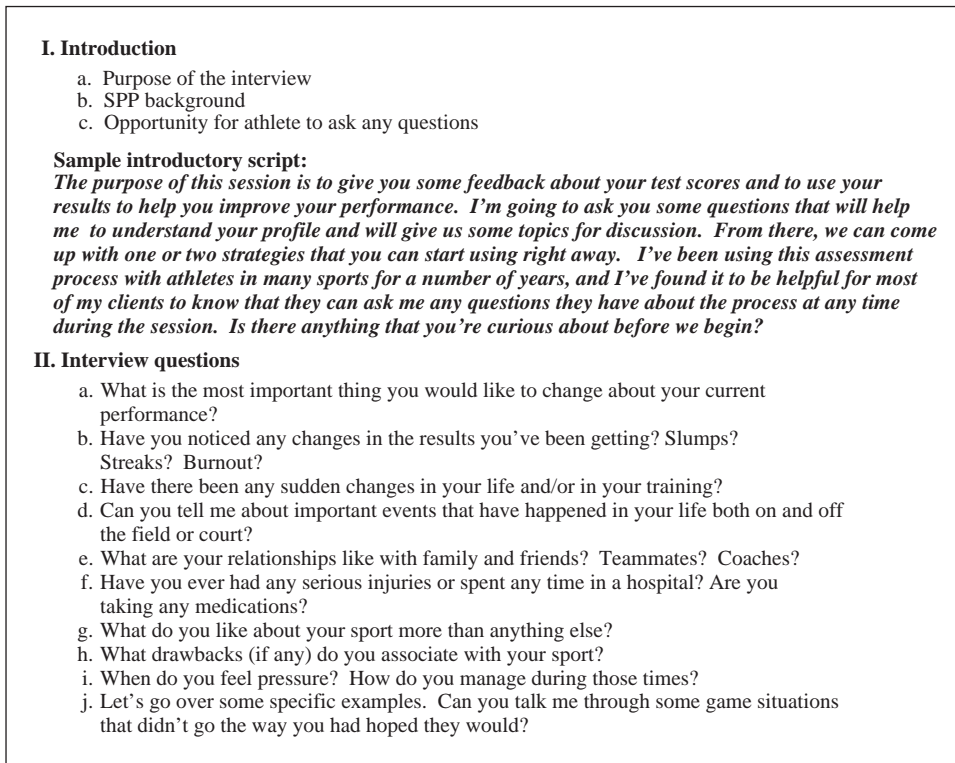

FIGURE 1 Sample interview outline.

of the issue(s), and the objective of the work. Many items on sport psychology inventories had their origins as interview questions. This should not be surprising. Like physicians who use intake forms and a wide range of tests to help learn about their patients, so too are SPPs interested in providing an efficient and consistent way in which to get to know their clients (Fig. 1).

3.2. Behavioral Observation

Behavioral observation is a straightforward process that involves watching live or recorded performance. It provides at least one distinct advantage over all of the other assessment methods in that SPPs can see firsthand how athletes behave in the most relevant settings (e.g., practice, competition). This information is invaluable because there are cues that may be identified in real-life settings that might not arise under less realistic conditions. Athletes might consistently make mistakes in situations but be unaware of the cause. The purpose of behavior observation is to watch athletes perform in those situations where insight into psychological performance factors can be ascertained. Both structured (i.e.,

controlled) and unstructured observation can be used to acquire this type of information. Trained SPPs can learn a great deal by attending to a variety of “targets” that include, but are not limited to, actual performance, verbal behavior, and body language. For example, slumped shoulders after a missed shot might reflect a slip in confidence. These kinds of observations can provide invaluable discussion points that can be critical in helping athletes to understand themselves and their performances (Table II).

TABLE II
Behavioral Observation Checklist

<ul style="list-style-type: none"> • <i>Verbalizations and utterances:</i> Listen for content, intensity, and timing. • <i>Attention and nonverbal expressions:</i> Look for facial reactions, eye movement, and frequency, intensity, and general indicators of stress. • <i>Posture and movement:</i> Look for bracing (stiffness), fluidity, limping, or other awkward positioning. • <i>Social:</i> Observe interactions with teammates, parents, coaches, and the like.
--

3.3. Psychological Testing, Surveys, and Inventories

Although the definition of assessment offered here is rather broad, most people identify assessment with the printed questionnaire. Ranging from several questions to several hundred questions, these instruments usually ask athletes to respond to items by selecting from some form of multiple-choice response list. It should be noted that many SPPs are careful not to use the label “test” and prefer instead to use a variety of more “acceptable” names (e.g., survey, inventory, assessment). There are many ways in which instruments may be categorized, with some being more theoretically sophisticated than others. The following labels are commonly applied:

- Clinical
- Cognitive
- Attentional
- Personality and emotional intelligence
- Sport-specific
- Team/Social interactive

Although these different kinds of information are not uniquely attainable through psychological testing, the advantage of such testing is that it provides a more objective, more scientific means of acquiring data. Presumably, SPPs want to be able to know as much as possible so as to improve performance. Testing can provide a scientific psychological portrait of the athletes with whom they work. Clinical inventories can inform SPPs about qualities such as depression, anxiety, bipolarity, and mania. Cognitive inventories measure things such as verbal intelligence and speed of learning. Attentional inventories identify preferred styles of concentration. Personality tests involve measures of confidence, self-esteem, social attitudes, and risk taking. Sport-specific tools provide information about performance-relevant variables in sport settings. Team and social interactive inventories can help to identify factors particularly relevant in group settings. Examples would include measures of cohesion and communication style.

3.4. Third-Party Anecdotal Data Collection

Important information that is helpful to SPPs is often acquired through formal and informal communication with people in a special position to provide insight about clients. Third-party data collection may be as

simple as an interview conducted by someone other than the SPP (and, as such, may be viewed as a type of interview), but it can also be much less formally acquired information by parents, teammates, coaches, or other individuals who come in contact with the athlete. One formal version of this often-overlooked method of assessment is similar to the 360-degree review process widely used in business consulting, where an individual receives feedback on performance strengths and weaknesses from his or her superiors, peers, and subordinates so as to help formulate an individual action plan for career development. Informal versions include casual conversations and other means of information exchange.

4. COMMON DISTINCTIONS

4.1. Formal Assessment Versus Informal Assessment

Behavior can be studied formally or informally. An informal assessment is one that does not incorporate psychometrics or data collected for statistical analysis. Examples of informal assessment include reading non-verbal cues when speaking with someone, watching sport competitions, observing practice sessions without recording data, and interviewing athletes, coaches, and parents. Formal assessment involves data collection through psychometric tools, surveys, frequency distributions, and the like. Discussion of assessment in sport psychology is dominated by formal topics because it is relatively easy to examine the rationale, experimental design, reliability, validity, and motivation for construction of formal instruments. Informal assessment is, on the other hand, undervalued and less stable due to the difficulty in standardizing techniques. But veterans in the field develop a balance of formal assessment (which provides a scientific base for their work) and informal assessment (which allows them to anticipate client needs and come up with practical solutions to identified problems as they happen in real time). It should be noted that although this distinction is commonly accepted, it is not always so clear. For instance, controlled observations (not usually viewed as formal assessment) can incorporate observation schedules with preestablished behavior categories and, thus, provide data eligible for statistical analysis.

There is both an art and a science to assessment. It is certainly worth noting that there are a fair number of “gurus” in the field who work primarily by intuition

and feel. Many respected SPPs rely most heavily on this “sixth sense,” and it is likely that assessment by gut feelings will continue into the future.

4.2. Subjective Assessment Versus Objective Assessment

The distinction between subjective assessment and objective assessment is one commonly encountered in discussions of sport psychology. In general, subjective assessment encompasses various forms of interviews and observations on the part of SPPs. Objective assessment typically refers to psychological tools such as inventories and tests. Here, the distinction seems to hinge on the role of SPPs in the assessment process. In subjective assessment, SPPs are called on to interpret behavior directly. In objective assessment, SPPs use an appropriate instrument to provide additional information or clarification relevant to assisting athletes. What tends to confuse this distinction is that there are subjective components within objective assessment as well as objective components within subjective assessment. For example, formal scripted interviewing includes a measure of objectivity, and the interpretation of psychological inventories contains a large subjective component.

4.3. State Versus Trait

Because SPPs are ultimately interested in modifying behavior to improve performance, it is critical to understand whether a particular individual characteristic is likely to change over time. Traits are enduring characteristics that are likely present in a variety of situations. States are temporary conditions that are determined by situational factors. For example, even the most confident people can experience anxiety before an important speech or a big game. This could be called “state anxiety” and would be dependent on the situation in which an individual found himself or herself. However, an anxious person (i.e., one with “trait anxiety”) would likely become anxious before every speech or game. Gauging where certain characteristics fall on the state–trait continuum is helpful to SPPs as they use assessment information and apply methods of intervention.

4.4. Sport-Specific Measures Versus General Measures

Some assessment tools contain items that are framed in a sport-specific context to elicit responses more

relevant to the actual performance environment of the individual test-taker. Believing that sport-specific measures provide uniquely valuable information, many test developers have created sport-specific versions of existing inventories. This raises an interesting question: Is it more or less useful for items to focus on behavior within the situational context of primary concern? Not surprisingly, there is disagreement on the answer. Some believe that important information can be missed with sport-specific measures and that generally framed items will be more likely to pick up on those factors that are important in a variety of situations, including sport. This camp also believes that sport-specific items are more transparent and, thus, more easily faked or manipulated. Those who embrace sport-specific measures believe that the closer the context matches the particular performance environment of the athlete, the more validity the test will have and ultimately the more useful the results will be.

5. HISTORY AND CURRENT ASSESSMENT TOOLS (NORTH AMERICAN)

Assessment has played an integral role in the history of sport psychology. Most historical reviews identify the Triplett social facilitation experiments in 1898 as the first recorded studies in the field. In showing that cyclists raced faster with a pacer than they did by themselves, Norman Triplett used a simple measurement tool still believed by many to be the most critical component in athletic competition—results.

Nearly 30 years passed before a definitive text on the subject of athletes and their thought processes would appear. In 1926, Griffith published the first of two books that would become the “big bang” in the creation of sport psychology. *Psychology of Coaching* and *Psychology and Athletics* were written by Griffith as collections of his findings from the first ever sport psychology laboratory on the campus of the University of Illinois. In *Psychology of Coaching*, Griffith attempted to identify character types of coaches and men. His typologies included the “crabber,” the “silent type,” the “talker,” the “loafer,” the “leader,” and the “follower.”

The 1960s were a watershed for assessment and sport psychology. The first modern inventory created specifically for use with athletes was created in 1969 by Tutko, Ogilvie, and their colleagues. The Athletic Motivation Inventory (AMI) was born out of Tutko and Ogilvie’s *Problem Athletes and How to Handle Them*. Until

this time, application of assessment in sport settings had meant adapting results of general personality and mental health diagnostics such as the Minnesota Multiphasic Personality Inventory (MMPI), 16 Personality Factor Questionnaire (16PF), and Thematic Apperception Tests. AMI attempted to measure traits categorized under the rubric of “Desire” factors and “Emotional” factors. Desire factors were drive, determination, aggression, leadership, and organization. Emotional factors were coachability, emotionality, self-confidence, mental toughness, responsibility, trust, and conscience development.

When international organizations began forming, communication increased between SPPs and assessment became a central focus. Could anxiety, personality, attention, moods, and motivation be tangibly measured, and could results be reliably reproduced, over time? If so, how would these tools contribute to the evolution of professional and amateur sport cultures in the real world? SPPs set to work on developing an arsenal of assessment tools for the sport environment.

One significant contributor, Rainer Martens, was a wrestling coach at the University of Montana who began to explore sport psychology after failing to help his talented team captain overcome prematch anxiety. In 1977, he published the Sport Competition Anxiety Test (SCAT) and, with help from colleagues in 1980, the Competitive State Anxiety Inventory (CSAI). Martens’ work was preceded by Spielberger’s theory that anxiety was present in both state and trait forms. Spielberger’s State–Trait Anxiety Inventory (STAI) was published in 1970.

Meanwhile, Robert Nideffer’s strong interest in aikido, as well as his expertise in MMPI research, led him to conclude that attention was the key psychological factor in sport performance. He developed The Attentional and Interpersonal Style (TAIS) Inventory while at the University of Rochester in 1976. His assessment tool directly measured the attentional preferences of athletes and helped practitioners to understand the conditions in which their clients would make concentration mistakes. In a survey taken 22 years later, only one other inventory, the Profile of Mood States (POMS), was being used more than TAIS by applied SPPs. POMS is a general inventory initially created in 1971 for use in psychiatry populations. Its popularity stems from its ability to assess both current moods and dominant mood traits.

The current state of assessment in sport psychology is one of many options. A directory of sport psychology assessments published by Ostrow in 1996 included 314 different inventories, questionnaires, and surveys. Sport psychology clients now include more than just elite

athletes; they include a population of serious recreational athletes and aspiring juniors in many sports. Assessment tools such as Jesse Llobet’s Winning Profile Athlete Inventory (WPAI) have been created to support developing athletes as well as professionals. Many assessments are now available on the Internet, where they can be used by athletes and practitioners from anywhere in the world in the privacy of their own homes. In professional ranks, player development and scouting departments count on psychological assessments and sport psychology consultants to help them in their coaching and drafting efforts. Examples of this application of psychological assessment include the use of AMI by the Major League Baseball Scouting Bureau and the use of Wonderlic by the National Football League (NFL) to assess intelligence levels of draft-eligible college players at the annual scouting combine. In addition, many professional teams rely on information from experts with self-designed assessments such as Robert Troutwine’s Troutwine Athlete Profile (TAP).

Biddle’s *European Perspectives on Exercise and Sport Psychology* provides a greater international perspective on history and current assessment tools.

6. LIST AND DESCRIPTION OF FREQUENTLY USED TESTS

This section contains descriptions of frequently used assessments employed in the field of sport psychology. The instruments are presented alphabetically by instrument name. Table III identifies the kinds of factors or variables measured by each assessment.

6.1. 16 Personality Factor Questionnaire (16PF)

Year created: 1950

Author: Cattell

Cattell believed that human personality consisted of 46 surface traits, from which 16 primary traits can be derived. Used primarily for sport psychological research, several studies showed meaningful differences on several scales for athletes and a significant correlation between extraversion and sport success. The 16 dimensions are Warmth (cool vs warm), Intelligence (concrete thinking vs abstract thinking), Emotional Stability (easily upset vs calm), Dominance (not assertive vs dominant), Impulsiveness (sober vs enthusiastic), Conformity (expedient vs conscientious), Boldness (shy vs venturesome),

Sensitivity (toughminded vs sensitive), Suspiciousness (trusting vs suspicious), Imagination (practical vs imaginative), Shrewdness (forthright vs shrewd), Insecurity (self-assured vs self-doubting), Radicalism (conservative vs experimenting), Self-Sufficiency (group-oriented vs self-sufficient), Self-Discipline (undisciplined vs self-disciplined), and Tension (relaxed vs tense).

6.2. Athletic Coping Skills Inventory (ACSI-28)

Year created: 1995

Authors: Smith, Schutz, Smoll, & Ptacek

This is a 28-item inventory designed with the intent to understand how athletes deal with competitive stress. ACSI-28 measures seven sport-specific subscales and then provides an overall “power” ranking that is a composite of those scale scores. The power ranking is called the Personal Coping Resources score, and the subscales are Coping with Adversity, Peaking under Pressure, Goal Setting/Mental Preparation, Concentration, Freedom from Worry, Confidence and Achievement Motivation, and Coachability.

6.3. Athletic Motivation Inventory (AMI)

Year created: 1969

Authors: Tutko, Lyon, & Ogilvie

This is a 190-item, forced-choice inventory that is historically the most widely referenced in the field of sport psychology. It was developed specifically to measure traits related to elite athletic success. Traits measured are grouped as Desire factors or Emotional factors. Desire factors are drive, determination, aggression, leadership, and organization. Emotional factors are coachability, emotionality, self-confidence, mental toughness, responsibility, trust, and conscience development.

6.4. Competition Reflections

Year created: 1986

Author: Orlick

This is composed of 12 open-ended items that provide opportunities for athletes to reflect on their “best” and “worst” selves by recalling details about great and poor performances. Included within these items are four

10-point rating scales that provide some reference for perceived arousal and anxiety. Direction of the reflections leads to the athlete brainstorming changes in training, preparing for competition, and interacting with coaches.

6.5. Competitive State Anxiety Inventory (CSAI-2)

Year created: 1990

Authors: Martens, Burton, Vealey, Bump, & Smith
Originally born out of Martens' work with SCAT, this is a modification of Spielberger's State Anxiety Inventory (SAI). The original version, created in 1980, isolated 10 items from SAI that measured competitive anxiety. A multidimensional version of the original, CSAI-2, includes three 9-item subscales measuring cognitive state anxiety, somatic state anxiety, and state self-confidence. In applied settings, a "Mental Readiness" form has derived from CSAI-2 that allows athletes to put themselves through a more convenient assessment of their anxiety levels while on the field or court.

6.6. Myers–Briggs Type Indicator (MBTI)

Year created: 1962

Authors: Myers & Briggs

Based on Jungian personality theory, this is the most widely used personal inventory in the world, with more than 2 million test takers annually. MBTI has a variety of applications in the worlds of personal development and management consulting. Its primary use in sport settings is for team cohesion and increasing awareness between teammates and coaches. Personality preference is measured along four dichotomies: Extraversion/Introversion, Sensing/Intuition, Thinking/Feeling, and Judging/Perceiving. Combinations of these scales produce a four-letter acronym that reflects the dominant score on each factor. These acronyms correspond to 16 different personality types that describe persons in detail according to behaviors associated with their personalities.

6.7. Minnesota Multiphasic Personality Inventory (MMPI-2)

Year created: 1942

Authors: Hathaway & McKinley

This is one of the cornerstones of psychiatric and clinical psychology assessment. MMPI is used to identify personality and psychosocial disorders as well as

for general cognitive evaluation in adults and adolescents. A number of versions of MMPI exist, including the most recent version, MMPI-2, MMPI-A (an adolescent version), and short and long forms. Although MMPI is widely used in clinical settings, its use is limited in current applied sport psychology settings.

6.8. Profile of Mood States (POMS)

Year created: 1971

Authors: McNair, Lorr, & Droppleman

This is a 65-item instrument assessing tension, depression, anger, vigor, fatigue, and confusion. A 5-point scale (from "extremely" to "not at all") is used to rate responses. This inventory can be used to measure both state- and traitlike factors, depending on the "set" provided to the test taker by the proctor.

6.9. Psychological Skills Inventory for Sports (PSIS)

Year created: 1987

Authors: Mahoney, Gabriel, & Perkins

Consisting of 45 items with 5-point Likert response options, this instrument measures Anxiety Control, Concentration, Confidence, Mental Preparation, Motivation, and Team Emphasis. PSIS was created with input from 16 leading sport psychologists who answered the inventory questions as they thought the "ideal" athlete would. The original inventory asked true/false questions and contained 51 items. Test construction involved 713 athletes from 23 different sports.

6.10. Sport Competition Anxiety Test (SCAT)

Year created: 1977

Author: Martens

This is a 15-item inventory that was created to measure "state" anxiety levels in people anticipating competition. Martens was very clear in the original publication of the assessment that SCAT was not to be used to predict performance outcomes even if there was a relation to anxiety levels. Therefore, functional use of SCAT is optimal when gauging manifestations of anxiety in athletes during pregame or prematch periods.

6.11. State–Trait Anxiety Inventories (STAI)

Year created: 1970

Authors: Spielberger, Gorsuch, & Lushene

This was originally developed as a research tool for measuring anxiety in adults and has contributed mightily to sport anxiety research in a variety of populations. STAI is composed of two 20-item scales: one measuring State Anxiety and one measuring Trait Anxiety. The context for the A-State section is how the test taker is feeling at the current time, whereas the A-Trait section is based on general feelings of anxiety. Application of STAI has led to many significant findings in athlete work. For example, Yuri Hanin used STAI to create his Zones of Optimal Functioning (ZOF) model.

6.12. The Attentional and Interpersonal Style (TAIS) Inventory

Year created: 1976

Author: Nideffer

This is a 144-item inventory with an emphasis on concentration and the critical interpersonal factors affecting performance under pressure. The latest version of TAIS is composed of 20 scales that range principally over attentional and interpersonal factors. The two newest scales are Focus over Time and Performance under Pressure. Athletes Mental Edge (AME) used a 50-item version of TAIS and was introduced in 1999. AME was the first widely used, Internet-based sport psychological assessment tool.

6.13. Troutwine Athletic Profile (TAP)

Year created: 1988

Author: Troutwine

This is a 75-item questionnaire that receives considerable attention prior to the NFL draft. Troutwine does not publish his assessment for distribution, so there are few SPPs using TAP. However, this may be the most well-known, “self-written for self-use” assessment in the field. The questionnaire generates a Player Report for development and a Coach Report for recruiting and selection; this is why many NFL teams privately contract with Troutwine and value his data. The Player Report measures Competitive Nature, Coping Style, Work Style, and Mental Characteristics. The Coach Report topics are Mental Makeup, Social Style, Personal Characteristics, Coaching Suggestions, and Performance Tendencies.

6.14. Test of Performance Strategies (TOPS)

Year created: 1999

Authors: Thomas, Murphy, & Hardy

This is a 64-item inventory intended for use when measuring psychological skills and strategies used by athletes both in competition and while at practice. TOPS results differentiate between practice and competitive skills and strategies on the following scales: Goal Setting, Use of Imagery, Ability to Relax, Ability to Activate/Energize, Use of Positive Self-Talk, Emotional Control, Attentional Control, Automaticity (i.e., performing without thinking), and Negative Thinking. Although TOPS is a fairly new inventory, its applied use was already seen with U.S. and Australian Olympic teams and coaches in preparation for the Sydney Games in 2000.

6.15. Winning Profile Athlete Inventory (WPAI)

Year created: 1999

Author: Llobet

This is composed of 55 items with 5-point Likert response options that measure a wide variety of psychological skills in athletes. WPAI responses load onto 10 factors: Competitiveness, Dependability, Commitment, Positive Attitude, Self-Confidence, Planning, Aggressiveness, Team Orientation, Willingness to Sacrifice Injury, and Trust. Functional use is intended for athletes from high school to professional levels for recruiting and development purposes.

6.16. Wonderlic Personnel Test (WPT)

Year created: 1937

Author: Wonderlic

This is a 50-item test of general intelligence that the user has 12 minutes to complete. Originally designed for use with job applicants in both blue- and white-collar settings, WPT has become a mainstay in the assessment of collegiate football players at the NFL's scouting combine. The test has 16 different versions with problems that include algebra, word analogies, mathematical word problems, and various other tests of verbal, computational, and analytic abilities. It measures an individual's ability to learn, adapt, solve problems, and understand instructions.

7. FORMAL ASSESSMENT GUIDELINES AND ETHICAL CONSIDERATIONS

When done well, psychological testing provides professionals with an efficient, objective, and repeatable approach to assessing behavior. Many factors affect the quality of the information gathered through the various assessment means. Sensitivity to issues around test validity, confidentiality, response sets, and response styles is critical for effective use of sport psychology assessment.

7.1. Test Validity

It is incumbent on SPPs to evaluate the validity of the assessment methods they use. A test's validity determines how accurately it measures what it purports to measure. There are three commonly referenced types of validity: face, construct, and predictive. Face validity is a surface measure that acts as a first step toward the integrity of an assessment. Face validity is attained when the parameters of a test seem like they would generate the results that SPPs hope to generate. Construct validity links theory with practice. It can be summed up as the ability that an assessment has to demonstrate, with results, the topic it is intended to measure. Predictive validity is simply the likelihood that the results of an assessment can predict the occurrence of a specified behavior in the future.

7.2. Confidentiality

According to the code of ethics set forth by the American Psychological Association, the confidentiality of the

psychologist–client relationship is protected. Because many nonlicensed individuals function as sport psychology consultants, the status of such a relationship is less clear and not likely afforded the same kind of protection. When it comes to the confidentiality of assessment results, SPPs should be careful to protect confidentiality explicitly and to explain clearly to clients who will have access to their assessment information. Because it can sometimes be difficult to identify exactly who the client is (e.g., the athlete, the coach, the organization), it is advisable to have a written policy that describes how assessment information will be kept and shared. Many SPPs use informed consent forms to establish clearly the confidentiality of assessment data (Fig. 2).

7.3. Response Sets and Styles

When asking athletes to answer any set of questions about themselves, it is important to take into account variables that will influence the accuracy of their responses. Response sets are situation-specific attitudes that individuals adopt when completing a psychological assessment. They are often employed when athletes are skeptical of how their assessment data may be used. Faking can occur in situations where athletes feel pressure to present themselves in an ideal light.

In contrast to response sets, response styles reflect cross-situational, core personality characteristics. Common response styles include overly conservative and extreme appraisals. People who adopt a conservative response style see the world in shades of gray and tend to respond with middle-range answers such as “maybe” and “sometimes” on inventories with Likert

Assessment Consent Form	
<p>I hereby grant permission to _____ for sport psychology assessment. I understand that any information gained from testing will be used for the purpose of performance enhancement and will be kept confidential. I further understand that none of my personal data will be released to anyone without my consent. I agree that although my individual data may be used as part of a database for research, my identity and other personal information will not be disclosed.</p>	
<p>I understand that my access to sport psychology services is not contingent on my granting of this permission. In addition, I understand that if at any time during the assessment phase I feel uncomfortable, I can end the assessment process.</p>	
<p>_____ Signature</p>	<p>_____ Date</p>
<p>_____ Printed name</p>	<p>_____ Sport psychology professional</p>

FIGURE 2 Sample informed consent form.

scale choices. Extreme response styles are often seen in individuals who have either an overly optimistic outlook or an overly critical outlook. Aside from the impact that response sets and styles have on individual scores, SPPs must be careful when comparing different athletes' assessment results. Although some degree of influence from both response sets and response styles is always likely to be present, their effects can be minimized by encouraging open and honest answering and by providing points of comparison for various response choices. Many SPPs prefer not to control for response sets because the sets and styles themselves provide a great deal of information about the athletes.

7.4. Consensual Validation

To ensure that test information is accurate, it is important to have the opportunity to speak directly with the individuals who have completed the assessments to determine the impact of any existing response sets or response styles.

Consensual validation is the process of verifying the interpretations made from test information, which typically occurs through interview or direct observation. Effective consensual validation requires the ability to define operationally psychological constructs (e.g., confidence, control). By translating these concepts into specific behaviors, SPPs can determine their presence or absence more accurately. Imagine that a client completes a personality inventory and scores very high on control and self-esteem. A high score on these dimensions would lead the interpreting SPP to assume certain behaviors in various circumstances. More often than not, the SPP would expect the client to speak up, take charge, be reluctant to listen to contrary opinions, and oppose authority. The SPP would be looking to verify that these behaviors occur with the kind of frequency commensurate with the scores on the performance-relevant construct(s). *Table IV* offers a number of suggestions to increase effective consensual validation.

8. FUTURE DIRECTIONS

Just as athletes engage in the "pursuit of perfection," SPPs seek the most effective means of helping the athletes with whom they work. Technology is already having a pronounced effect on how assessment is carried out. Psychological testing can now take place over the Internet with the tester and the testee thousands of miles apart. More and more individuals will gain access to assessment information. Feedback

TABLE IV
Consensual Validation Techniques

-
- Select tests that measure constructs that are easily translatable into observable behaviors.
 - Select tests that measure a number of performance-relevant variables or choose several tests that measure a variety of constructs. The reason for this is that individual constructs are rarely able to explain performance across individuals and situations. A number of distinct cognitive and interpersonal characteristics must be examined to effectively account for the influences that individual and situational differences have on performance.
 - Translate each construct into expected behaviors (for the performance arena in which they operate).
 - Create conditions under which the individual's behavior can be observed under varying degrees of pressure. Remember that most people are able to control even dominant behaviors when they are not experiencing significant stress. The key is to see how much difference increasing the pressure has on the presence or absence of particular behaviors.
-

Source. Adapted from Nideffer and Sagal (2001).

reports delivered instantaneously, and sometimes without professional interpretation, will most certainly force the field of sport psychology to confront what is and is not acceptable practice.

As athletes are exposed to the benefits of working with SPPs, it is inevitable that more athletes themselves will develop a professional interest in the field. Consequences of this are likely to include the following:

- An increased respect for the field of sport psychology itself
- A greater emphasis on practical applications in specific sports
- Increased pressure on SPPs to have significant sport-specific athletic experience of their own

Although the focus of this article has been on assessment in applied sport psychology, it is important to note that it is nearly always the case that application follows research. Advancements in medicine and new insight into the mind-body connection will likely increase the use of neurological, chemical, and physiological testing to help predict and influence performance. The ongoing search for strong ties between emotions and body chemistry may bring new kinds of SPPs to the field. For example, heart rate monitors and other biofeedback mechanisms are already being used to help athletes achieve optimal levels of arousal and to help SPPs better understand the competitive experience (*Fig. 3*).

GLOSSARY

anxious–avoidant attachment An insecure form of attachment; during the Strange Situation, infants classified as avoidant appear to be relatively indifferent to separation from the caregiver even though physiological markers indicate that they are in fact distressed, and on reunion, they actively ignore and avoid the caregiver, diverting their attention to exploration.

anxious–resistant (ambivalent) attachment An insecure form of attachment; during the Strange Situation, infants with this classification exhibit extreme distress on separation, and when the caregiver returns, they refuse to settle down, clinging while at the same time pushing the caregiver away in anger.

attachment An emotional connection to another individual that develops between an individual who is seen as able to provide protection, comfort, and support in times of need; early attachment develops between an infant and a primary caregiver through patterns of caregiving interactions that evolve over the first year of life.

disorganized attachment A Strange Situation classification given in addition to one of the other three classifications; infants classified as disorganized/disoriented show sequences of behavior that appear to lack a clear intent, purpose, or organization (e.g., freezing).

internal working models Internal mental representations that are established during the formation of an attachment relationship; these mental representations refer to both self and the attachment figure, and later in life they guide a person's processing of relevant information and behavior in the context of interactions and relationships.

secure attachment A positive and adaptive form of attachment between an infant and his or her caregiver; the infant uses the caregiver as a base for independent exploration of the environment and as a source of comfort and support during times of stress and distress.

Strange Situation procedure A systematic laboratory observational method designed to assess the quality of attachment organization of a 12- to 18-month-old infant to a caregiver.

Attachment theory, put forth by John Bowlby, postulates that infants develop strong emotional ties to consistent caregivers during the first year of life and that these ties are crucial for the individual's normal social–emotional development and well-being. Bowlby, a British psychiatrist, combined ideas from psychoanalysis, ethology, and evolution to develop a theory regarding the attachment behavioral system—its nature, function, and development. Mary Ainsworth, Bowlby's collaborator, provided empirical support for many of Bowlby's ideas in her in-depth observations of

mother–infant interactions at home and in a laboratory environment. Ainsworth also developed a laboratory observation procedure, the Strange Situation, which enabled her to identify individual differences in attachment organization among 1-year-old infants. The Strange Situation procedure, currently the most widely used and validated measure of attachment security during infancy, is composed of a series of short separations and reunions between an infant and his or her caregiver, usually the mother. It enables psychologists to classify the quality of an infant's attachment to a caregiver into one of three major categories: secure attachment, anxious–avoidant attachment, or anxious–resistant attachment. A fourth category, disorganized/disoriented attachment, was added more recently. Ainsworth and colleagues also demonstrated that the caregiver's sensitive responsiveness to the infant's signals and cues is important for the formation of secure attachment. This finding has been replicated in many subsequent studies, although not always so strongly. Research on attachment yields some interesting findings regarding the inter-generational transmission of attachment, the stability of attachment throughout the life span, and the role of early attachment in later child outcomes, particularly in the areas of emotion regulation, cognition, social adjustment, and mental health. Because early attachment relationships are viewed as crucial to later development, there is a growing number of prevention and intervention programs designed to promote attachment security among populations at risk for insecure attachment relationships. The effectiveness of these programs has varied. Ever since it was first introduced, attachment theory has played a central role in shaping our understanding of child development and parent–child relations, as reflected in developmental theory and research, clinical and applied settings, and policymaking.

1. INTRODUCTION

Attachment theory centers on the notion that emotionally responsive care, including love and nurturance from a primary caregiver, is essential for healthy and normal development. John Bowlby, the founder of attachment theory, used the term “attachment” to describe the emotional connection that develops between an infant and a primary caregiver through patterns of interaction that evolve over time. According to attachment theory, during the first year of life, infants develop special ties to their primary caregivers (i.e., attachment figures). Every infant invariably becomes

attached unless no single caregiver is continuously present to care for the child (e.g., as in some institutions and orphanages). The particular nature or quality of the attachment relationship will vary, depending on the history of interaction patterns within the dyad. In particular, the consistency and appropriateness of the caregiver's response to the infant during times when the infant feels stressed or threatened, defines the pattern of interactions that develop during the first year. When the caregiver is consistently sensitive and responsive, a secure attachment typically ensues, whereas insensitive or inappropriate responding usually leads to an insecure attachment relationship.

After the attachment is formed, the infant shows a preference for the attachment figure. This is particularly evident during times of stress or emotional upset. When scared or distressed, the infant actively seeks comfort and reassurance from the caregiver and is not easily comforted by other individuals. The presence of the attachment figure is reassuring and enables more competent exploration of the environment. Mary Ainsworth, Bowlby's collaborator, noted that in a secure attachment relationship, the attachment figure provides both a “safe haven” during times of need and a “secure base” from which to explore.

Bowlby viewed the attachment system as a biobehavioral system that organizes behavior. The set goal of this system is to maintain proper access and proximity to the caregiver during times of need to ensure the protection and survival of the young. The attachment system operates in interaction and in collaboration with other behavioral systems (e.g., fear, exploration, sociability).

Attachment relationships are believed to play an important role throughout the life cycle. Although the specific behavioral markers of attachment change, their function remains the same. During times of need, infants, older children, and adults alike all seek comfort and support from significant others who are seen as more capable of coping with these situations. As individuals mature, new attachments are typically formed, but the early attachment relationships remain important because they are thought to exert an effect on subsequent behavior and close relationships.

2. HISTORY

2.1. John Bowlby (1907–1990)

Bowlby, a British child psychiatrist and psychoanalyst by training, was one of the first to systematically

observe the negative effect of impoverished family life and the lack of consistent care on the development of young children. He suggested, based on his work with hospitalized and homeless children during the 1940s, that a child needs to experience a close, warm, and consistent relationship with his or her mother or another permanent caregiver so as to develop normally.

Influenced by ethology and evolutionary theory, Bowlby rejected the then widely accepted notion that an infant's tie to his or her mother is rooted in the mother's role as a provider of food or oral gratification. Lorenz's observations of the "imprinting" phenomenon in geese during the 1930s demonstrated that an organism can become "attached" to its caregiver through a process unrelated to feeding. Harlow's laboratory studies of rhesus monkeys during the 1950s and 1960s also demonstrated that needs other than hunger are important in the formation of the infant-mother tie. For example, monkeys "raised" by two kinds of surrogate mothers—a wire mesh "mother" to which a bottle with milk was attached and a terrycloth surrogate "mother" with no milk bottle—preferred the soft cloth mother, spending most of their time clinging to her for comfort and rushing to her when frightened. They spent little time on the wire mother, approaching her only when wanting to be fed. Influenced by these and other studies, Bowlby posited that the need for proximity to a caregiver is a biologically based primary need that evolved to ensure the protection and survival of the young.

Bowlby also argued that it is children's actual experiences with caregivers (e.g., lengthy separations, lack of consistent care) that determine their well-being and adjustment. This view was at odds with the notions accepted by the psychoanalytic community, which placed greater emphasis on children's fantasy lives than on their actual experiences with caregivers.

These disagreements led Bowlby to establish his own research unit at the Tavistock Clinic in London, where he proceeded to develop his groundbreaking ideas. His work is summarized in the trilogy titled *Attachment and Loss*, published in 1969, 1973, and 1980, as well as in many other books and articles. The focus in Bowlby's writings was primarily on the evolutionary origin and function of the attachment system, how it organizes behavior, its developmental course, and the effects of early separations and loss of attachment figures on a person's well-being and adjustment. The work of Ainsworth provided empirical grounding for Bowlby's theoretical thinking, extended Bowlby's ideas on attachment, and brought to the forefront a focus on different patterns of attachment organization.

2.2. Mary Ainsworth (1913–1999)

Ainsworth met Bowlby during the early 1950s at the Tavistock Clinic. She subsequently carried out an observational study in Uganda designed to examine Bowlby's ideas empirically. After returning to the United States, she proceeded to conduct a second attachment study in Baltimore, Maryland, involving intensive home observations of 23 mother-infant dyads. As part of the Baltimore study, Ainsworth also developed a systematic laboratory observational method that enabled her to observe the reactions of infants to short sequences of separations from their mothers. This procedure, known as the Strange Situation, allowed her to identify individual differences in infants' attachment to their mothers, that is, their different strategies of using the mother when dealing with the stress brought about by brief separations. The Strange Situation procedure initially yielded three types or classifications of attachment: a secure pattern and two insecure classifications (anxious-avoidant and anxious-resistant attachment). The procedures and findings of the Baltimore study are summarized in the book *Patterns of Attachment*, published in 1978. Ainsworth's work generated a surge of empirical studies that employed the Strange Situation and focused on individual differences in attachment security.

3. MEASUREMENT

Over the years, researchers have developed a variety of measures to assess attachment patterns at various ages. The most widely used and best validated assessment procedures employed with infants, children, adolescents, and adults are described in what follows.

3.1. Assessing Infant Attachment

3.1.1. The Strange Situation

3.1.1.1. Procedure For more than 30 years, quality of parent-infant attachment has been assessed using the Strange Situation procedure developed by Ainsworth in the Baltimore study. This procedure, which is appropriate to use with infants ages 12 to 18 months, involves a series of moderately stressful separations (3 minutes each) and reunions (3 minutes each) between the infant and a caregiver while in an unfamiliar playroom. Two systems are activated during the Strange Situation procedure: exploration (of a new environment, toys, and people) and attachment (through the repeated separations

and reunions). The Strange Situation procedure enables researchers to examine how the infant uses the caregiver to cope with stress. The infant's strategy is thought to reflect his or her accumulated experience as it pertains to the caregiver's availability during times of need.

3.1.1.2. Attachment Patterns Ainsworth identified three major attachment classifications. Secure infants use their caregivers as a "secure base" for exploration. These infants rely on occasional visual, verbal, or physical contact with their mothers as a basis for their own initiated exploration of the environment. When their mothers leave the room, secure infants may or may not cry. On reunion, these infants either greet their mothers positively or, if upset, go to them for comfort and then shortly after return to activities associated with exploration.

Infants who show patterns of insecure attachment of the avoidant type exhibit little or no reference to their mothers while exploring the room and show no overt signs of distress on their mothers' departure (although some studies have shown that these infants do show physiological markers of stress during separation). Most important, on reunion, these infants actively ignore and avoid their caregivers (e.g., by looking away).

Insecure-resistant (or ambivalent) infants are preoccupied with their mothers' presence, often unable to leave their sides even in light of curious attempts to explore their new environment. When their mothers leave the room, these infants become extremely distressed, and on reunion, the infants refuse to settle and to resume exploration, clinging to their mothers and at the same time expressing anger and dissatisfaction.

The large body of work using the Strange Situation shows that across cultures, the majority of all infants (approximately 65%) are securely attached to their mothers, whereas the remainder are classified as insecure. The distribution of insecure attachment classifications (i.e., frequencies of the avoidant and resistant patterns) appears to be affected by cultural context. In Western Europe and the United States, the avoidant type is more prevalent than the resistant pattern, whereas the opposite has been observed in some other cultures (e.g., in Israel).

A fourth category of attachment classification was added in 1986 by Main and Solomon because studies showed that there are infants whose behavior does not correspond with any of the three existing classifications. During the Strange Situation, these infants showed sequences of unusual behavior with no clear purpose or orientation (e.g., freezing, falling prone).

They seemed to lack an organized strategy for coping with the stress of the situation and looked "confused"; thus, they were classified as having disorganized/disoriented attachment to their caregivers. Disorganized classification is given in addition to one of the other classifications. In normative middle-class populations in North America, approximately 14% of infants are judged to be disorganized. The rate is somewhat higher (24%) in low-socioeconomic status samples.

3.1.1.3. Validity Evidence supporting the validity of the Strange Situation (i.e., its capacity to indeed capture the organization of the child's attachment system) comes from the correspondence between Strange Situation classification and Ainsworth's home observations of the same 23 infant-mother pairs. Ainsworth and colleagues found a strong association between infants' Strange Situation classification and their secure base behavior in the home. Secure infants were much more likely than insecure infants to exhibit a good balance of exploratory and proximity-seeking behavior, to transition smoothly between the two, and to enjoy and be comforted by physical contact. In contrast, insecurely attached infants showed disturbed balance between attachment and exploration behavior, had difficulty in transitioning from one to the other, and often expressed negative affect during physical contact with their mothers. Further supporting evidence comes from several studies that found links between the Strange Situation classification and infants' secure base behavior in the home as assessed by the Attachment Q-sort. Finally, additional less direct evidence for the validity of the Strange Situation comes from its links to prior maternal behavior and subsequent child outcomes.

3.1.2. The Attachment Q-Sort

An alternative to the Strange Situation is the Attachment Q-sort developed by Waters and Deane in 1985. The AQS requires observers to describe a target child's home behavior by sorting a set of items according to how well they each describe the particular child (from most characteristic to least characteristic). Version 3.0 of the AQS consists of 90 items depicting a wide array of child home behaviors. A continuous measure of security is derived by comparing the sort describing the child of interest with a criterion sort developed to describe the ideal secure child. An advantage of the AQS is that it is suitable for use with a relatively wide age range (from 1

to 4 years). Both mothers and independent observers may use the AQS, although mothers have to become familiar with its items and observe their children for a few days in the home environment prior to their finally sorting all of the items from most characteristic to least characteristic of their children.

Findings regarding the association between the Strange Situation classifications and AQS security score have been mixed; some studies have found correspondence, whereas others have not. Overall, it appears that correspondence is better when independent observers, rather than mothers, are used. Summarizing more than 130 studies, a recent meta-analysis showed moderate convergence between observer-reported AQS security and Strange Situation security. Observer reports of AQS security were also found to be quite strongly linked to maternal sensitivity. This suggests that the AQS, when rated by observers, is a reasonable alternative to the Strange Situation. On the other hand, maternal-reported AQS security had weaker associations with both Strange Situation security and maternal sensitivity assessments, suggesting that mother-reported AQS scores are less adequate at assessing attachment security.

3.2. Measuring Attachment During Childhood

Beyond infancy, measurement of the attachment relationship relies heavily on observations of children's behavior on reunion following relatively long separations from parents (30–60 minutes). Children's emotional expression during separation and reunion, as well as their patterns of verbal and nonverbal communication with their caregivers, is examined and used to determine their attachment classification. The three main attachment patterns identified in children parallel those identified in the Strange Situation. A child can be described as secure (also referred to as balanced), as avoidant (also termed defended), or as dependent (parallel to the resistant classification during infancy and also referred to as coercive or involving). Children classified as disorganized during infancy typically exhibit controlling role-reversing behavior on reunion during childhood, taking either a caregiving or a punitive role toward their parents.

Narrative measures attempting to assess children's symbolic representations of attachment have also been developed. These measures use projective techniques. They ask children to respond to pictures or story-stems depicting relevant attachment scenes. The narratives constructed by the children are then coded and scored for attachment

style. Finally, the AQS can also be used with young children to obtain a measure of attachment security.

3.3. Assessing Adult Attachment Representations

During adolescence and adulthood, attachment is most often assessed through structured interviews or questionnaires. The central instrument is the Adult Attachment Interview (AAI) developed by Main and colleagues. Throughout the interview, the individual is asked to describe his or her relationships with caregivers during childhood and to illustrate these descriptions with specific examples. The individual is also asked to describe situations where he or she needed support from those attachment figures (e.g., when the individual was hurt or upset) as well as relevant experiences of loss or trauma. The interviews must be transcribed verbatim and scored by a trained coder.

The AAI is designed to assess the individual's current state of mind with respect to attachment rather than what his or her early attachment classification might have been. Thus, scoring of the AAI is based on the coherence of the narrative produced by the individual during the interview rather than on an assessment of his or her early life experiences.

The AAI yields adult attachment classifications that mirror the patterns identified in the Strange Situation. Securely attached adults are referred to as "autonomous" or "free to evaluate" because they appreciate close relationships and value their effect. They are reflective and open, and they speak about early experiences in a coherent and objective manner, even when such experiences were difficult or painful. Insecure adults could be classified as either "dismissing" (parallel to avoidant during infancy) or "preoccupied" (parallel to resistant attachment during infancy). Dismissing individuals minimize the effect of meaningful relationships in their personal history. They may idealize or derogate their attachment figures. When asked to support their descriptions of their relationships with specific examples, they are often unable to remember relevant incidents. Preoccupied (or "enmeshed") individuals are unable to detach themselves from irrelevant details associated with their past history and are so wrapped up in their "old" experiences and feelings that they fail to provide an overview. They appear to still be immersed in anger over old issues and unable to "let go."

Finally, the coding of the AAI also yields a score of the individual's unresolved loss or trauma (when such painful experiences had occurred). This score is based on indications of disorganization and disorientation in thinking and affect during the discussion of the loss/trauma (e.g., speaking of a dead person as if he or she were alive, going into an extreme amount of detail when describing the events surrounding the loss).

AAI classifications have been found to be stable over time and unrelated to intelligence, general memory skills, or the individual's narrative style about topics irrelevant to attachment. Some empirical evidence regarding the validity of the AAI comes from numerous studies that found links between mothers' AAI classification and the quality of their caregiving behavior to their own children at home as well as their own children's attachment classification. More direct evidence that the AAI indeed reflects how adults interact with attachment figures when coping with stress is still relatively scarce. In one relevant study, engaged couples who completed the AAI were observed during a standard marital interaction task. AAI security was associated with more adaptive use of the partner as a secure base to obtain support as well as with greater propensity to serve as a secure base for the partner and provide such support. More research linking the AAI to adult secure base behavior is still needed.

Other interview procedures have also been developed to assess adult attachment. For example, the Current Relationship Interview (CRI) was developed by Crowell and Owens to assess attachment within current close relationships. Finally, self-report questionnaires are used as well for the assessment of attachment styles, particularly in the context of adult romantic relationships. Of these, the most widely used are Hazan and Shaver's Attachment Style Questionnaire and Bartholomew and Horowitz's Relationship Questionnaire. Overall, studies examining the associations between questionnaire measures and the AAI have produced mixed findings; several studies find little or no relationship, whereas a few studies report moderate associations. More research is still needed concerning the relationship among various measures of adult attachment.

4. THE ANTECEDENTS OF ATTACHMENT SECURITY

Because attachment describes an aspect of the relationship that develops between an infant and a caregiver,

both members of the dyad influence the nature and quality of the attachment relationship that emerges. These two classes of antecedents are reviewed in what follows. Genetic influences on attachment are also considered.

4.1. Caregiver Influences on Attachment Security

4.1.1. Parental Caregiving Behavior

In Ainsworth's studies, infant attachment classification was found to be strongly linked to prior maternal behavior in the home. The extensive home observations revealed that the mothers of secure, avoidant, and resistant infants differed qualitatively in their styles of caregiving. Specifically, mothers of infants later found to be secure during the Strange Situation at 12 months were highly sensitive, responsive, and accepting. They responded consistently and appropriately to their infants' signals (e.g., crying) and were affectionate when holding and taking care of their infants. In contrast, the mothers of avoidant infants were observed to be consistently insensitive and rejecting. They were interfering and showed an aversion to close physical contact with their infants as well as a relative lack of emotional expression. Finally, infants classified as resistant had mothers who were inconsistently responsive. They were generally insensitive to their infants' signals but were not highly rejecting. They were inept at holding their infants and responding to signals, but they showed no aversion to close physical contact with their infants. Therefore, the strategies employed by the insecure infants during the Strange Situation were seen as adaptations to the nonoptimal caregiving they have received and come to expect.

Overall, Ainsworth and colleagues found a very strong positive association between observer ratings of maternal sensitive responding and Strange Situation security. A considerable body of subsequent work employing the Strange Situation has generally replicated this link between early maternal sensitive and responsive caregiving and secure attachment in the Strange Situation, although the effects observed in those replication studies were considerably weaker than those reported by Ainsworth and colleagues. Three separate meta-analytic studies summarizing this body of work all concluded that the replication studies, taken together, showed a moderate linkage between maternal sensitive responding and infant security. Therefore, it appears that maternal sensitive and

responsive caregiving plays an important, but not an exclusive, role in the formation of infant attachment security as assessed by the Strange Situation.

In addition to attachment security, the antecedents of attachment disorganization have been the subject of much theorizing and research. Hesse and Main posited that disorganized attachment is the result of frightening or frightened behavior on the part of the caregiver. The underlying assumption is that these circumstances present a very difficult situation for the infant because the same person who is supposed to help alleviate the child's fear is also the person who causes it or is also afraid and unable to help the child. This leads to an approach–avoidance conflict and to behavioral disorganization. Support for this proposition is found in studies of children who are maltreated. These children show significantly higher rates of disorganized attachment than do children who were not abused or neglected.

4.1.2. Parental Attachment Representations

Another variable that has been systematically linked to infant attachment security in the Strange Situation is maternal attachment security as assessed by the AAI. Thus, secure autonomous mothers typically have secure infants, dismissing mothers tend to have avoidant babies, and preoccupied mothers often have resistant infants. Finally, maternal unresolved loss or trauma as assessed by the AAI has been found to predict disorganized/disoriented infant attachment. This correspondence in attachment patterns, referred to as the “intergenerational transmission of attachment,” has been found across many studies, even when the AAI was assessed prior to the infants' births. One study involving grandmothers as well as mothers and infants also found transmission of attachment across three generations. The correspondence between parental and child attachment is greater for mothers than for fathers, possibly because mothers typically serve as the primary caregivers.

How is attachment security passed on from parent to child? The main process suggested by attachment theory is through the quality of caregiving provided by the parent. Indeed, research has shown that a substantial part of the correspondence between parent AAI and infant Strange Situation classification (approximately 23–25%) is due to the level of maternal sensitive responsive caregiving. However, a large portion (75–77%) of the correspondence is not explained by quality of caregiving, at least as assessed in the relevant studies

(this discrepancy has been labeled the “transmission gap”). Thus, additional processes must play a role in the transmission of attachment security from generation to generation. Some of these processes may involve genetic transmission of attachment or child influences on attachment security.

4.2. Genetic Transmission of Attachment

Beyond caregiver sensitive responding, another mechanism that might underlie the transmission of attachment from parent to child is through their shared genes. Several twin studies have explored the potential genetic component of attachment development. Overall, these studies show a negligible role for genes, and a paramount role for the environment, in the formation of attachment security during infancy. However, it is possible that genes might be implicated in attachment security beyond infancy; one twin study with preschoolers found evidence for a small genetic effect. With respect to attachment disorganization, the pattern of findings has been inconsistent. Some studies (including a small-scale molecular genetics study) found evidence for heritability, whereas a recent twin study found no evidence for genetic influence on attachment disorganization. Further research is needed to elucidate the role played by nature on the formation and maintenance of attachments throughout the life cycle.

4.3. Child Influences on Attachment Security

4.3.1. Child Temperament

Although attachment researchers have traditionally focused on caregiver contributions to attachment security, infants themselves also play an important role in the formation of parent–child interaction patterns. Recall that attachment to caregivers is established during the first year of life, but long before then infants already exhibit their individuality in their affect and behavior, referred to as temperament. Many different aspects and components of early temperament have been identified, and their effects on the nature of parent–child interactions have been examined. Some aspects of temperament seem particularly relevant to infants' expression and regulation of attachment behavior, for example, proneness to distress (e.g., difficulty, emotionality, negative reactivity) and ability

to regulate distress effectively. Therefore, the potential influence of these temperamental features on the development of attachment security has been the subject of much debate and investigation.

In the strongest form of critique, some temperament researchers have argued that the Strange Situation reflects infants' temperamental characteristics rather than their accumulated experience regarding caregivers' responsiveness to their expressed needs. However, this analysis seems too biased in the direction of temperament effects and overlooks some important evidence. It appears that attachment classifications cannot be reduced to temperamental characteristics.

Today, it is generally acknowledged that both parent and child characteristics play a role in the formation of a secure attachment. In general, small to moderate associations between aspects of temperament and attachment security have been found, particularly when the AQS, rather than the Strange Situation, was used to assess attachment security. These studies show that infants who are more prone to distress early in life (e.g., difficult, reactive) generally show less secure base behavior later on.

However, beyond ascertaining the relative contribution of parent and child effects, it seems that the greater challenge for researchers during the upcoming years is to uncover how the two classes of antecedents interact in the formation of attachment. It seems likely that infants' temperament affects parents' ability to provide sensitive and responsive caregiving. Keeping highly irritable infants soothed and content is more demanding than caring for "easy" babies. Thus, infants prone to distress may elicit a lower level of sensitive responding, compared with calmer infants, from the same parents. Moreover, aspects of the environment (e.g., SES, family constellation, culture, support systems) also exert their effects on the two partners and the dyadic process. For example, parents who are exposed to high levels of stress or have little social support may be less able to provide responsive caregiving, particularly when caring for highly irritable infants.

4.3.2. Attachment in Children with Special Needs

In addition to temperament, other infant characteristics can influence the development of attachment security. Of special interest to researchers is the potential effects of infants' special needs (e.g., a serious medical condition, premature birth, developmental delay) on the formation of attachment security. It has been speculated that infants' medical or developmental problems (and parental perceptions of these problems)

might disrupt parent–infant interactions and thus hamper the development of secure attachments. However, studies have generally found that this is not the case. A meta-analysis summarizing this work showed that the majority of medically compromised infants were securely attached to their mothers. Yet, some conditions can delay the time course of the formation of early attachments. For example, studies on infants with Down's syndrome generally show that the emergence of early attachment is slower in this group.

5. ATTACHMENT THROUGHOUT THE LIFE SPAN: STABILITY AND CHANGE

Attachment theory posits that early attachment relationships serve, to a large extent, as a model for later close relationships. According to Bowlby, based on the early history of interactions with a caregiver, an infant develops internal representations or implicit ideas of both self and the attachment figure (e.g., a view of the self as worthy of love and of the mother as available and responsive). These internal representations, termed "internal working models," guide the individual's processing of relevant information and thus affect how the person approaches new situations. It is through these internal working models that early attachments are thought to influence later development and relationships. Because internal working models are believed to operate largely outside the realm of consciousness, they are considered quite resistant to change. However, such change is possible as a result of significant life events and new relationships. Thus, attachment theory hypothesizes that (a) there should be some degree of stability in individuals' attachment representations or internal working models throughout the life span and (b) change in the nature of these internal representations is not random but rather linked to important life events (negative or positive) or to new meaningful relationships (dysfunctional or constructive).

Findings from a number of independent long-term longitudinal studies generally reflect this complex mixture of stability and change. In these studies, attachment security was assessed during infancy using the Strange Situation and again during late adolescence or early adulthood using the AAI. Some of these studies found considerable stability in individuals' security status, whereas others found no such continuity. Importantly, stability of attachment appears to be linked to the

characteristics of the samples involved. Thus, stability of attachment from infancy to adulthood is more likely to be found in individuals brought up in stable and low-stressed families than for those raised in highly stressed and unstable family environments. Moreover, across various samples, change from early security to later insecurity was not arbitrary. Rather, such change was often linked to negative life events that likely affected the quality of caregiving experienced by the child (e.g., loss of a parent, divorce, serious physical or mental illness).

6. ATTACHMENT AND SUBSEQUENT CHILD OUTCOMES

With the gradual unfolding of attachment theory, and particularly since the Strange Situation was established as a valid measure of attachment during infancy, researchers began to examine the implications of early attachment relationships for later child outcomes. The underlying assumption in the majority of these studies is that positive attachment relationships (usually classified as secure) would be associated with positive outcomes and that negative attachment relationships (usually classified as insecure) would be associated with less positive or even negative outcomes. In other words, researchers hypothesized, and findings generally support the notion, that secure infants would subsequently show better adaptive skills in the areas of cognitive, emotional, and social development, whereas insecure infants' development may be associated with maladaptive characteristics in various domains.

6.1. Emotion Regulation

Emotional regulation refers to an individual's ability to manage and cope successfully with various levels of emotional arousal, including negative emotions, in response to external events and internal stimulation (e.g., anxiety, excitement). Current views suggest that the attachment system itself provides a basic mechanism for emotional regulation. Studies show that during the years when the attachment relationship is formed, children who develop secure attachment ties to their caregivers express a variety of emotions freely, whereas children who form insecure-avoidant attachment ties tend to inhibit emotions. Overall, studies following children from infancy to early childhood have found that secure children are spontaneous in their expression of a variety of emotions, read the emotional cues of

others better, and generally tend to be more emotionally positive. Insecure children, particularly those with an avoidant classification, tend to exhibit minimal emotional expressiveness overall, and particularly restrain the expression of negative emotions. Also, these children tend to misperceive others' emotional displays, and to exhibit inappropriate affect considering the emotional climate of the circumstances (e.g., show anger when expressing positive emotions would be more appropriate).

6.2. Prosocial Behavior and Interpersonal Relationships

Longitudinal studies have found that a history of responsive care resulting in secure attachment is associated with a number of positive social developmental outcomes. Yet it is difficult to draw certain conclusions as to the role of early attachment security in later social competence because the parent-child relationship involves many aspects in addition to attachment. In general, findings suggest that children who were classified as securely attached during the first year of their lives were judged during the preschool years to be more socially competent and empathic toward their peers, as well as to have higher self-esteem, than children with a history of insecure attachment. During middle childhood, children who were classified as secure in their early attachment relationships were also found to be more socially accepted by their peers and more adept at forming close friendships than children who were classified as insecure. Moreover, secure infants grow to be adolescents who are more capable of creating intimacy than do insecure infants. However, the correlational nature of this evidence precludes any firm conclusions regarding the causal role played by attachment security. The early attachment relationship is only one component within a larger developmental context predicting later competence in interpersonal domains.

6.3. Cognitive Development

Studies have found relations between classification of attachment during infancy and specific cognitive functions during childhood. The most consistent evidence indicates that secure infants grow to have some cognitive advantages over insecure infants. Caution should be exercised in interpreting results regarding the relations between early attachment classification and later cognitive performance given that findings generally

refer to the social aspects of cognition (social cognition), particularly problem solving, reasoning, and information processing within social contexts. However, there is some evidence suggesting that secure infants grow to have better cognitive functioning in the areas of attention, memory, and generalization during childhood than do insecure infants.

6.4. Problem Behavior and Mental Health

Research has shown that children with an insecure attachment history are more likely to develop behavioral and emotional problems than are children who had secure attachment relationships during infancy. Children with an insecure-avoidant history were found to exhibit more negative “acting out” behaviors, as well as to suffer from more depressed moods and anxiety during the preschool and early school years, compared with children who were securely attached, although the magnitude of these effects was generally small. Moreover, an avoidant-disorganized attachment classification during infancy was found to predict hostile and aggressive behavior during the school years. As with the other domains of development, no research provides evidence that insecure attachment is the primary factor, or even one of the more important factors, underlying any psychological disturbance.

It has also been argued that early insecure attachment contributes to psychopathology during adolescence and adulthood. Most notably, disorganized attachment during infancy has been linked to greater psychopathology in general during late adolescence, as well as to a specific type of psychological disturbance, namely dissociative symptoms. Infants identified as disorganized during the Strange Situation were found to report more dissociative states and experiences during late adolescence, reflecting disturbances of memory, identity, awareness, and cognition (e.g., lack of memory for significant past events). In addition, studies examining adult attachment have found a high proportion of insecure AAI classifications among psychiatric patients, although it might be that the psychiatric problems are affecting these individuals’ responses during the AAI (rather than these individuals’ state of mind with respect to attachment, or their attachment history, being the cause of the disturbance). A recent review suggested that dismissive adult attachment style is associated with acting out or externalizing disorders, whereas preoccupied attachment is associated with depression and anxiety or internalizing disorders. More research is still needed to

elucidate the role played by early attachment in psychological disturbance later in life.

7. APPLIED ASPECTS OF ATTACHMENT

Since attachment theory was first articulated by Bowlby during the 1950s and 1960s, it has had a substantial impact on how early parent-child relationships are viewed. This, in turn, has shaped the thinking and practices of clinicians and policymakers. These influences are presented in this final section.

7.1. Interventions with Infants and Young Children

Although Bowlby’s ideas, when first introduced, were met with strong resistance on the part of the psychoanalytic community, over the years practitioners have come to incorporate many of these notions into their clinical work. Specifically, because early secure attachment is associated with positive child outcomes, interventions that focus on the enhancement of attachment security in populations at risk for developing insecure attachment have been developed. There are two main approaches that guide these intervention attempts. The first aims at improving the quality of parental caregiving behavior, particularly parental sensitivity. The second approach is typically more long term and focuses on altering the parent’s insecure mental representations or implicit ideas of attachment into more adaptive secure ones. Of course, the two approaches are not mutually exclusive, and both can be incorporated into the same intervention.

7.1.1. Enhancing Parental Sensitivity

Improvement of the quality of caregiving behavior is typically done by first observing how the mother interacts with her infant. Many programs, as well as individual clinicians, that practice mother-infant psychotherapy use videotaping of mother-infant interactions to learn through observation about the strengths and weaknesses of each mother’s caregiving style. Portions of the videotaped material are then shown to the parent to identify moments where she interpreted her child’s signals correctly and responded appropriately as well as moments where she ignored or misinterpreted her child’s cues. More general patterns of parental responding to the infant are also identified and discussed. Through this process,

the clinician improves the parent's ability to read the child's various cues and signals and to respond more sensitively and appropriately to them. Examples of the use of this process in interventions are the STEEP (Steps Toward Effective Enjoyable Parenting) program developed at the University of Minnesota, the Infant Parent Program at the University of Michigan, and a preventive intervention study conducted in The Netherlands by van den Boom. In addition, similar principles of enhancing responsive caregiving through the provision of information, feedback, modeling, and support often guide individual clinicians when working with mother–infant dyads.

7.1.2. Changing Internal Working Models

Interventions and therapies that attempt to modify insecure internal working models of attachment typically involve parents discussing and reflecting on their experiences with their own early attachment figures (i.e., their parents). The goal is to gain insight into the effects of these early (often negative) childhood experiences on the parents' current caregiving practices. The underlying assumption is that working through these early anxiety-provoking experiences will lead to the adoption of more secure internal working models of attachment, thereby preventing the replication of the same maladaptive interaction patterns with their own children. Note that although this approach focuses on the parents' internal representational level, parenting behavior is also addressed, but without the intense behavioral focus involved in the first approach to intervention discussed in the previous subsection.

Overall, a meta-analytic review of intervention programs using attachment theory in individual, dyadic, or group settings suggested that short-term, behaviorally based interventions with a specific focus were more effective in improving mother–infant quality of interaction and attachment security than were interventions focused on parental internal representations. However, the magnitude of the effects was generally small. Moreover, enhancing maternal sensitivity was found to be a more consistent outcome of interventions than was the effect on infant attachment classification.

7.2. Policy

Attachment theory has had an impact not only on the work of researchers and individual clinical practitioners

but also on policymakers. Early on in his career, Bowlby and his colleague, John Robertson, observed and documented the emotional difficulties that hospitalized children exhibited when forced to separate from their parents. At the time, parents were not allowed to stay with their sick children, and children were forced to spend days and weeks with only brief, highly controlled visits from their parents. A filmed documentation of one hospitalized child's grief and pain over her separation from her parents had a tremendous impact on hospitals' practices and policies. Today, in most hospitals, parents are allowed and encouraged to spend unlimited time with their hospitalized children.

Child care policies were also largely affected by Bowlby and his followers' views on the importance of high-quality caregiving. One important area is the care provided for orphans and children who need to be removed from their parents' care. In the past, these children were typically put in institutions such as residential nurseries and orphanages. This practice was criticized by attachment theorists because the emotionally detached style that characterized care in these institutions did not enable the children to form meaningful relationships with consistent caregivers. As a response to the criticism of institutionalization, there has been a growing tendency to rely on foster care in an attempt to promote more intimate personalized caregiving within a family context. However, this alternative often appears to be less successful than expected because many children are passed on from one foster family to another for short amounts of time.

Finally, another area in which attachment theory has had an influence is how nonmaternal care during the day, and particularly group day care for infants and young children, is perceived and evaluated. In general, research shows that nonmaternal care, including group day care, does not, in and of itself, disrupt children's attachment security to their parents. However, low-quality day care—marked by large group size, high caregiver–child ratios, high turnover of caregivers, and lack of personalized caregiving—can be detrimental to infant–mother attachment security, particularly when other risk factors are present. This highlights the importance of providing infants with good quality day care settings to enable them to form meaningful relationships with consistent caregivers.

GLOSSARY

alerting Achieving and maintaining a state of high sensitivity to incoming stimuli.

attention The mental ability to select stimuli, responses, memories, and thoughts that are behaviorally relevant among a host of others that are behaviorally irrelevant.

attentional networks Neural circuits subserving attentional processing that preserve a degree of anatomical and functional independence but interact in many practical situations.

cognitive control Processes such as conflict resolution, error correction, inhibitory control, planning, and resource allocation.

executive The mechanisms for monitoring and resolving conflict among thoughts, feelings, and responses (e.g., an attentional system concerned with such tasks as working memory, planning, switching, and inhibitory control).

neuroimaging Technological advances, often noninvasive, that permit tapping neurophysiological aspects of the behaving brain.

orienting The selection of information from sensory input.

top-down modulation A downstream (vs bottom-up) effect (e.g., cognitive control).

self-regulation Key mediator among genetic predisposition, early experience, and adult functioning (e.g., in controlling the reaction to stress, the capacity to maintain focused attention or the ability to interpret mental states both internally and in others).

Attention, endowed with a rich set of empirical findings, is a central theme in psychological research. Since the 1980s, human neuroimaging studies have allowed examination of the whole brain during tasks involving attention and, consequently, have provided much information on how the brain houses attentional processes. Brain networks subserving attention have been identified and described both anatomically and functionally. It is now possible to use these networks as model systems for the exploration of symptoms arising from various forms of pathology. This article outlines selective attention, its phenomenology, and its constituent attentional networks.

1. HISTORICAL CONTEXT

Attention, one of the oldest and most central issues in psychological science, is the problem of selecting for active processing certain aspects of the physical environment (e.g., objects) or ideas in a person's mind (which are stored in his or her memory). Many great minds have wrestled with the definition of attention. In 1890, William James wrote, "Everyone knows what attention

is. It is the taking possession of the mind in clear and vivid form of one out of what seem [to be] several simultaneous objects or trains of thought." James's account heavily joined attention with subjective experience. Moreover, James's effort to deal with both attention to objects and attention to "trains of thought" is important for understanding current approaches to sensory orienting and executive control. However, because attention in the sense of orienting to sensory objects can actually be involuntary and can occur unconsciously, attention is not, as the quote from James implies, the same as being aware.

Behavioral psychology postponed research into the internal mechanisms of attention after 1900. The quest for attentional mechanisms resumed following World War II, when Donald Broadbent proposed a filter, limited for the amount of information (in the formal sense of information theory), that was located between highly parallel sensory systems and a limited-capacity perceptual system. This view was of immense aid in making possible objective studies of limitations in the human ability to deal with more than one signal at a time in a variety of practical tasks.

As psychology moved toward the study of cognitive mechanisms, the new objective methods made it possible to ask about the processes of selection. It was found that words could activate their semantic associates even when there was no awareness of the words' identities (i.e., priming). The highly parallel organization found for sensory information extended to semantic processing. The act of selecting a word meaning for active attention appeared to suppress the availability of other meanings of the selected item and of competing items. More recently, it became increasingly clear that although attention can be contextualized as a form of "alertness" as well as an index to resource allocation/limitation, it has been viewed less as a filter or bottleneck and more as a mechanism for providing priority for motor acts, consciousness, and some kinds of memory.

Although the psychology of attention furnished a number of interesting results about the limits of performance and of unconscious processing, there was no agreement on whether attention involved separate mechanisms from those used to process data, let alone any analysis of what these mechanisms might be in neural terms. Advances in the understanding of neural systems underlying attention developed from experimental paradigms involving selection of sensory information and more recently from the technological innovation of noninvasive tools for imaging the living brain.

Brain imaging has forged an impressive link between psychology and neuroscience. As early as 1990, some

scholars suggested that the human brain entertains several attentional systems of different but interrelated functions (e.g., orienting, target detection, alerting). More recently, it has been demonstrated that distinct brain areas indeed mediate different attentional processes and that it is possible to examine selective attention as an organ system with its own functional anatomy, circuitry, and cellular structure. Although still incomplete, this information has illuminated multiple important questions in cognitive science and has provided insights into neurological and psychiatric disorders of both children and adults. Attention allows humans to exercise voluntary control over thoughts, feelings, and actions. Variations in the operational efficiency of these attentional systems serve as a basis for differences in self-regulation and emotional control, and they promise to help describe mechanisms of volition and sustained effort.

2. GROSS CHARACTERISTICS OF ATTENTION

Humans are largely visual animals, perhaps due to a common adaptation to visual predation generally found in primates. Researchers and clinicians have investigated the optics, anatomy, development, pathology, and underlying neural processes of the visual system, making it the most widely studied perceptual system. Therefore, it is didactically advantageous to discuss attention within the visual realm. Visual attention allows humans to move attention around to various areas of the visual field and to change the detail with which they look at any given area. For example, a reader can look at this page and pay attention to its setup as a whole, or he or she can zoom in on specific words and certain letters therein. If the reader is paying attention to single characters, he or she can glean a lot of information about punctuation marks, catch typos, and even spot minute imperfections on the physical sheet. But in that case, the reader might miss the idea that a paragraph is trying to convey. A person has the ability to change the location of attention and also to change the size of the attentional focus. This has been called the "zoom lens" idea, or the "attentional spotlight," and relates to humans' common experience concerning the kind of attention needed for reading versus proofreading.

Given a large visual array of individual features, a person can have a choice of examining it globally or instead examining its specific features. The person can shift back and forth between them by changing the

focus. Some patients have difficulty in examining the local features; these patients usually have damage to the left temporo-parietal lobe. Other patients may do well with the local features but fail to get the overall contour; they usually have damage to the right temporo-parietal lobe. The parietal lobe tends to emphasize the shifting between local and global, whereas the temporal lobe seems to determine whether one can actually examine a local feature or a global feature of the stimulus.

People usually foveate, or look at, exactly the thing in which they are interested, and that generally relates people's attention to where they fixate. However, it is easy to dissociate the two: to cue people to attend to some location in space other than the center of gaze and then to show that they are very sensitive (i.e., have a low threshold or fast response time) to information that occurs at the cued location and are relatively slow or insensitive to information that occurs at the fovea. These covert shifts are believed to be used to select the part of the visual field to which people usually want to move their eyes. In everyday life, people usually follow covert shifts of attention with eye movements. Attention to visual elements can also apply to other modalities (e.g., auditory).

When multiple people talk simultaneously, it is sometimes necessary to select one of these streams of conversation to follow it in detail. An individual usually does that based on the location of the other person by visually orienting toward the person and/or honing in on the frequency of his or her voice (e.g., it is easier to separate a male voice from a female voice than to separate two male voices) or on the content of the information (e.g., following by content). When an individual attends to one stream, the other information goes into the background; it is present but does not reach focal analysis.

There are data indicating that much of this unattended information is processed in subtle and complicated ways. Unattended information can suddenly get interesting because a person's name is mentioned or because something happens that is related to the conversation he or she is following and the person then finds himself or herself orienting to the new information. These phenomena have been studied experimentally in some detail.

3. ATTENTION AND PERCEPTION

The psychophysics literature provides good accounts of how visual thresholds correlate with attentional

investment. However, improvement in "visual acuity" is not synonymous with altered thresholds for detection, better performance, or faster reaction times. For example, acuity requires the resolution of detail, whereas detection thresholds and reaction time can involve the summation of luminance, and this might obscure detail.

There is evidence that attention improves performance in spatial resolution tasks. Cognitive scientists draw a distinction between how attention may be useful for simple detection of events and how performance can improve at those events. Although performance may improve on increased attentional investment, there has been great controversy over what orienting attention to a sensory (e.g., visual) stimulus actually does. There is general agreement that the attended stimulus receives priority, so that reaction time to it is usually faster. For example, in the visual modality, there is evidence of enhancement of brain electrical activity over extrastriate visual areas by approximately 90 milliseconds after visual presentation. On the other hand, attention is not a panacea to perception, and there is a great deal that attention cannot do. For example, it is clear that attention to a peripheral stimulus does not compensate for the lack of acuity that would be present for a foveal stimulus. Stimuli in the fovea always have an advantage in detail, although the priority for processing the input has been placed elsewhere. Thus, while orienting to a location, attention can give priority to that location (i.e., targets that appear there will be perceived more rapidly and with lower thresholds), but it cannot substitute for the acuity provided by the fovea. Although the fovea is critical for acuity, the costs in reaction time for an unexpected foveal stimulus are just as great as those for an unexpected peripheral event. Thus, visual attention influences priority or processing preference.

Whereas investing attention is frequently associated with looking directly at the scene of interest, covert attention is the ability to select visual information at a cued location, without eye movements, and to grant such information priority in processing. Researchers have shown that the performance improvement at attended locations results, to some extent, from an enhanced spatial resolution at the cued location. Findings from further psychophysical studies support the hypothesis that attention increases resolution at the attended location. Studies exploring the relationship between visual attention and contrast sensitivity show that covert attention not only improves discriminability in a wide variety of visual tasks but also can speed up the rate at which information is processed. There are findings indicating that a person's contrast

sensitivity is greater in the lower visual meridian (not the higher one). The bulk of the evidence sets limits to the effects of attention on spatial resolution and specifies that certain visual (not attentional) constraints determine aspects of spatial resolution.

4. ATYPICAL ATTENTION

Attentional performance is affected by the biological rhythm. Diurnal reductions in attention normally occur during the hours of maximum sleepiness (2–7 AM) when body temperature is at a nadir, and enhanced performance is usually seen during the evening when body temperature peaks. During sleep, voluntary attention is often considered to be markedly attenuated or indeed absent. However, there is evidence to suggest that certain attentional, as well as preattentive, mechanisms remain intact. Dreaming is usually divorced from a sense of controlled awareness, but purported accounts of lucid dreaming (i.e., dreaming while knowing that one is dreaming) suggest that some control mechanisms may be available during sleep. Other common anecdotes include the incorporation of ambient sound into the dream content and the idea of sensitivity to a person's own name.

One of the ways in which to investigate information processing in sleep involves electrical recordings from the scalp (EEG). By averaging the brain's electrical response potentials to stimuli (ERP), it is possible to examine the processing capability of the sleeping brain. One such component to examine is the mismatch negativity (MMN). The MMN is an electrophysiological manifestation of involuntary preattentive processing in response to oddball stimuli. In a typical MMN paradigm, a "deviant" auditory stimulus is infrequently interspersed within a sequence of "standard" auditory stimuli. The MMN is evident in the difference waveform resulting from the subtraction of the ERP elicited by the standard stimulus from that elicited by the novel auditory stimuli (the deviants). The difference waveform, occurring even without attention, normally peaks between 100 and 250 milliseconds from the onset of the deviant event, depending on the dimension of deviance and its magnitude. The MMN is presumably associated with a mechanism that compares the current auditory input with the memory traces formed by previous auditory inputs and signals the occurrence of a mismatch.

In adults, MMN tends to decline during drowsiness. Whether it persists into adult human sleep is still debated, but other EEG components do reflect the brain's reaction to novelty. Although active midbrain inhibition blocks

cortical activity in the developed brain, there is reason to believe that the sleeping infant brain is not as capable of blocking and inhibiting information efficiently. Indeed, MMN is obtainable from newborns and young infants, and there are nascent experimental data showing that the brain can learn (e.g., certain language contrasts), even while asleep, during those early developmental stages.

Another special cognitive state sometimes confused with sleep is hypnosis. Some people (e.g., highly hypnotizable individuals) may experience attentional and perceptual changes, which might not typically occur during common awareness, following particular suggestions. Similar phenomena can occur in certain patient populations. For example, within vision, hypnotic suggestions have been demonstrated to induce tunnel vision, color-blindness, hallucinations, alexia, and agnosia. Such phenomena can manifest in other modalities as well (e.g., auditory).

Hypnosis has been used clinically for hundreds of years and is primarily a phenomenon involving attentive receptive concentration. Clinicians practicing hypnosis suggest that when a person is in a hypnotic state, attentional and perceptual changes may occur that would not have occurred if the person had been in a more usual state of awareness. In a responsive individual, hypnotic perceptual alteration is accompanied by reproducible changes in brain action. For example, the activity of the anterior cingulate to painful stimuli or conflict resolution can be modulated by hypnotic suggestion. Most children are highly hypnotizable and are more easily inducted into the hypnotic state than are adults.

5. SUBSTRATES OF ATTENTIONAL NETWORKS

Attention can enhance neural processing at multiple levels. It is a selective aspect of information processing; some things are privileged and some things are ignored. The modulation of neural response by attention has been studied vigorously. For example, one recent hypothesis suggests that as processing becomes more complex, it becomes advantageous to spread processing across more neural areas (e.g., both hemispheres). Another experimental approach carefully crafted a behavioral task to probe and assess at least three distinct attentional networks: (a) achieving and maintaining the alert state, (b) orienting to sensory objects, and (c) selecting among conflicting actions. Behavioral and imaging data suggest that these networks

are independent. It is further possible to identify the neuroanatomy subserving these attentional networks.

Alerting involves a change in the internal state in preparation for perceiving a stimulus. The alert state is critical for optimal performance in tasks involving higher cognitive functions. Neuroimaging studies have shown activity in the frontal and parietal regions, particularly of the right hemisphere, when people are required to achieve and maintain the alert state even for a brief period. Lesions of these areas will reduce the ability to maintain alertness. Right frontal lesions have been shown to impair ability to voluntarily sustain attention, producing a larger number of errors over time than is found for left frontal patients in tasks involving continuous performance. Right parietal patients show deficits in maintaining the alert state and difficulty in attentional orienting that together produce a profound neglect in the visual field opposite the lesion. Alerting is thought to involve the cortical distribution of the brain's norepinephrine system arising in the locus coeruleus of the midbrain.

The orienting network involves the selection of information from sensory input. Cholinergic systems arising in the basal forebrain play an important role in orienting. The pulvinar, superior colliculus, superior parietal lobe, and frontal eye fields are often activated in studies of the orienting network. Orienting can be reflexive (e.g., when a sudden target event directs attention to its location), or it can be more voluntary (e.g., when a person searches the visual field looking for some target). Orienting typically involves head and/or eye movements toward the target, that is, overt orienting. However, it can also be covert. A few dorsal brain areas, including the superior parietal lobe and temporo-parietal junction, serve as a common source of attention to sensory stimuli. They produce effects within a network of areas that depend on modality (e.g., ventral visual areas in the case of visual input). The strongest evidence for localization of mental operations stems from the area of attentional orienting toward sensory stimuli, where a confluence of methods and experimental sophistication has demonstrated how separate brain areas can be invoked to organize a simple attentional shift. There is agreement that orienting of attention to a visual stimulus produces amplification in prestriate regions and that this affects processing in all subsequent regions and feeds back to influence processing in the primary visual cortex and perhaps in the lateral geniculate nucleus of the thalamus.

Executive control of attention involves more complex mental operations in monitoring and resolving conflict among computations occurring in different

brain areas. Executive control is most needed in situations that involve planning or decision making, error detection, novel (or not well-learned) responses, and conditions judged to be difficult or dangerous as well as in overcoming habitual actions. The anterior cingulate and lateral frontal cortex are target areas of the ventral tegmental dopamine system. Brain imaging data have shown repeatedly that the anterior cingulate cortex (ACC) is an important node in this network. Toward that end, a number of neuroimaging studies have shown activation of the dorsal anterior cingulate in tasks requiring people to respond either to a prepotent response or to a rather strong conflicting dimension. For example, in the classic Stroop task, experienced readers name the ink color of a displayed word. Readers are usually slower and less accurate in responding to the ink color of an incompatible color word (e.g., the word "red" displayed in blue ink) than in identifying the ink color of a control item (e.g., the word "lot" displayed in red ink). Another task involves participants responding to the direction of a central arrow when flanking arrows could point in either the same (congruent) direction or the opposite (incongruent) direction. The Attention Network Test uses this flanker task to measure conflict and shows strong activation in the dorsal ACC. Neuroimaging studies have shown that these conflict tasks activate midline frontal areas (e.g., ACC), lateral prefrontal cortex, and basal ganglia. These experimental tasks provide a means of fractionating the functional contributions of areas within the executive attention network. Chiefly, the ACC was more active on incongruent trials than on congruent trials. This result could reflect the general finding that lateral areas are involved in representing specific information over time (i.e., working memory), whereas medial areas are more related to the detection of conflict.

Patients with focal brain lesions of the ACC initially display deficits of voluntary behavior. The notion of ACC involvement in cognitive control and volition has been a topic of much interest recently. Based on behavioral, optical, and neuroimaging data, it was reported that effective suggestion (i.e., verbal exhortation) prevented word reading and modulated focal brain activity in highly suggestible individuals. This top-down influence was both potent and selective in that it annihilated the Stroop interference effect and reduced ACC activity, respectively. Interpretation of these data implies that, at least in highly suggestible individuals, attentional manipulations can influence aspects of self-regulation by affecting neural activity in specific brain areas. Although attention and self-regulation have arisen

within two different research traditions, there have been some recent efforts to integrate these two directions considering hypotheses about specific neural mechanisms involved in both attention and cognitive control. For example, these prospective approaches advocate a synthesis that is likely to be productive in linking brain systems to aspects of child socialization.

selective attention The ability to "zoom in" on task-relevant information while blocking out distractions.

simulation training The use of simulated sport situations in practice in an effort to help athletes become accustomed to anticipated pressures and distractions.

trigger words Instructional cues that remind athletes what to focus on in competitive situations.

GLOSSARY

attention People's ability to focus on information derived either from the external world or from internal sources such as memory and imagination.

concentration The ability to focus effectively on the task at hand while ignoring distractions.

divided attention The ability to perform two or more concurrent actions equally well.

mental practice The systematic use of mental imagery to rehearse actions covertly before they are executed physically.

meta-attention People's informal theories about how their attentional systems work.

performance goals Specific tasks or actions that lie within the control of the athlete.

preperformance routines Sequences of preparatory actions that athletes tend to engage in before they execute self-paced skills.

The term "attention" refers to people's ability to focus on information derived either from the external world or from internal sources such as memory and imagination. In sport psychology, attentional processes such as "concentration," or the ability to focus mental effort on the task at hand while ignoring distractions, are regarded as vital determinants of successful athletic performance. Given this importance of attention in sport, a variety of psychological exercises and techniques have been postulated to enhance athletes' concentration skills. Although none of these interventions has been validated adequately so far, some theoretical support exists for the use of the following strategies: simulation training, performance goal setting, preperformance routines, trigger words, and mental practice. Following an explanation of each of these concentration interventions, this article considers some unresolved issues along with potentially fruitful new directions for research in this field.

1. “ATTENTION” AND “CONCENTRATION” IN SPORT

Cognitive sport psychology is concerned with the scientific study of how the mind works in athletic settings. Within this field, the term “attention” refers to people’s ability to focus on information derived either from the external world or from internal sources such as memory and imagination. This ability is regarded as a multi-dimensional construct that has at least three key components that can be explained as follows. First, when an athlete is asked to “pay attention” to an instruction provided by a coach at a training session, the athlete is required to concentrate on, or to exert mental effort in absorbing, the information presented. The second component of attention involves selective perception and occurs when sport performers “zoom in” on task-relevant information while blocking out distractions. To illustrate, a soccer goalkeeper who is preparing to catch a corner kick must focus only on the flight of the ball while ignoring the potentially distracting movements of other players in the penalty area. Finally, attention involves “multitasking,” that is, the coordination of simultaneous skilled actions. For example, when a basketball player dribbles with the ball while scanning the court for a teammate to pass the ball to, the player is engaging in a form of mental time sharing called “divided attention.” In summary, the construct of attention refers to three distinct cognitive processes: concentration or effortful awareness, selectivity of perception, and the ability to coordinate two or more concurrent actions successfully.

Since the 1950s, two main theoretical models of selective attention have been postulated in cognitive psychology. First, the “spotlight” metaphor suggests that selective attention resembles a mental beam of light that illuminates targets located either in the external world around us (sensory information) or in the subjective domain of our own thoughts and feelings (mental events). Another popular theoretical approach is the “resource” model of divided attention. This metaphor suggests that attention is analogous to a pool of mental energy that is allocated to fulfill processing demands according to certain strategic principles. To illustrate, the principle of “automaticity” suggests that the more practiced a task is, the more automatic it becomes and the less attentional resources it requires. Based on this principle, it may be predicted that expert athletes are especially vulnerable to distractions because they have “spare” mental resources due to the automated

nature of many of their perceptual motor skills. The issue of how to refocus the minds of such performers is addressed later in this article.

Athletes, coaches, and sport psychologists regard attentional skills such as concentration, or the ability to focus effectively on the task at hand while ignoring distractions, as essential prerequisites of success in sport. This claim is supported by both descriptive and experimental evidence. First of all, surveys of expert sport performers such as U.S. Olympic athletes indicate that concentration is consistently rated among the most important mental skills required for sporting excellence. Next, qualitative studies suggest that total absorption in the task at hand is a key feature of “flow” or “peak performance” experiences in sport, that is, those coveted yet elusive moments during which athletes perform at the best of their abilities. Finally, there is growing experimental evidence that athletes (e.g., sprinters) who have been trained to use certain concentration strategies (e.g., deliberately focusing on task-relevant cues) tend to perform better than their counterparts who are assigned to nonfocusing control conditions. Taken together, these sources of evidence converge on the conclusion that the ability to pay attention to the task at hand is a vital determinant of success in sport.

Based on peak performance research, three key principles of effective concentration can be identified. First, a focused state of mind requires intentionality and a willingness to expend deliberate mental effort on the part of the athlete concerned. Put simply, one must prepare to concentrate effectively rather than merely hope that it will happen fortuitously. Second, although skilled athletes might be able to divide their attention efficiently between two or more concurrent actions, they can focus consciously on only one thought at a time. This principle stems from the fact that “working memory,” or the cognitive system that regulates people’s attentional deployment, is limited in its capacity and duration. Accordingly, it can be overloaded easily when several thoughts and/or behavioral intentions compete for conscious attention. Interestingly, this danger of cognitive overload is increased when athletes become preoccupied with winning a competitive encounter. In this situation, they may find themselves torn between trying to focus on performing an action and worrying about the likely outcome of the encounter in which they are participating. Finally, as mentioned earlier, research on flow states indicates that athletes’ minds are focused optimally when they are totally absorbed in the task at hand. In such a state of

mind, there is no difference between what they are thinking about and what they are doing. In summary, athletes tend to concentrate most effectively when they prepare to exert mental effort and can aim their attentional spotlight at actions that are specific, relevant, and under their own control.

2. TRAINING ATTENTIONAL SKILLS IN ATHLETES: CONCENTRATION EXERCISES AND TECHNIQUES

Given the importance of attentional processes in sport, a wide range of strategies has been promulgated by applied sport psychologists in an effort to enhance athletes' focusing skills. In general, these interventions fall into two types of activities: concentration training exercises and concentration techniques. Theoretically, the main distinction between these activities is that the former are designed for use during athletes' training sessions, whereas the latter tend to be practiced most frequently in actual competitive situations. Not surprisingly, however, this distinction is blurred by the fact that athletes are increasingly aware of the value of replicating competitive situations in their training regimes. Accordingly, there may be an overlap between the concentration exercises and techniques they employ in training and in competition.

2.1. Concentration Exercises

One of the most popular focusing exercises recommended by sport psychologists is a visual search task called the "concentration grid." In this task, participants are presented with a random array of two-digit numbers (from 00 to 99) on a page and are required to scan and "tick off" as many digits as possible in a given sequence (e.g., beginning with 00 and increasing consecutively) within the specified time limit of 1 minute. The number of digits marked in the correct sequence within this duration serves as an alleged index of the athletes' concentration skills. Unfortunately, although the concentration grid may have some intuitive plausibility, it has not been validated as a concentration exercise either theoretically or empirically. Therefore, its conceptual rationale and practical utility remain unresolved.

In contrast to the grid, a more recent concentration exercise known as "simulation training" seems to have some merit. Briefly, this exercise is based on the proposition that athletes can learn to improve their

concentration skills if they simulate real-life competitive situations in practice. Anecdotal testimonials to the value of this practice in various sports have emerged during recent years. For example, some leading soccer coaches have prepared their players for the pressure of penalty "shoot-outs" by requiring them to practice walking from the center circle of the pitch to the penalty area—as happens in actual match conditions. Unfortunately, despite its apparent face validity, simulation training has received little or no empirical scrutiny as a concentration strategy. Nonetheless, some support for its theoretical rationale may be found within the field of cognitive psychology. For example, research on the "encoding specificity" principle of learning shows that people's recall of information is facilitated by conditions that resemble those in which the original encoding occurred. Applying this principle to simulation training, it may be argued that replication of real-life conditions in practice inoculates athletes against anticipated pressures and distractions. By this reasoning, it is conceivable that simulation training could enhance athletes' concentration skills.

2.2. Concentration Techniques

The second category of concentration strategies recommended for use by athletes in competitive situations involves the use of psychological techniques such as (a) performance goal setting, (b) preperformance routines, (c) trigger words, and (d) mental practice. These techniques are explained in what follows.

2.2.1. Performance Goal Setting

In psychology, a "goal" is a target or an objective that people strive to attain such as sinking a putt, winning a match, or being selected for a given team. Therefore, "goal setting" is the process by which people establish desirable objectives for their actions. Typically, sport psychologists distinguish between "result goals" (e.g., the outcome of a competition) and "performance goals" (i.e., specific actions that are under the athlete's control). Using this distinction, some psychologists have speculated that the process of setting performance goals can improve athletes' concentration skills. For example, a golfer could improve his or her concentration on the course by focusing on specific "controllable" goals such as keeping his or her head steady and/or maintaining a slow rhythmic swing. Empirical support for this conjecture springs from studies on the correlates of people's "best" and "worst" athletic performances.

In particular, research shows that collegiate athletes performed worst when they were preoccupied with result goals. Conversely, their best performances tended to occur when they adopted explicit performance goals. In summary, there is a legitimate theoretical rationale for the use of performance goals as a concentration technique by athletes.

2.2.2. Preperformance Routines

It has long been apparent that many athletes display distinctive idiosyncratic sequences of preparatory actions before they perform key skills, especially in individual sports. For example, top tennis players tend to bounce the ball a consistent and characteristic number of times before their first serve and a different yet equally consistent number of times before their second serve. These bounce patterns help the player to focus on the first step in his or her pre-serve preparatory sequence. Similarly, expert golfers tend to adhere to a preferred number of practice swings and “waggles” of the club before they strike the ball. These distinctive action sequences and/or repetitive behaviors are called “preperformance routines” and are especially prevalent prior to the execution of “self-paced” skills (i.e., actions that are carried out largely without interference from other people).

Three main types of routines are evident in sport. First, “pre-event” routines are general patterns of preparation that athletes display on the days preceding competitive action. Included here are preferences with regard to food and sleeping arrangements. Second, “pre-performance” routines are characteristic sequences of thoughts and actions that athletes adhere to prior to skill execution. Finally, “postmistake” routines are action sequences that may help performers to put errors behind them so that they can refocus on the task at hand. For example, a tennis player may “shadow” the correct movement of a volley that led to an error.

Support for the value of preperformance routines as concentration techniques comes from both theoretical and empirical sources. Theoretically, preperformance routines may improve concentration for at least two reasons. First, they may enable athletes to concentrate on the current moment rather than on past events or on possible future outcomes. In addition, they may prevent athletes from devoting too much attention to the mechanics of their well-learned skills. This habit, which is also known as “paralysis by analysis,” can “unravel” automaticity and lead to a deterioration in performance. In other words, routines may help to

suppress the type of inappropriate conscious control that often occurs in pressure situations. Empirically, there is some evidence from case studies that routines can improve athletes’ concentration skills and performance. For example, research suggests that more proficient golfers benefited more from using routines than did less skilled golfers.

Unfortunately, advocacy of preperformance routines gives rise to two practical issues that need to be addressed. First, routines may lead to superstitious rituals on the part of the performer. Thus, certain athletes feel compelled to wear “lucky” clothes (e.g., Tiger Woods likes to wear something red on the final day of a golf tournament) or to listen to “lucky” songs before important competitive events. Indeed, athletes’ precompetitive behavior is often a mixture of routines and superstitions. A second problem with routines is that they need to be revised regularly as a precaution against the possibility that they will become automated through frequent practice. In other words, if athletes maintain the same preperformance behavior indefinitely, their minds may begin to wander as they proceed through the various steps of the routine. Because of this problem, applied sport psychologists face the challenge of helping athletes to develop consistent but not automated preparatory actions.

2.2.3. Trigger Words

Most athletes talk to themselves covertly as they train or compete. For example, gymnasts may use words such as “forward” to remind themselves to push their bodies upward as they attempt to master a floor routine. Similarly, tennis players may try to trigger a smooth service action by telling themselves to “reach and hit.” In general, this internal speech (or “self-talk”) may involve praise (e.g., “well done—that’s good”), criticism (“you idiot—that’s a stupid mistake”), or instruction (“swing slowly”).

Typically, the purpose of instructional verbal triggers is to help athletes refocus their minds on task-relevant cues just before skill execution. For example, when standing over a putt, golfers may use phrases such as “steady head” to prevent themselves from looking up to see whether or not the ball has gone into the hole.

Theoretically, self-talk could enhance concentration skills by reminding athletes about the most important cues in any given situation. Interestingly, this strategy was used by Serena Williams during the 2002 Wimbledon women’s singles tennis final in which she defeated her sister Venus. During this match, Serena

read notes to herself during the “change-over” time between games. Afterward, she explained that these notes had contained trigger words to remind her to “hit in front of you” or to “stay low.”

Despite such anecdotal testimonials to the value of trigger words, few studies have tested the validity of self-talk as a concentration technique. However, it is generally believed that for optimal efficacy, instructional self-statements must be short, vivid, and positively phrased.

2.2.4. Mental Practice

The term “mental practice” or “visualization” refers to the systematic use of mental imagery to rehearse physical actions. Put simply, it involves “seeing” and “feeling” a skill in one’s imagination prior to its actual execution. This strategy is used by golfers such as Tiger Woods when preparing to play a shot. Although there is considerable experimental evidence that mental practice facilitates skill learning and performance, few studies have been conducted on imagery as a concentration technique. Anecdotally, however, many athletes report using imagery to prepare for anticipated scenarios, thereby reducing the likelihood of being distracted by unexpected events.

3. UNRESOLVED ISSUES IN TRAINING ATTENTIONAL SKILLS IN SPORT

At least five issues need to be addressed before attentional and/or concentration training techniques can be used effectively with athletes in applied settings. First, before they attempt to train concentration skills, sport psychologists should try to find out why athletes lose their focus in the first place. Unfortunately, until recently, little research was available on the causes of distractibility in sport performers, especially distractibility that arises from “internal” sources such as athletes’ own thoughts and feelings. However, some recent theoretical models have examined the role of unconscious factors in this regard. Augmenting this research, self-report scales have been developed by sport psychologists to assess athletes’ susceptibility to self-generated cognitive interference. Second, sport psychologists have much to learn about the attentional demands of various sports. For example, whereas some activities (e.g., weightlifting) may require short periods of intense concentration, others (e.g., cycling) appear to demand

sustained alertness for longer periods of time. Intuitively, it seems unreasonable to expect that the same toolbox of concentration interventions will work equally well in all sports. Third, some researchers have raised the question of whether or not sport performers know exactly what they should be concentrating on in various athletic situations. For example, should a tennis player focus only on the ball during a rally, or should the player use cues from his or her opponent’s behavior (e.g., position of feet) in an effort to anticipate the likely target of a subsequent shot? Unfortunately, this question has been largely neglected by sport psychologists in their enthusiasm to provide practical mental skills training programs for athletes. Fourth, what is the best way in which to measure concentration skills in athletes? Until this question has been answered empirically, it is difficult to evaluate whether or not concentration skills interventions are effective. Finally, no explicit criteria currently exist for evaluating the maintenance of attentional skills improvements over time. In the absence of such criteria, researchers have not yet ruled out the possibility that athletes’ concentration patterns may return to preintervention levels despite athletes’ participation in mental skills training programs.

4. NEW DIRECTIONS IN RESEARCH ON CONCENTRATION SKILLS TRAINING

At least four potentially fruitful new directions in research on concentration skills training in athletes may be identified. First, further research is required on the “meta-attentional” processes of athletes, that is, their theories on how their own concentration systems work. It may be argued that the entire program of concentration skills training in sport psychology is really an exercise in meta-attentional training, whereby athletes are empowered psychologically by gaining an understanding of, and control over, their own concentration processes. As yet, however, little is known about the nature, accuracy, and/or modifiability of athletes’ meta-cognitive theories. Second, additional research is required on the relationship between the structure of various athletic activities and their attentional demands. For example, do untimed activities such as golf place different cognitive demands on athletes’ concentration systems compared with those imposed by timed competitions such as soccer? If so, what theoretical mechanisms could account for such differences? Third, more research is needed to establish

how emotional factors (e.g., anxiety) affect athletes' concentration processes. This task could be achieved by exploring the effects of anxiety on the visual search behavior of athletes tackling laboratory simulations of sport-relevant tasks. Finally, research is required to evaluate the efficacy of simulation training and the various concentration techniques described earlier in improving athletes' focusing skills in competitive sport situations.

GLOSSARY

antecedent-based intervention Any treatment strategy that involves manipulating environmental events prior to a target behavior occurring so as to increase or reduce the probability that the target behavior will occur; these interventions are considered to be proactive preventive strategies.

consequent-based intervention Any treatment strategy that involves manipulating environmental events after a target behavior occurs so as to increase or reduce the probability that the target behavior will occur; these interventions are considered to be reactive strategies.

curriculum-based measurement (CBM) Assessment of a student's math or reading skills using brief (2- to 3-minute) probes derived directly from the curriculum being taught in the classroom; CBM provides a cost-efficient and sensitive method of documenting a child's instructional level and changes in skills over time.

functional assessment Collection of interview and/or observation data to establish the environmental events that increase the probability that a target behavior will occur.

point of performance The exact time that a target behavior is most likely to occur and the setting where a behavior is likely to be exhibited.

Attention deficit/hyperactivity disorder (AD/HD) is associated with academic and social impairments that significantly compromise school performance. Effective school-based interventions include antecedent-based and consequent-based strategies that are implemented by teachers, peers, parents, computers, and/or the target students themselves.

1. DESCRIPTION AND DEFINITION OF ATTENTION DEFICIT/ HYPERACTIVITY DISORDER

Attention deficit/hyperactivity disorder (AD/HD) is a psychiatric disorder characterized by developmentally inappropriate levels of inattention, impulsivity, and/or overactivity. There are three subtypes of AD/HD: predominantly inattentive, predominantly hyperactive-impulsive, and combined type, with the latter being most common among clinic referrals and research participants. AD/HD affects approximately 3 to 5% of the school-aged population in the United States, with boys outnumbering girls by two to one in epidemiological

samples and by six to one in clinic samples. The symptoms of AD/HD frequently are associated with impairment in academic, social, and behavioral functioning. The disorder tends to be chronic and often is a precursor to the development of other disruptive behavior disorders, including oppositional defiant disorder and conduct disorder. Among the greatest long-term risks associated with AD/HD are scholastic underachievement, grade retention, and school dropout. The most effective treatments for this disorder include psychotropic medication, especially psychostimulants (e.g., methylphenidate), behavioral strategies applied at home and school, and (when necessary) academic interventions. It is assumed that most children with AD/HD will require a combination of these treatments to successfully ameliorate symptomatic behavior over the long term.

The most widely studied and used medications for AD/HD are central nervous system (CNS) stimulants such as methylphenidate (Ritalin, Concerta, and Metadate), combined stimulant compounds (Adderall), and dextroamphetamine (Dexedrine). CNS stimulants are associated with improved attention and impulse control in the majority of treated children with AD/HD. Side effects are benign in most cases, with insomnia and appetite reduction being the most common adverse effects. Behavioral effects vary considerably across individuals as well as across doses within individuals. Furthermore, stimulant medication effects are observed primarily during the school day because their duration of action ranges from 4 to 8 hours. For these reasons, it is important that information regarding behavior changes at home and school, as well as possible improvement or deterioration in academic performance, is taken into account when making medication decisions. For those individuals who do not respond to a CNS stimulant, alternative medications that may improve AD/HD symptoms include antidepressants (e.g., bupropion), antihypertensives (e.g., clonidine), and selective norepinephrine reuptake inhibitors (e.g., atomoxetine).

2. CONCEPTUAL FOUNDATIONS OF SCHOOL-BASED INTERVENTIONS

There are several principles that are critical to the design of effective school-based interventions for students with AD/HD: gathering assessment data that directly inform intervention planning, implementing interventions at

the point of performance, individualizing intervention strategies for each student, using a balanced treatment plan composed of both antecedent-based and consequent-based interventions, using strategies to address both academic and behavioral difficulties, and employing multiple individuals to implement treatment components.

2.1. Linking Assessment Data to Intervention

The assessment of children suspected of having AD/HD not only should be directed at establishing a diagnosis but also should provide data that can directly inform treatment planning. Thus, although norm-referenced measures such as behavior rating scales are helpful for making diagnostic decisions, additional measures should be included to provide information about possible directions for treatment. Specifically, functional assessment procedures, such as observations of target behaviors (e.g., calling out in class without permission) in the context of environmental events (e.g., classmates laughing), can be used. Data from a functional assessment can help to identify antecedents and consequences that may be maintaining a target behavior and that can be manipulated to change the frequency of a behavior. For example, disruptive behavior that consistently leads to peer attention as a consequence can be reduced by designing an intervention that provides the student with peer attention for engaging in appropriate behavior (e.g., peer tutoring).

2.2. Intervening at the Point of Performance

Because children with AD/HD typically exhibit poor impulse control, their behavior is more likely to be controlled by immediate environmental events than by long-term contingencies. For this reason, the most effective intervention strategies will be those that are implemented as close to the “point of performance” as possible. For example, if an intervention is necessary to reduce disruptive behavior occurring in math class and the latter is conducted from 9:00 to 9:45 AM each school day, the most effective interventions will be those that are implemented in math class from 9:00 to 9:45 AM. Treatment procedures that are removed in time and place from the point of performance (e.g., weekly counseling sessions in the school psychologist’s office) will be less effective.

2.3. Individualizing Intervention Strategies

Children with AD/HD exhibit a wide range of possible symptoms, disruptive behaviors, and academic difficulties. Thus, a “one size fits all” approach to treatment, wherein it is assumed that all students with AD/HD respond the same way to the same interventions, is likely to fail. The selection of intervention components should be made on the basis of individual differences in symptom severity, presence of comorbid conditions (e.g., oppositional defiant disorder), possible functions of the target behaviors, teacher acceptability of prescribed interventions, and empirical evidence supporting specific treatments for the target behaviors.

2.4. Combining Antecedent and Consequent Interventions

The application of both antecedent and consequent intervention strategies allows for students to have clear expectations of what is expected of them in advance (antecedent) as well as what will occur if problem behavior arises (consequent). Combining antecedent and consequent interventions also provides for more positive interactions and experiences, thereby potentially increasing the chances that the student will behave appropriately. Interventions based solely on aversive consequences or punishments often result in increased negative interactions between the student and the teacher and minimize the opportunity for positive reinforcement.

Antecedent or proactive intervention strategies are those that are implemented to prevent or preempt academic and/or behavioral difficulties from occurring. These could involve implementing classroom strategies and rule systems to provide structure, making environmental modifications (e.g., placing a child with academic or behavioral difficulties near the teacher or near children who are less likely to interact negatively with the child), having a child repeat instructions before beginning an assignment or activity, and/or providing limited task choices to a child prior to beginning seatwork.

Alternatively, consequent or reactive strategies are those implemented to respond to both appropriate and problem behavior when it does occur. An example of a consequent intervention might be a response cost system in which the student is “fined” for exhibiting problem behavior (e.g., loses points or reinforcement)

yet also has the ability to earn and receive positive feedback when appropriate behavior is exhibited.

2.5. Combining Behavioral and Academic Interventions

Children with AD/HD often exhibit both academic and behavioral difficulties in the classroom. It is important to address both areas because a student who is frustrated academically may be more likely to exhibit negative behavior. Based on the results of a 1997 meta-analysis performed by DuPaul and Eckert on studies of school-based interventions from 1971 to 1995, improving a child’s academic skills may potentially improve his or her behavior in the classroom as well. In addition, targeting the attention difficulties associated with AD/HD and improving on-task behavior through behavioral intervention may potentially have a positive impact on academic skills. By including strategies targeting both academic skill areas as well as relevant behavior problems, teachers may be able to maximize the effectiveness of the interventions implemented. Collecting curriculum-based measurement and functional assessment data can lead to a better understanding of the factors contributing to academic and behavioral problems. Identifying the specific instructional needs and environmental variables that reliably proceed or follow inappropriate behavior can be a key component in the formulation of effective interventions

2.6. Using Multiple Intervention Agents

Effective intervention strategies can be implemented by a variety of mediating or intervention “agents.” Interventions can be mediated by teachers, peers, computers, parents, and/or the students themselves. By using multiple agents, sole responsibility for addressing all academic and behavioral difficulties associated with AD/HD does not fall on the teacher. Instead, multiple resources can be used to provide a more comprehensive, and potentially more cost-effective, method to support teacher instruction as well as to deliver interventions. [Table I](#) provides some possible intervention strategies listed by mediating agent. Specific intervention strategies organized by mediating agent and setting (elementary school vs secondary school) are discussed in more detail in later sections.

TABLE 1
Intervention Strategies by Mediating Agent

3. INTERVENTIONS FOR ELEMENTARY SCHOOL-AGED STUDENTS

As described previously, combinations of interventions appear to be most effective in improving and maintaining appropriate classroom behavior. This section discusses intervention strategies for improving academic and behavior performance using both antecedent and consequent intervention strategies across mediating agents. Typically, the most effective interventions include the use of multiple strategies and intervention agents.

3.1. Teacher-Mediated Strategies

Classroom strategies that have previously been found to be effective in improving the academic and behavior

performance of children with AD/HD include teaching classroom rules, using response cost systems, altering the structure of the classroom environment, adjusting academic expectations to match students' current skills or instructional level, modifying instructions, and arranging for choices in academic tasks.

Most classrooms have rules that are typically reviewed with students at the beginning of the academic school year. Periodic review and reteaching of these rules throughout the year can be an effective support system for maintaining appropriate behavior. Teachers should develop four or five positively phrased classroom rules. By stating them in a positive manner, the rules themselves help to inform students as to how to behave instead of providing an example of what "not" to do. Initial teaching should include both examples and nonexamples of following the rules, and examples should be elicited from the students to ensure their understanding. Periodic review should include a few minutes spent each week reviewing one or two of the rules and their importance and again eliciting examples from students to confirm their understanding. This frequent review and discussion of rules enables students to have a clear understanding of what is expected of them. In addition, pairing classroom rules with a response cost system can be an effective combination of antecedent- and consequent-based strategies.

A response cost system requires a clearly defined rule system that is reviewed on a frequent basis. Within a response cost system, students may earn "tokens" (e.g., points, chips) for following rules and can lose tokens when rules are broken. The tokens can then be applied toward privileges such as taking the attendance to the office, passing out papers, and purchasing items from a "class store." For a response cost system to be effective, students must have clear expectations of when the rules are in effect and what behavior will result in both the earning and losing of tokens. Examples of both situations should be given to confirm students' understanding while the rules are being reviewed. Students should also understand what privileges are available, when they may exchange their tokens for privileges, and how many tokens are necessary for each privilege. Student motivation is a key component of an effective response cost system. Therefore, it may be beneficial to have students participate in a discussion of which privileges will be available and at what cost. It may also be helpful to determine ahead of time what privileges students are working for and to remind them periodically.

It is important to note that although classwide systems are widely effective for most students in the classroom,

individual modifications may be necessary for those students whose behavior problems are more severe. If a student typically breaks 20 rules in a 30-minute class period, asking the student to break only 2 rules may be an unrealistic expectation and the child may be unmotivated by the system. Therefore, the amount of tokens necessary to earn a privilege might need to be altered on an individual basis. Similarly, if students can earn points for following rules for a certain amount of time, it might be necessary to decrease the required duration for specific students to allow them to earn points. Adjusting the time period also provides for more immediate feedback to those students who might need more frequent reinforcement.

In addition to classroom rules and response cost systems, children with AD/HD may benefit from alterations to the classroom environment to allow for increased monitoring of classroom behavior. Children with AD/HD may benefit from being placed near the teacher or with peers who are less likely to interact negatively with them. In addition, although it may seem advantageous to place children with severe attention and behavior difficulties in isolated areas of the classroom, it is important that they remain a part of important classroom activities and have access to teacher instruction and positive peer interactions.

Behavior and academic difficulties often associated with AD/HD may be exacerbated by instructional demands that are too high for students' current level of functioning. Frustration with tasks that are too difficult may increase the likelihood that some children will exhibit negative behaviors. Thus, it is important to assess and adjust academic expectations to match a student's current skills or instructional level. Curriculum-based measurement (CBM) data may be a helpful tool for teachers to determine the appropriate level of instruction that a child should receive. CBM can also provide information as to areas in which a child might need additional instruction and academic intervention. Instructional modifications and interventions for children may include direct instruction in particular skills that a child is lacking as well as drill and practice activities such as flashcard drills and structured worksheets.

Students with attention or behavior difficulties may also benefit from being provided with choices in academic tasks within a particular academic area. For example, students may be provided with a menu of acceptable tasks for a particular subject from which to choose. For this strategy, the teacher offers a menu of tasks that he or she finds acceptable, and the student chooses one to complete during the time allotted. The menu and choice component allows for both the teacher and the student to

maintain control over the work completed. Thus, providing choices in academic tasks may increase the student's work productivity and on-task behavior.

3.2. Peer-Mediated Interventions

Peers working together on an instructional activity can also have a positive impact on the academic engagement and performance of students with AD/HD. In addition, peer tutoring strategies, by targeting academic instruction through peer interaction, are able to address both academic and social skills simultaneously. Because children with AD/HD have often been found to have difficulty in both areas, peer-mediated strategies can be a particularly useful tool.

Although different peer-mediated strategies vary regarding their foci of instruction and the structure and procedures of the tutoring teams, Barkley's 1998 handbook for diagnosis and treatment of AD/HD listed the following four common characteristics that have been shown to enhance task-related behaviors of children with AD/HD: (a) working one-on-one with another individual, (b) letting the learner determine the instructional pace, (c) continually prompting academic responses; and (d) providing frequent immediate feedback about quality of performance.

In 2002, Greenwood and colleagues described peer tutoring as an instructional strategy in which classroom teachers train and supervise students to teach their peers. Peer-directed instruction allows for high levels of student engagement, sufficient practice, immediate error correction and feedback, and the integration of students with varying abilities. In their review of peer tutoring strategies, Greenwood and colleagues described four programs that have been found to have well-defined procedures and supporting evidence in the research for use with students with disabilities: Classwide Peer Tutoring (CWPT), Peer-Assisted Learning Strategies (PALS), Classwide Student Tutoring Teams (CSTT), and Reciprocal Peer Tutoring (RPT).

3.3. Computer-Assisted Interventions

Computer-assisted interventions (CAI) can be an effective tool for promoting skill acquisition through the use of instructional technology as well as for providing additional drills and practice to promote mastery of previously acquired skills. Features of computer programs (e.g., provision of immediate performance

feedback) may be able to positively affect on-task behaviors and work production of children with AD/HD. In 2003, DuPaul and Stoner listed the following important design features of CAI that may be beneficial for children with AD/HD: specific instructional objectives presented along with activities, use of print or color to highlight important material, use of multiple sensory modalities, content divided into manageable sized chunks of information, the ability to limit nonessential distracting features (e.g., sound effects, animation), and immediate feedback on response accuracy.

3.4. Parent-Mediated Interventions

Parents should also be considered a valuable resource in promoting the academic success of their children. Frequent and clear communication between teachers and parents provides parents with knowledge about their children's academic and classroom-related behaviors and also provides teachers with information regarding events at home that may affect classroom behavior and performance. Parents can then support and reinforce instruction in the classroom as well as help to promote appropriate classroom behavior.

Parents, in providing instructional support to their children, can engage their children in flashcard drills for additional practice in an area, act as tutors to aid in skill acquisition, and make themselves available for homework support. Many parents may already participate in similar activities or would like to participate but are unsure as to how they can be most helpful. A key component to effective instructional support at home is parents' knowledge regarding instruction that their children are receiving at school, areas in which their children are struggling and could use additional support, and areas in which their children are succeeding.

Communication can take place through multiple methods. Brief notes can be sent home on a daily or weekly basis, weekly phone calls or e-mails can be scheduled, brief conversations can occur when picking up children, or another system that is mutually agreeable between families and the school can be arranged. One example of school-home communication that supports positive behavior in the classroom is a school-home contingent reinforcement system (i.e., daily report card). This type of system involves setting goals and contingencies for students. When appropriate, parents, teachers, and students should collaboratively create a template of student behaviors or goals. Approximately three to five target areas or goals should be chosen and can be rated by all teachers who are participating. Goals are individualized for each

student, should generally consist of areas of primary concern for the student, and should be stated in a positive manner. Some examples of classroom goals may include participation in class discussions, appropriate interactions with peers, work completion, and accuracy. Goals can be rated on a yes/no scale (e.g., appropriately participates in class discussion two times, completes work with 85% accuracy) or on a range of scores (e.g., a 5-point scale ranging from "excellent" to "terrible"). The report card ratings should be filled in by each teacher (in ink to prevent alterations by students) and carried from class to class by students. At home, scores on the report card can then be used in a token economy to be exchanged for privileges or points to be applied to later privileges (e.g., television time, computer time, later bedtime). Table II lists components of effective school-home communication programs.

As with classroom-based response cost systems, students should be aware of specific criteria necessary to earn privileges, which privileges they can work toward, and when they may exchange tokens for them. Exchanges for privileges might need to occur on a more frequent basis during the initial stages of a school-home contingency system and should be adapted based on the age and developmental level of each student. Motivation of the students is vital to the success of the school-home contingency system. Therefore, it may be beneficial for students to have input into goals and privileges. In addition, a space for teacher comments and parent

TABLE II
Components of Effective School-Home Communication Programs

1. Daily and/or weekly goals are stated in a positive manner.
2. Both academic and behavioral goals are included.
3. A small number of goals are targeted at a time.
4. The teacher provides quantitative feedback about student performance.
5. Feedback is provided by subject or class periods.
6. Communication is made on a regular basis (either daily or weekly).
7. Home-based contingencies are tied to school performance. Both short- and long-term consequences are employed.
8. Parental cooperation and involvement are solicited prior to implementation.
9. Student input into goals and contingencies is solicited, particularly with older children and adolescents.
10. Goals and procedures are modified as necessary.

signatures can be provided to allow for frequent brief communications between parents and teachers. Figure 1 shows an example of what a school-home daily report card might look like.

3.5. Self-Mediated Interventions

Students can also be taught to monitor their own behavior or completion of academic-related steps. Although each student acts as the primary mediator for such strategies, it is important to note that a teacher must be present to signal recording and/or to monitor the accuracy of the student's self-recording. Checklists for work completion, or for procedures for completing tasks in specific academic areas, can be created. The presence of these checklists while the student is completing work can provide a prompt as to what steps are necessary to complete the task as well as provide for communication between the teacher and the student as to what steps have been completed.

Students can also be taught to observe and record occurrences of their own behavior—both positive and negative. A checklist or grid can be provided for each student to keep on his or her desk. The student could then record occurrences of a behavior or be taught to

respond to a signal (e.g., a beep from a tape recorder) and record whether or not he or she is currently performing a specific behavior (i.e., on task) at that time. In this way, not only is the student monitoring the occurrence of his or her own behavior, but the signal also acts as a prompt to demonstrate the behavior. To be most effective, it might be advantageous to have the teacher also record occurrences. These records can then be “matched” and reinforcement can be provided based on how well the results from the teacher and the student match up. Frequency of teacher-student match checks and reinforcement schedules can then be decreased as the child becomes more adept at the procedures.

3.6. Intervention Considerations for Secondary School-Aged Students

Typically, AD/HD symptoms are chronic and can be associated with myriad additional difficulties for secondary school-aged students. Adolescents with AD/HD often exhibit problems with study and organizational skills, test performance, and social and emotional adjustment. Unfortunately, minimal research has been conducted examining school-based interventions for secondary-level students with this disorder. Although

Child's Name: _____	Date: _____				
	<u>Special</u>	<u>Language Arts</u>	<u>Math</u>	<u>Reading</u>	<u>SS/Science</u>
Follows class rules with no more than 3 rule violations per period	Y N	Y N	Y N	Y N	Y N

many of the interventions discussed for children with AD/HD may be helpful for adolescents, modifications must be made to account for expected differences in developmental level and degree of independence. For example, token reinforcement and/or response cost systems must be modified in several ways. First, the adolescent should be involved in “negotiating” the specific responsibilities and privileges that are included in the contingency management system. Second, the system will be less concrete than what typically is used with younger children. In particular, a written contract specifying reinforcement and punishment is used rather than token reinforcers such as stickers and poker chips. Third, the time period between completion of a responsibility and receipt of reinforcement might be longer than with younger children because adolescents are presumably able to handle longer delays in reinforcement. As is the case for younger students, interventions for adolescents with AD/HD should include a variety of mediators (e.g., teachers, parents, computer, peers, self), especially because secondary school students have multiple teachers who might not have the time to implement complex treatment protocols. Self-mediated interventions have particular promise for those adolescents who have demonstrated progress with other-mediated strategies and who appear to have the requisite skills for self-monitoring and self-evaluation.

In addition to the various interventions enumerated previously, secondary school students with AD/HD may require other interventions to address study and organizational skills deficits as well as difficulty in interacting with peers and authority figures. First, students can be provided with direct instruction in study and organizational skills, including taking notes, preparing for and taking tests, and completing long-term assignments. A second promising avenue for intervention for adolescents with AD/HD is the implementation of “coaching” to support students in achieving self-selected academic, behavioral, and social goals. Peers, older students, siblings, or adults can serve as coaches for students, who are assisted in setting goals, developing plans to reach stated goals, identifying and overcoming obstacles to goal attainment, and evaluating progress. Third, adolescents with AD/HD and their families are likely to require some form of counseling support to address possible difficulties in adherence with household rules as well as in interactions with family members. Support may include promoting an accurate understanding of AD/HD and its influence on families’ interaction patterns; planning the education

of adolescents with AD/HD; and/or negotiating privileges and responsibilities.

4. CONCLUSIONS AND FUTURE CONSIDERATIONS

Children and adolescents with AD/HD frequently experience difficulties in school settings, most notably in the areas of academic achievement and interpersonal relationships. Thus, a comprehensive treatment plan often includes a variety of school-based interventions in combination with psychostimulant medication and home-based behavioral strategies. Effective classroom interventions include both proactive strategies that are designed to modify antecedent events and reactive strategies that focus on changing consequent events. Although treatment strategies are usually implemented by teachers, plans should include peer-mediated, self-mediated, computer-mediated, and/or parent-mediated components. Interventions that directly address the function of disruptive behavior and that are applied as close to the point of performance as possible are more likely to be effective. Students with AD/HD at the secondary school level will require additional support to enhance study and organizational skills as well as coaching to improve social relationships. Empirical investigations conducted to date have emphasized the use of reactive, consequent-based interventions. Research efforts must be directed toward establishing efficacious, antecedent-based strategies as well as toward providing more support for interventions to address the unique needs of secondary school-aged students with this disorder.

self-management training Education in methods of regulating a person's behavior (e.g., self-instruction, anger control).

Attention deficit/hyperactivity disorder (ADHD) is a psychiatric disorder affecting 3 to 5% of children. Recent data suggest that the incidence of ADHD may be even higher (5–7%). ADHD is a chronic disorder, with approximately 75 to 80% of affected individuals showing evidence of significant impairment during adolescence and adulthood. Estimates suggest that 1.5 to 2.0% of adults and 2 to 6% of adolescents have ADHD. Research indicates that children with persistent ADHD have more severe symptoms, significant impairment in functioning, stressful family environments, and more adverse risk factors. There are a number of factors that interact with ADHD and further compromise adjustment over the life span.

GLOSSARY

behavioral disinhibition Poor self-regulation or the inability to control one's activity level, attention, and emotions.

inattention Difficulties with distractibility, alertness, and arousal as well as with selective, sustained, and persistent attention to tasks.

negative parental interactions Parental interactions that are undesirable (e.g., fewer interactions, less affection, higher parental stress) or produce undesirable effects in their children.

preventive parental measures Behaviors of social control, including reinforcing prosocial behaviors, training preschool teachers, and using behavioral management principles.

psychosocial stressors Conditions in a person's social environment that affect levels of stress (e.g., poverty, family dysfunction).

1. CORE CHARACTERISTICS OF ATTENTION DEFICIT/HYPERACTIVITY DISORDER

Core symptoms of inattention, impulsivity, and hyperactivity comprise the major characteristics of attention deficit/hyperactivity disorder (ADHD), with new conceptualizations emphasizing poor self-control and

behavioral disinhibition. Behavioral disinhibition is synonymous with poor self-regulation or the inability to control one's activity level, attention, and emotions. In 1997, Barkley posited that disinhibition interferes with executive control functions, including working memory, internalization of speech to guide one's behavior, motor control for goal-directed behavior, the ability to analyze and synthesize responses, and self-regulation of emotions, motivation, and arousal.

The fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) outlined three subtypes of ADHD: attention deficit disorder/predominantly inattentive type (ADD/PI), attention deficit disorder/predominantly hyperactive-impulsive type (ADD/PHI), and attention deficit disorder/combined type (ADD/C). Inattention is multifaceted and refers to difficulties with distractibility, alertness, and arousal as well as with selective, sustained, and persistent attention to tasks. Individuals with ADD/PI appear to have cognitive disabilities (e.g., spacey, "daydreamy," sluggish, easily confused) that arise from slow information processing and poor focused/selective attention. There is some debate in the literature as to whether ADD/PI is a separate disorder distinct from ADD/PHI or ADD/C. Further research is warranted on this issue, particularly as it relates to gender differences. For example, some studies report that girls have higher rates of inattention than of impulsivity and hyperactivity.

Impulsivity encompasses the inability to inhibit behavior, delay responding, and delay gratification to reach long-term goals and perform tasks. Hyperactivity is one of the more obvious core features of the disorder and refers to excessive activity (both verbal and physical). Individuals with ADD/PHI display primary problems with hyperactivity and impulsivity, whereas those with ADD/C show deficits in all core symptoms, including impulsivity, inattention, and hyperactivity.

2. ASSOCIATED PROBLEMS

The core symptoms of ADHD lead to impairment in all aspects of life activities, including school attainment, family adjustment, social relations, occupational functioning, and self-sufficiency. Sleep disorders, health problems (e.g., allergies), and accidental injuries (e.g., bone fractures, poisoning) also appear to be higher in children with ADHD than in controls. More accidental injuries may occur in youth with high levels of aggression than in those with hyperactivity alone. Long-term complications associated with ADHD

include risk of substance abuse problems; problems in marriage, family cohesiveness, and chronic family conflict; employment difficulties such as frequent job changes, stress on the job, and underemployment; increased health risks such as early cigarette smoking, early sexual activity, increased driving accidents and eating disorders, and sleep disorders in children and adolescents; and risk of comorbid psychiatric disorders.

3. ADHD WITH OTHER DISORDERS

ADHD places individuals at risk for other psychiatric disorders. Oppositional defiant disorder (ODD, 54–67%) and conduct disorders (20–56%) are among the most frequent comorbid disorders in children due to impulsivity and an inability to follow rules. Conduct disorders are also common in teens (44–50%). The presence of ADHD with conduct problems increases the risk of later difficulties, including drug use and abuse, driving accidents, and additional psychiatric problems. Social problems are common in individuals with ADHD, where intrusive, inappropriate, awkward, and/or ineffective behaviors lead to rejection or strained relations with others. Mood disorders are also high (20–36%), with 27 to 30% having anxiety and 15 to 70% having major depression or dysthymia. Stimulant medication might not be as effective in individuals with ADHD plus anxiety, and side effects might be higher than in nonanxious ADHD groups. Learning disabilities are also frequent, with as many as 20 to 50% of children exhibiting significant learning problems due to difficulties with attention, work completion, and disruptive problems in the classroom.

In 1997, Jensen and colleagues cautioned that clinic-based longitudinal studies may increase the appearance of comorbidity because persons with more severe and comorbid conditions may be more likely to participate in ongoing studies. Rates of psychiatric comorbidity differ somewhat in community-based studies of children with ADHD. For example, the Multimodal Treatment Assessment (MTA) study of youth with ADHD reported comorbidity rates as follows: In the sample of children, 31.8% had ADHD alone, 33.5% had anxiety, 14.3% had conduct disorders, 39.9% had ODD, 3.8% had an affective disorder, and 10.9% had tic disorders.

Adults with ADHD have comorbidity rates of 16 to 31% for major depression, 24 to 35% for ODD, 17 to 25% for conduct disorders, 4 to 14% for obsessive-compulsive disorders, 35% for alcohol dependence or abuse, 24% for substance abuse (i.e., cannabis or other

drugs), 43% for generalized anxiety disorder, and 52% for overanxious disorder. Rates of conduct disorders or antisocial personality disorder are also high in adults with ADHD (22%).

The mechanisms of comorbidity are not well understood, but it appears that ADHD places an individual at risk for other psychiatric disorders and the presence of comorbid disorders interacts with and alters the developmental trajectory and treatment responsiveness of ADHD. In 2003, Pliska and colleagues provided an assessment and treatment approach for children with ADHD and comorbid disorders. It is recommended for addressing more complex cases of ADHD.

4. GENDER AND CULTURAL ISSUES

National reports have highlighted the disparity of diagnosis and treatment for mental illness for girls and non-White children. Despite similarities in the incidence rates of hyperactivity in Black children, service delivery is lower in Black children than in Whites with similar problems. Referral and treatment rates are lower for girls (three times less likely to receive treatment compared with boys) and for Black children (three times less likely to be referred compared with White children).

There is some evidence that gender differences may be a function of the referral source, that is, clinic-referred children versus non-clinic-referred children. In a review of 18 studies on girls with ADHD in 1997, Gaub and Carlson found that nonreferred samples of girls with ADHD, as compared with boys with ADHD, had more intellectual impairments but were less aggressive, were less inattentive, and had lower levels of hyperactivity. However, when compared with clinic-referred samples, girls and boys with ADHD had more similarities than differences on core ADHD symptoms.

Other studies of clinic-referred girls indicate that girls with ADD/C are indistinguishable from boys with ADHD on measures of comorbid disorder, behavioral ratings of core symptoms, psychological functioning, and family history of psychopathology. However, when differences did occur, girls had lower reading scores and higher parent-rated measures of inattention. Furthermore, referred girls were a more extreme sample than were boys, with the former having higher rates of familial ADHD. Girls also showed a more positive response to stimulant medication than did boys. In 1999, Biederman and colleagues found similar results in girls referred to pediatricians and psychiatrists. Girls referred for ADHD were more likely to show conduct problems, mood and

anxiety disorders, a lower intelligence quotient (IQ), and more impairment on social, family, and school functioning than were nonreferred girls. Conduct problems were lower in girls than in boys with ADHD, and this may account for lower referral rates. However, high rates of mood and anxiety disorders suggest the need for comprehensive treatment. It was of particular note that girls in this study also had high rates of substance abuse disorders, including alcohol, drug, and cigarette use, and were at an increased risk for panic and obsessive-compulsive disorders.

In sum, clinic-referred girls with ADHD present with more symptoms than do girls without ADHD and are indistinguishable from clinic-referred boys with ADHD. It is important to note that girls who are referred for ADHD may represent a more severely impaired group than do community-based samples of girls. Further evidence suggests that girls who are in need of treatment for ADHD may be overlooked because they tend to be less disruptive than boys. Additional longitudinal research investigating gender differences would be helpful to resolve these critical issues.

5. ETIOLOGY OF ADHD

Research indicates that problems in behavioral inhibition or self-control are a result of dysfunction in fronto-striatal networks, whereas other brain regions (e.g., basal ganglia that includes the caudate nucleus and cerebellum) are also implicated. The evidence of genetic transmission of ADHD, primarily involving the dopamine systems that innervate frontal-striatal regions, is strong. Studies estimate that 70 to 95% of deficits in behavioral inhibition and inattention are transmitted genetically. Research investigating the manner in which the environment interacts with subtle brain anomalies and genetic mutations is ongoing. Traumatic events, the presence of comorbid disorders, and other psychosocial stressors (i.e., poverty, family dysfunction) complicate ADHD but are not considered to be causal.

Although neurological and genetic substrates appear to be compromised, multiple interacting factors are likely involved in the expression of ADHD. It is likely that compromised neural systems influence adaptive functioning and that family, school/work, and community environments affect how ADHD is manifested and may contribute to the development of various coexisting disorders. There may be other factors, including exposure to environmental toxins (e.g., elevated lead exposure), prenatal smoking, and alcohol use, that

increase the risk for ADHD. However, these risk factors are not present in all children with ADHD. Some environmental explanations are inaccurate and non-scientifically based, including high sugar ingestion, allergies or sensitivities to foods, family discord, parental alcoholism, poor or ineffective parenting, and poor motivation. Furthermore, inaccurate beliefs about the nature of ADHD often lead to ineffective treatment approaches.

6. DEVELOPMENTAL CONTEXT FOR ADHD

Although ADHD has been considered to be a disorder of childhood, there is compelling evidence that a majority of children do not outgrow ADHD. This section highlights the major challenges of ADHD throughout the life span.

6.1. ADHD During Early Childhood

Symptoms of ADHD typically first appear during early childhood. Infants are often described as temperamental, difficult to care for due to excessive crying and irritability, difficulty in calming, overly sensitive to stimulation, and overly active. These complications often interfere with normal parent–child bonding and often lead to negative parental interactions (e.g., fewer interactions, less affection, higher parental stress). These patterns affect child compliance and lead to frustrating and challenging interactions. In preschool, hyperactivity levels are pronounced and lead to difficulty in adjusting to expectations to sit, listen, and get along with other children. Impulsivity interferes with play and often leads to rejection. Referral rates are high during this stage of development as children come into contact with other adults and face greater demands for self-control. Interventions at the stage frequently focus on increasing parenting skills, building positive parent–child relationships, increasing parent support, and implementing other preventive measures (e.g., reinforcing prosocial behaviors, training preschool teachers, using behavioral management principles).

6.2. ADHD During Middle Childhood

Most research on ADHD has been conducted on children between 6 and 12 years of age. Deficits in self-control continue to be problematic and are highlighted by disruptive, noncompliant, and off-task behaviors at home and at school. Poor attention to schoolwork,

poor work completion, low motivation, low persistence to challenging tasks, and poor organizational skills negatively affect academic and school adjustment. Difficulties with social situations, negative peer and adult interactions, poor anger control, and low self-esteem create secondary problems that can be chronic. Parent–child relationships are often strained due to noncompliance, failure to complete household chores, and the need for constant monitoring of everyday activities (e.g., bathing, eating, getting dressed, going to bed). These difficulties can increase family stress and interfere with sibling relationships. Other comorbid disorders, including oppositional deviance, conduct problems, depression, and anxiety, may also emerge during this stage. Severe oppositional deviance is problematic and often presages antisocial behavior during later adolescence and adulthood. Treatments during this stage typically are multimodal, including parent training, behavior classroom management, academic interventions, self-management training (e.g., self-instruction, anger control), and medication.

6.3. ADHD During Adolescence

Longitudinal studies reveal significant difficulties for approximately 70 to 80% of teens who had ADHD as young children. Although cognitive deficits and learning disabilities are common in children with ADHD, they are less well documented in adolescents and adults. Longitudinal studies show that youth with ADHD have significant academic difficulties, including high suspension rates (46%), high dropout rates (10%), and placements in special education for learning disabilities (32.5%), emotional disturbance (35.8%), and speech language disorders (16.3%). Negative academic outcomes were present even after intensive treatments, including medication, individual therapy, family therapy, and special education placement. In general, children with hyperactivity are less well educated, have higher rates of grade retention, and have lower grades compared with controls at 5- and 10-year follow-ups. Adolescents with ADHD also show higher rates of automobile accidents and speeding tickets than do teens without ADHD. Both cigarette use and marijuana use are higher according to parental reports, whereas teens with ADHD report higher rates of cigarette use but not of alcohol use, or of marijuana, cocaine, heroin, and other illegal substances use, compared with non-ADHD teens. Antisocial behaviors, including theft, breaking and entering, disorderly conduct, carrying a weapon, assault with a weapon, assault with fists, setting fires,

and running away from home, were reported in the Milwaukee Longitudinal Study.

In general, treatment options for teens are less well researched than are those for children. Treatment for adolescents with ADHD typically focuses on increasing problem solving and communication between parents and teens, psychopharmacotherapy, and classroom accommodations for academic difficulties. More systematic study is needed to investigate the strength of these various interventions. It has been suggested that children with ADHD might not receive needed treatment.

6.4. ADHD During Adulthood

In 1996, Barkley and colleagues found that adults with ADHD had similar levels of educational achievement and occupational adjustment but differed from controls on symptoms of ADHD and oppositional problems in college and at work. They also had shorter duration of employment, more psychological distress and maladjustment, and more antisocial acts and arrests for disorderly conduct and thefts compared with controls. Even though conduct problems and risk for comorbid antisocial personality disorder appear in approximately 25% of individuals with ADHD, the majority of adults with hyperactivity do not engage in criminal behaviors.

According to driving instructors and self- and parent-reports of driving skills, young adults with ADHD were more distractible and impulsive while driving. High rates of driving-related difficulties, including license suspensions or revocations, serious accidents (i.e., involving a wrecked car), and hit-and-run accidents, were also reported. In 1998, Barkley indicated that young adults with ADHD had sexual intercourse at an earlier age, more sexual partners, and higher rates of pregnancy. Contraceptive use was lower, sexually transmitted diseases were higher, and testing for HIV/AIDS was higher in the ADHD group than in controls.

Treatments for adults with ADHD are not well documented but often include multiple approaches, including family and couples therapy, occupational and career counseling, occupational accommodations, medication, and treatment for comorbid disorders (e.g., alcohol or drug treatment, depression, bipolar disorders). Others have emphasized the need for counseling to change the negative mind-set that results from years of failure and coaching for everyday responsibilities. Although empirical studies are needed to determine the efficacy of various treatment options, studies do show the efficacy of stimulant medication in the treatment of ADHD in adults.

7. EVIDENCE-BASED INTERVENTIONS FOR ADHD

The American Academy of Child and Adolescent Psychiatry (AACAP) has developed practice guidelines for the diagnosis and treatment of ADHD. The American Academy of Pediatrics (AAP) recommends that stimulant medication should not be used as the only treatment for ADHD and should be administered only after a careful evaluation. Practice guidelines recommend a comprehensive multimethod approach for the diagnosis of ADHD in children and youth.

7.1. Multimodal Treatment Regimens

The MTA study, funded by the National Institute for Mental Health, reported that children with ADHD received suboptimal care in the community. Even though two-thirds of the sample received stimulant medication, care in the community was less effective than were carefully managed medication, behavioral treatment, and combined treatments. Only 25% of children receiving care in the community were normalized after a 14-month trial, whereas 68% of the combined group, 56% of the carefully managed medication group, and 34% of the behavioral treatment group showed normalization. When community care is provided, it is not carefully monitored, nor is it as effective as multimodal intensive treatment. The MTA study showed that children with ADHD had the best response to multimodal treatment that included 35 sessions of parent training, a full-time summer treatment program for children to learn social and sports skills and to practice academic skills, weekly teacher consultation, a paraprofessional aide in the classroom, contingency management in the classroom, and medication. This extensive treatment was highly effective in reducing the major symptoms of ADHD and was superior to treatment generally found in the community. It is difficult to discern whether the quality and level of treatment described in the MTA study can be easily implemented in the community.

7.2. Other Evidence-Based Interventions

Other empirically supported treatments for children with ADHD include behavioral therapy and contingency management techniques; a summer treatment program with a systematic reward/response cost program, sports skills

training, a 1-hour daily academic special education class, training in effective social skills, daily report cards, and parent training; parent training combined with contingency management and didactic counseling to increase parent knowledge of ADHD; a community-based family therapy program; the good behavior game, response cost, using the “attention trainer”; modification of classroom assignments and task demands; and the Irvine Paraprofessional Program. Self-management, direct contingency management, and intensive behavioral and social skills training have also been shown to be effective.

8. MEDICATION MONITORING AND ADHERENCE

Research on the short-term efficacy of stimulant medication is well documented for 75 to 80% of children with ADHD; however, medication monitoring and adherence is problematic. For example, in 2001, Vitiello stated, “For optimal pharmacological treatment of children with ADHD, medication adjustments are needed for long-term treatment even when the initial dose is chosen in a careful, comprehensive, and unbiased manner.” In the MTA study, more than 70% of children assigned to the medical management group were on different doses after a 13-month trial. Although the majority of children receiving community care in the MTA study were treated with stimulant medication, as a whole, children in the medical management group received more careful medication monitoring from physicians and showed greater improvement of symptoms than did children in the care in the community group.

In 2001, Thiruchelvam and colleagues investigated medication adherence in children 6 to 12 years of age. The most salient factors affecting compliance were the absence of ODD, the severity of ADHD symptoms, and the age of the children. Children with ODD were 11 times more likely to refuse medication. Youth with more symptoms were more responsive to the medication and were more compliant when taking medication as well. Positive stimulant response may encourage parents and children to stick to the medication regimen at higher rates than in cases where medication is not very helpful. Older children were also more likely to refuse medication. Because there is a decrease in hyperactivity symptoms with age, older children may perceive less benefit from medication and choose not to adhere. Social stigma may also play a role in adherence at this stage. Physicians are advised to develop adherence plans for youth on medication.

In sum, research indicates that multiple therapies are needed to adequately address the problems associated with ADHD. Stimulant medication with behavioral and psychosocial interventions, including classroom behavior management and parent management training, improve ADHD symptoms and associated problems in children with ADHD. Initial research indicates that stimulant medication is effective for adults and that other cognitive-behavioral interventions (e.g., self-management) show promise. Currently, treatment within a single modality (medication vs behavioral) appears to have very little long-term impact. Effective treatments are less well documented for adolescents and adults with ADHD. Although studies have shown that stimulant medication is effective, less is known about the effects of multimodal treatment in older groups.

9. RISK AND RESILIENCY FACTORS THAT AFFECT ADHD

Although ADHD presents challenges throughout the life span, some factors complicate the disorder, whereas others appear to be protective. Risk factors that alter the course of ADHD include child characteristics (e.g., severity of ADHD symptoms, intelligence levels, comorbidity), family discord or environmental distress, and early treatment for ADHD and the presence of coexisting disorders. In an effort to optimize outcome, comorbid disorders should be targeted for treatment along with the ADHD symptoms. Oppositional defiant behavior problems are among the most debilitating difficulties over time because they often lead to conduct disorders and antisocial personality disorders during adolescence and adulthood. There is evidence that effective parenting skills can interrupt this progression in many children. Other family factors that increase the complexity of ADHD include parental psychopathology such as maternal depression and paternal antisocial personality disorder. These parental difficulties often interfere with effective parenting and produce added stress to vulnerable families whose members are already challenged by disruptive noncompliant child behaviors. There is strong evidence that raising a child with ADHD is stressful, so additional parental problems make this challenge even more overwhelming. Furthermore, as noted by Goldstein in 2002, “Living in a household, above the poverty level, with parents who are free of serious psychiatric problems, consistent in their parenting style, and available to their children appear to be among the most

powerful variables at predicting good outcome.” Parents are also advised to seek individual and family therapy for their own problems in an effort to strengthen interpersonal effectiveness and family cohesiveness.

The extent to which treatment alters the developmental course of ADHD is not well understood. Some studies of children who received extensive treatment showed that these youth still had poor outcomes during adolescence. However, the MTA study showed short-term improvement (over a 14-month period) in children receiving comprehensive multimodal treatment in highly controlled and monitored programs. Furthermore, growing evidence suggests that medication may buffer some of the negative effects of ADHD. Although there are reasons to be cautious about the use of stimulant medication in young children, recent studies suggest that early treatment may alter the neurodevelopmental pathways of ADHD in positive ways. Stimulant treatment also appears to improve outcomes for adults. In 1999, Wilens and colleagues also found that 70% of adults receiving a year of cognitive therapy and stimulant medication showed a reduction of ADHD symptoms and were less anxious and depressed.

Current studies of ADHD are focusing on the long-term effects of multimodal treatment for children and are investigating what works best for adolescents and adults with ADHD. Current research is promising, but researchers are still exploring how the outcome and course of ADHD can be altered with effective treatments. The impact of environmental events on the development of attention and self-regulation is of particular interest.

GLOSSARY

accessibility The ease with which a memory can be activated; it is often measured by the time it takes a person to react to a stimulus.

action What a person is actually going to do or not do; it is usually the verb in the attitude measure.

associative hypothesis The hypothesis that a person forms associations between behavioral beliefs and other behavioral beliefs, between normative beliefs and other normative beliefs, but not between behavioral beliefs and normative beliefs.

construct validity The extent to which a measure of a variable actually measures what it is supposed to measure.

context The situation in which a person will perform or not perform the behavior of concern.

factor analysis A statistical technique that reduces a large number of test items or scales to a smaller number of dimensions.

internal consistency The extent to which different scales that comprise a measure correlate with each other.

open measurement A way in which to measure repeated behaviors that may increase the validity of the measures of corresponding attitudes.

predictive validity The extent to which a measure of a variable predicts the measure of another variable.

principle of correspondence The extent to which an attitude and behavior measure match each other with regard to action, target, time, and context.

repeated behavior A behavior that is performed several times or more; such a behavior presents a challenge for the valid measurement of its corresponding attitude.

skewed distribution A distribution that deviates from normality as a result of more extreme scores at one tail than at the other tail; response latencies are notorious for having extreme scores at the tail that represents slow latencies (i.e., long times).

target The object that is or is not acted on by a person whose attitude is being measured.

test-retest reliability The correlation between a test and itself when it has been taken at two different times.

time When the behavior will or will not be performed by a person whose attitude is being measured.

Because attitudes have been assumed to be predispositions for behaviors, consumer researchers

have assumed that attitudes should predict behaviors. However, the success of predicting behaviors from attitudes largely depends on how reliably and validly attitudes are measured. The validity of attitude measures, in turn, depends on a variety of issues, the most important of which is correspondence of measurement. Other concerns are whether one is measuring attitudes toward objects or toward behaviors, whether one wishes to obtain implicit or explicit attitude measures, whether the attitude pertains to a single behavior or to repeated behaviors, and whether attitudes can be distinguished from other variables.

1. INTRODUCTION

The vast majority of applied researchers who measure attitudes do so because they wish to predict or affect people's behaviors. Health psychologists wish to increase healthy behaviors such as exercise, healthy eating, and use of condoms; consumer researchers wish to induce people to buy products; and politically motivated researchers wish to predict and affect people's votes and financial contributions. Researchers usually assume that attitudes are an important determinant of behaviors, with the accompanying assumption that knowledge of people's attitudes implies an ability to predict and control behaviors. To obtain such knowledge of people's attitudes, however, it is absolutely crucial to be able to measure them reliably and validly—the main topic of this article.

2. TWO MEANINGS OF RELIABILITY

An attitude measure can be reliable in one of two general ways. To understand the simplest type of reliability, suppose that a set of participants completes an attitude measure at a particular time and then completes it again at a later time. The correlation between the two test-taking occasions is the attitude measure's test–retest reliability. However, there is a second meaning of reliability in that the term can be used to denote internal consistency. To understand internal consistency, suppose that an attitude measure is composed of several scales. If these scales truly measure the participants' attitudes, all of the scales should correlate with each other. Another way of saying that the scales correlate with each other is to say that they have a high degree of internal consistency. Although there are different formulas for calculating different kinds of internal consistency, all of these formulas

require an assumption that all of the scales that compose the measure are equally good. Based on this assumption, all of the formulas imply that increasing the number of scales increases the internal consistency of the whole attitude measure. Because both test–retest reliability and internal consistency are usually considered to be prerequisites for validity, it is common practice to use several scales to measure attitudes.

3. TWO MEANINGS OF VALIDITY

How does one know whether a particular attitude measure is valid? To answer this question, one must first ask “valid for what?” An attitude measure can be valid if it predicts another variable that is considered desirable to predict such as behaviors and behavioral intentions (i.e., motivations to perform behaviors). For example, a measure of condom use attitudes that actually predicts whether people will intend to use condoms, or whether they actually use condoms, can be said to have predictive validity.

Another answer to the “valid for what?” question is that the measure must actually measure attitude and not something else. It is possible that a particular attitude measure might predict behavior, not because it measures attitude but rather because it measures something else that is correlated with behavior. Researchers who are concerned with this are forced to deal with the issue of how to define an attitude. Not surprisingly, various researchers have used different definitions, depending on their theories. From this perspective, the valid measurement of attitudes depends on the theories in which attitudes play an important role. Empirically obtained evidence in support of a particular theory also supports the validity of the attitude measurement as it is specified by that theory, whereas empirical evidence against a particular theory tends to disconfirm the validity of the attitude measurement as it is specified by that theory. When the theory in which the attitude construct is embedded is empirically supported, the attitude measure that is part of that theory is said to have construct validity.

4. THE HISTORICAL PROBLEM: ATTITUDES DID NOT PREDICT BEHAVIORS

Since the 1920s, researchers have assumed that attitudes are predispositions for behaviors. If this is true, it

follows that attitudes should predict behaviors. However, the vast majority of researchers from the 1920s through the 1960s obtained correlations that were either low or not statistically significant. The consistent inability of researchers to predict behaviors from attitudes suggested one of two possibilities. First, perhaps attitudes really do not matter very much for predicting behaviors. Second, perhaps attitudes do matter, despite the lack of empirical support, but the attitude measures used in previous studies were not valid. Although many researchers argued for the first possibility, other researchers eventually achieved a good deal of success by assuming the second possibility. These latter researchers redefined the idea of attitude in two ways, both of which resulted in attitude measures with greater construct and predictive validity.

4.1. Attitude Accessibility

One view derives from the social cognition tradition, but it does not receive much attention here because it has not been used much by applied researchers. Fazio used the idea of attitude accessibility to explain low correlations between attitudes and behaviors. He assumed that attitudes affect behaviors, but only when they are easy to retrieve from memory. When attitudes are not accessible, there is no reason to believe that they would affect behavior. Therefore, researchers who subscribed to this view explained previous findings of low attitude–behavior correlations by assuming that they were due to a failure on the part of researchers to measure accessible attitudes. In support of the accessibility view, much research during the 1980s and 1990s indicated that accessible attitudes are more predictive of behaviors than are less accessible attitudes.

Nevertheless, applied researchers have, for the most part, ignored the accessibility view. The reason for this is not clear. One possible reason is that many applied researchers are not particularly knowledgeable about this view. Another possible reason is that researchers who have favored the accessibility view have not been clear about how this view can be applied to predict and control behaviors.

4.2. Principle of Correspondence

Fishbein proposed the principle of correspondence, which provided the other solution to the problem of low attitude–behavior correlations. His main assumption is that behaviors have four components: action, target, time, and context. It is easiest to understand this

idea with an example. Suppose that a researcher wishes to predict whether people will give blood at the campus blood drive on Tuesday. The action is “give,” the target is “blood,” the time is “on Tuesday,” and the context is “at the campus blood drive.” If the attitude measure does not correspond with the behavior measure in regard to action, target, time, and context, it is invalid and a respectable attitude–behavior correlation is not likely to be obtained. For example, if a researcher measures people’s attitudes toward “giving blood,” there is no reason to expect that this attitude measure will successfully predict whether people will “give blood at the campus blood drive on Tuesday.” Rather, to predict this behavior, it is necessary to measure people’s attitudes toward “giving blood at the campus blood drive on Tuesday.” This is often done by having people make a check mark on a scale with various options such as the following:

I extremely like/quite like/slightly like
/neutral/slightly dislike/quite dislike
/extremely dislike giving blood at the
campus blood drive on Tuesday.

(Whether people actually performed the behavior could be assessed in a variety of ways such as checking the lists of people who donated at the campus blood drive on Tuesday and simply asking people whether they had given blood at the campus blood drive on Tuesday.)

The correspondence view explained previously obtained low attitude–behavior correlations in a straightforward way. The reason for the low correlations is that the attitude measures used in those studies were not valid because they did not obey the principle of correspondence. Results from two types of research paradigms supported this view. First, researchers measured attitudes and behaviors (or behavioral intentions, which are often assumed to be direct precursors to behaviors) according to the principle of correspondence and obtained much higher correlations than those that researchers had been able to obtain previously. Second, some researchers manipulated the degree of correspondence of attitude and behavior (or behavioral intention) measures experimentally and obtained much higher correlations when there was a high degree of correspondence than when there was not. In combination, the findings provided a very convincing case for the importance of measuring attitudes in accordance with the

principle of correspondence. Therefore, it is now common practice for applied researchers to measure attitudes in this way, and the result has been a dramatically improved ability to predict behavior in a variety of domains such as dieting, exercising, drinking, smoking, voting, using seat belts, using condoms, and getting screened for cervical cancer.

5. FACTOR ANALYSIS

As was discussed earlier, increasing the number of scales can increase the internal consistency of the attitude measure. Consequently, many researchers do not stop at having one attitude scale and instead have several scales. For example, in addition to the like-dislike example given previously, participants could respond to scales that include pairs such as wise-foolish, beneficial-harmful, enjoyable-not enjoyable, good-bad, and pleasant-unpleasant. When multiple scales are used to measure an attitude, the mean of a participant's responses to the scales is often taken as the representation of his or her attitude.

Depending on the behavior of interest, it may happen that not all of the scales are equally good for measuring attitude. It may even turn out that, for some behaviors, some of the scales will measure something other than attitude. To test this possibility, many researchers habitually submit the various scales to a factor analysis. Factor analysis is a statistical technique that reduces a large number of items down to a smaller number of underlying dimensions. For example, on intelligence quotient (IQ) tests, a large number of items may be reduced down to dimensions such as verbal ability and mathematical ability. As another example, on personality tests, hundreds of items have been factor analyzed and reduced to five basic factors of personality. Ideally, when various attitude scales are submitted to a factor analysis, one factor that represents attitude should result. Although one factor is often obtained, it sometimes happens that more than one factor is obtained. In this case, the researcher must determine which factor is the "true" attitude factor—a determination that depends on a variety of issues that are too complicated and numerous to discuss here. In addition, obtaining more than one factor can be interpreted to mean that there is more than one component to the attitude. In this case, the answer to the question of which factor represents attitude is that all of them may do so.

6. ATTITUDES TOWARD OBJECTS OR BEHAVIORS AND BEHAVIORAL CATEGORIES

The principle of correspondence implies a distinction between attitudes toward objects and attitudes toward behaviors. Suppose that a researcher is interested in using advertising to reduce discrimination and wishes to measure relevant attitudes. Unfortunately, it is not clear what the relevant attitudes are. In general, researchers in this area have measured attitudes toward the groups of interest such as women, African Americans, Jews, handicapped people, and people with AIDS. However, the principle of correspondence suggests that if one wishes to predict discriminatory behavior, this is not going to work. This is because although a measure of attitudes toward a particular group includes the target component of the behavior to be predicted, it does not include the action, time, and context components. If one wishes to predict a particular discriminatory behavior, it is necessary to use an attitude measure that includes all of the components of the criterion behavior. At the very least, this implies that the attitude measure will have to include the action component, which makes it a measure of an attitude toward a behavior rather than a measure of an attitude toward an object. For example, an attitude toward "hiring women" is an attitude toward a behavior, whereas an attitude toward "women" is an attitude toward an object. For a more mundane example, one could measure an attitude toward "Skippy peanut butter" or toward "buying Skippy peanut butter"; the former is an attitude toward an object, whereas the latter is an attitude toward a behavior.

An argument has been made against using the principle of correspondence in some situations. In brief, the argument is that researchers are sometimes interested in a large number of behaviors. For example, a researcher might be interested in a wide range of behaviors that discriminate against women and not just hiring behaviors. Obviously, an attitude measure toward a single behavior is likely to be inadequate for predicting a variety of discriminatory behaviors. One solution to this problem is for the researcher to measure attitudes toward all of the discriminatory behaviors that are of interest and to predict each discriminatory behavior from its corresponding attitude measure. Another solution is for the researcher to list a set of discriminatory behaviors of interest and then lump all of them under the general category of "discriminatory behaviors." Participants can then give their attitudes toward the

whole behavioral category, and these can then be used to predict the behaviors in that category. Although there is some evidence that either of these solutions may have some validity, there is insufficient evidence for a strong conclusion. However, there is strong evidence that attitudes toward behaviors are better predictors of behaviors than are attitudes toward objects.

7. ATTITUDE SPECIFICITY, BEHAVIORAL INTENTIONS, AND BEHAVIORS

Attitudes have been shown to be good predictors of behaviors, but they have also been shown to be good predictors of people's intentions to perform behaviors. In addition, such behavioral intentions have often been shown to be good predictors of behaviors, and most researchers believe that intentions are proximate causes of behaviors. This combination of empirical findings and theorizing in the area, along with the practical point that behavioral intentions tend to be much easier to measure than are real behaviors, has resulted in the widespread use of behavioral intentions as a substitute for behaviors. This substitution has resulted in two controversies that have not yet been settled. First, there is a controversy about whether behavioral intentions are close enough to real behaviors to justify using the former as a substitute for the latter. A large part of this controversy is based on the issue of how well behavioral intentions predict behaviors. To the extent that intentions do a good job of predicting behaviors, the substitution would be supported, whereas a lack of prediction would support the reverse conclusion. In fact, results vary widely. In general (but there are exceptions), behavioral intentions do a better job of predicting behaviors when the intention and behavior measures conform to the principle of correspondence than when they do not. Thus, the substitution of behavioral intentions for behaviors is most acceptable when one uses correspondent measures.

The use of behavioral intentions as a criterion measure brings up a second controversy. To understand the underlying reason for the controversy, consider that all behaviors are performed with a target, an action, a time, and a context, meaning that the measured behavior will automatically have these four elements. Therefore, the trick to obeying the principle of correspondence is to make sure that the attitude measure specifies all of these elements in a way that matches the behavior measure. But matters change when attitudes are used to predict

behavioral intentions rather than actual behaviors. A behavioral intention does not necessarily have a target, an action, a time, and a context, as is illustrated by the following example. Imagine the behavior of "buying a television set." For a person to actually perform this behavior, he or she must buy a particular brand of television set, at a particular time, at a particular store or from a particular Web site. But for this person to intend to perform the behavior, many of these elements need not be specified. In the case of this example, the intention specifies a rather vague target (television set rather than a specific brand of television set) and an action (buy) but not a time or a context. Therefore, to have an attitude measure that is correspondent with the intention measure, it too should specify the target (in a similarly vague way) and the action but not a time or a context. Consequently, when one attempts to predict behavioral intentions from attitudes, it is possible to fully specify target, action, time, and context or to not fully specify these four elements. In either case, the principle of correspondence is obeyed so long as the degree of specification of the four elements is the same for both the attitude and behavioral intention measures. Does the degree of specification affect the size of the obtained correlation between the attitude and behavioral intention measures? Currently, there is insufficient empirical evidence to answer this question. Moreover, even for the prediction of actual behaviors, it is possible for the researcher to be uninterested in a particular element (e.g., the store at which the television set was bought). In this case, the behavior measure can ignore the uninteresting element or not ignore it, and the attitude measure can ignore it or not ignore it, and so long as the two measures match, the principle of correspondence is obeyed. Will the prediction of the behavior from the attitude measure be greater if the uninteresting element is specified? Again, there is insufficient empirical evidence to know. In sum, whether one predicts behavioral intentions or behaviors, whether one predicts clear-cut behaviors or behavioral categories, and whether one is interested in more of the elements (e.g., target, action, time, context) or fewer of them, there is insufficient research to determine whether it is better to have measures that are as specific as possible or not.

8. OPEN ATTITUDE MEASURES

Although there is widespread agreement that it is crucial to measure attitudes in accordance with the principle of

correspondence, it has not always been clear how to do this. In particular, it has not always been clear how to measure attitudes toward repeated behaviors in accordance with this principle. To see the problem, suppose that a researcher is interested in predicting exercise behaviors from attitudes toward exercising. If the researcher were interested in only one performance of an exercise behavior, it would be easy to obey the principle of correspondence as follows:

Attitude measure: I like/dislike to engage in vigorous physical activity at least one time during the month of October. (Participant makes a check mark on a scale.)

Behavior measure: I engaged in physical activity at least one time during the month of October. (Participant confirms or disconfirms that he or she performed the behavior.)

Unfortunately, this method of measuring attitudes and behaviors does not work well for repeated behaviors. Suppose that a researcher is interested in regular exercise. There is no clear dividing line between “regular” and “not regular” exercise; therefore, it is not satisfactory to arbitrarily specify a number of exercise occasions that qualifies as regular. Courneya proposed the idea of open attitude and behavior measures to address this problem. His idea was to have the participant, rather than the researcher, specify the number of behaviors. Although the use of open measures has not been tested exhaustively (and the tests have focused more on predicting behaviors from intentions than from attitudes), preliminary evidence suggests that it results in an increase in the prediction of behaviors compared with other methods. The following is an example of open measures:

Attitude measure: I like to engage in vigorous physical activity _____ times during the month of October.

Behavior measure: I engaged in vigorous physical activity _____ times during the month of October.

To see why open measures often improve the prediction of behaviors from attitudes, consider an example. Suppose that a person believes that exercising 16 days during the month of October is “regular exercise,” whereas exercising 15 days or less is not. In addition, suppose that the person has a positive attitude toward regular exercise but that he or she exercised only 15 days during October. With traditional measures, the person’s behavior would seem to be inconsistent with his or her attitude; exercising only 15 days is inconsistent with a positive attitude toward regular exercise

(16 days). In contrast, using open measures, it can easily be seen that exercising for 15 days is quite consistent with the person’s positive attitude toward exercising for 16 days.

9. IMPLICIT ATTITUDE MEASURES

Attitude researchers have often found it useful to distinguish between implicit and explicit attitude measures. Explicit attitude measures are usually characterized as being conscious, deliberative, and controllable, whereas implicit attitude measures are usually characterized as being unconscious, unintentionally activated, and not controllable. Whether the distinction between explicit and implicit measures should be considered to be a dichotomy or a continuum is not a settled issue, although many researchers who favor implicit measures seem to favor a dichotomous interpretation.

There are several examples of implicit attitude measures. One kind of implicit measure makes use of response latency, where participants respond to a computer-presented stimulus by pressing a key, and faster reaction times are interpreted to indicate a stronger attitude toward the stimulus. Other kinds of implicit measures include memory tasks, physiological measures (e.g., galvanic skin response, heart rate), and indirect questionnaires (where participants are not asked directly about the attitude object or behavior).

Implicit measures, when compared with explicit ones, have both advantages and disadvantages. Some advantages are as follows. First, if the issue of interest is a socially sensitive one, it may be difficult to get honest responses through explicit measures, and so implicit measures provide a way in which to avoid this difficulty. A finding that supports this argument is that implicit and explicit attitude measures have been found to be more highly correlated for socially insensitive attitude objects than for socially sensitive ones. Second, if the researcher is interested in unconscious attitudes, a case can be made that implicit measures are more valid than explicit ones. Supporting evidence indicates that implicit attitude measures tend to be more predictive of implicit measures of other variables than do explicit attitude measures. Third, it is possible that implicit measures are more direct than explicit ones. This is because explicit attitude measures must be funneled through the conscious processing system, whereas implicit ones do not.

On the other hand, implicit measures also have disadvantages. First, if one is interested in predicting

behavior, it is reasonably clear how to use the principle of correspondence to obtain valid explicit attitude measures, whereas it is less clear how the principle of correspondence can be used for implicit attitude measures. Second, the reliability of implicit attitude measures has not been thoroughly investigated, and the preliminary evidence suggests that they have less test-retest reliability than do explicit measures. Because reliability is a precursor to validity, this preliminary evidence also suggests that implicit measures may also be less valid than explicit ones. Third, some of the same studies that suggest that implicit attitude measures are better than explicit ones for predicting implicit measures of other variables also suggest that implicit attitude measures work less well than explicit ones for predicting explicit measures of other variables (e.g., behavioral intentions). Finally, the presumed advantages for implicit attitude measures depend on assumptions about the nature of consciousness, cognitive resources, controllability, and others that, although supported in the literature, have not been proven beyond a reasonable doubt.

Once a researcher has decided to use an implicit measure such as response latency, there is a further issue of how to characterize the central tendency of the person's responses to repeated exposures to the attitude object. Although many researchers have used mean scores, there are problems with this. For one, response latency distributions tend to be highly skewed in the direction of longer response latencies. This is because a large number of factors, such as blinking, distraction, and daydreaming, can increase response latencies. Consequently, mean scores are likely to present a distorted view of participants' actual central tendencies.

Several solutions to this problem have been proposed. The simplest solution is to use median, rather than mean, response latencies as the attitude measure. Another solution is to perform a reciprocal transformation of the data to reduce their skewness [$1/x$, $1/(x + 1)$ if any of the response latencies are less than 1 second, where x is the raw response latency]. A third solution is to perform a logarithmic transformation, which has the consequence of bringing the tail involving slower latencies closer to the center of the distribution. An additional recent solution involves a transformation of all of the latency data to z scores, and then mean or median z scores can be used as the attitude measure. In sum, there are several ways in which to deal with the problem of skewed latency distributions, and the choice of which method to use depends on considerations that are too numerous and complex to describe here.

10. DIRECT AND INDIRECT ATTITUDE MEASURES

Several expectancy-value attitude theories were proposed during the 1950s and 1960s. According to these theories, attitudes are a function of people's assumptions about the probability of various consequences arising from the performance of a behavior and evaluations of how good or bad those consequences are. Although the theories differ in the precise ways in which people are postulated to combine subjective probabilities and evaluations of consequences, they nevertheless have a common implication. Because attitudes are caused by a combination of beliefs about consequences and evaluations, this combination can be used as an indirect attitude measure. Consistent with expectancy-value theories, a large number of findings indicate that indirect and direct attitude measures are highly correlated, at least when the measures are created in accordance with the principle of correspondence. Consequently, many researchers have used indirect attitude measures, rather than direct ones, to predict other variables of interest, notably behavioral intentions and behaviors.

There has been some controversy about whether direct or indirect attitude measures are better predictors of behavioral intentions or behaviors. Although indirect measures have the advantage of specifying the subjective probabilities and evaluations of consequences that determine attitudes, there are both theoretical and empirical reasons to prefer direct attitude measures if one wishes to predict behavioral intentions or behaviors. The theoretical reason stems directly from the assumption that indirect measures assess variables (subjective probabilities and evaluations) that determine attitudes that, in turn, are a determinant of behavioral intentions or behaviors. According to this reasoning, attitudes are a more proximal cause of behavioral intentions or behaviors than are subjective probabilities and evaluations. Under the assumption that more proximal predictor variables work better than do less proximal ones, it follows that because direct attitude measures are assessing a variable (attitude) that is more proximal to behavioral intentions and behaviors than are indirect measures (which assess subjective probabilities and evaluations), direct measures should be a better predictor of behavioral intentions and behaviors than are indirect measures.

Numerous studies have provided tests of this theoretical reasoning. In the vast majority of cases, the reasoning has been supported; direct measures are generally

superior to indirect ones for predicting behavioral intentions and behaviors. An exception is when the attitude measure is not in accord with the principle of correspondence.

11. DISTINCTIONS THAT ARE IMPORTANT FOR ATTITUDE MEASUREMENT

With the problem of low attitude–behavior correlations having been solved by the principle of correspondence, recent researchers have changed their focus to three other problems that are now addressed. First, there is an important issue of whether attitudes are really an amalgamation of a cognitive (thinking) and affective (feeling) component. If there are separate cognitive and affective components, an implication is that each of these components should be measured separately, thereby improving the prediction of behaviors in a variety of applied domains. Second, there has been a great deal of controversy over whether attitudes should be measured separately from subjective norms. It was not until recently that this controversy was finally resolved. Finally, there are some attitudes that are not easily measured according to the principle of correspondence, and it might be necessary to make an adjustment. These issues are addressed in the following subsections.

11.1. The Separate Measurement of Cognition and Affect

Most researchers believe that there are both cognitive (thinking) and affective (feeling) components to attitudes. Three types of evidence support this belief. First, many researchers have used factor analysis to reduce a large number of attitude scales down to a smaller number of factors. In most cases, two factors result, with cognitive items loading on one factor and affective items loading on the other.

A second type of evidence comes from hierarchical regression analyses. Put simply, it is possible to consider the unique contribution of cognition to predicting general attitudes (or intentions) or to consider the unique contribution of affect. The results of these studies tend to indicate that, for any particular behavior, either cognition or affect will make a statistically significant unique contribution—a finding that should not occur regularly if attitude does not have these two components. An additional nicety of hierarchical regression analyses is

that the results are often consistent with researchers' intuitions. For example, cognition has been shown to be the more important contributor for what seems to be the cognitively controlled behavior of "studying over winter break," whereas affect has been shown to be the more important contributor for what seems to be the affectively controlled behavior of "smoking cigarettes."

Finally, Trafimow and Sheeran have made use of the associative hypothesis. They assumed that people have different types of beliefs about the consequences of behaviors and that some beliefs are more cognitive, whereas other beliefs are more affective. Given this, people are assumed to compare cognitive beliefs with other cognitive beliefs in the interest of forming the cognitive component of an attitude, and people are assumed to compare affective beliefs with other affective beliefs in the interest of forming the affective component of an attitude. But when people compare cognitive beliefs with other cognitive beliefs, or compare affective beliefs with other affective beliefs, they form associations; people form associations between cognitive beliefs and other cognitive beliefs, or between affective beliefs and other affective beliefs, but not between cognitive beliefs and affective beliefs. Consequently, when people are later asked to write down their beliefs about a behavior, writing a cognitive belief should cue the retrieval of another cognitive belief, whereas writing an affective belief should cue the retrieval of another affective one, thereby causing people's belief lists to be clustered by belief type. In contrast, if people do not distinguish between cognitive and affective beliefs (or between cognitive and affective components of attitudes), such clustering should not occur. In fact, such clustering is obtained, further supporting the distinction between cognitive and affective components of attitudes.

Empirical support for the distinction between cognitive and affective attitude components has led researchers to measure them separately to maximize the prediction of other variables such as behavioral intentions. Recent findings indicate that the prediction of behavioral intentions is significantly enhanced when the cognitive and affective attitude components are measured separately, and this finding has been replicated across a wide range of behavioral domains.

11.2. The Separate Measurement of Attitudes and Subjective Norms

Since the 1960s, researchers have assumed that attitudes and subjective norms are different causes of behaviors

(or, more often, behavioral intentions). Whereas attitudes have been assumed to be caused by beliefs about the personal consequences of performing a behavior, subjective norms have been assumed to be caused by beliefs about what important others think one should do. Because attitudes and subjective norms have been assumed to be different causes of behavioral intentions, it made sense to measure them separately to maximize the prediction of behavioral intentions. However, during the 1970s and 1980s, many researchers questioned the distinction between attitudes and subjective norms and argued that these were really different names for the same underlying idea. Obviously, if attitudes and subjective norms are different names for the same underlying construct, there is no reason to have distinct measures of each of them. Thus, there is an important measurement issue at stake in this controversy: Should attitudes be measured separately from subjective norms or not?

The argument against the distinction between attitudes and subjective norms was based on three issues. First, attitudes and subjective norms were often found to be highly correlated with each other, consistent with the notion that they are merely different names for the same underlying construct. Second, path analyses have sometimes indicated “crossover” effects, whereby attitudes and subjective norms affect each other. Third, philosophical arguments have been made that beliefs about consequences (i.e., behavioral beliefs) that are presumed to cause attitudes are not different from beliefs about the opinions of important others (i.e., normative beliefs) that are presumed to cause subjective norms. An example should make this issue clear. Suppose that someone has the behavioral belief that “my father will disagree if I eat chocolate” or the normative belief that “my father thinks I should not eat chocolate.” Many researchers have argued that these two statements are just different ways of saying the same thing; therefore, if the cause of attitudes and subjective norms is the same, attitudes and subjective norms must also be the same.

Five kinds of findings have resolved most of the disagreement in favor of the distinction between attitudes and subjective norms. First, in general, behavioral beliefs have been found to be more highly correlated with attitudes than with subjective norms, and normative beliefs have been found to be more highly correlated with subjective norms than with attitudes—precisely what one would expect if behavioral beliefs cause attitudes and normative beliefs cause subjective norms. Second, although attitudes and subjective norms sometimes have been found to be highly correlated, the correlation often has been

found to be low or moderate. Third, attitudes and subjective norms have been manipulated experimentally, with different effects on behavioral intentions pertaining to different types of behaviors; manipulating attitudes has a larger effect on some behaviors, whereas manipulating subjective norms has a larger effect on others. Fourth, behavioral beliefs have been shown to be more strongly associated with other behavioral beliefs than with normative ones, and normative beliefs have been shown to be more strongly associated with other normative beliefs than with behavioral ones. Clearly, regardless of philosophical validity of the distinction between the two types of beliefs, people do make the distinction, contradicting the argument that attitudes and subjective norms have the same cause. Finally, there are individual differences between people in that some people are more under attitudinal control across a large number of behaviors, whereas others are more under normative control. If attitudes and subjective norms were the same thing, reliable individual differences in attitudinal or normative control should not be obtained. In sum, there is a great deal of evidence that attitudes and subjective norms are different from each other, and they should be measured separately.

12. CONSUMER APPLICATIONS

Attitude measurement is of more than just theoretical interest. Consumer and marketing researchers have applied the forgoing principles of attitude measurement in a variety of domains such as substance abuse among adolescents and tobacco use among college athletes as well as trying a new diet suppressant, getting mammograms, using condoms, drinking and driving, eliciting donations, purchasing environmentally friendly products, paying more for energy from renewable sources, purchasing food, voting, purchasing software, and even purchasing attitude research (by marketing directors). In these domains, as well as in many other domains, improved attitude measurement has resulted in an improvement in the prediction of behavioral intentions and behaviors from attitudes.

Improving the prediction of behavioral intentions and behaviors is not the only function of good attitude measures. It sometimes happens, although not very often, that an attitude does not do a good job of predicting a particular behavior. Before psychologists and consumer researchers had valid attitude measures, a low correlation between an attitude and a behavior was susceptible to at least two explanations. First, the

low correlation could show that the behavior is caused by something other than an attitude. Second, the low correlation could be due to an invalid attitude measure. An advantage of valid attitude measures is that they decrease the plausibility of the latter explanation and thereby increase the plausibility of the former one. Thus, when valid attitude measures nevertheless result in low correlations between attitudes and behaviors, researchers can be more confident in exploring other variables. A well-researched example of such an area is condom use. Although attitudes are capable of predicting condom use to some degree, other variables have also been shown to be good (perhaps better) predictors. Two of these are subjective norms and confidence that one knows whether others (e.g., one's sexual partner) think a condom should be used.

To illustrate the importance of valid attitude measures for consumer research regardless of whether the measures show that attitudes are a strong or weak predictor of behaviors, consider an example of a consumer researcher who wishes to increase sales of a particular product. Before investing money in an ad, the researcher needs to know what variables to address in the ad. If the behavior of buying the product is under attitudinal control for the population of interest, it makes sense for the ad to focus on variables that are likely to affect people's attitudes toward buying the product. Some of these variables might be beliefs about the product and affect. But what if the behavior is not under attitudinal control? In that case, there is little point in focusing an ad on variables designed to affect attitudes; for a behavior that is not under attitudinal control, there is no reason to believe that causing attitude change will increase sales. Consequently, the consumer researcher would be better served by creating an ad that focused on a different variable such as subjective norms. In general, having valid attitude measures increases the confidence that researchers can have in their data and provides a more solid basis for creating ads. Data showing that attitudes are good predictors of the behavior of concern provide a strong reason for creating an ad that is designed to affect attitudes; otherwise, the data provide a strong reason for creating an ad that focuses on other variables.

A further issue in attitude measurement, as applied to evaluating the effects of advertising, concerns the types of attitudes that should be measured. Consumer researchers have measured the effects of an ad on attitudes toward the ad, the product, or the brand. It has been rarer for researchers to measure the effects of an ad on attitudes toward the behavior the ad was

designed to influence (e.g., buying the advertised product, voting for the advertised candidate). According to the principle of correspondence, if the reason for creating an ad is to influence behavior, it is precisely this last type of attitude that should be measured. Although there have been some demonstrations that an ad affects attitudes toward the behavior rather than merely attitudes toward the ad, the product, or the brand, more research is needed to establish the size of these effects. This is particularly so because the effects are likely to depend on a large number of variables such as the product domain, the type of ad, the type of use to which the product is put, and the frequency with which people are exposed to the ad.

One final example illustrates the importance of whether one measures attitudes toward the ad, the brand, the product, or the behavior of buying the product. Suppose that a consumer researcher for a company wishes to increase sales of a particular product. In addition, suppose that this researcher is evaluating an ad that has been shown to cause a change in people's attitudes toward the ad, the brand, or the product. It should be clear from the principle of correspondence that these attitudes, despite their seeming importance, are likely to not be particularly relevant to whether people will buy the product.

There may be cases where the consumer researcher's goal is something other than increasing sales of a particular product. Perhaps the goal is to increase sales of all of the products made by the company. In that case, it might be worthwhile to run an ad that focuses on increasing people's attitudes toward the brand. Even though such an ad might be unlikely to cause much of an increase in the sales of a particular product, a small increase in the sales of several products may justify the cost of the ad.

13. CONCLUSION

There has been a great deal of progress in how attitudes are measured. Current attitude measures are more reliable, more valid, and more correspondent to behaviors than were attitude measures in the past. In addition, more is known about some of the relevant issues that underlie attitude measurement. For example, recent research indicates that cognition and affect are both components of attitudes and should be measured separately. Recent research also indicates that attitudes are different from subjective norms and that the two variables should be measured separately. The consequence of such progress is that the prediction of behavioral intentions and behaviors from attitudes is

much greater than it has ever been before, and this has been demonstrated in a wide variety of domains.

GLOSSARY

attitude A relatively enduring evaluation that a person holds about a target.

attitude change A process by which a person's evaluation toward a target is made more positive or negative.

attitude strength The extent to which an attitude is persistent over time, resists attempts to persuade, influences behavior, and influences cognition.

central route to persuasion The process of attitude change that relies on thoughtful processing of [the arguments within] a persuasive message.

Likert scale A tool for measuring attitudes in which respondents indicate to what extent they believe a series of items are characteristic of them regarding an attitude object.

peripheral route to persuasion The process of attitude change that does not rely on thoughtful processing of [the arguments within] a persuasive message.

semantic differential A tool for measuring attitudes in which respondents indicate how well a series of adjectives describes an attitude object.

tripartite model of attitudes Model suggesting that attitudes are derived from and/or influence affective, behavioral, and cognitive [components].

Attitudes are the relatively enduring evaluations that people hold toward all sorts of things in the world. Attitudes can be held toward people, objects, issues, and concepts. Researchers have devoted a great deal of effort to understanding attitudes because attitudes have been shown to be useful in predicting human behavior. Because of this interest, researchers have developed theories to explain where attitudes come from and tools with which to measure attitudes. Some research has focused on the distinctions between strong and weak attitudes, whereas other research has examined how attitudes can be changed. Because they are such an important part of everyday life, attitudes are one of psychology's most important constructs.

1. INTRODUCTION

A college student may like her psychology course but dislike her literature course. A consumer may prefer liquid laundry detergent over the powdered variety. And a city's populace may prefer the incumbent mayor over the challenger. Liking and disliking the objects in our world is a fundamental part of human nature. Psychologists use the term "attitude" to refer to these likes and dislikes that people hold—the relatively enduring evaluations that people hold toward all sorts of things. We can hold attitudes toward people (e.g., friends, celebrities), objects (e.g., automobiles, candy bars), political or social issues (e.g., capital punishment, immigration policy), and even abstract concepts (e.g., conservatism, democracy).

For years, researchers have spent a great deal of effort in attempting to better understand attitudes. One of the reasons why the concept has attracted so much attention is that attitudes serve an important role in our daily lives. The attitudes of college students influence which courses they decide to attend, the attitudes of consumers guide their decisions about which products to purchase, and the attitudes of a city's population affect voters' decisions about which candidate to elect. It is obvious that human behavior has a variety of causes, but understanding a person's attitudes is often a reliable way in which to predict the person's behavior. But attitudes also serve other roles. Sometimes, attitudes help us to gain rewards and avoid punishments. Other times, attitudes help us to define who we are as people; people may feel so strongly about an attitude that they define themselves in terms of that attitude (e.g., people may consider themselves to be "staunch Democrats" or "hardcore pro-lifers"). In addition, some research has even shown that holding negative attitudes toward other people may make us feel better about ourselves. Thus, because the attitudes we hold play important roles in many arenas, they are indeed a fundamental part of our everyday lives.

2. THE TRIPARTITE MODEL OF ATTITUDES

Where do attitudes come from? Research on the tripartite model of attitudes suggests that attitudes can be based on

three different sources (for a visual representation of the tripartite model, see Fig. 1). One part of the tripartite model is the affective component. This affective basis of attitudes refers to the feelings, moods, and emotions that are associated with the attitude object. Consider a person who likes to exercise—a person who could be said to have a positive attitude toward exercise. This person's feelings of being "invigorated" or "distressed" whenever he or she exercises could serve as the affective basis of the attitude. Next, the behavioral basis refers to how the person has acted or would act in the future in regard to the target. If the person visits the gym to work out four times per week, this activity would serve as the behavioral basis. Finally, the cognitive basis refers to the overt thoughts or beliefs that the person has in regard to the target. If the person thinks that exercise is "healthy" and "worthwhile," such thoughts would serve as the cognitive component of the attitude.

In this example, the affective, behavioral, and cognitive components of the attitude all are positive, and this would suggest that the person will likely hold an overall positive attitude toward exercise, that is, the attitude object. However, the three components will not necessarily be consistent. A person may think that chocolate cake tastes wonderful (affective) and may eat chocolate cake often (behavioral) but may also think that chocolate cake is loaded with calories and fat (cognitive). In such cases, the overall attitude toward the object may be based more heavily on some components than on others.

It is important to note, however, that the components of attitudes can also be influenced by the attitude itself.

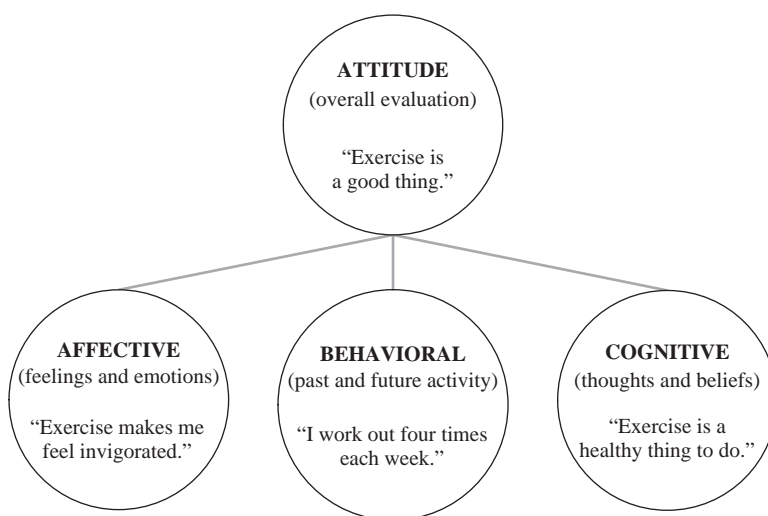

FIGURE 1 Visual representation of the tripartite model.

For example, in 1993, Eagly and Chaiken discussed how the attitude can also influence the three components. In other words, a person's affect, behaviors, and cognitions not only may guide and create the attitude but also may be driven or influenced by the attitude. As such, the three components of the tripartite model can be conceptualized in terms of both antecedents and consequences of their associated attitudes.

3. ATTITUDE MEASUREMENT

Because attitudes are so important, researchers have developed a variety of tools with which to measure them. Two of the most commonly used techniques are the Likert scale and the semantic differential. As shown in Fig. 2, participants reporting attitudes on a Likert scale are asked to what extent a variety of statements are characteristic of them. In a similar vein, as shown in Fig. 3, participants reporting attitudes on a semantic differential measure are asked to indicate how well a series of adjectives describe the attitude object. In either case, the researcher will typically provide a variety of items for the participant to complete. The scores from the items are combined to create an overall measure of the person's attitude toward the target.

There are several guidelines that researchers can follow in attempting to tap a person's attitude with as little error as possible. One guideline is to reverse code some of the items by framing them negatively as done in the third and fifth items in Figs. 2 and 3. Doing so

Oranges:					
Healthy	<u> x </u>	—	—	—	Unhealthy
Good-tasting	<u> x </u>	—	—	—	Bad-tasting
Expensive	—	—	—	<u> x </u>	Affordable
Pleasant	<u> x </u>	—	—	—	Unpleasant
Messy	—	—	<u> x </u>	—	Clean

FIGURE 3 Example of a semantic differential scale.

serves two purposes. First, it reduces the likelihood that a person will simply check the leftmost or rightmost box down the entire instrument in attempts to save time or cognitive resources. A person is less likely to do so if he or she realizes that various items are indeed reverse coded. Similarly, if a person does simply check the leftmost or rightmost box down the entire instrument, the researcher may recognize this and treat the data accordingly. Also, some research suggests that providing respondents with five to seven options from which to select provides the most valid data. Scales with fewer than five options lack the precision necessary to measure attitudes accurately, whereas scales with more than seven options tend to suffer from additional noise without benefiting from any additional precision.

Likert scales and semantic differential scales are ubiquitous. Students typically use Likert scales when evaluating their professors at the end of a semester, and departments and universities use these data in part to make personnel decisions. Companies also use such techniques to measure customers' attitudes toward the products and/or services the companies offer. By learning which aspects of the companies customers like and dislike, managers can direct resources to improve deficient areas of their companies. In short, proper attitude measurement can gauge the likes and dislikes of a person or a group of people. Behavior of a person or a group of people can then be predicted based on the attitude measure.

4. ATTITUDE STRENGTH

Although attitudes typically predict behavior, this is not always the case. Some attitudes have tremendous

Please indicate the extent to which the following statements are or are not characteristic of you:

3. Oranges are expensive.	<u> 2 </u>
4. Oranges are pleasant.	<u> 5 </u>
5. Oranges are messy.	<u> 3 </u>

FIGURE 2 Example of a Likert scale.

influence over our lives, whereas others are largely inconsequential. For example, consider two people's attitudes toward environmental protection. The two people both may think that protecting the environment is a good thing—they both may hold positive attitudes toward environmentalism—but the strength of those attitudes may be quite different. One person's attitude may lead her to vote only for pro-environment candidates, drive a fuel-efficient car, and donate money to pro-environment organizations. On the other hand, the other person's attitude may have very little impact. He will occasionally recycle and has on occasion voted for pro-environment candidates. Why would two people who hold equivalent attitudes act so differently?

The difference lies in attitude strength. In 1995, Petty and Krosnick defined attitude strength as the extent to which an attitude persists over time, resists change when exposed to persuasive information, influences cognitive processes, and influences behavior (as in the preceding example). Although two people may hold what appear to be equivalent attitudes—perhaps as observed by identical scores from Likert scales—the attitudes might not be functionally equivalent. Researchers have identified a wide variety of ways in which attitudes can become stronger, including thinking about attitudes, learning about the attitude object, or expressing attitudes repeatedly.

Attitude strength can be measured by observing the four defining features directly: how long attitudes persist over time, how well attitudes resist persuasive attempts, the extent to which attitudes predict cognitive processes, and the extent to which attitudes predict behavioral processes. But there is a wide variety of other features that are associated with these defining features. Some researchers have investigated the certainty with which attitudes are held: when a person feels certain of an attitude, that attitude is likely to show the four defining features of attitude strength. In a similar vein, researchers have shown that accessible attitudes, attitudes based on much knowledge, and attitudes on issues that people find to be personally important also tend to manifest the four defining features of attitude strength.

Therefore, many researchers measure not only attitudes but also the strength of those attitudes. For example, consider an incumbent governor's campaign manager determining in which counties to invest scarce advertising funds. Although two counties may show roughly equivalent positive attitudes toward the incumbent, such a report tells only part of the story. Based on this information alone, the manager might decide to split the advertising dollars across both counties equally. However, it is

possible that the citizens of County A may be, on average, highly certain of their positive attitudes, whereas the citizens of County B may be, on average, not certain at all. In such a case, one would expect that the positive attitudes would predict vote choice better among the residents of County A than among those of County B. Therefore, the manager would benefit more from investing advertising in the county with the weaker attitudes (as measured by certainty) than in the county with the stronger attitudes. Thus, measuring attitudes alone is only part of the story. One must also measure the strength of those attitudes to predict the behavioral and cognitive consequences of attitudes most effectively.

5. ATTITUDE CHANGE

Attitudes are thought to be relatively enduring evaluations. However, there is a wealth of research on how attitudes can and do change in the face of a persuasive communication. One of the most widely studied theories of persuasion is Petty and Cacioppo's elaboration likelihood model. In their 1986 article, these researchers posited that there are two routes through which persuasion can take place. When people have the motivation and the ability to carefully process and think about the arguments within a counterattitudinal message, they will use the central route to persuasion. When people process messages centrally, they evaluate the arguments within the message—the logical factual information that is directly relevant to the attitude object. People will then change their attitudes to the extent that their cognitive responses—the thoughts they have about the arguments while reading the message—are positive. However, when people lack either the motivation or the ability to carefully process and think about the arguments within a counterattitudinal message, they will use the peripheral route to persuasion. When people process a message peripherally, instead of elaborating on the arguments within the message, they respond to cues that exist within the message—images or heuristics not directly relevant to the message that can persuade without requiring much thought.

For example, consider an advertisement for a new car that appears in a general-interest magazine. At the top of the advertisement is the name of the car, and at the bottom of the page are three paragraphs detailing the car's resale value, horsepower, gas mileage, and safety record. In the background is an image of the car being driven across a sun-drenched beach with beautiful palm trees swaying in the background. A reader who is in the market for a new automobile may have the motivation to

use the central route to persuasion when processing the advertisement. This person will carefully read the arguments at the bottom of the page and, assuming that the reader's cognitive responses are positive, will end up with a more positive attitude toward the car. However, consider another reader who does not plan to purchase a car for years and therefore has no motivation to use the central route. This person may instead simply observe the beautiful palm trees and the beach and therefore simply create an association between the positive imagery and the car. Thus, the second person may also end up with a more positive attitude toward the car but will do so through the peripheral route instead of the central route.

If both the central and peripheral routes can lead to the same effect (e.g., attitude change), why does it matter which route to persuasion people take? Perhaps the most important reason is that attitudes resulting from central route persuasion tend to be stronger than attitudes resulting from peripheral route persuasion. That is, attitudes formed from central route processing tend to be more persistent over time, more resistant to future persuasion, and more impactful on behavior and cognitive processes than do attitudes formed from peripheral route processing. So, from this standpoint, it would seem better to engage an audience in central route processing due to the enhanced strength that would result. However, peripheral route processing may be the best option when (a) the audience does not have the ability or motivation to use the central route or (b) there are very few compelling arguments that can be presented in a message in the first place. In short, persuasion practitioners must balance the costs and benefits when determining whether to use primary central route or peripheral route persuasive appeals.

6. CONCLUSION

Attitudes, as the representations of what we like and dislike, play an important role in our daily lives. From

important decisions such as choosing one presidential candidate over another to more mundane decisions such as which flavor of ice cream to purchase, attitudes play a fundamental role in all sorts of behavioral and cognitive processes. Because they are such an important part of our lives, they have all sorts of important applications. Political scientists study attitudes in attempting to predict voters' choices, consumer psychologists study attitudes in attempting to understand consumers' purchasing decisions, and health promotion researchers study attitudes in attempting to understand the healthy and unhealthy behaviors in which people engage. In short, because they play a fundamental role in explaining behavioral and mental processes, attitudes are one of psychology's most important constructs.

GLOSSARY

attitude Persistent mental state of readiness to react to a certain object or class of objects in a certain way; learned disposition to behave in a consistent way toward a given class of objects.

disposition Relatively long-lasting emotionally rooted attitude.

ethnocentrism Tendency to divide the social world into groups with which one identifies and to which one submits (in-groups) and groups of outsiders (out-groups) to which one is hostile; characterized by glorification of the in-group and defamation of the out-group.

personality structure Unit that underlies individual ways of behaving and gives consistency to otherwise contradictory-seeming mannerisms and behavioral or attitudinal specialties.

personality syndrome Acquired pattern of personality characteristics bearing resemblance to the personality structures of others who shared similar experiences and problems and made similar adaptations.

xenophobia Abnormal fear of strangers.

Authoritarianism is a psychological concept that assumes the existence of a more or less unconscious

general orientation of individuals toward being antidemocratic, prejudiced, and fascist. The so-called “authoritarian personality” is characterized by two ambivalent tendencies: subordination to authorities and the desire to become an authority himself or herself. Authoritarianism as a personality syndrome is predominantly measured by using the so-called F-scale and later revisions of that instrument.

1. AUTHORITARIANISM: THE CONCEPT

There is no concept in the social sciences that is more closely connected to the events in Germany and throughout the world in the 1930s and 1940s than the authoritarianism concept. For decades, this approach served as the main explanation of fascism and anti-democratic thoughts or action in psychology.

1.1. Historical Background

Precursors of the authoritarianism concept can be traced back to the early and mid-1930s. At that time Marxist psychoanalyst Wilhelm Reich studied voting behavior of Germans between 1929 and 1933 to find reasons for the increase in the number of voters for the fascist NSDAP party from less than 1 million to approximately 17 million voters during that period. Within his framework of thinking, he concluded that ideologies of subordination to authority were

internalized by subordinate individuals and eventually became a stable personality structure. Some years later, researchers of the so-called Frankfurt School, such as Erich Fromm, Theodor Adorno, Max Horkheimer, and Herbert Marcuse, carried out a study on “Authority and Family” and systematized the idea of an authoritarian personality structure that is strongly determined by the societal context. In the 1940s, members of the Frankfurt School, who had to leave Germany due to their Jewish and Marxist background, engaged in a much larger research project—partly supported by the American Jewish Committee—in their American exile. Influenced by their experience of racism and inhumanity in fascist Germany, the group around Adorno set out to uncover psychological forces that promote fascist and antidemocratic attitudes and to find possible ways to fight fascist tendencies in society. They used quantitative and qualitative research methods (e.g., questionnaire-based surveys and qualitative semistructured interviews). Individuals surveyed in the U.S.-based studies were mainly students and members of the American middle class.

1.2. Concept of the Authoritarian Personality

The main thesis of Adorno was that the political, economic, and social attitudes of an individual form a coherent structure of thought, which is an expression of an underlying, hidden personality structure. In accordance with Freudian psychodynamic theory, this personality structure is assumed to have developed during early childhood. Authoritarian relations within the family, an authoritarian parental style, and a general lack of love and warmth determine it. Antidemocratic individuals often experience feelings of hatred against authorities—namely their father as the family’s bread winner—during their childhood. Because they never could express this hatred in any way against their father or their parents, they direct such feelings of hatred toward convenient scapegoats—inferiors and social minorities (e.g., immigrants/foreigners, homosexuals, and the handicapped)—later in life. Main characteristics of authoritarian personalities include a preoccupation with superiority and one-upmanship, an intolerance of behavior and objects that are different, a tendency to classify all things into black and white/right and wrong, a strict adherence to received views and prevailing social trends, and superficial respect for authority figures. Adorno and

collaborators developed the so-called F-scale (fascism scale) to measure such an antidemocratic personality structure (Fig. 1).

The scale is constructed to measure a syndrome that comprises nine dimensions or subscales not always present simultaneously:

1. Conventionalism: rigid adherence to the conventional values of the middle class
2. Authoritarian submission: an uncritical and submissive attitude toward idealized in-group authorities
3. Authoritarian aggression: a tendency to look out for and to condemn, reject, and punish people who violate conventional values
4. Anti-intracception: rejection of all inwardness, of the subjective, the imaginative, the tender-minded, and of self-criticism
5. Superstition and stereotypicality: the belief in mystical determinants of the individual’s fate, a disposition to think in rigid categories
6. Power and toughness: a preoccupation with the dimension of dominance–submission, strong–weak, leader–follower; identification with power figures; overemphasis on the conventionalized attributes of the ego; exaggerated assertion of strength and toughness
7. Destructiveness and cynicism: a generalized hostility and vilification of the human
8. Projectivity: to project unconscious emotional impulses onto the outside world and to believe that wild, evil, and dangerous things go on in the world
9. Sexuality: an exaggerated concern with sexual matters

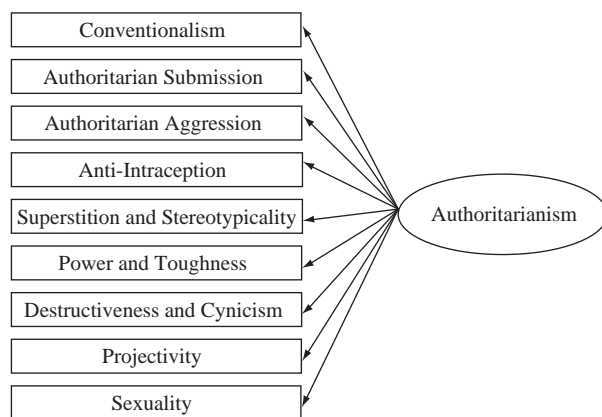

FIGURE 1 The authoritarianism construct.

1.3. Criticism

The accomplishment of Adorno and collaborators was to create an insight into the phenomenon of an authoritarian personality. However, there are methodological and empirical limitations. One of the foremost points of criticism is that the theory attempts to explain societal processes (Germany's turn to fascism) on the basis of knowledge about individual personality development. Another major criticism is that the authoritarianism concept and the F-scale questions appear highly ideological. This criticism is repudiated by a number of psychologists, including Gerda Lederer, who points out that F-scale items are related to moral and individual values, human relations, the self, family, and sexuality and are not at all ideological. At least the popular reception of the concept, however, is highly politicized. Particularly in the 1950s, it was used to characterize not only fascist but also communist movements. Yet other points of criticism are concerned with methodological problems of Adorno's empirical work, indicating, for instance, a sampling problem. Adorno generalized from a nonprobability sample that consisted of white middle-class Americans. Also, several studies showed problems with the construct validity of the F-scale, i.e., they doubt that the F-scale measures exactly what it intends to measure. Furthermore, semi-structured interviews conducted with individuals in order to gain information on their parents' educational style were criticized as being more of a memory exercise than a pool of information about parental authoritarianism. Some studies replicating Adorno's work found no evidence to support the central findings, particularly on the impact of authoritarian socialization. One study even reports evidence for a positive relationship between authoritarianism and xenophilia. However, taking into account the multitude of existing studies, one can see the existence of the phenomenon authoritarian personality as confirmed.

1.4. Contemporary Developments of the Authoritarianism Concept

The initiator of the new research stream on authoritarianism is Robert Altemeyer. His approach leaves the theoretical basis of the Freudian psychodynamic theory behind and focuses on learning processes highlighting agents of socialization, such as family and peer group, and the context of society. In his work the so-called right-wing authoritarianism is influenced by situation or environment rather than just personality

development. Altemeyer reduces the dimensions of authoritarianism to three: authoritarian submission, authoritarian aggression, and conventionalism. In the 1980s, many social scientists attempted to develop new instruments to measure the authoritarian personality. Others tried to explore by qualitative research methods the conditions that lead to such a personality structure.

1.5. Similar Contemporary Concepts

There are two contemporary competitors to the authoritarianism concept. During the past decade, Sidanius and Pratto studied what they call the social dominance orientation (SDO). SDO refers to fundamental values to accept social hierarchies. These values form a personality structure in the Freudian sense and determine so-called legitimizing myths, which are moral and intellectual justifications of individual or institutional discrimination. Whereas SDO still recognizes psychodynamic assumptions, the concept of hierarchic self-interest (HSI) is based on a paradigm of lifelong socialization in a market-oriented economy. HSI is an expression of the individual effort to perform "better than others" in a hierarchically structured society, an internalized elbow mentality, and it appears as a syndrome of values that comprises three core dimensions (success orientation, competitiveness, and individualism), as Hagan and collaborators showed in their youth studies. Since HSI is a syndrome and second-order construct (see Fig. 2 for an example from empirical research), it is not ultimately determined but can

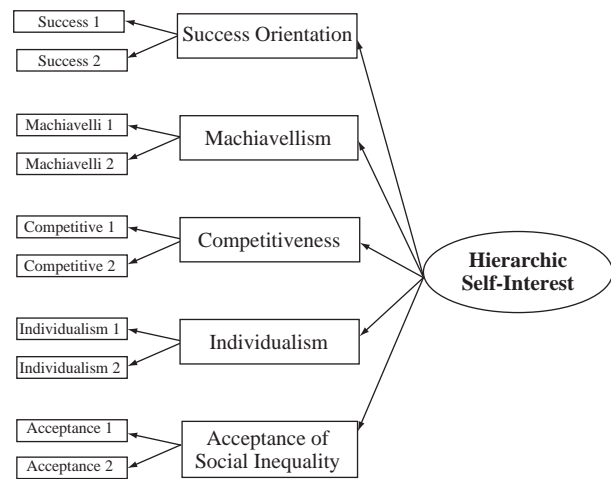

FIGURE 2 Hierarchic self-interest (structural model).

be modified by integrating other first-order factors (e.g., machiavellism and acceptance of social inequality). HSI turned out to be a stable predictor of xenophobia. This finding is in a way paradoxical because market-oriented HSI values apparently lead—under the condition of increasingly limited resources—to a tendency of ethnocentric market restriction. Roots of HSI are seen in modes of workforce participation of men and women and parental styles so that high HSI values may be interpreted as expressions of familial or socioeconomic disintegration.

2. CORRELATES OF AUTHORITARIANISM

2.1. Antecedents

2.1.1. Class and Socioeconomic Status

Empirical evidence suggests that authoritarianism is found among the lower classes to a higher degree than among the middle classes. Lipset assumes in his working class authoritarianism thesis that lower classes tend to have an authoritarian view on politics; therefore, they are more likely to support extremist movements that promise fast and simple solutions to social problems and that blame inferior scapegoats for the problems. This authoritarian view results from low education, the degree of isolation of the class, economic and psychological uncertainty, and the particular family life in lower classes. Depending on the exact kind of authoritarianism scale that was used and how class was measured, results of empirical studies support this thesis, particularly the influence of education on authoritarianism. A higher level of education seems to be the decisive characteristic of nonauthoritarian people.

2.1.2. Family Socialization

Adorno *et al.* emphasize the role of the family for the development of the authoritarian personality. Other scientists studied the mechanisms that lie behind the relationship of socialization and authoritarianism in more detail. They suggested that the transmission of authoritarian attitudes from the parents onto the children depends heavily on the strength of social and emotional ties between parents and children. Central to an authoritarian socialization are parental styles that include violence and do not recognize the

needs of the children. Authoritarian families usually are ruled by the father and do not allow children to participate in family decisions.

2.1.3. Cross-Cultural Differences

In dealing with the concept of authoritarianism, it must be discussed whether this concept applies only to the Western world or whether it is universal. Based on data from more than 100 countries, Meehan shows that there is a strong relationship between culture, attitudes, and politics. State authoritarianism is highly related to authoritarian attitudes among the citizens. These attitudes seem to result from a culture that is based on hierarchies and a traditional family structure. Comparisons of authoritarianism among adolescents in East and West Germany after the fall of the Berlin Wall show very clearly that different socialization cultures lead to different degrees of authoritarianism: East German adolescents agreed with authoritarian statements more than West Germans did. However, scales to measure authoritarianism cannot be used throughout the world in the same way and the same composition. Words and contexts are interpreted differently in different cultures. Studies in Japan, for example, showed that authoritarian structures and authoritarian attitudes do exist but cannot be measured in terms of American authoritarianism instruments.

2.2. Consequences

The best studied and most powerful relation is the one obtained for authoritarianism and ethnocentrism. Ethnocentrism is an attitude characterized by the glorification of one's own group (in-group) and the defamation and discrimination of other groups (out-group). Xenophobia, racism, and nationalism are other orientations similar to ethnocentrism. An authoritarian personality tends to be more ethnocentric. In certain circumstances (situational factors), the just mentioned attitudes can lead to discrimination, violence, and hate crimes.

Authoritarianism is also connected to other attitudes, namely sexism, anti-Semitism, cognitive rigidity (dogmatism), and political and economic conservatism. Authoritarian personalities tend to devalue women, homosexuals, and Jews. They strongly support the market economic system and back conservative political movements. Authoritarianism also may explain oppression, chauvinism, and negative put-downs on

the individual level and the level of society. Many of the empirical findings on consequences of authoritarianism may, however, rightly be accused of bearing an element of tautology because almost all consequences addressed could also be seen as elements of the authoritarian syndrome per se.

3. TREATMENT APPROACHES

From knowledge about explanatory factors of authoritarianism, particularly socialization, a list of treatment measures can be derived. The founders of the Frankfurt School suggested enlightenment and an education fostering responsibility. That means making the mechanisms of society transparent to a broad audience. The psychologist Kurt Lewin, who conducted several experiments on group conflicts in small groups, pointed out that democratically acting group leaders are necessary to prevent authoritarianism. Group leaders as well as all other group members must be enabled to play their role in the democratic process. Authoritarian leadership styles must be replaced by consultative and participative leadership styles. To support this process of democratization, the democratic leader has to leave space for self-determination with clearly defined and reasoned borders to the group members rather than predetermining a more or less restricted space with rigid borders. Democratic skills cannot be passed on in a simple way; they must be learned and interactively developed in every generation, in all institutions of society, including the family, the school, and the workplace. Whereas a Freudian approach to authoritarianism would suggest that there is no treatment for authoritarian personalities in adulthood, from the perspective of lifelong socialization a cure seems possible. To push back authoritarian tendencies in daily life settings, people's integration into groups (working groups, peer groups, and families) must be supported. People must be given participation opportunities in group decisions; rules, actions, and decisions shall be explained to them in a detailed and reasoned way; they shall be encouraged to look at themselves and others from different perspectives; and every kind of rigid discipline and physical or

mental violence must be absent in dealing with people who tend to be authoritarian.

GLOSSARY

circumscribed interests Areas of profound interest pursued with great interest and intensity; the usual focus is on the acquisition of facts. These interests come to dominate the child, and the family's, life and interfere with acquisition of skills in other areas.

echolalia Repetition of words/phrases/sentences; may be immediate (i.e., occurring in the immediate context) or delayed (repetition of words used in the past).

nonverbal learning disability A profile of strengths and weaknesses on neuropsychological testing with detrimental effects on social skills.

savant skills Areas of unusual ability typically seen in people who otherwise exhibit mental retardation/intellectual disability.

stereotypies Repetitive motor mannerisms typically involving the whole body (body rocking) or extremities (hand flapping and toe walking).

Autism and Asperger's syndrome are disorders characterized by marked disturbances in the basic

aspects of social development and are associated with unusual behaviors. In autism, marked disturbances in language and communication are present and the disturbances in behavior can take the form of unusual purposeless mannerisms (stereotypies), behavioral rigidity and compulsive adherence to rituals and routines, unusual preoccupations, or preoccupation with nonfunctional aspects of materials. In Asperger's syndrome, language skills are, in general, preserved, although social use of language may be impaired; typically unusual, all encompassing, circumscribed interests are present. The relationship of these two conditions is the topic of some debate. There is general agreement on the important role of genetic and other neurobiological factors in causing these conditions. Treatment, particularly if delivered early, can significantly improve outcome.

1. DEFINITION AND DIAGNOSIS

Autism was first described by Leo Kanner in 1943 when he described a group of children who he believed were born without the usual predisposition to be social. Kanner's description has, in general, proven remarkably accurate. He emphasized two essential features for autism: (i) The autism involved what appeared to be self-absorption, and (ii) the insistence on sameness involved the unusual preoccupation with objects and difficulties in dealing with change. Kanner described many of the other clinical features often observed in autism

(e.g., unusual “splinter” skills on psychological testing, profound problems in communication, and difficulties with echolalia and language use for those children who did speak). In 1944, Hans Asperger, unfamiliar with Kanner’s paper, published his description of a small group of boys with what he termed autistic personality disorder or, as it was more commonly translated, autistic psychopathy. Like Kanner, he emphasized the marked social difficulties in these cases; unlike Kanner, he mentioned that in his cases words seemed to serve as the “lifeline” for the child. Asperger also noted the presence of strong circumscribed interests that dominated the child’s life (and often the family life as well) to the point that these interfered with acquiring other skills. His paper also mentioned some other point of divergence from Kanner’s description; for example, Asperger believed that the disorder tended to run in families (particularly in fathers) and was associated with motor clumsiness.

In the years following Kanner’s description (which was much more widely known in the English-speaking world) there was much controversy about the possible continuity of autism with schizophrenia and other forms of psychosis; the etiology of the condition was also controversial, with some clinicians implicating deviant experience. However, as data accumulated it became clear that autism was not an early form of schizophrenia and various lines of evidence strongly implicated neurobiological factors in pathogenesis. Asperger’s work was largely ignored in the English-speaking world until a paper by Lorna Wing (1981) introduced his concept and stimulated much research.

Autism was first officially recognized in 1980 as diagnosis apart from childhood schizophrenia. Asperger’s disorder was only recognized in 1994, and its definition remains the topic of debate.

2. EPIDEMIOLOGY

More than 30 studies have been conducted on the epidemiology of autism, with most focusing on more stringently diagnosed autism. A prevalence rate of approximately 1 case per 1000 children appears reasonable, with lower rates observed for Asperger’s disorder (approximately 2.5/10,000 children). Recent studies have generally reported higher rates than older ones, but changes in diagnosis, an increased awareness of the disorder, and other factors complicate our understanding of this increase.

Although Kanner’s initial report suggested high rates of professional and educational achievement in parents, it appears that this was due to a bias in cases referred to him; children with autism and Asperger’s come from parents of all levels of educational and occupational achievement and from all races and cultures. Studies consistently report higher rates in boys than in girls for both conditions (3.5 or 4 boys for every girl); girls with autism are more likely to have significant mental retardation, raising the possibility that males have a lower threshold for expressing the disorder.

Autism is associated with a range of medical conditions. Most strikingly, perhaps 20% of children with autism will develop seizure disorder (epilepsy). Although autism has been associated with a range of other medical conditions, the two strongest associations have been for Fragile X syndrome and tuberous sclerosis—two strongly genetic disorders.

3. BIOLOGICAL MECHANISMS

Various lines of evidence suggest the importance of neurobiological factors in causing autism and Asperger’s disorder. For example, children with autism exhibited an increased rate of persistent primitive reflexes, delayed development of hand dominance, EEG abnormalities, and seizure disorder. During the past few decades, there has also been an increased appreciation of the role of genetic factors in both conditions. This evidence includes the observation of much higher rates of concordance for autism in identical as opposed to (same-sex) fraternal twins, an approximately 50-fold increase in the disorder among siblings, and an increased risk to siblings of a range of other developmental problems. Although the data for Asperger’s disorder are more limited, there is evidence for significant rates of this condition in family members as well.

Studies of neurochemistry have not found specific biological markers, although it is clear that as a group, individuals with autism exhibited elevated levels of the neurotransmitter serotonin. Neuroimaging and neuropathological findings have included a general increase in brain size and abnormalities in the cerebellum and in structures such as the amygdala.

4. PSYCHOLOGICAL PROCESSES

In his initial report of infantile autism, Kanner mentioned that children with autism likely had good

cognitive potential given their ability to perform well on some parts of intelligence tests. Whereas subsequent research has confirmed the observation that there are some areas of strength in autism, it also has made it clear that approximately 70% of children with autism do exhibit mental retardation. Areas of strength on psychological testing typically include nonverbal skills, whereas verbal skills are generally areas of weakness. In Asperger's disorder, a reverse profile (often of the type termed nonverbal learning disability) is often identified.

People with autism do, at times, exhibit unusual skills ("islets of special abilities") that stand in marked contrast to overall intellectual level. For example, there might be unusual facility in decoding letters and numbers (hyperlexia) or feats of memory, calendar calculation, drawing, or musical abilities. Such individuals are sometimes termed autistic savants. In Asperger's disorder, special interests often take the form of considerable knowledge about some circumscribed area of interest (e.g., clocks, time, dinosaurs, the operas of Wagner, and snakes).

Various psychological theories have been proposed to account for the unusual constellation of abilities in autism. One theory focuses on what is termed a lack of central coherence with a resulting difficulty in integrating information. Another theory posits deficits in executive function (i.e., in organizational and forward planning skills). Yet another theory suggests that individuals with autism lack a theory of mind (i.e., have difficulties in putting themselves in another person's place). This theory has been highly productive for research but fails to account for the significant social disability of high functioning individuals who usually can perform theory of mind tasks with ease; a lack of developmental orientation is also problematic (i.e., children with autism exhibit social deficits in areas that typically would precede emergence of theory of mind).

Recent work has highlighted the importance of studying specific social processes in autism, for example, in the ways individuals with autism view social scenes or look at faces.

5. TREATMENT

Educational and behavioral interventions are the mainstay of treatment for autism and Asperger's disorder. Goals of treatment include minimizing disruptive behaviors, promoting learning and "learning to learn" skills, and increasing social, communication, and self-help skills. Generally, a fairly intensive and highly structured

program is needed, particularly for younger children with autism. Changes in syndrome expression with increased age and development require periodic updates of treatment goals. Given the tendency toward rigidity and perseveration, generalization of skills is an important aspect of intervention. Augmentative communication systems may be helpful. For children with Asperger's disorder, better verbal skills sometimes mask the extent of problems in other areas. Consideration of the child's pattern of strengths and weaknesses should be included in educational planning. Most educational programs for children with autism utilize behavioral management techniques to some extent. Psychodynamic, play therapies have a limited role in treatment; for verbal individuals, structured and focused psychotherapy/counseling may be helpful.

Although no drug treatment has proven curative, important target symptoms, such as self-injury, aggression, and overactivity, can be significantly improved. For individuals with autism, the major tranquilizers (particularly the atypical neuroleptics) have been used. For higher functioning individuals with autism and Asperger's, antidepressants and selective serotonin reuptake inhibitors may be of some benefit.

6. COURSE AND PROGNOSIS

Earlier detection and intervention has significantly improved the outcome in autism. Prior to provision of educational services, relatively few individuals with autism were able to attain personal self-sufficiency and independence as adults. However, longitudinal data suggest that with provision of early diagnosis and intervention perhaps 15% of individuals with autism are able to be relatively independent and self-sufficient as adults, with another 20% of cases able to function in the community with some support. Positive prognostic factors include overall intelligence and communication skills (particularly the presence of communicative speech by age 5). Although data are relatively more limited, individuals with Asperger's disorder appear to have more positive outcomes (as a group, they also have higher IQs and good verbal skills). A major medical complication is the development of seizures in perhaps 20% of individuals with autism; the risk for developing seizures is increased through childhood and adolescence. Depressive and anxiety symptoms may appear in higher functioning adolescents, who may become more aware of their areas of disability, become painfully aware of their inability to form friendships despite

a desire to do so, and begin to suffer the cumulative effect of years of failed contact with others and teasing.

GLOSSARY

- aviation psychology** Scientific discipline focused on understanding and improving human performance in aviation.
- crew resource management** A collection of procedures, techniques, and communications strategies that fosters the use of all available resources (including people and available technology) to provide optimal levels of safety and mitigate the consequences of error.
- cultural factors** Procedural, communications, equipment, and design-related issues that are unique to an organization or a society.
- electroencephalogram (EEG)** Measurement of aggregate brain electrical activity recorded at the scalp.
- FAA** Abbreviation for Federal Aviation Administration.
- NASA** Abbreviation for National Aeronautics and Space Administration.
- National Airspace System** The complex system of people, equipment, and procedures that guides how aircraft are operated in the United States.
- NTSB** Abbreviation for National Transportation Safety Board.
- situation awareness** How people keep track of critical features in their environment, such as their position in space and time, and the current and future status of systems.

Aviation psychology is a simple name for a deceptively broad multidisciplinary applied domain. Its goal is plain: understanding and improving human performance in aviation. As a formal discipline, it draws on other established areas of psychology and engineering. For example, within the discipline of psychology, aspects of applied, experimental, social, clinical, industrial, organizational, and engineering specializations have been incorporated into aviation psychology.

1. HISTORY

The origins of aviation psychology are nearly as old as powered flight. Whether it played a role in the selection of the Wright *Flyer's* first pilot on the sands of Kitty Hawk, North Carolina, a century ago is debatable. Lindbergh's self-account of his 33-hour transatlantic crossing in the *Spirit of St. Louis* in 1927 is among the earliest accounts of the effects of sustained wakefulness on pilot performance. However, aviation psychology is generally described as having its formal beginning coincident with the increased military use of aviation in the two world wars. During those times, there was a fundamental need to rapidly select and adequately train the pilots required to fly the fighters, bombers, and transport airplanes for the war efforts. As aviation became increasingly important to worldwide commerce, and with the advent of the space program, aviation psychology as a discipline expanded during the postwar years. This expansion paralleled technological

advances that increased the complexity of some facets of aviation and the continuing need to understand human performance capabilities and limitations in these domains. Several detailed recent reviews of the domain exist that expand on the history and basic applications in this area.

2. SCOPE AND EXTENT OF THE DOMAIN

Enhancing pilot performance is a major focus of aviation psychology; however, its reach in aviation extends far beyond pilots. For example, early efforts of aviation psychologists included enhancing the training of aircraft gunners and selection of aircraft mechanics. Aviation psychology focuses on understanding the operator's basic limitations and needs. Basic needs for optimal performance typically include adequate selection and training, sufficient real-time information, appropriate human-machine interfaces and equipment, and compensated environmental conditions. The scope of aviation psychology has generally kept pace with the rapid expansion of aviation itself since the advent of powered flight.

The National Airspace System is described on the Federal Aviation Administration's (FAA) Web site as "a complex collection of systems, procedures, facilities, aircraft, and . . . people [that] represents the overall environment for the safe operation of aircraft." With its focus on the people and equipment involved in this complex system, aviation psychology is broad in scope but singular in purpose: to understand and promote optimal human performance. Aviation psychologists have contributed to our knowledge of human performance in both civilian and military applications. They have examined and sought ways in which to improve the performance of pilots, flight attendants, mechanics, air traffic controllers, and ground support personnel. It is clear that aviation psychologists now also have an important contribution to make in the study of human performance factors in civil aviation security, for example, in selecting and training security screening personnel and in identifying methods to augment and support human search capabilities during repetitive inspection tasks.

A peer-reviewed journal, the *International Journal of Aviation Psychology*, serves as a central focus for the dissemination of research in this area, and a survey of its contents can quickly provide a comprehensive

overview of this area. Other professional journals, such as *Human Factors* (published by the Human Factors and Ergonomics Society) and *Aviation, Space, and Environmental Medicine* (published by the Aerospace Medical Association), also contain work by aviation psychologists. In the latter case, there are some who may be more appropriately titled "aerospace psychologists" given that their focus involves understanding human performance in space-related applications such as low-g environments and crew coordination issues during long-duration space flights.

3. SOURCES OF BASIC PRINCIPLES AND THEORETICAL APPROACHES

Aviation psychology draws on basic principles, findings, and tenets from other specialized domains of psychology, sociology, physiology, and human factors. For example, knowledge of sensory processes, memory limitations, psychomotor skills, and cognitive functioning translates directly to the aviation environment and can be used to optimize the design of instruments, procedures, and warning devices. Other areas of experimental and cognitive psychology that provide insight into attention and decision making also contribute to aviation psychology in areas such as evaluating instrument scan behavior, understanding visual detection capabilities for pilots (or inspectors detecting defects in manufacturing/maintenance inspection processes), and aeronautical decision-making skills. Finally, knowledge of basic human performance capabilities under exposure to noise, vibration, motion, and altitude facilitates aviation psychologists' understanding of human capabilities and limitations.

Methods derived from industrial, organizational, and educational psychology can aid in the selection and training of aviation personnel. Components from cognitive psychology, social psychology, and sociology can contribute to the study of crew coordination and cultural factors in aviation. For example, cultural factors in aviation are not just associated with design stereotypes for the movement of controls and switches. They also include crew coordination issues that can vary across cultures, include variations in the acceptance of automated technology, and can even affect the coordination of operating practices when airlines merge.

Physiological psychology has contributed to the measurement of workload and assessment of fatigue in aviation environments. Although few operational

examples of the former exist, the use of physiological measures to infer the state of operators has taken place in basic and applied aviation research environments. These include traditional measures such as heart rate and electroencephalogram (EEG). In addition, eye movements have been used to study operator scan patterns for complex displays or while performing aviation-related tasks.

There are few, if any, theoretical approaches unique to aviation psychology. Instead, basic theories generated elsewhere are applicable to basic and applied questions in aviation. Some theoretical or worldview approaches are especially salient as applied to the aviation environment. For example, information processing theories that outline and predict how operators process information from the environment and manage conditions of increasing workload are useful in evaluating aviation work environments to ensure that workload and capabilities are not exceeded. Also, during recent years, significant effort has been focused on understanding and establishing theoretical and methodological approaches to the study of situation awareness, that is, how operators learn about and keep track of critical features in their environment, such as their position in space and time, and the current and future status of systems. Theoretical models for the acquisition and maintenance of situation awareness by personnel involved in aviation tasks have been developed, although acceptance of their utility is not universal.

Aviation psychology presents a unique application and research environment. However, with few exceptions (e.g., operations in extreme environments, operations under conditions of *g* loading, specific examination of flight- or domain-specific tasks such as the visual processes involved in landing), knowledge, methods, and concepts derived elsewhere in psychology and engineering can readily translate to applications and research questions in this area. For additional information on the basic tenets, principles, and theoretical approaches used by aviation psychologists, there exist recent compendiums of work outlining these issues from both historical and contemporary perspectives.

4. APPLICATIONS AND ONGOING ISSUES

Aviation psychology is an incremental and evolving discipline that is generally responsive to the dynamic challenges it faces as aviation itself continues to evolve.

Following are some of the areas of inquiry in which aviation psychologists are engaged.

4.1. Error Management

Studies and training methods for crew coordination have evolved from attending static personality and “charm school” sessions to delivering strategies for the prompt identification and timely recovery from human errors that are inevitable. Work continues on determining optimal methods for enhancing crew coordination and error management, on developing instructional methods for distributing these error management concepts through technical training, and on reinforcing during routine operations through robust procedures.

4.2. Decision Making and High-Stress Situations

Research continues on understanding how personnel in the aviation environment arrive at decisions under conditions of stress, often having limited information. Some of these efforts are targeted to developing methods to enhance pilot decision making and judgment. Other efforts examine factors that affect human performance in stressful situations such as passengers evacuating an airplane under an emergency situation.

4.3. Fatigue Countermeasures

Substantial work in the area of fatigue has been performed by aviation psychologists at the National Aeronautical and Space Administration (NASA) Ames Research Center, and work continues to better understand the effects of fatigue on aviation operations. Research conducted by the FAA has looked at shiftwork and fatigue in air traffic control operations. Aviation psychologists working for the military have examined scheduling practices and pharmacological countermeasures to mitigate the effects of fatigue in military aviation.

4.4. Automation and Human–Machine Interfaces

The study of human interaction with automation remains a dominant focus for many aviation psychologists. The use of automated aids is increasing in both air carrier and general aviation, and this trend is expected to continue with the refinement of more complex aircraft

system status displays, horizontal and vertical navigation displays, airport situation awareness displays, highway-in-the-sky flight path aids, and the like. Automated aids are also increasingly being applied to other aviation operations such as air traffic control and maintenance.

4.5. New Training Technologies

Simulators have found widespread use in the training of air carrier flight crews. Methods for enhancing the training environment using these tools continue to be evaluated. The use of computer-based training and part task simulators is also spreading to other areas of aviation, including general aviation and maintenance technicians. Ensuring that the transfer of training effects is positive and predictable will continue to be a focus for aviation psychologists.

4.6. Accident Reduction

Methods to study human error in accidents continue to be examined to identify broad causal factors common to multiple accidents for which targeted intervention strategies could be applied. Strategies for this work include the use of surveys, the use of simulator studies, and review of accident data.

4.7. Maintenance and Other Aviation Applications

Some areas that have received relatively less attention in the past, as compared with flight deck and pilot issues, are receiving increasing attention by aviation psychologists. These include maintenance and ground support personnel, and recent accidents have shown that human error in these areas can also yield catastrophic outcomes. Strategies for increasing performance on the flight deck, such as crew resource management, are being translated to optimize performance by operators in these areas. Similarly, additional focus is being placed on the information needs of maintenance personnel to complement work done previously to examine environmental and ergonomics needs.

5. EDUCATION AND TRAINING

Because of the multidisciplinary characteristics of aviation psychology, there is no single training or education path to become an aviation psychologist (although

for decades some institutions, such as the University of Illinois and Ohio State University, have produced professionals who made significant contributions in this area). Like the applied domain of human factors, successful performance in aviation psychology requires a professional who has developed a strong grounding in basic psychological principles, experimental methodology, and basic familiarity with engineering concepts. Creativity and the ability to adapt are essential traits that facilitate interaction with experts from the many facets of aviation, and formulation of strategies to cope with the short-cycle time periods (from question to required answer) characteristic of many issues aviation psychologists may be called on to study.

Equally important to becoming an effective aviation psychologist is a strong interest in, some observational experience in, or (optimally) direct experience in an operational facet of aviation (e.g., holding a pilot certificate). This experience will also help to facilitate communication with subject matter experts and provide the aviation psychologist with practical knowledge that will augment his or her professional training in a chosen area of psychology or in an allied discipline. Aviation has many regulatory and procedural boundaries that have been established by regulators, manufacturers, companies, and labor groups. These areas, whether they involve hours of service regulations for pilots or the maintenance and inspection routine, should be mastered to the extent possible for an aviation psychologist to contribute optimally.

6. OCCUPATIONS AND EMPLOYMENT

Aviation psychologists can be found employed by organizations in and on the periphery of the aerospace industry. For example, they are employed by agencies such as NASA, the FAA, and the National Transportation Safety Board (NTSB) in the federal government and are involved in basic research, certification, design, oversight, and safety investigations. In addition, most branches of the U.S. Department of Defense (DoD) have similar areas in which aviation psychologists are employed to facilitate military aviation. In the private sector, aviation psychologists are employed by manufacturers, airlines, and private research institutions. Academia is another area where aviation psychologists can be found working on basic and applied research questions, often funded by DoD, NASA, and/or FAA grants and projects.

- aviation psychology** Scientific discipline focused on understanding and improving human performance in aviation.
- crew resource management** A collection of procedures, techniques, and communications strategies that fosters the use of all available resources (including people and available technology) to provide optimal levels of safety and mitigate the consequences of error.
- cultural factors** Procedural, communications, equipment, and design-related issues that are unique to an organization or a society.
- electroencephalogram (EEG)** Measurement of aggregate brain electrical activity recorded at the scalp.
- FAA** Abbreviation for Federal Aviation Administration.
- NASA** Abbreviation for National Aeronautics and Space Administration.
- National Airspace System** The complex system of people, equipment, and procedures that guides how aircraft are operated in the United States.
- NTSB** Abbreviation for National Transportation Safety Board.
- situation awareness** How people keep track of critical features in their environment, such as their position in space and time, and the current and future status of systems.

Aviation psychology is a simple name for a deceptively broad multidisciplinary applied domain. Its goal is plain: understanding and improving human performance in aviation. As a formal discipline, it draws on other established areas of psychology and engineering. For example, within the discipline of psychology, aspects of applied, experimental, social, clinical, industrial, organizational, and engineering specializations have been incorporated into aviation psychology.

1. HISTORY

The origins of aviation psychology are nearly as old as powered flight. Whether it played a role in the selection of the Wright *Flyer's* first pilot on the sands of Kitty Hawk, North Carolina, a century ago is debatable. Lindbergh's self-account of his 33-hour transatlantic crossing in the *Spirit of St. Louis* in 1927 is among the earliest accounts of the effects of sustained wakefulness on pilot performance. However, aviation psychology is generally described as having its formal beginning coincident with the increased military use of aviation in the two world wars. During those times, there was a fundamental need to rapidly select and adequately train the pilots required to fly the fighters, bombers, and transport airplanes for the war efforts. As aviation became increasingly important to worldwide commerce, and with the advent of the space program, aviation psychology as a discipline expanded during the postwar years. This expansion paralleled technological

advances that increased the complexity of some facets of aviation and the continuing need to understand human performance capabilities and limitations in these domains. Several detailed recent reviews of the domain exist that expand on the history and basic applications in this area.

2. SCOPE AND EXTENT OF THE DOMAIN

Enhancing pilot performance is a major focus of aviation psychology; however, its reach in aviation extends far beyond pilots. For example, early efforts of aviation psychologists included enhancing the training of aircraft gunners and selection of aircraft mechanics. Aviation psychology focuses on understanding the operator's basic limitations and needs. Basic needs for optimal performance typically include adequate selection and training, sufficient real-time information, appropriate human-machine interfaces and equipment, and compensated environmental conditions. The scope of aviation psychology has generally kept pace with the rapid expansion of aviation itself since the advent of powered flight.

The National Airspace System is described on the Federal Aviation Administration's (FAA) Web site as "a complex collection of systems, procedures, facilities, aircraft, and . . . people [that] represents the overall environment for the safe operation of aircraft." With its focus on the people and equipment involved in this complex system, aviation psychology is broad in scope but singular in purpose: to understand and promote optimal human performance. Aviation psychologists have contributed to our knowledge of human performance in both civilian and military applications. They have examined and sought ways in which to improve the performance of pilots, flight attendants, mechanics, air traffic controllers, and ground support personnel. It is clear that aviation psychologists now also have an important contribution to make in the study of human performance factors in civil aviation security, for example, in selecting and training security screening personnel and in identifying methods to augment and support human search capabilities during repetitive inspection tasks.

A peer-reviewed journal, the *International Journal of Aviation Psychology*, serves as a central focus for the dissemination of research in this area, and a survey of its contents can quickly provide a comprehensive

overview of this area. Other professional journals, such as *Human Factors* (published by the Human Factors and Ergonomics Society) and *Aviation, Space, and Environmental Medicine* (published by the Aerospace Medical Association), also contain work by aviation psychologists. In the latter case, there are some who may be more appropriately titled "aerospace psychologists" given that their focus involves understanding human performance in space-related applications such as low-g environments and crew coordination issues during long-duration space flights.

3. SOURCES OF BASIC PRINCIPLES AND THEORETICAL APPROACHES

Aviation psychology draws on basic principles, findings, and tenets from other specialized domains of psychology, sociology, physiology, and human factors. For example, knowledge of sensory processes, memory limitations, psychomotor skills, and cognitive functioning translates directly to the aviation environment and can be used to optimize the design of instruments, procedures, and warning devices. Other areas of experimental and cognitive psychology that provide insight into attention and decision making also contribute to aviation psychology in areas such as evaluating instrument scan behavior, understanding visual detection capabilities for pilots (or inspectors detecting defects in manufacturing/maintenance inspection processes), and aeronautical decision-making skills. Finally, knowledge of basic human performance capabilities under exposure to noise, vibration, motion, and altitude facilitates aviation psychologists' understanding of human capabilities and limitations.

Methods derived from industrial, organizational, and educational psychology can aid in the selection and training of aviation personnel. Components from cognitive psychology, social psychology, and sociology can contribute to the study of crew coordination and cultural factors in aviation. For example, cultural factors in aviation are not just associated with design stereotypes for the movement of controls and switches. They also include crew coordination issues that can vary across cultures, include variations in the acceptance of automated technology, and can even affect the coordination of operating practices when airlines merge.

Physiological psychology has contributed to the measurement of workload and assessment of fatigue in aviation environments. Although few operational

examples of the former exist, the use of physiological measures to infer the state of operators has taken place in basic and applied aviation research environments. These include traditional measures such as heart rate and electroencephalogram (EEG). In addition, eye movements have been used to study operator scan patterns for complex displays or while performing aviation-related tasks.

There are few, if any, theoretical approaches unique to aviation psychology. Instead, basic theories generated elsewhere are applicable to basic and applied questions in aviation. Some theoretical or worldview approaches are especially salient as applied to the aviation environment. For example, information processing theories that outline and predict how operators process information from the environment and manage conditions of increasing workload are useful in evaluating aviation work environments to ensure that workload and capabilities are not exceeded. Also, during recent years, significant effort has been focused on understanding and establishing theoretical and methodological approaches to the study of situation awareness, that is, how operators learn about and keep track of critical features in their environment, such as their position in space and time, and the current and future status of systems. Theoretical models for the acquisition and maintenance of situation awareness by personnel involved in aviation tasks have been developed, although acceptance of their utility is not universal.

Aviation psychology presents a unique application and research environment. However, with few exceptions (e.g., operations in extreme environments, operations under conditions of *g* loading, specific examination of flight- or domain-specific tasks such as the visual processes involved in landing), knowledge, methods, and concepts derived elsewhere in psychology and engineering can readily translate to applications and research questions in this area. For additional information on the basic tenets, principles, and theoretical approaches used by aviation psychologists, there exist recent compendiums of work outlining these issues from both historical and contemporary perspectives.

4. APPLICATIONS AND ONGOING ISSUES

Aviation psychology is an incremental and evolving discipline that is generally responsive to the dynamic challenges it faces as aviation itself continues to evolve.

Following are some of the areas of inquiry in which aviation psychologists are engaged.

4.1. Error Management

Studies and training methods for crew coordination have evolved from attending static personality and “charm school” sessions to delivering strategies for the prompt identification and timely recovery from human errors that are inevitable. Work continues on determining optimal methods for enhancing crew coordination and error management, on developing instructional methods for distributing these error management concepts through technical training, and on reinforcing during routine operations through robust procedures.

4.2. Decision Making and High-Stress Situations

Research continues on understanding how personnel in the aviation environment arrive at decisions under conditions of stress, often having limited information. Some of these efforts are targeted to developing methods to enhance pilot decision making and judgment. Other efforts examine factors that affect human performance in stressful situations such as passengers evacuating an airplane under an emergency situation.

4.3. Fatigue Countermeasures

Substantial work in the area of fatigue has been performed by aviation psychologists at the National Aeronautical and Space Administration (NASA) Ames Research Center, and work continues to better understand the effects of fatigue on aviation operations. Research conducted by the FAA has looked at shiftwork and fatigue in air traffic control operations. Aviation psychologists working for the military have examined scheduling practices and pharmacological countermeasures to mitigate the effects of fatigue in military aviation.

4.4. Automation and Human–Machine Interfaces

The study of human interaction with automation remains a dominant focus for many aviation psychologists. The use of automated aids is increasing in both air carrier and general aviation, and this trend is expected to continue with the refinement of more complex aircraft

system status displays, horizontal and vertical navigation displays, airport situation awareness displays, highway-in-the-sky flight path aids, and the like. Automated aids are also increasingly being applied to other aviation operations such as air traffic control and maintenance.

4.5. New Training Technologies

Simulators have found widespread use in the training of air carrier flight crews. Methods for enhancing the training environment using these tools continue to be evaluated. The use of computer-based training and part task simulators is also spreading to other areas of aviation, including general aviation and maintenance technicians. Ensuring that the transfer of training effects is positive and predictable will continue to be a focus for aviation psychologists.

4.6. Accident Reduction

Methods to study human error in accidents continue to be examined to identify broad causal factors common to multiple accidents for which targeted intervention strategies could be applied. Strategies for this work include the use of surveys, the use of simulator studies, and review of accident data.

4.7. Maintenance and Other Aviation Applications

Some areas that have received relatively less attention in the past, as compared with flight deck and pilot issues, are receiving increasing attention by aviation psychologists. These include maintenance and ground support personnel, and recent accidents have shown that human error in these areas can also yield catastrophic outcomes. Strategies for increasing performance on the flight deck, such as crew resource management, are being translated to optimize performance by operators in these areas. Similarly, additional focus is being placed on the information needs of maintenance personnel to complement work done previously to examine environmental and ergonomics needs.

5. EDUCATION AND TRAINING

Because of the multidisciplinary characteristics of aviation psychology, there is no single training or education path to become an aviation psychologist (although

for decades some institutions, such as the University of Illinois and Ohio State University, have produced professionals who made significant contributions in this area). Like the applied domain of human factors, successful performance in aviation psychology requires a professional who has developed a strong grounding in basic psychological principles, experimental methodology, and basic familiarity with engineering concepts. Creativity and the ability to adapt are essential traits that facilitate interaction with experts from the many facets of aviation, and formulation of strategies to cope with the short-cycle time periods (from question to required answer) characteristic of many issues aviation psychologists may be called on to study.

Equally important to becoming an effective aviation psychologist is a strong interest in, some observational experience in, or (optimally) direct experience in an operational facet of aviation (e.g., holding a pilot certificate). This experience will also help to facilitate communication with subject matter experts and provide the aviation psychologist with practical knowledge that will augment his or her professional training in a chosen area of psychology or in an allied discipline. Aviation has many regulatory and procedural boundaries that have been established by regulators, manufacturers, companies, and labor groups. These areas, whether they involve hours of service regulations for pilots or the maintenance and inspection routine, should be mastered to the extent possible for an aviation psychologist to contribute optimally.

6. OCCUPATIONS AND EMPLOYMENT

Aviation psychologists can be found employed by organizations in and on the periphery of the aerospace industry. For example, they are employed by agencies such as NASA, the FAA, and the National Transportation Safety Board (NTSB) in the federal government and are involved in basic research, certification, design, oversight, and safety investigations. In addition, most branches of the U.S. Department of Defense (DoD) have similar areas in which aviation psychologists are employed to facilitate military aviation. In the private sector, aviation psychologists are employed by manufacturers, airlines, and private research institutions. Academia is another area where aviation psychologists can be found working on basic and applied research questions, often funded by DoD, NASA, and/or FAA grants and projects.

GLOSSARY

analogue assessment An observational measure of the child's behavior(s) of interest elicited through the use of simulated conditions to predict behavior in real-life settings.

direct observation Observation and recording of problem behaviors in the context in which they occur.

effect size A calculation of preintervention and postintervention scores as well as the standard deviation or standard error of the instrument to produce an index of the amount of change assessed for the individual or group.

error variance The contribution of various sources of error (e.g., biases, drift) to a set of data.

functional behavioral assessment (FBA) Assessment of environmental conditions that are correlated with the occurrence and nonoccurrence of behaviors for the purpose of identifying those things that serve to initiate and maintain behavior.

generalization The degree to which learned skills or changes in behavior patterns are displayed in untrained situations.

informed consent The legal and ethical requirement to inform children and their legal guardians regarding the pur-

pose of assessment procedures and to receive appropriate agreement to these procedures prior to their initiation.

interviews Direct questioning of the child himself or herself, or of the child's parents, teachers, and/or other caregivers, for the purpose of assessing strengths, weaknesses, and patterns of behavior; interviews can be highly structured (following a strict line of questioning), unstructured (based entirely on the interviewer's clinical direction), or semistructured (some combination thereof).

mediators/moderators Characteristics of the individuals receiving interventions and characteristics of the intervention process that affect treatment outcomes.

normative sample A group of people identified as being representative of a population who are assessed, with their data being used to compare with results obtained from subsequent administrations of the assessment instrument.

rating scales Assessment instruments that provide a standardized format to gather information about an individual's behavioral characteristics; these are usually paper-and-pencil forms that may be completed outside of an assessment setting.

response bias Trends in the way in which informants respond to assessments that result in error variance.

traditional assessment Behavioral assessment strategies that focus on assessing the presence or absence of diagnostic categories.

The assessment of social and emotional functioning in the schools is needed for purposes of classification, intervention development, and measurement of

outcomes. Procedures for completing these evaluations, as well as the relative strengths and weaknesses of the techniques, are described in this article. The descriptions are organized by purpose, beginning with techniques for problem identification and followed by the application of these techniques to measuring outcomes. Legal, ethical, and cultural issues as they relate to these procedures are described at the end.

1. RATIONALE FOR SCHOOL-BASED ASSESSMENT

There are two primary contexts for behavioral assessment in schools: special education and expanded school mental health (ESMH). When considering behavioral assessment in the context of special education, it is important to keep in mind that these services are guided in part by legislative acts such as the Individuals with Disabilities Education Act (IDEA) and the amendments to the IDEA in 1997 (IDEA '97). These legislative acts provide funds for public schools to fulfill the mandate of a "free and appropriate public education" for all children and adolescents with disabilities, including those with emotional and behavioral disabilities. In this context, behavioral assessment of students is critical for two reasons: (a) to assist in understanding how behavioral and emotional issues interfere with learning and (b) to develop appropriate intervention strategies to enhance learning success. Within IDEA '97, there is specific reference to the role of "functional behavioral assessment" (FBA) for the analysis and monitoring of student behavior. Although the law stops short of defining this requirement, FBA is widely assumed to include interviews, structured observations, and assessment of the function or purpose of student behavior. Based on the language of IDEA '97, FBA is intended to go beyond the mere question of eligibility for special education services or simple "gatekeeping." Rather, its intended purpose is to address those issues surrounding the creation and monitoring of appropriate interventions. To this end, IDEA '97 requires school professionals to assess behaviors that impede a student's ability to learn or that impede the ability for his or her peers to learn, although the language of the law does not specifically define those behaviors. Legal precedents based on case law suggest that physical aggression, noncompliance, verbal abuse, and disruptive classroom behaviors can rise to this level. For those students with disabilities who exhibit these types of behaviors, a decision must

be made as to the severity of the behaviors and whether or not they warrant specific interventions. If so, school professionals are legally bound to design a behavioral intervention plan (BIP) to address these needs. IDEA is being reauthorized in the U.S. Congress, and many hope that with this reauthorization there will be increased funding and an emphasis on prevention and support for youth before formal referral into special education. These changes would increase the need for assessment earlier in the process than is currently required.

Whereas IDEA '97 is applicable only to students in public schools who meet diagnostic criteria for specific areas of disability, Section 504 of the Rehabilitation Act of 1973 protects individuals from discrimination in any institution receiving federal funding, based on a much wider range of disabling conditions. Section 504 is not program legislation but rather civil rights legislation. In addition to its application to schools as a mechanism to receive special services, this act also requires that school districts ensure that all of their procedures and techniques are nondiscriminatory. When conducting behavioral assessment, professionals must be cognizant of potential cultural biases that may occur within the process. For example, behavioral assessment instruments that are standardized and norm referenced with samples that do not reflect the cultural differences of minority students may classify their behavior inaccurately. In such instances, it is imperative for school professionals to interpret results within the appropriate framework of the students' cultures and backgrounds. In other words, results from instruments that are based on norm samples that do not accurately reflect students' cultural backgrounds must be qualified. This is particularly true if these instruments have the potential for overidentifying minority students for disabilities based solely on cultural differences. Conversely, it is also important to not deny minority students special education services as a result of attempting to be culturally competent or politically correct.

The second primary context for behavioral assessment in schools is ESMH programs. ESMH programs involve collaboration between schools and community agencies to move toward a full continuum of mental health promotion, including early intervention and treatment for youth in special and regular education. These programs are developing progressively in the United States, as well as in other countries, as a result of their documented ability to reach underserved youth and preliminary evidence that they lead to outcomes valued by schools and communities (e.g., improved student attendance and behavior, decreased inappropriate referrals to

special education). Behavioral assessment is of foundational importance in the ESMH context and for special education and Section 504 plans to evaluate the nature of the presenting behavioral and emotional problems, provide guidance in the development of effective interventions, and measure the outcomes of those interventions.

2. EVALUATING BEHAVIORAL AND EMOTIONAL PROBLEMS

2.1. Purpose

The evaluation of behavioral and emotional problems in the classroom is warranted by the difficulties experienced by children who contend with these problems on a day-to-day basis. A number of behavioral and emotional problems that can prevent a child from functioning at a level commensurate with his or her same-age or same-grade peers are commonly evidenced in the school setting. Some of the more common behavioral and emotional problems that cause such impairments include anxiety, attention deficit/hyperactivity disorder (ADHD), anger/aggression, attachment disorders, conduct problems, depression, delinquency, posttraumatic stress disorder (PTSD), and bullying. The school environment is unique in that it places demands on children that are not otherwise required of them. For example, in the school setting, children are expected to sit quietly and attend to classroom activities. Furthermore, schools require students to function within demanding social contexts that youth may avoid or not be exposed to outside of school. The difficulties these expectations pose for children with behavioral and emotional problems are substantial, and assessment of these problems in the setting where they often occur has important implications for the development of effective interventions. It logically follows that assessment should occur, at least in part, in the school setting.

Evaluation of behavioral and emotional problems in schools is frequently done to determine whether a child or an adolescent is eligible for, or would benefit from, special services. Under these circumstances, evaluation is done to answer questions pertaining to classification and to guide the development of effective interventions. Although determining eligibility for special services is important, it is the development of interventions that is vital for changing problem behaviors. Effective interventions are those that target the presenting behaviors and not the label. Therefore, school professionals should place an emphasis on the development and

implementation of interventions that target the specific needs of the students who are referred for evaluation rather than their diagnoses or labels.

2.2. Traditional Assessment

There are a number of assessment methods used to evaluate behavioral and emotional problems in the schools. Traditional assessment involves the examination of scores from norm-referenced measures to determine a particular individual's difference from or similarity to a normative sample. In other words, traditional assessment asks the question, "How does this student's behavior compare with that of similar children?" Standard tests of cognitive abilities and academic achievement, as well as many rating scales, are structured in this way. Using traditional assessment techniques, the inferred construct being measured (e.g., attention, depression) is thought of as a cause of a particular behavior in a specific setting. Although identifying the underlying syndrome or "label" related to a child's behavior is certainly important for diagnosis and classification, this information is not always the most useful for designing interventions. In contrast, measurement approaches such as behavioral observation, analogue assessment, interviews, and rating scales provide highly useful information about the functional relationship between the environment and particular behaviors. These techniques attempt to uncover the causes and consequences of behavior that often lead directly to effective intervention strategies.

2.3. Direct Observation

Direct observation is likely the most straightforward of all assessment techniques because it involves just what it implies: the direct observation and recording of problem behaviors in the context in which they occur. Three methods of direct observation are narrative recording (i.e., writing down what is happening in a narrative fashion, often following the antecedent-behavior-consequence [ABC] pattern or what occurs before, during, and after specific behaviors), event recording (i.e., tallying the instance of a target behavior), and time sampling (i.e., breaking down observations into intervals and recording the number of times a behavior occurs relative to the number of intervals observed to form a ratio). Direct observation differs from other methods of assessment in that little inference is required, making it one of the less biased methods for evaluating potential target behaviors.

There are some measurement issues related to observational methods that can negatively influence the data that are collected, including poorly trained observers, observer drift, poor operational definitions of target behaviors, poorly constructed data-recording systems, and reactivity (i.e., when the act of observation affects the student's behavior). Establishing interobserver agreement is one way in which to ensure that the data collected from direct observation are reliable and useful. A common procedure used to measure and enhance the quality of direct observation data is having another trained observer collect data simultaneously with the primary observer and then comparing data across observers to yield a measure of interobserver agreement. Direct observation is a labor intensive procedure that requires significant training time and effort to maintain reliability.

An additional problem with direct observation is the limited availability of the technique to assess infrequently occurring behavior. For example, children who are perceived as aggressive by teachers might exhibit only two or three episodes of these behaviors per week (or even fewer). The likelihood of observing these defiant or aggressive behaviors during discrete classroom observations is small. The technique is probably most practical for high-frequency behaviors such as on-task behavior and "talking out."

Finally, most observational data are difficult to put into context because there are no norms. In the school environment there is considerable variability in behavioral expectations across classroom activities and between teachers, resulting in various and shifting definitions of what is "normal." There are observational techniques that allow one to begin to account for this shifting context. For example, some time-sampling procedures require the observer to shift back and forth between observing the target child and same-sex classmates or a randomly selected peer. Pooling the data from the target and peer intervals provides the evaluator with a definition of what was normal during the context observed. However, no strategy will always work to overcome the problem of shifting contexts, and school professionals must interpret the results of their observations carefully.

2.4. Analogue Assessment

Analogue assessment provides an alternative to direct observation and is useful in situations where direct observation is not feasible. Analogue assessment is an observational measure of the child's behavior of

interest elicited through the use of simulated conditions; observations are made in the simulated setting to predict behavior in real-life settings. Assessments of this type can be administered by paper and pencil, by audiotape or videotape, or through the use of role-plays or enactments. In a controlled environment, the evaluator creates a situation parallel to one that the child experiences in school and observes and records the behavior of interest. As with direct observation methods, this technique can be labor intensive; however, it does allow the evaluator to assess specific conditions that may occur only rarely. Some of these situations may be easy to recreate, for example, asking a child who is poor in math to complete some math and reading work. In this example, differences in the child's reactions to the various academic tasks may be observed, and these data may contribute to an understanding of behavior problems experienced during math class.

Among the problems associated with this method of assessment is the lack of standardization, issues related to reliability and validity, and problems with generalization. The most basic of these is the fact that analogue assessments are contrived situations, and regardless of how similar the situation is to the targeted environment, the child usually knows that it is contrived, and this knowledge may influence his or her behavior. Whenever analogue assessment techniques are used, all of these potential issues should be considered when interpreting the results.

2.5. Interviews

Interviews to assess behavioral and emotional problems in children can be conducted with the child himself or herself or with the child's parents, teachers, and/or other caregivers. A variety of different interview formats exist. An omnibus interview is designed for gathering a wide range of information, whereas a behavior-specific interview is narrower in scope and focuses on the assessment of specific problem areas. An interview that is problem solving in nature focuses on presenting concerns with the goal of developing an intervention plan. Interviews can be structured, unstructured, or semistructured.

Although it is often the case that interviews focus on reaching a diagnostic conclusion, interviews that focus on both problem assessment and the development of intervention plans are useful in school settings. Behavioral interviewing addresses the assessment of the current behaviors and environmental factors that contribute to the initiation and maintenance of problem

behaviors. These interviews are designed to detect specific problems that can be targeted for intervention and include phases of problem identification, problem analysis, treatment implementation, and treatment evaluation.

Interviews may be a valuable and efficient method for collecting information about a wide range of behavioral and emotional problems. The evaluator can efficiently collect data about behavior over a long period of time and in a variety of situations. In addition, the adults being interviewed may provide information about their reactions to this behavior or interventions related to the targeted behavior. Ideally, interviews are conducted by staff members who will continue to be involved in developing and implementing interventions with students in need. In these cases, the interview can be used to establish the initial relationship and communicate empathy and support to the child while collecting valuable information.

2.6. Rating Scales

Rating scale measures provide a standardized format to gather information about an individual's behavioral characteristics and can be administered to children to obtain self-report data or to parents, teachers, and/or other caregivers to obtain informant-report data. A few of the advantages of rating scales are their ability to provide behavioral information in a short amount of time, their moderate cost, and their technical precision and practical utility. Rating scales can be used in the comprehensive assessment of potential behavior problems and deficits in functioning for screening, diagnosis/classification, treatment selection/intervention planning, progress monitoring, and outcome evaluation.

As with most other forms of assessment, there are some problems associated with the use of rating scales. These problems typically fall under one of two categories: response bias and error variance. Response bias refers to trends in the way in which informants respond to rating scales. Some examples of response bias are halo effects (i.e., rating the student in a positive or negative manner based on characteristics unrelated to what is being measured), leniency or severity effects (i.e., the tendency to have an overly generous or overly critical response set), and central tendency effects (i.e., the tendency to rate down the middle and avoid end point ratings). Error variance refers to the differences among several ratings of the same individual. The different types of error variance include source variance (i.e., differences in ratings provided by various persons), setting variance (i.e., differences in ratings across

situations), temporal variance (i.e., inconsistency of behavior ratings over time), and instrument variance (i.e., differences in ratings using different instruments).

Although rating scales are valuable tools, it is frequently tempting to overrely on them due to their minimal costs. Although they are efficient, there are many questions they do not answer (e.g., the role of environmental contingencies). Although environmental concerns are critical to the development of interventions, this information is generally not provided by rating scales. Furthermore, rating scales are only as useful as the sources. For example, children are fairly poor raters of their own disruptive, off-task, and inappropriate behaviors; consequently, adults have been identified as a better source for this information. On the other hand, children appear to be better at reporting their internal affective states and, as a result, are generally better raters of their own depressive and anxious characteristics. However, although these are general trends that should be considered when interpreting rating scales, there is considerable individual variability.

2.7. Functional Behavioral Assessment

A primary goal of FBA is to identify environmental conditions that are correlated with the occurrence and nonoccurrence of behaviors. This type of assessment provides a systematic analytic method for identifying those things that serve to initiate and maintain behavior. FBA incorporates many methods of assessment to gain a complete understanding of an individual's behavior in a particular environmental context. Approaches to FBA can be indirect (i.e., gathering behavioral information from rating scales, interviews, etc.), direct (i.e., directly observing the behavior in the context of the natural environment in which it occurs), or experimental (i.e., generating hypotheses about the maintaining contingencies for the problem behavior and testing them with the individual serving as his or her own control). Completing these assessments is an iterative process of data collection, hypotheses generation, and collection of additional data. The hypotheses provide the specific questions that guide the subsequent data collection that either confirms or redirects the hypotheses.

The identification of the cause-effect relations in the interaction of an individual and his or her environment is integral to the development of interventions aimed at changing behavior. Because FBA focuses on the relationship between particular environmental circumstances

and behavior, it has the potential to contribute greatly to the development of effective interventions for problem behaviors. A successful FBA provides information about these environmental circumstances affecting the problem behavior and also provides a clear direction for treatment.

2.8. Current Issues

Because all of the assessment techniques discussed present their own unique advantages and limitations, the use of multiple assessment techniques with multiple informants is often considered the best method for evaluating behavioral and emotional problems. Although the use of multiple informants (e.g., parents, teachers, students) has the potential to provide a wealth of information, inconsistencies in data from one source and method to another is an issue that is often encountered in behavioral and emotional assessment. Such inconsistencies must be taken into consideration when assessing behavioral and emotional problems and especially when identifying behaviors to target for intervention. Frequently, careful evaluation relying on multiple informants using multiple methods will yield data that are contradictory and inconsistent, making interpretation difficult. Nevertheless, this comprehensive strategy is recommended to reduce the influence of specific sources of error and to produce the opportunity to recognize and interpret convergent themes used to generate explanations and interventions.

3. EVALUATING OUTCOMES

3.1. Purpose

As noted in the previous section, children and adolescents manifest many of their problems related to behavioral and emotional problems at school. This not only warrants school-based evaluation of these problems, it frequently results in school-based provision of services. These services take many forms, ranging from universal interventions, to disorder-specific treatment, to school-based day treatment programs. Professionals providing these services are expected to assess the progress of children and adolescents participating in them so as to modify interventions and know when interventions are no longer needed. As a result, the questions that guide outcome evaluations pertain to understanding an individual's progress in treatment with implications for modifying or discontinuing services. These assessment

procedures frequently include observations, rating scales, and performance measures.

3.2. Observations

Observations have inherent advantages and disadvantages that are described in the previous section. The use of observation measures to measure outcomes is warranted with high-frequency behavior or with behavior that has a high degree of situational specificity. Observed rates of on-task behavior is a common outcome measure of a high-frequency behavior. Defiant and disruptive behavior is usually difficult to evaluate with observational techniques because its frequency is low even for students who teachers perceive as defiant or disruptive. This is especially true in secondary schools, where episodes of defiant behavior can be quite intimidating and need not occur very often for a teacher to report a problem. Low-frequency behavior with a high degree of situational specificity is conducive to observational measures because the observer can efficiently target the specific situation that elicits the problematic behavior. For example, a child referred for problematic behavior in the cafeteria may warrant observational assessment because the observation period is limited and the likelihood of observing the problematic behavior within this situation may be quite high. Observational measures have been found to be sensitive to intervention effects when administered frequently and reliably.

3.3. Rating Scales

The use of rating scales can be a very efficient method for collecting outcome data. Compromises to validity can occur when raters are invested in the intervention process, resulting in a bias to perceive improvement. Collecting data from some raters who are blind to treatment or not invested in its success can be a valuable assessment strategy; however, sometimes these people are not available or are not able to provide useful assessment data. Collecting rating scale data from multiple sources and then interpreting convergent findings has been recommended so as to minimize individual biases. This technique can be helpful, but it also presents evaluators with unique challenges. It is quite common to receive rating scale data with tremendous variability and little convergence around any conclusion. Although this may indicate poor reliability, it may also indicate that the child's behavior changes as a function of classroom, activity, or teacher. In these situations, it is sometimes helpful to evaluate improvement in relation to

specific situations and settings. In other words, a child may be making considerable improvement in Mr. Smith's math class but demonstrating no improvement in Mrs. Martin's English class.

One of the problems with the use of rating scales as measures of outcomes pertains to the instruments possessing the necessary sensitivity to detect meaningful change. Changes resulting from effective interventions might not appear in changes in scores on rating scales because the targeted behavior change may have been more specific than can be indicated on most rating scales. For example, interventions may effectively reduce a set of behavior that annoys peers in math class; however, this may produce very little change in the child's overall social functioning or acceptance by other children and adults. As a result, the use of most rating scales as an outcome measure in this situation is probably inappropriate.

To measure changes in behavior, it is frequently useful to have repeated measurement of target behavior so as to track change. One of the practical problems with administering rating scales is the timely completion and return of assessments by parents and teachers. It is usually necessary to closely monitor their return, check for completion (e.g., whether the rater completed the back of the form), and follow-up with raters whose forms are incomplete or late.

3.4. Performance Measures

Performance measures assess the ability of a child or an adolescent to exhibit a skill. They are frequently used in academic achievement testing, but they also have applications related to behavioral and emotional problems. Pre- and post-assessments can be administered to assess whether a child had a skill (e.g., social skill, problem-solving skill) prior to the intervention and possesses the skill after the intervention. These assessments tend to be straightforward and based on an appraisal of the child's ability to demonstrate through role-play, written responses, and/or verbal description a set of skills that have been taught directly. These techniques are useful for determining whether a child or an adolescent is ready to begin applying the skills in actual situations because generalization is not likely to occur if the child cannot produce the behavior on cue. A common misapplication of these measures in evaluating outcomes is an overreliance on them as the end point of the need for interventions. Many socially impaired youth have been successfully taught numerous social skills that have resulted in no change in

behavior in other settings. Generalization, or the degree to which learned skills are displayed in novel or untrained situations, is usually the most challenging part of any behavioral intervention, and measures assessing behavior change in the target settings is a necessary outcome measure.

3.5. Current Issues

Successfully evaluating outcomes requires giving attention to many issues, including generalization, mediators and moderators, and size of effects. Attention to generalization requires evaluators to focus key outcome measures on the settings in which the problems that led to the initial evaluation occurred. Although measurement of the process of interventions can help to inform treatment decisions, it is possible to understand the ultimate success of interventions only when assessments target the problems in the context in which they have occurred. Moderators and mediators refer to characteristics of the individuals receiving interventions and characteristics of the intervention process that affect treatment outcomes. For example, interventions provided by different teachers in different classrooms may result in mixed results, not as a result of the intervention but rather as a result of whether or not each teacher implemented the techniques correctly. In this example, it could be said that the implementation of the technique "mediated" the outcomes.

Although data indicating improvements are encouraging, questions will remain as to how much improvement is necessary before it is concluded that meaningful changes have taken place. This issue is at the heart of indexes of effect size and clinical significance. These calculations rely on data from the same assessment techniques as described previously but include analyses to assist in the interpretations of the size of the effects. There are various approaches to this topic, including measures of whether change moved a student from outside of the normal range to within the normal range as well as indexes of the size of change in relation to the standard error of measurement and standard deviation. Unlike many other analyses, these techniques can be applied to data for an individual child or a group of children.

4. LEGAL AND ETHICAL ISSUES

For states to receive federal funding, there must be strict adherence to the principles of the applicable

program legislation and civil rights legislation passed at the federal level. State laws are often more specific than federal legislation and act to flesh out federal mandates, such as IDEA '97, by defining the means that school professionals use to meet the requirements outlined in these laws. With states operating independently in this fashion, there are often differences among states in terms of how the federal laws are interpreted. One state's procedures for conducting an FBA or a BIP may differ from those of another state. Furthermore, requirements set forth in IDEA that are not addressed by the state may be interpreted and defined at the school district level, sometimes resulting in dramatic differences in assessment and classification procedures between adjacent neighborhoods. Therefore, the onus is placed on schools to train their staff to be able to conduct behavioral assessment in accordance with the pertinent laws and local procedures.

In terms of behavioral assessment, perhaps the two most relevant areas of legal and ethical concern are informed consent and procedures for ensuring cultural competence in assessment. As with any form of non-academic assessment in the school setting, legal and ethical issues arise around consent for assessment. IDEA and the American Psychological Association's Ethical Principles of Psychologists specifically require that informed consent be obtained from the parents or guardians of a minor before conducting an initial evaluation. For consent to be "informed," the signor must (a) fully understand the purposes and means of the assessment, (b) provide consent voluntarily, and (c) be legally competent. It is generally assumed that children are incompetent to provide independent consent, although there are situations where exceptions are made. For example, students who are emancipated from their parents may be eligible to give consent on their own behalf, and many states allow independent consent for mental health services under 18 years of age. In general, however, parents or guardians are typically required to consent to any assessment services provided to children.

When obtaining consent, professionals must keep in mind that the school environment creates a unique situation for behavioral assessment because, in contrast to clinical settings, it is not automatically assumed that a child's participation will include such services. The clinical practice of "passive consent," or the assumption of consent based merely on participation, is not applicable in the school setting. In fact, some argue that the school setting is inappropriate for mental health services in general and

that the practice of assessing children in a school in domains outside of academia is inappropriate. Therefore, professionals in the school setting have the legal and ethical duty to ensure that parents or guardians understand the purpose and means of any assessment that is conducted. It is strongly recommended that school professionals obtain "active consent," which includes formal documentation of parental consent and meets all of the requirements of consent described previously. Ultimately, this might mean that students will not receive the services they need due to parental disapproval or apathy. Although this is unfortunate, the need for active consent presents such an ethical, and at times legal, concern that it is suggested that professionals in the schools always seek active consent despite the possible consequences.

Another area of legal and ethical concern is cultural competence. In simplest terms, there are two components of cultural competency. First, professionals must understand and respect the values, beliefs, customs, and traditions of the families they serve. This component of cultural competence involves interacting appropriately with people from diverse cultures, implementing a communication process whereby practitioners interact with people as equals (and not as experts), and demonstrating a genuine commitment to understanding students' strengths and weaknesses in the context of the culture, resources, and environment in which the behaviors occur. As mentioned previously, when a professional uses assessment instruments that are normed on non-representational samples, there is a need to interpret the results with great care. Cultural competence in this respect may involve the ability to interpret the results within the correct framework. For example, a child of Hispanic background who appears to be significantly "introverted" or to lack "leadership" skills on some rating scales may in fact exhibit behaviors well within ranges that would be expected of his or her family-oriented cooperative culture. It is the culturally competent professional who can interpret these results in the correct context.

The second component to cultural competence is an awareness of how professionals' own cultural backgrounds affect their services to the students. In some cases, whole schools can adopt a white middle-class culture as a result of the dominant cultural makeup of the faculty and staff. In these instances, there may be a tendency within the school to place an emphasis on timeliness, parental involvement (to the exclusion of extended family members), and a lack of emotional display. Although this might not be self-evident

among the faculty and staff members of the school, these cultural norms can be at odds with families of diverse cultural backgrounds. For example, school personnel can mistakenly interpret students who arrive late for an assessment, or parents who arrive late to meetings, as uncaring or uninvolved. However, in a family's culture, there might not be the same emphasis on timeliness. Similarly, students who openly weep at unfortunate news or seem to be unmoved by positive feedback may be mistakenly considered to be unstable or unconcerned. Again, these reactions might not fit with the dominant culture of the school or professionals themselves, but they still fall well within the norm for the student's culture. As a result, professionals must continually assess their own cultural influences and be willing to recognize instances where their own cultural values do not match those of the students and their families.

pseudodementia Reversible symptoms of dementia (i.e., memory, attention, and other cognitive deficits) that are caused by an underlying depression.

sleep hygiene An educational treatment for insomnia that provides instruction on how the sleep environment, caffeine, alcohol, nicotine, food, and exercise affect sleep.

sleep restriction A treatment for insomnia that involves restricting the time allowed for sleep, beginning with a very short period and gradually increasing. This method promotes a state of sleep deprivation in order to facilitate learning to fall asleep faster and stay asleep.

stimulus control A treatment for insomnia that requires the individual to leave the bed when he or she is not able to sleep and to not use the bed or bedroom for any activities during the day.

GLOSSARY

depressed psychophysiologic functioning A complication from hospitalization (increased incontinence, confusion, agitation, and loss of appetite) often observed in the frail old.

excess disability A substantially lower than expected level of physical functioning for a given medical condition, attributable to behavioral factors (i.e., noncompliance, lack of activity, and depression).

frail elderly The old-old (age 85+ years) segment of the population with significant, multiple medical illnesses that limit functioning. These individuals typically do not live independently.

masked depression A presentation of depression in older adults characterized by the presence of more physical symptoms (i.e., reduced appetite, sleep disturbance, fatigue, and increased aches and pains) and fewer mood symptoms.

Behavioral medicine encompasses the study of how behavior impacts the onset, progression, and recovery from illness and the application of those behavioral factors to promoting health and preventing illness. Due to national demographic trends and the prevalence of chronic diseases in late life, older adults are emerging as a critical target group for behavioral medicine interventions. In the older adult age group, behavioral factors relating to comorbid depression, excess disability, pain, and sleep are of particular importance for behavioral medicine.

1. APPLYING BEHAVIORAL MEDICINE TO OLDER ADULTS

Due to the twin factors of increased life expectancy and reduced birth rates, most nations throughout the world are experiencing a dramatic shift toward an older adult population. It is projected that by 2030, 70 million Americans (20% of the U.S. population) will be 65 years or older, compared to approximately 35 million (14%) in 2000. This aging revolution has led to increased public and scientific interest in how behavioral and psychological factors influence the aging process. In addition, with the great strides made in the successful treatment of acute illness in the past century, people are living longer but at the same time are accruing more age-related chronic illnesses. In response, the focus of the U.S. health care system is shifting toward managing chronic illness and disability, with an emphasis on maximizing independence and quality of life in late adulthood. The goal is to help people live well rather than simply live longer.

By necessity, the field of behavioral medicine will play an increasingly important role in the health care system of the future. Behavioral medicine encompasses the study of how behavior impacts the onset, progression, and recovery from illness and the application of those behavioral factors to promoting health and preventing illness.

Older adults are in many ways the ideal age group to apply behavioral medicine principles and interventions. First, they are at much greater risk for chronic medical conditions, such as heart disease, lung disease, diabetes, cancer, and arthritis, and they often have multiple chronic conditions. Interventions aimed at preventing the onset or progression of such conditions are most cost-effective when they are designed for and delivered to this age group. In-home exercise interventions designed specifically for older adults, for example, have been shown to yield substantial benefits to patients with cardiovascular disease, partly due to the fact that older adults are more vulnerable to diminished cardiovascular capacity when they do not engage in systematic exercise.

Second, each chronic medical condition typically requires several different medications, multiplying the risk for side effects (e.g., memory impairment) and drug interactions. Accordingly, behavioral interventions that can manage symptoms without the use of medications are particularly important for this population.

Last, and perhaps most important, is the fact that physical and psychological conditions become more

interdependent and reactive to each other with advancing age. Therefore, interventions aimed at psychological conditions, such as depression and anxiety, as well as the enhancement of psychosocial coping resources can have a significant impact on the physical health of older adults. Mind-body group interventions that teach a range of skills (e.g., relaxation training, problem solving, and cognitive approaches to managing stress) have been shown to be effective in enhancing coping and quality of life in older adults with chronic illness.

2. DEPRESSION AND HEALTH IN OLDER ADULTS

The greater interplay between psyche and soma (body) in older adults is perhaps most evident in research on depression and health. When older adults have a depression overlaid on a medical condition, they are at much higher risk for excess disability. Excess disability is defined as a substantially lower than expected level of physical functioning for a given medical condition, attributable to behavioral factors (i.e., noncompliance and lack of activity). After a stroke or hip fracture, for example, when depression is detected an aggressive psychological intervention is required to prevent poor physical rehabilitation outcomes.

Even mortality has been shown to be affected by depression in older adults. In the Cardiovascular Health Study, depressive symptoms were related to 6-year mortality in a large sample of adults older than age 65, after controlling for medical and demographic variables known to affect mortality. The hypothesized mechanism by which depression affected mortality was decreased motivation to initiate and sustain cardiac health behaviors.

Unfortunately, medical professionals often fail to detect the presence of depression in older adults. This failure in detection is partly accounted for by the atypical presentation of depression in many older adults. One such presentation is as masked depression, which is characterized by the presence of more physical symptoms (i.e., reduced appetite, sleep disturbance, fatigue, and increased aches and pains) and fewer mood symptoms. Furthermore, depressed older adults are far less likely to have a negative view of themselves (e.g., "I am a failure" and "I am worthless"), which is a hallmark of depression in other stages in life. Another presentation, called pseudodementia, is characterized by reversible symptoms of dementia

(i.e., memory, attention, and other cognitive deficits) that are caused by an underlying depression.

Fortunately, cognitive-behavioral and other psychotherapy treatment approaches have been found to be as effective as medication in the treatment of depression; moreover, older adults are as likely to benefit from these treatments as younger adults. Furthermore, there is no evidence to suggest that when chronic illness coexists with depression that psychotherapy treatment for depression is any less effective, although the situation is likely to contribute to the range of cognitive errors and distortions that need to be addressed in cognitive-behavioral therapy (Table 1).

A positive development is a growing trend toward improved screening and treatment of depression in older medical patients as well as a greater presence of mental health professionals in primary care settings. This trend is particularly important given the fact that older Caucasian males are at the highest risk of any group for suicide and as many as 70% of suicide victims visit their primary care physicians prior to committing suicide. Tragically, these older male patients were unable to communicate their depression to their physicians and/or their physicians failed to ask the appropriate questions. Once depression is detected, psychotherapy that is provided on-site in a primary care office is often more acceptable to older adults. This detection treatment model highlights the importance of integrating mental health and medical treatment for older adults in particular.

TABLE 1

Common Cognitive Errors and Distortions in Depressed Chronically Ill Older Adults

Irrational belief: disability = inevitable misery	"Anyone would be depressed in my shoes."
All-or-none thinking	"If I can't do everything that I used to do, in the ways I was accustomed to, I might as well not do anything . . . because it won't be satisfying."
Negative filtering	"I'm nothing but a burden to my family."
Negative forecasting	"If I continue to have all these medical problems, my friends won't want to be around me anymore."
Mind reading	"The medical staff is getting tired of working with me."

3. BEHAVIORAL SLEEP MEDICINE AND AGING

Sleep has emerged as an important area in behavioral medicine. Treatment of insomnia, in particular, has been an important area of research and intervention because it is frequently caused or made worse by behavioral factors that are amenable to cognitive-behavioral intervention. In this case, again, the older adult population may be the ideal target group for these interventions.

There are numerous sleep disorders that increase in frequency with age, including sleep apnea, restless legs syndrome, and periodic limb movement disorder, but chronic insomnia is the most prevalent in late life. The risk for developing chronic insomnia doubles between the ages of 55 and 85 and is present in 20–30% of the population older than age 65. It usually manifests itself as a combination of different problems, including difficulty falling asleep, excessive time spent in bed awake, more frequent and longer awakenings after sleep onset, and fewer total hours of sleep. Furthermore, there is an increasing recognition that sleep disturbance at night leads to daytime fatigue and/or sleepiness, which is associated with decreased quality of life in older adults.

During the past 30 years, several different behavioral interventions have been developed and shown to be highly effective. In fact, it has been noted that behavioral interventions for insomnia are probably the most effective and durable interventions in the behavioral medicine repertoire, with typical success rates after only six to eight sessions of treatment of 60% or greater. In addition, most of these treatment effects have been measured and sustained over periods of as long as 2 years.

The most effective cognitive-behavioral interventions tested to date include all or most of the following components: sleep hygiene instruction, relaxation training, sleep restriction, stimulus control, and cognitive modification. Sleep hygiene involves basic education on how the sleep environment, caffeine, alcohol, nicotine, food, and exercise affect sleep. Several different types of relaxation training (e.g., progressive muscle relaxation, deep breathing, and visual imagery) have been provided under the premise that mental and physical arousal that accompanies stress and anxiety will inhibit and disrupt sleep. If patients can train themselves to relax before sleep or at night after an awakening, they are more capable of falling asleep and staying asleep.

3.1. Sleep Restriction

Sleep restriction is the most difficult to adhere to but is probably the most essential component of treatment of insomnia in older adults. Its aim is to counter the sleep fragmentation and daytime sleeping that is commonly observed in older adults by restricting the time allowed to sleep to a specific “sleep window.” This sleep window is initially set for a very short period of time, determined by the average amount of time that the individual slept per night (based on a sleep diary that is kept throughout treatment). For many individuals, this period is 5 or 6 h long, so they are required to be awake for as many as 19 h each day prior to going to bed. During the first few weeks the individual experiences a high level of sleep deprivation, compounded by the fact that he or she is not yet capable of sleeping all the time during the sleep window. This prolonged sleep deprivation creates “sleep pressure,” which makes it easier for patients to train themselves to sleep without interruption during the sleep window.

After each week of sleep restriction treatment, the patient’s sleep efficiency (percentage of time slept during the sleep window) is calculated and 30 min is added to the sleep window if the patient achieves a sleep efficiency of 85% or greater. The eventual goal is to give the patient enough time in bed to meet his or her particular sleep needs (i.e., enough sleep to feel refreshed and not sleepy during the day) while maintaining a high level of sleep efficiency.

3.2. Stimulus Control

The stimulus control method is designed to increase the association between being in bed and being asleep. Predicated on operant learning theory, it involves instructing individuals to greatly limit their activities in the bed and bedroom. Basically, the only activities allowed in bed are sleep and sex. They are not permitted to do such activities in bed as watching television, reading, eating, worrying, listening to the radio, working, or simply resting. In addition, they are not allowed to be awake in bed for longer than 15–20 min at any time during the night, whether they are trying to fall asleep or trying to get back to sleep after awakening in the middle of the night or early morning. If they cannot fall asleep or back to sleep after 15–20 min, they are to get out of bed and engage in a nonstimulating activity until they become sleepy enough to try again. If they are unable to fall asleep again within 15–20 min, they are to repeat the same procedure. In addition, to facilitate the functioning of the body’s

circadian clock system, they are instructed to use an alarm clock and get up at the same time every morning.

The final component of treatment is cognitive modification. Similar to cognitive restructuring for anxiety or depression, this approach emphasizes changing unrealistic beliefs and irrational fears involving sleep or sleep loss. Research shows that older adults with insomnia endorse stronger beliefs about the negative consequences of insomnia, express more fear of losing control of their sleep, and express more helplessness about its unpredictability compared to older adults without insomnia.

Dysfunctional cognitions about sleep create a vicious cycle by increasing performance anxiety about sleep, which in turn leads to arousal and greater difficulty falling asleep. Common misconceptions about sleep include the following: blaming daytime impairments, such as fatigue and inability to concentrate, exclusively on sleep loss; the fear that insomnia will worsen a medical condition; the belief that not getting 7 or 8 h a sleep per night will threaten one’s health; and the belief that sleeping late the next morning or napping is a good way to compensate for poor sleep at night. Finally, the belief that a bad night of sleep results in a “lost day” leads to cancellation or avoidance of activities, such as socializing and physical activities, that are important to maintaining health and promoting sleepiness at night.

Initially, the focus of research on behavioral treatment for insomnia was on younger adults and later it moved to older adults who had no other medical conditions. Until recently, individuals with chronic illness were excluded from these studies under the presumption that insomnia in these individuals was likely caused by a medical condition or a medication and therefore needed to be treated by directly managing the medical condition. However, it is now understood that insomnia in virtually all cases, regardless of coexisting medical conditions, is made worse by behavioral factors that are responsive to behavioral treatment. Indeed, two studies have demonstrated that older adults with multiple medical conditions are as responsive to treatment as individuals without medical conditions.

Insomnia in older adults occurs mostly in those with age-related chronic diseases, such as cardiac disease, arthritis, and lung disease. When insomnia coexists with chronic disease, these patients have significantly reduced quality of life, experience more pain, use more medical services, and are more likely to develop depression. Thus, providing behavioral treatment to ameliorate insomnia in these individuals has numerous benefits that go beyond improvement of sleep, leading to improved daytime mood, alertness, and physical functioning.

4. CHRONIC PAIN INTERVENTIONS FOR OLDER ADULTS

Another important application of behavioral medicine to the older adult population is the management of chronic pain. Pain is a constant factor in the lives of a great many older adults. Due to the greater prevalence of conditions that cause pain (e.g., arthritis and diabetes), older adults have more chronic pain and are more likely to have multiple sites of pain than younger adults. Pain in older adults has been strongly linked to excess disability, insomnia, depression, and increased health care utilization. Older adults with a combination of pain and depression have been shown to be particularly vulnerable to physical disability.

The two types of behavioral treatments for chronic pain that have been applied to older adults are cognitive-behavioral therapy (CBT) and operant conditioning. CBT methods focus on modifying beliefs, thoughts, attitudes, and skills that affect different aspects of the pain experience. They also employ relaxation training to reduce the sympathetic nervous system component of the pain experience. Operant conditioning focuses on modifying observable behaviors, such as activity level, medication usage, and pain signaling (i.e., grimacing, limping, and complaining). This method uses operant conditioning principles to reward activity, change environmental contingencies, and shift medication usage from an as-needed to a time-contingent approach. Both treatment methods use learning techniques such as consistent self-monitoring, graded practice, and homework. CBT and operant techniques are compatible and are often used together in clinical practice.

Contrary to traditional bias among professionals that older adults may not benefit from CBT interventions due to the introspection that is involved, studies demonstrate that older adults obtain equal benefits from CBT pain interventions compared to younger adults. In addition, they are no less likely to drop out of treatment. Older adults have also been shown to be as capable of learning relaxation procedures as younger adults. Nonetheless, research exploring age bias in inpatient and outpatient pain treatment programs has found that rehabilitation professionals remain less confident that older adults will benefit from their program. This bias is confirmed by the much smaller than expected percentage of older adults enrolled in these programs, which means they are being underserved by these invaluable treatments.

Older adults may also have some unique, age-related strengths and resources that help them cope better

with pain. The majority of studies suggest that older adults have a higher pain threshold compared to younger adults. In addition, older adults may be more tolerant of pain due to the fact that they are more willing to accept certain levels of pain and discomfort as a part of growing older. This is consistent with studies showing that older adults report diminished emotional responses to pain, such as depression, anxiety, anger, or fear. Similarly, according to the life span theory of control, as individuals move into late adulthood there is a shift from a focus on primary control (control over the external world) toward an emphasis on secondary control (control of the internal mental and emotional life). This may equip older adults with a greater skill to cope with stressors that are irreversible or cannot be easily controlled, such as chronic pain.

5. BEHAVIORAL MEDICINE ISSUES IN THE FRAIL OLD

Among the old-old (age 85+ years) with significant medical illnesses, sometimes called the frail old, behavioral medicine has perhaps an even greater role to play due to the even stronger interplay between psyche and soma. When the frail old develop new medical problems that compound existing ones, they often experience the onset of new psychological symptoms, such as delirium, depression, or paranoia. Similarly, older adults residing in nursing homes have been shown to experience increased mortality and medical illness, not accounted for by medical factors, when they are required to relocate from one institutional setting to another. Even “timing of death” research has shown that, remarkably, the old-old are more likely to die of natural causes after, rather than before, a holiday or important family event. This suggests that the psyche exerts some degree of control over the timing of death.

When frail older individuals are hospitalized they often experience depressed psychophysiological functioning in the form of increased incontinence, confusion, agitation, and loss of appetite. These complications lead to further medical interventions, such as catheterization for incontinence, the administration of sedating medications or use of restraints for agitation, or tube feeding in the case of failure to eat. These treatments, in turn, lead to iatrogenic effects (i.e., complications from treatment) such as bladder infections (from catheterization), blood clots (from being restrained to the bed), and pneumonia (from tube feeding).

6. SUMMARY

Due to the increased risk of chronic illness and the increased interaction between psyche and soma in late life, behavioral medicine interventions that target older adults are among the most cost-effective and essential. Interventions that reduce anxiety and depression or enhance coping in older adults with chronic diseases have much potential to yield crossover effects on medical variables, such as functional status, symptom severity, and cognitive functioning. These factors combined with the aging revolution in the United States will lead to an increased focus within behavioral medicine on providing services to older adults.

GLOSSARY

frequency or event recording Involves counting the number of times a behavior is observed during a specified time period.

interobserver agreement Technique in which the consistency of recording across two or more observers is compared to assess the reliability of measurement.

interval recording Divides the observational session into a number of equal intervals and simply records the presence or absence of specified behaviors during each interval.

narrative recording Refers to the observation and collection of information on student behavior in naturally occurring arrangements with little constraints placed on the observer for how and/or what to observe and record.

partial-interval recording An interval recording technique in which the interval is scored if the target behavior is present during any part of the interval.

systematic direct observation Refers to the observation of behavior that is explicitly defined under predetermined settings.

whole-interval recording An interval recording technique in which the interval is scored if the target behavior is present throughout the entire interval.

Behavioral observation refers to a method of assessment whereby human observers objectively record the ongoing behavior of a person or persons in specific environmental circumstances.

1. INTRODUCTION

Direct observation is one of the most widely used individual assessment procedures by school-based professionals. In a survey of more than 1000 school-based professionals, of the 26 different types of individual assessment instruments listed across seven different assessment categories (e.g., aptitude, social-emotional, and personality), behavioral observation methods ranked highest in terms of frequency of use. Overall, respondents indicated that on average they conduct approximately 15 behavioral observations during the course of a typical month.

2. GENERAL METHODS OF BEHAVIORAL OBSERVATION

When conducting behavioral observations, school-based professionals generally rely on one of two basic approaches to gathering information. One form, narrative recording, refers to the observation and collection of information on student behavior in naturally

occurring arrangements with little constraints placed on the observer for how and/or what to observe and record. With narrative recording, the observer generally describes the observed situation making notes of specific behaviors as they occur. The method(s) of observation, the type of information noted, and the manner in which the information is summarized are left to the discretion of the observer. The strength of such procedures lies in the flexibility that the observer has in choosing when and how to observe and the minimization of obtrusiveness or reactivity that may occur as a result of the presence of the observer. For interpretative purposes, narrative recording is often used to help develop hypotheses about the various behavioral and environmental factors that may be worthy of further observation and analysis. This flexibility, however, is also one of the main weaknesses of narrative recording. Because the observer has great autonomy in choosing how and what to observe, judgments about the worth of such reports are inextricably bound to the subjective judgments of the observer. As such, it would be highly unlikely for two independent observations collected at the same time to appear identical in the information provided. Therefore, narrative recording is generally best used as a precursor to more specific, objective accounts of behavior.

In contrast to narrative recording, systematic direct observation refers to the observation of behavior that is explicitly defined under predetermined settings. Although this approach is also concerned with observing behavior under naturally occurring environmental contexts, the aim is to define beforehand the behaviors of interest, choose specific recording strategies, and have observers record whenever behavior corresponding to the predefined operational definitions occurs. In particular, systematic direct observation is distinguished by five characteristics: (i) The goal of observation is to record specific behaviors, (ii) the behaviors being observed have been operationally defined *a priori* in a precise manner, (iii) observations are conducted using standardized procedures and are highly objective in nature, (iv) the times and settings for observation are carefully selected and specified, and (v) scoring and summarizing of data are standardized and do not vary from one observer to another. In comparison to narrative recording, a main objective of systematic direct observation is to have independent observers agree on what is observed and recorded, assuming that they have observed the same stream of behavior.

3. MEASURING AND RECORDING BEHAVIOR SYSTEMATICALLY

Various types of data can be collected during systematic direct observation. A workable definition of a target behavior is one that provides an accurate description of the behavior and clearly defines the boundaries of its existence and nonexistence. Therefore, constructs and reifications do not lend themselves well to direct forms of observation. For example, raising one's hand to be called on is an observable and measurable behavior. Behaving "off the wall" is not something that can be directly observed (although operational definitions of the behaviors that constitute "off the wall" could be developed). Once behavior is defined, the calibration of the operational definition is determined by the nature of the data—the frequency of its occurrence and the particular interests of the observer. In addition, practical considerations, such as the availability of observers, the amount of time a student is accessible, or any combination of these factors, all dictate the type of data collected.

4. CODING SCHEMES

When observing behavior systematically, observers generally use any one of a number or a combination of approaches to recording behavior. The more common approaches usually involve counting the number of times a behavior occurs during a specified time period and/or noting the presence or absence of behavior at specific time intervals of an observational session. Frequency or event recording involves counting the number of times a behavior is observed during a specified time period. When the time periods vary across multiple observational sessions, frequencies are converted to rate of behavior per unit time. For example, an observer may report that a child got out of his or her seat at an average rate of one time per minute during three separate observations conducted over the course of 3 days, even though the actual duration of each observation period varied. By using rate of behavior rather than frequency, comparisons can be made across observational sessions that differ with respect to time. Frequency recording is most useful for observing behaviors that have a discrete beginning and ending and are relatively consistent in the length of time that they take to occur. For example, "tantruming" may not lend itself well to frequency recording because the beginning and end of each tantrum might be difficult

to discern and the length of time of each tantrum might vary from a few minutes to hours. Moreover, frequency recording is usually better suited for behaviors that occur at lower rather than higher rates. With higher rates of behavior, accurately detecting each instance of behavior can be challenging.

In addition to frequency recording, another commonly used recording schedule is interval recording. In comparison to frequency recording, which notes each occurrence of behavior, interval recording divides the observational session into a number of equal intervals and simply records the presence or absence of specified behaviors during each interval. For example, a 20 min observation session could be broken down into 120 10 s intervals. Moreover, unlike frequency recording, in which each instance of behavior is noted, interval recording is only concerned with whether the targeted behavior occurs during the interval. As such, distinctions are not made regarding how many behaviors were observed during the interval. For example, an interval in which there were nine instances of out-of-seat behavior would be coded the same as an interval in which only one instance of out-of-seat behavior occurred.

In practice, interval-recording data are generally collected using one of three coding techniques. When using whole-interval recording, an interval is scored when the target behavior was present throughout the entire interval. Since the behavior must be present for the entire interval, whole-interval recording is well suited to behaviors that are continuous or intervals of short duration. One of the drawbacks of whole-interval recording is that it tends to underestimate the presence of the behavior. For example, if “off-task” behavior were the target behavior of interest and it was observed to have occurred for 8 s of a 10 s interval, the interval would not be scored for the presence of off-task since it did not occur for the entire 10 s. In contrast to whole-interval recording, partial-interval recording codes the occurrence of a behavior if it occurs during any part of the interval. Partial-interval recording is a good choice for behaviors that occur at a relatively low rate or for behaviors of somewhat inconsistent duration. However, because the interval is scored for any presence of the target behavior, partial-interval recording tends to overestimate the actual occurrence of behavior. Lastly, momentary time sampling codes the presence or absence of the target behavior at only one predefined instant of the interval (e.g., usually the instant in which the interval begins). As such, the target behavior is coded as occurring or not on the basis of a fractional observation of the total interval. Once the

target behavior is coded, no other behaviors are noted for the balance of the interval. Although momentary time sampling appears counterintuitive because it is based on the smallest sample of behavior, it actually provides the least biased estimate of behavior, generally providing neither over- nor underestimates of actual behavior. In addition to frequency and interval recording, other less commonly used coding methods include duration (i.e., the actual amount of time that a behavior occurs), latency (i.e., the time it takes for a behavior to be initiated following a prompt or directive), and intensity (i.e., the amplitude of behavior).

5. OBSERVATIONAL INSTRUMENTS

In addition to observer-designed coding schemes, observational instruments have been developed to assess a specific range of behaviors in specific environmental circumstances. For example, an observer might choose to use an observational instrument designed specifically to quantify the percentage of time a student is academically engaged in or on-task, the frequency with which the student interacts with other students on the playground, or the number of times a teacher provides directives, opportunities to respond, or positive reinforcement. In comparison to observer-developed coding schemes, observational instruments can be somewhat more limited in their flexibility since they are usually developed with specific standardized operational definitions and recording schedules. On the other hand, since observational instruments are usually developed with a specific purpose in mind, they often provide a more detailed account of the student’s behavior under the specific environmental context of interest.

6. SUMMARIZING BEHAVIORAL OBSERVATION DATA

Once behavioral observation data are coded they are usually summarized across the entire observational period to provide a description of behavior. As previously indicated, frequency data are reported as a function of rate (i.e., number of behaviors noted divided by the amount of time observed). By doing so, summary data collected across observational sessions of varying time can be compared. Interval data are expressed as a percentage of the intervals that the target behavior occurred compared to the total number of intervals observed. In summarizing

and reporting interval recording results, it is important to note that the behavior was coded for a certain percentage of intervals observed and not time (e.g., "Off-task behavior was noted for 60% of the intervals observed," not "Off-task behavior was noted 60% of the time"). This subtle distinction highlights that the coding scheme used was interval recording, and that intervals and not actual time was the unit of analysis. Duration recording is generally reported as the cumulative amount of time that a behavior was observed. However, it is not uncommon to record the duration of each instance of observed behavior separately and then sum the durations for a final cumulative total. In addition to providing total duration, the latter procedure can also provide the average duration per instance of behavior. Latency recording is summarized similarly to duration, with either cumulative latency or average latency per behavior generally noted. Lastly, intensity is usually summarized using some form of subjective ordinal scale of analysis (e.g., spoke in a voice loud enough to be heard by a person sitting next to him or her, spoke in a voice loud enough to be heard by a person in the room, spoke in a voice loud enough to be heard by a person outside the room, etc.) or by some mechanical recording device specifically designed to measure the dimension of interest (e.g., amplimeter).

7. RELIABILITY AND VALIDITY OF BEHAVIORAL OBSERVATION

The applicability of reliability and validity to behavioral observation has been equivocal, with some suggesting that classical psychometric concepts based on differences between persons are irrelevant to an assessment methodology that focuses on behavior and its variation within individuals, and others suggesting that the differences between traditional and behavioral assessment are primarily conceptual, not methodological, and as such reliability and validity considerations apply.

Traditionally, behavioral assessors and researchers have approached the issue of reliability using accuracy and interobserver agreement as substitutes. Specifically, accuracy refers to the extent to which observed values of behavior approximate the "true" state of the behavior as it actually occurs. When the true state of the behavior is known, comparing the observed values to the true values derives accuracy of measurement. In this case, the behavioral notion of accuracy is the same as reliability in the classic measurement case in which reliability is represented by the extent to which an observed

score represents the true score. As such, in order for a measurement system to be accurate it must be sensitive to the occurrence of true behavior, its repeated occurrence, and its occurrence in multiple settings.

The problem with accuracy, however, is obtaining measures of behavior that can legitimately be considered true values. In particular, when systematic direct observation by humans are used to collect data, developing an incontrovertible index against which to compare scores generated from such an observation system can prove difficult. When possible, some form of technological reproduction is typically used to generate the true values of the behavior. For example, sample sessions of behavior may be videotaped and studied carefully in order to determine the true values for the target behavior. The ability to replay the tape as many times as necessary or to use stop action and reverse options helps avoid error, although it can never be proven that error is completely absent. In this manner, observed behavioral values can be compared to the true value template and accuracy assessed.

The problems in assessing accuracy are obvious. First, the practicality and feasibility of obtaining true values or an incontrovertible index of behavior are low. Simply, most behavioral assessors and many researchers are not equipped with the type of technological assistance that is required to capture the true essence of the target behavior. Second, the issue that one can never fully know the true value behavior because it is impossible to separate what we know from how we know it is ever present. Therefore, accuracy is highly time and context dependent and only represents point estimates of reliable measurement. For these reasons, accuracy is rarely considered or reported in the behavioral assessment literature.

In addition to accuracy, a second commonly used proxy for reliability is that of interobserver agreement. Here, concurrent observations are made independently by two observers and the degree of association between the observers is assessed. It is important to note, however, that interobserver agreement provides no information with respect to accuracy and reliability. Reliable or accurate observations are those that demonstrate a consistent relationship to the behavior as it actually occurs; interobserver agreement provides no such information. Simply, the fact that two observers agree on the number of times a target behavior occurred says nothing about whether their observations were accurate or reliable. For example, two observers may both note the occurrence of 10 instances of the target behavior. The level of their agreement would appear to be 100%. However, if 20 instances of the behavior actually

occurred, and observer A witnessed only the odd-numbered occurrences and observer B noted only the even-numbered occurrences, their actual agreement would be 0%. As such, although complete agreement between two observers might seem like a comforting piece of information, the only conclusion that can be made is that their total values (not the actual behaviors) for the session were in agreement.

As can be seen, both interobserver agreement and accuracy involve comparing an observer's data to some other source. However, they differ considerably in the extent to which the source of comparisons can be entrusted to reflect the true behavior as it actually occurred. Accuracy, which makes a direct comparison to an incontrovertible index of the real behavior, is obviously the more reliable (and valid) of the two; however, it is difficult to estimate in applied research settings. Interobserver agreement, although easier to acquire and often used interchangeably with reliability, suffers from an inability to demonstrate accuracy and makes obvious the problems with using consensus as a replacement for reliability.

8. SUMMARY

Behavioral observation is one of the most widely used assessment strategies in schools. Given its flexibility and ease of use, behavioral observation procedures can be used to collect a range of data that provide helpful information and are useful for making a variety of psychoeducational decisions. Because of its direct nature, behavioral observation is particularly well suited for

everyday life settings and can provide a systematic record of behavior that can be used in preliminary evaluation, intervention planning and design, the documentation of changes over time, and as part of a multi-method-multisource evaluation that integrates other forms of assessment (e.g., interviews and rating scales) and sources (e.g., teachers, parents, and children).

GLOSSARY

affect circumplex A two-dimensional model of affect, with orthogonal dimensions of pleasure–displeasure and high–low activation (arousal).

flow Experiences in which people are highly engaged and focused on what they are doing. When in a flow state, one can complete tasks well and with ease.

monotony Perceived repetitiveness or tedium of a task.

output curve Plot of the rate of output produced during a specified time interval (e.g., a workday).

vigilance The ability to maintain attention and respond to stimuli over an extended period of time.

Boredom is an unpleasant, short-lived, affective state in which a person feels a pervasive lack of interest in, and difficulty attending to, a task or activity. Despite the absence of a single model or theory to explain boredom at work, research has made some progress on

identifying its causes and a wide range of interventions to prevent or alleviate its occurrence.

1. INTRODUCTION

Interest in boredom at work can be traced to the early 1900s. In 1913, Munsterberg, the father of applied psychology, identified boredom as a valuable area of inquiry in the workplace. The first scientific study, “The Physical and Mental Effects of Monotony in Modern Industry,” was conducted more than a decade later by Davies in 1926. Since these early studies, the research on boredom has been sporadic and fragmented, resulting in a nascent understanding of a construct that is thought to have significant performance outcomes and personal consequences for employers and employees. Smith’s 1981 article succinctly summarizes the then—and current—state of research on boredom at work: “The amount of research devoted to the topic of boredom by psychologists and psychiatrists is astonishingly small when compared to literary treatments and to the acknowledged importance of [boredom at work]” (p. 338). Although the focus of this article is on boredom at work, it is important to recognize that other areas of applied psychology have also investigated the causes and consequences of boredom, including education, occupational health, ergonomics, military psychology, mental health, and interpersonal relationships.

In fact, the recent research on boredom has not been conducted in the domain of work. Much of the recent work has been in the areas of clinical psychology and personality.

2. DEFINITION OF BOREDOM

A single clear definition of boredom has been elusive. Boredom has often been used interchangeably with other related but not identical constructs (monotony, repetitiveness, ennui, and tedium) or its observed or hypothesized phenomenological correlates (fatigue, irritation, depression, dissatisfaction, hopelessness, and stress). Others have approached boredom by focusing on methods of alleviating boredom: novelty, interest, complexity, curiosity, enrichment, and “flow” (i.e., experiences in which people are highly engaged, focused, and able to do well). Progress has been made toward a single definition of boredom, complicated by the fact that differing models or theories of boredom (e.g., psychological, psychophysiological, and motivational) necessarily affect its definition. Commonalities across definitions lead to the working definition of boredom used here, as proposed by Fisher in 1993: “Boredom is an unpleasant, transient, affective state in which an individual feels a pervasive lack of interest in and difficulty concentrating on the current activity.” By definition, boredom is viewed as a negative reaction in response to a personal assessment of a work situation that is more short-lived than attitudes such as job satisfaction. The relation of boredom to other affective constructs in a larger nomological net has been acknowledged. In the framework provided by the “affect circumplex,” “boredom” is located on the negative ends of the orthogonal dimensions of pleasantness and activation, along with “tired” and “drowsy.”

3. MODELS OF BOREDOM

Despite 90 years of investigation, there is no single, agreed upon model of boredom at work. Smith’s 1981 research provides a good historical overview of the development of boredom at work, including some models of the causes and consequences of boredom: conflict models, psychoanalytic models, signal detection models, cognitive models, and drive models. Four models serve here as exemplars of the existing approaches to the understanding of boredom at work:

the psychodynamic model, the cultural normative model, the psychophysical model, and the cognitive–affect model.

3.1. Psychodynamic Model

Sigmund Freud’s psychodynamic approach to the understanding of underlying psychological forces has been applied to explain boredom at work. Boredom at work is thought to reflect an inability to identify and ascribe emotional meaning to one’s work. In this view, workers avoid or deny finding meaning in their work because they expect that individual work is not meant or designed to provide personal meaning. The meaninglessness of their work is experienced as boredom, which may be hidden from awareness and understanding through repression, denial, and defense mechanisms, resulting in tension (between what a person wants and what a person gets from work) that manifests itself in psychosomatic complaints, pathology, and so forth.

3.2. Cultural Normative Model

This model proposes that prior socialization makes employees highly dependent on authority figures to ascribe meaning to their work. Workplace norms develop that lead workers to accept without question boredom at work. In this workplace, boredom is denied and suppressed. Individual workers are not free to share or discuss their perceptions or emotions due to these normative pressures. Instead, they are relegated to chronically boring and meaningless jobs.

3.3. Psychophysical Model

The psychophysical model of boredom at work holds that the human nervous system is an active searcher, rather than a passive recipient, of environmental stimulation. Boredom results from exposure to monotonous or repetitious sensory stimulation. Habituation or reduced arousal to the task will result unless the worker voluntarily exerts additional attention and effort to the task. This increased overall arousal offsets the declining sensory stimulation provided by the monotonous task while maintaining a level of arousal adequate to satisfactorily perform the task. Overall, a psychophysical model suggests that if individuals cannot compensate for inadequate arousal from a task by increasing their level of effort, boredom will result.

3.4. Cognitive–Affect Model

The cognitive–affect model proposed by Hill and Perkins in 1985 posits that boredom is a psychological (as opposed to psychophysical) phenomenon. If the sensory stimulation from work fails to meet the needs or expectations of the individual employee, and the employee is unable to supplement the task through additional or alternative stimulation, frustration (negative affect) will result, leading to the overall experience of boredom. In this model, it is the subjective interpretation of the cognitive components of the task that is critical, rather than the actual sensory stimulation. If the task is perceived as monotonous and unable to meet the instrumental needs of the employee engaged in the task, it will lead to an affective disturbance and the experience of boredom.

4. MEASURING BOREDOM

Early assessments of boredom in the workplace were based primarily on the observation of workers, unstructured self-reports, or the inference of boredom based on patterns of responses to related items on structured surveys. For instance, early studies used subjective perceptions of output as a criterion of boredom. In this method, employees indicate the time of the day in which they think they work better and have higher production rates while also indicating when they felt bored. Studies of production workers found higher levels of boredom in the morning and attributed the increased effort and interest as the day progressed to the impending goal of reaching the end of the workday. This pattern of findings supports Wyatt's 1929 rich metaphor for boredom at work—a long hike:

When activities provide little or no interest, the prospects are depressing and discouraging, and the effect seems to bear some relation to the magnitude of the task to be accomplished. To a person who dislikes walking, the prospects of a 20-mile tramp over uninteresting country may be almost painful, and although he starts with a certain amount of forced effort and enthusiasm, this soon disappears and leaves him in a darkened mood. At this stage the magnitude of the task may be appalling, but as the time for lunch and rest draws near interest is awakened and depression recedes. The distance still to be traversed now shrinks considerably, and bears little resemblance to the endless trail conceived a few hours before. A new swing

and liveliness characterize (sic) his step as he again takes to the road, and although these may diminish after a few more miles, they reappear with increased intensity as he enters the lap which separates him from his goal. (p. 162)

Several researchers sought an objective index of boredom in the curve of piece-rate output. This curve is a plot of the total number of pieces completed for some fixed period of time (e.g., 1 h intervals) throughout the day. Work output showed U-shaped curves with a sag in the middle of the morning and again in the middle of the afternoon. The declines in performance were attributed to slower rates of performance when machine operators were bored, with higher rates at the beginning of work and in anticipation of the end of the workday. However, when researchers actually observed and timed workers, the drop in production proved to represent voluntary rest pauses, including rest room and smoking breaks, which may be needed or scheduled at predictable times throughout the workday. Output rate was not slower when the operators were actually working at their machines. Overall, although the hiking metaphor may explain what is happening psychologically, observations of workers that experimentally control for employees who leave their workstations (e.g., a smoking break) do not necessarily support this assumed pattern of motivation and performance.

Following the era in which boredom in the workplace was measured through unstructured employee self-reports of boredom or objective measures of work output over time, a number of self-report rating instruments have been developed. For example, Lee's 1986 Job Boredom Scale measures boredom through employee responses to 17 items concerning satisfaction, interest, and connectedness to the job. Measures also exist that assess workers' susceptibility or proneness to experience boredom. The most common measures are Farmer and Sundberg's 1986 Boredom Proneness Scale and Zuckerman, Eysenck, and Eysenck's 1978 Sensation Seeking Scale (e.g., measuring aversion to repetition and dull people). Unfortunately, there is no single source reference that provides descriptions and psychometric evaluations (e.g., does the instrument measure boredom at work in a consistent and conceptually appropriate manner?) of available measures. College and university research libraries and Internet search engines may be the best sources for finding well-constructed measures for predicting or assessing boredom at work.

5. CAUSES AND CORRELATES OF BOREDOM

Despite the absence of a single unified model or theory to explain boredom at work, the state of research has progressed on identifying its causes. The hypothesized causes of boredom can be grouped into three general categories: the task, the work environment, and the person.

5.1. Task as a Cause of Boredom

The traditional view of boredom at work assumes that boredom resides in the task itself. Specifically, tasks that provide low stimulation (i.e., are repetitive and monotonous) have been thought to result in boredom. Fisher's 1993 article offers a conceptual framework of work tasks that may lead to boredom: quantitative underload (jobs that provide the worker with nothing to do or jobs with a high degree of workload variability, e.g., periods of inactivity after high levels of activity), qualitative underload (jobs that are simple, repetitive, limited in mental demand, unchallenging, or do not use the individual's skills), and qualitative overload (jobs that are too challenging, difficult, or incomprehensible).

5.2. Work Environment as a Cause of Boredom

The work environment may be seen as a lens through which feelings of boredom are reduced or intensified. The mere presence of coworkers can enhance arousal directly through conversation or interdependent work. However, dull, unhappy, or uncommunicative colleagues may actually contribute to feelings of boredom. From a social influence perspective, fellow employees may magnify or reduce boredom through statements or actions that make work seem challenging and interesting or boring and repetitive. Organizational policies and practices may also contribute to the presence or absence of boredom. Rules that prohibit talking, limit work breaks, or prescribe precise work procedure may be so constraining as to induce feelings of boredom.

5.3. Person as a Cause of Boredom

Individual differences among employees may also contribute directly to boredom at work. Research suggests that males tend to be more prone to boredom than females,

particularly when there is a perceived lack of stimulation. However, this gender finding may be culture-specific. Individuals with high cognitive ability or capacity may be more likely to experience boredom on tasks that underutilize their abilities. Conversely, the more intelligent worker may perceive work differently and find a higher degree of variety in a seemingly homogeneous and repetitive task. Personality differences may also contribute to feelings of boredom. Extraverted people may require more stimulation to keep them aroused and engaged at work. The expectations and alternatives available to the person may also affect the perception of interest versus boredom. If a job is the only available job without the hope of other prospects, it may be perceived as less boring. The psychiatric literature has also identified pathologically bored individuals who are unable to perceive the stimulation inherent in work activities or are unable to focus their attention at work as do their better adjusted colleagues.

It is also probable that the task, environment, or person characteristics that cause feelings of boredom interact to accentuate or attenuate these feelings. For example, an employee with limited cognitive capacity performing a challenging and demanding task (i.e., qualitative overload) may experience strong feelings of boredom, whereas an employee with a greater intellectual capacity would not. Conversely, the high-capacity employee may feel more bored on a simpler task (i.e., qualitative underload) than would a person of more limited capacity. As another example, employees who do not perceive any value or instrumentality in their participation at work are likely to feel more bored regardless of whether their work tasks are repetitive or challenging. Finally, individuals who have more complex approaches to the world (i.e., high in schema complexity) may be able to perceive more nuances and details in their work, making them more engaging and less boring. They also may be more likely to engage in goal setting, enhancing the meaning and motivation from their work. Overall, the causes of boredom are likely to be a combination of the direct and interactive impact of task, environment, and person characteristics.

6. CONSEQUENCES OF BOREDOM AT WORK

Boredom at work has negative consequences for workers, their organizations, and society as a whole. Research

suggests that the predicted or demonstrated effects of boredom for individual employees include work stress, job dissatisfaction, physical and mental health problems, workplace hostility, increased risk taking or thrill seeking, horseplay and sabotage, alcohol and drug problems, absenteeism, work-related injuries among adolescent employees, and poor performance. There is also evidence that boredom leads to the perception that time passes more slowly, although individuals' objective estimates of time passed seemed to be unaffected by high levels of boredom. The consequences of boredom for businesses and organizations include higher employment costs (due to employee turnover, absences, and health care costs), performance problems (work quality and work quantity), and reduced organizational effectiveness (including profitability). Finally, boredom at work may also have consequences for society as a whole, including lost productivity, reduced quality of work life, and reduced consumer safety. Numerous studies of vigilance—the ability to maintain attention and respond to stimuli over an extended period of time—reveal that an observer's ability to detect critical signals declines over time. This may be exhibited by a reduction in accuracy or increased response time. High levels of boredom experienced in vigilance tasks have been associated with stress and potentially more serious outcomes. Especially disconcerting is the case of a commercial airliner that overflew its destination by more than 100 miles before the sleeping flight crew was awakened by air traffic controllers. Clearly, boredom at work has significant consequences.

7. PREVENTION AND ALLEVIATION OF BOREDOM

Repetitive assembly, continuous manual control, and inspection and monitoring tasks may be most likely to lead to boredom at work. A wide range of interventions have been suggested to prevent or alleviate boredom at work. One would suspect that the intervention would be most effective if it corresponded to the cause of boredom (e.g., if boredom is caused by the task, the intervention should also focus on changing the task or the perception of the task). Consistent with the framework for categorizing the causes of boredom at work, interventions to prevent or alleviate workplace boredom are therefore organized around the task, the work environment, and the person.

7.1. Task Interventions to Prevent and/or Alleviate Boredom at Work

Although some work tasks may be inherently boring, interventions have been identified that can help minimize boredom on even these tasks. One category of intervention is to design work that is stimulating and psychologically rewarding rather than monotonous and fractionated. Morgeson and Campion described a number of conceptual models for redesigning work to reduce the effects of stressors such as workload and repetitive work. Such interventions can be focused on the motivational aspect of the task (e.g., job enrichment to enhance task meaningfulness) or a reduction in exposure to the stressor that induces boredom or its effects (e.g., ergonomic changes in the work environment to reduce the effects of repetitive work).

In addition, for repetitive tasks, grouping output into recognizable “lots” or batches and providing a system for tracking the number of lots completed may be a useful intervention. Job rotation, or changing work assignments throughout the day, may help employees stay alert and challenged at work. Finally, the use of performance goals (either self-set goals or the acceptance of company-set goals) and feedback on goal success can help prevent or alleviate boredom at work.

7.2. Work Environment Interventions to Prevent and/or Alleviate Boredom at Work

Employee selection and placement systems are an underused means for preventing boredom. Matching individuals to particular jobs may be particularly effective given differences in individual perceptions and reactions to different work tasks. The use of performance-based reward systems, including piece rate payment systems, may also create an incentive that increases employee effort and may prevent or reduce boredom for those who are prone to boredom. However, workers with a low proneness to boredom may benefit from jobs and work environments that emphasize intrinsic rewards such as job enrichment. Companies can also provide rest periods, which have been found to neutralize the unpleasant and unfavorable effects of repeated activity. Providing work that is employee paced rather than externally paced (e.g., a conveyor system) can allow the employees either individually or as a group to adapt their workload to cyclical levels of attention and effort throughout the day. Communicating the importance of the employee's work

contribution to the overall effectiveness of the work unit or company can increase interest in and attention to work. Finally, designing the workplace so that it allows for conversations and social interactions among employees can help prevent or alleviate boredom at work.

7.3. Person Interventions to Prevent and/or Alleviate Boredom at Work

Employees can take steps to reduce boredom at work. Fisher's 1998 article demonstrated that brief interruptions by both internal (e.g., mind wandering) and external (e.g., mobile phones and e-mail) sources may alleviate boredom, depending on the level of attention required to perform the task. In terms of internal mechanisms, forcing oneself to refocus attention or effort on the task can help minimize boredom, particularly at the outset of unstimulating tasks or in constraining work environments. Employees can also seek additional stimulation in an unstimulating work environment by playing mental games, assisting coworkers, and so forth. For well-learned repetitive tasks, employees might use daydreams to escape a tedious and monotonous task. Individual employees may also cope with boredom by learning to integrate their rhythm with that of machines, allowing them to accomplish their tasks through more automatic attentional processes. External interruptions have also been found to reduce boredom on simple low-attention tasks, perhaps by providing variety and additional stimulation to a monotonous work environment. However, such interruptions may be problematic in other situations or for other outcomes.

8. CONCLUSION

Given the individual, organizational, and societal consequences of boredom at work, it is surprising that more attention and effort have not been devoted to theory development, psychological measurement, and scientific investigation. The available research, spanning 90 years of work by practitioners and scientists, has provided a good foundation for expanding our knowledge and understanding of boredom at work. How will current and future changes in the workplace affect boredom at work? The growing use of robots and computers to complete repetitive and monotonous tasks could potentially reduce boredom at work. The migration of simple manufacturing and assembly jobs to other countries may, on average, reduce the level of boredom in the U.S. workplace—if

replacement jobs offer more stimulating tasks or work environments. Changes in the workplace that enhance workers' control over their jobs (i.e., meaningful assignments, goal setting, and feedback) and meet their social needs at work may reduce the level of boredom for future employees. Additional research is needed to ensure the prevention and treatment of boredom in today's workplace and the changing workplace of the future.

Most adults can remember bullies and victims of bullying from when they were in school. The impact of these events does not stop when students graduate; these events can have long-lasting effects on bullies, victims, and even students who only watched bullying occur. The term bullying refers to a specific type of peer aggression that is intentional, repeated, and involves an imbalance of power between the bully and the victim. Suggestions for intervention approaches at the individual, classroom, and schoolwide level are provided in this article.

GLOSSARY

bullying Aggression that is intentional and repeated over time, and there is an imbalance of power between the perpetrator and the victim. Bullying is a specific type of peer victimization that is categorized by these components, which indicate an ongoing relationship between the bully and the victim.

direct bullying When a bully is overtly aggressive toward a victim (e.g., repeatedly hits, teases, or steals from the victim).

indirect bullying When a bully expresses aggression toward a victim through a third party (e.g., spreads rumors and gossips). Although the bully and the victim do not actually interact with each other in instances of indirect bullying, this aggression still has an impact on the well-being of the victim.

1. INTRODUCTION

Bullying in school settings was once thought of as a normal, transient part of growing up. It was considered to have little lasting impact, and the best advice to the victim was to fight back or turn the other cheek. Beginning in the late 1970s and through the 1980s, pioneering research began to shed light on this behavior and to dispel common myths. Expanded studies during the 1990s started to examine bullying as a serious form of aggression and considered the possible impacts of this experience on the bully, his or her victim, and even bystanders. The results of these investigations have shown that not only is bullying a common occurrence but also it has lasting effects on all involved.

The pioneer work on bullying was conducted in the mid-1980s by Dan Olweus, a Norwegian psychologist commissioned to conduct a large-scale study on the topic. Norway's interest in bullying was driven by a string of suicides committed by adolescent boys who had been victims of severe bullying. These efforts were followed by a number of other investigations conducted by researchers in England (Smith), Canada (Peppler), and Australia (Slee, Rigby, and Griffiths). Detailed studies in the United States did not begin to focus seriously on bullying until later, primarily in response to several deadly school shootings that were perpetrated by students who were thought, at least in part, to be seeking revenge for past abuse by school bullies.

2. WHAT IS BULLYING?

Bullying is defined as aggression between peers that has three essential elements: It is intentional, it is repeated over time, and there is an imbalance of power between the bully and the victim. This definition (developed by Olweus) distinguishes bullying from other types of peer aggression, such as one-time fights or friendly teasing between friends. It is these three defining characteristics that make bullying potentially so damaging. Victims are intimidated or hurt repeatedly by someone who is more powerful; consequently, they may learn to accept the victim role and come to distrust others. Ongoing victimization can have a serious impact on the development and well-being of children who are bullied. In addition, bullies who abuse their power (e.g., physical strength and popularity) to single out and intimidate peers potentially become involved in a pattern of using this social control strategy throughout their lives. As such, bullying is considered an exploitative relationship between peers rather than a one-time event.

Despite relative consensus among researchers as to what constitutes bullying, this clarity does not always extend into practice. Many of the most commonly used measures of bullying do not specify that, by definition, bullying is a series of intentional, repeated acts of aggression that occur in peer relationships in which there is an imbalance of power. The omission of a precise definition in research is problematic because, without these specifications, studies may overreport the prevalence of bullying when students are asked about general aggression. In addition, when educators and others think of bullying as a specific event, rather than a series of encounters, interventions may be more punitive and less focused on changing the process of interactions between peers.

In the past, bullying was considered to be physical acts of aggression that primarily occurred between boys. It is now recognized that bullying can take many forms, including ongoing physical abuse (e.g., hitting and pushing), verbal abuse (e.g., taunting and name-calling), social manipulation (e.g., rumor spreading and purposeful exclusion from activities), and attacks on property (e.g., breaking or stealing belongings). One common distinction is between direct bullying (i.e., physical aggression or chronic teasing that occur overtly between the bully and the victim) and indirect bullying (i.e., gossip or rumors targeting the victim that occur between the bully and a third party). Recognition that bullying can include these additional behaviors has broadened the definition and it is now more inclusive of types of aggression that occurs more frequently between girls (e.g., gossip and exclusion). Regardless of its specific form, all bullying involves the repeated abuse of a student by another more powerful student who wants to harm the victim. The bully, in fact, comes to enjoy exercising power over his or her selected target. It is a myth that bullies abuse others to compensate for low self-esteem. In fact, they often have positive self-esteem, may be popular with their peers, and inappropriately come to enjoy having power over others.

3. HOW COMMON IS BULLYING ON SCHOOL CAMPUSES?

The incidence of bullying varies from country to country and school to school within countries. However, it is certain that bullying occurs at all comprehensive schools across all grade levels. Students consistently report that most bullying incidents take place away from an adult presence at the school, including on school playgrounds, during or between class, and walking to and from school. In addition, bullying is often unreported by the parties involved, primarily because the bullies wish to avoid punishment and the victims wish to avoid further aggravating the bully or prompting retaliation—bullies intimidate their victims. Current research practices for collecting information utilize a combination of teacher and/or parent reports as well as student self-reports and student identification or nomination. Because researchers use various methods, a definitive estimate of the prevalence of bullying in schools is difficult to obtain. It is also probable that the available statistics underestimate the extent and scope of this problem.

A 1998 survey of 15,686 students in the United States conducted by the World Health Organization found that 16% of boys and 11% of girls felt bullied, with 23% of boys and 11% of girls admitting to bullying other students. Research has also found an association between the frequency of short-term and long-term victimization. For example, in a 2003 study of Norwegian victims of bullying, Solberg and Olweus found that bullying that persisted over a period of 1 month or more was more frequently reported than short-term bullying events. In other words, bullying is often a chronic experience for its victims.

There are some developmental differences in bullying. A 1993 study by Whitney and Smith found that the occurrence of bullying decreases as students get older, with the highest rates occurring in the upper elementary and middle schools and the lowest rates in secondary schools. This is suspected to be due, in part, to increased social and physical maturity. By the time a child reaches secondary school, there is a decreased presence of older, more powerful peers who can single out and pick on smaller, weaker peers.

In addition to age differences, there are also gender differences in bullying trends. As mentioned previously, boys are more likely to report both bullying and victimization; however, girls are more likely than boys to experience indirect bullying as opposed to direct bullying. Although the consequences of social rejection and isolation associated with indirect bullying may not be immediately obvious, it may produce negative long-term effects on the victim's social development. Finally, female victims are more likely to tell a female peer about their experience, whereas males are more likely to turn to a trusted adult.

4. WHO ARE THE BULLIES?

Despite the increased awareness of female bullying, several researchers have found that most bullies tend to be boys or groups of boys. The results of studies designed to identify the etiology of bullying behavior have been mixed. Some experts suggest that bullies act to exert power over others with the primary purpose of gaining more power. Alternatively, other experts draw upon a social learning model in which bullying is a reaction to being bullied by other children or a reaction to a challenging home environment with associated authoritarian discipline experiences.

In cases in which bullies appear to be the popular children with no history of victimization, the bully behavior may be somewhat puzzling. In these cases, experts have suggested that bullying is a reaction to

some underlying need for power. Bullies are rewarded for exerting power over others by gaining greater power, which reinforces this negative behavior.

Alternatively, the social learning perspective suggests that children who have suffered bullying may begin to bully others less powerful than themselves either as a form of retaliation or as a way of gaining some sense of empowerment. These children have been categorized as bully/victims. Similar to these bully/victims, children from abusive family environments may experience bullying at the hands of family members and, in turn, become bullies themselves. For example, Roberts and Morotti suggest that bullying behavior stems from abusive, chaotic home environments in which families bully the child, who in turn bullies a peer (i.e., a "kick-the-dog" phenomenon). In this type of environment a child learns to normalize and eventually utilize negative social interactions, such as bullying. This idea is supported by the identification of common characteristics of children known to suffer from abusive family experiences. For example, children who bully often display behaviors indicating low social competence, antisocial behavior, a lack of empathy, and high levels of aggression (physical, verbal, and relational). In addition, when interviewed, bullies often describe home environments that are more negative and authoritarian in style than those of children without histories of bullying.

5. WHO ARE THE VICTIMS?

Identified victims of bullying share many similar characteristics. In one pattern, victims are classified as either passive (never behaving aggressively) or highly aggressive (often provoking peers). Most victims are children who spend more time alone than typical children, often falling into the socially rejected category when rated by their peers. They often have poor or less than desirable physical characteristics (e.g., smaller in height, weight, and strength), are younger than the majority of their peers, display low social competence, and emotional maladjustment including depression. In general, victims of bullying are those youth whose physical, psychological, or social status is diminished compared to that of school bullies, thus making them possible targets of repeated aggression.

6. WHAT ARE THE EFFECTS?

The commonly cited short-term effects of bullying to the victim include risks of diminished self-esteem and

depressed mood. Several physical symptoms, such as stomachaches and headaches, difficulty concentrating, and disruption of sleeping and eating habits, have been present among victims of bullying. Long-term effects can include depression, social anxiety, increased levels of aggression, lowered self-esteem, increased risk of suicide, decreased coping skills, and the presence of posttraumatic stress disorder symptoms. As a result of being traumatized by incidents of bullying, victims may carry these negative consequences into adulthood, leading to decreased levels of societal functioning.

Less well known are the effects of bullying on the bully himself or herself. It appears that the long-term effects include risks of school failure; further antisocial, criminal, and delinquent behavior; and an increase in depression, suicidal ideation, and global negative self-evaluations. In 1993, Olweus found that of the Norwegian children identified as bullies in grades 6–9, 60% were convicted of at least one crime by the age of 24. Surprisingly, of this 60%, 35–40% had three or more convictions. In addition, incidents of drug abuse in conjunction with depression and suicidal tendencies have often been high among individuals identified as bullies, especially in comparison to individuals with no history of bullying. Finally, bullying is a behavior that, once engaged in, becomes a pattern that is difficult to stop. The bully may become accustomed to and rewarded by getting what he or she wants through asserting power over other individuals. This behavior may continue throughout life and affect social interactions and interpersonal relationships. In short, someone who is abusive in one aspect of his or her life tends to be abusive in various other aspects of life, which can lead to an aggressive and typically frustrating pattern of social behavior.

7. WHAT CAN BE DONE?

Bully intervention programs implemented at schools seek to eliminate existing bully problems, prevent the development of new bully problems, and achieve better peer relations at school. Other goals of bully intervention programs are to create a positive school climate and increase caring behaviors toward bully victims. These goals are accomplished at the schoolwide level, the classroom level, and the individual level.

7.1. Schoolwide Responses

Before implementing a bully prevention program, the following must be considered:

1. Staff training: What type of staff training is required? Who will provide training? How will training occur?
2. Program funding: How much funding is available? How will funds be allocated?
3. Time commitments: How much time will be required by the trained individuals outside of normal duties? How often will the program be implemented and for how long?
4. Clear behavioral objectives: What will be expected of students after the intervention? Will the school rules be changed?
5. Alternative programs: Which programs will be available for students who are not affected by the intervention?
6. Program leadership: Who will take the lead? How will staff be chosen to participate? What qualifications and training are necessary?

In order to equip schools with appropriate tools to deal with bullying, training should include an awareness component through which the school staff is informed about the extent of bullying on campus. Staff should also be asked to examine their own beliefs about bullying. Training on bully prevention and intervention should include specific strategies as well as an overarching conceptual understanding of the nature of bullying as described in previous sections.

Because bullying often happens in unsupervised contexts, such as on the playground and in the lunchroom, where paraprofessionals and community volunteers often provide supervision, bus drivers, maintenance staff, and cafeteria workers should also receive training. Support staff should be aware of the school code and the school's general bully response procedures.

Bully intervention programs at the school level often restructure the school environment to remove the consequences and negative impacts of bullying. Comprehensive programs typically create specific school-site committees that coordinate aspects of the program, administer questionnaires to determine the nature and extent of the bully problem, hold meetings to raise community awareness, improve supervision and the outdoor environment, and involve parents.

7.2. Classroom-Level Responses

As part of an overall schoolwide plan, teachers implement many bully prevention programs within their classrooms. These programs ideally include a set of clear classroom rules and routines (preferably shared

across classrooms at the same grade level), comprehensive academic lesson preparation, ample classroom structure, opportunities for students to develop empathy for one another, a warm classroom environment, cooperative instructional groups, and shared responsibilities. In addition to basic preparation and creating a positive classroom environment, teachers should never overlook bullying incidents because in doing so they may inadvertently contribute to a broader “culture of bullying” on the school campus. It is important to create conditions that encourage both victims and bystanders to report bullying when it occurs. It is also important to implement programs that address the unique needs and provide assistance to all involved—bullies, victims, and bystanders. Many teachers also implement programs to develop student skills for resolving conflict in order to provide opportunities for “in-the-moment” social skill learning.

7.3. Individual-Level Responses

It is important to determine the function that bullying serves in specific incidents because this will influence the intervention approach. Most bullies know that what they are doing is wrong, but they often have limited empathy for the victim and may have a personal need to dominate others. Merely punishing the bully (by using power over him or her) may only reinforce the notion that power is an effective social tool. Immediately following a bullying incident, a teacher or staff member should have a serious talk with the bully to determine what steps should be taken next. The talk should include a documentation of the incident, a message that bullying is not acceptable, a referral to the school’s code of conduct, and a reminder that the bully’s behavior will be closely monitored in the future. Individual responses to bullying also include continued one-on-one discussions, counseling, parent involvement, follow-up discussions, and, in extreme cases, the change of class or school for the bully or the victim.

In addition to talking to the bully, the victim should be interviewed as soon as possible, separately from the bully. It is important to obtain information about the duration and frequency of the bullying incident(s), if the victim has had similar experiences in the past, and what the victim has done to try to stop it. During this talk, the incident and nature of discussion should also be documented, the victim should receive information about the plan of action for the bully, and the victim should be taught how to report any future incidents. Assessing the social skills and status of the victim should

be carried out as part of an effort to provide social skills training to enhance his or her sense of personal efficacy to cope effectively with any future bullying.

Because peers play different roles in the bully process, it is important that they be considered as a possible resource in the intervention process. Training for students should also contain an awareness component in which they are taught about the nature of bullying specific to their school and the resources available to them. It is important that their consciousness is raised about the general processes of bullying and the individual’s responsibility as a bystander. Training should focus on increasing empathy for the victims as well as provide peers with strategies to encourage them to withstand the pressures of their peer groups. Despite the common occurrence of bullying on school campuses, most students are not victims or perpetrators. They can have a powerful effect on the school climate as it relates to bullying. In part, bullying occurs on school campuses because it can. If bystanders recognize their important role in setting school standards, then its occurrence can be significantly reduced.

8. THE SPECIAL ROLE OF BYSTANDERS

Because peers are such an important part of the bullying process, they merit additional in-depth examination. By its nature, bullying is a social interaction that is embedded in a broader school context. The aggression that occurs between bullies and victims is rarely restricted in its impact to the bully–victim dyad. Rather, peers play an integral part in bullying and intervening. Olweus conceptualized student involvement in an acute bullying situation as being part of a continuum (or “bullying circle”) (Fig. 1). At one end of the continuum are students who take an active part in bullying, support the bully, or follow the bully. At the other end of the continuum are students who defend the victim and dislike the bully’s actions. Many students fit in roles that fall somewhere in between—supporting the bully but not taking an active part, supporting the victim but not helping in his or her defense, or as disengaged onlookers.

Simply by observing the bullying behavior, peers reinforce bullies who often gain social prestige through their aggression. In one study of school bullying, O’Connell, Pepler, and Craig found that when a higher number of peers were observing an incident of

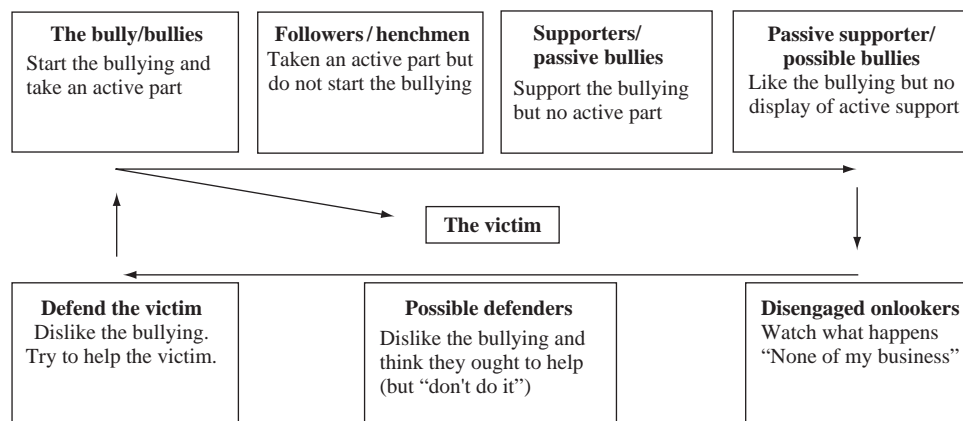

FIGURE 1 Continuum of student reactions in a situation involving acute bullying. Adapted from Olweus (2001).

bullying, the duration of the incident was longer. The presence of peers served to encourage the bully by giving him or her more peer attention. At least for some bullying behavior, one of the primary reasons that bullying occurs is because the bully gains social prestige through this peer attention. When peers are asked for their opinions of bullies and victims, they usually say that the bully is more likeable than the victim (this is thought to be true because the popularity and aggression of bullies are more appealing than the perceived weakness of victims).

Although the influence of peers encourages bullies, the intervention of peers is also one of the most powerful ways to stop bullying. In one investigation, bullying stopped in three-fourths of cases when a peer intervened on behalf of the victim. Because adults are often unaware of instances of bullying, the impact of this peer intervention should not go underestimated. Nonetheless, although 41% of students said that they would like to help the victim, in reality only 25% intervened. The question of what leads peers to action or inaction in the face of a bullying situation is an important consideration that should be discussed openly in every school.

Students with higher social status are more likely to intervene and help the victim than students who are less popular and perhaps fear that they will also be bullied. Another reason for failing to help the victim may be related to the fact that many acts of bullying occur in front of a group. When several students together observe a peer being bullied, they may feel a lack of individual responsibility to help the victim (social psychologists call this the bystander effect). Even when students would like to intervene, they

may not have the skills or know how to help the victim in a way that will be effective. These are topics that are addressed in several intervention programs that educate peers and involve the entire school community.

9. IMPLICATIONS

Research has identified the “culture of bullying” on school campuses. Students are less likely to report witnessing bullying or being personally victimized by a bully if they also perceive that in the past teachers at their school have not intervened to stop bullying. Thus, although many prevention and intervention efforts attempt to decrease the aggression of the bully and to enhance the social skills of victims, it is now recognized that if a school has a laissez-faire, inferred acceptance of, or a blind unawareness of bullying, then students are more likely to accept its occurrence as a “normal” part of the school experience. These developments in bullying research show that schools cannot afford to let students work out their conflicts. To do so may send a message that behaviors such as bullying are tacitly tolerated. Bullying is the largest violence/aggression problem in schools worldwide. As such, it is of the utmost importance that schools study their particular circumstances and take action to prevent its occurrence and to intervene when it occurs.

GLOSSARY

career choice The act of choosing a career path; it is often first done during adolescence and early adulthood but is often modified as changes in the self, the world, or work change in the course of an individual's life.

contextual factors in career planning Factors in an individual's environment that may influence his or her career development; these factors might include the person's social class, race/ethnicity, family structure, and so forth.

self-assessment The process of gaining information about oneself (e.g., personality, values, skills, interests) so as to make an informed career decision; it can be conducted using inventories, using computerized career information systems, or having discussions with a career counselor.

world of work information Information that often includes job duties, education and training required, salaries and other benefits, and employment outlook; gathering world of work information is often an integral part of the career planning process.

Career counseling is ongoing face-to-face interaction performed by individuals who have specialized

training in the field to assist people in obtaining a clear understanding of themselves (e.g., interests, skills, values, personality traits) and to obtain an equally clear picture of the world of work so as to make choices that lead to satisfying work lives. Career counselors help clients within the context of a psychological relationship with issues such as making career choices and adjustments, dealing with career transitions, overcoming career barriers, and optimizing clients' work lives across the life span. Career counselors are cognizant of the many contextual factors present in the lives of their clients and of the ways in which social and emotional issues interplay with career issues.

1. THE EVOLUTION OF THE DEFINITION

The current field of career counseling has been referred to by many different terms such as vocational counseling, career guidance, and vocational guidance. In fact, its definition has evolved to meet the changing context and needs of individuals within society. During the early writings about career counseling, it was described as a process of "matching men and jobs," reflecting the basic function of helping primarily male workers find jobs. As the field progressed, its purview was widened to involve helping both men and women with their career development more broadly and including issues such as decision making, career adjustment, and career

change. There have also been refinements of the definition, including an emphasis on career counseling being done over the life span as opposed to an activity primarily restricted to one's initial job choice. In addition, there has been growing acknowledgment of the intertwined nature of career counseling and social/emotional counseling, with some research indicating that career counseling may help individuals not only with their career adjustment but also with their personal and psychological adjustment. With the growing diversity in society, there has also been particular attention paid to the importance of the cultural context of an individual's life, including factors such as race/ethnicity, social class, age, ability level, sexual orientation, and religion. Thus, the definition and purview of career counseling continues to be dynamic, addressing the needs of a changing society.

2. HISTORY OF THE FIELD OF CAREER COUNSELING

The origins of career counseling, broadly defined, can be found during early Greek and Roman times, but the roots of the field as is practiced today can be traced to the last half of the 1800s and the early 1900s in the United States. This was a time when the origins of the human sciences were forming, particularly in experimental psychology, with the work of Wilhelm Wundt. It was also a time when "mental testing" was born, with James Cattell first using this term in an article in the journal *Mind*. Cattell was most interested in using mental tests to examine individual differences, particularly in measuring student achievement. Economically, this was a time of great turmoil and demographic change because the industrial revolution was under way and the country was moving from a primarily agrarian economy to an industrial-based economy. At this time, there was also an influx of immigrants, primarily from Europe, entering the country. Often, these individuals faced a host of social and employment problems in finding employment. Even once they secured jobs, they often faced unhealthy working conditions, overt discrimination, and physical and psychological abuse. There was a strong need for services to help these new workers find their place in the employment structure and to provide a range of social services and social advocacy on their behalf.

3. THE ROLE OF FRANK PARSONS

The need for a strong social advocate for these immigrants was found in the person of Frank Parsons, who is often referred to as the "Father of Career Development." Parsons developed what was termed the Breadwinners Institute under the Civic Service House in Boston. The institute was designed to provide a range of educational services for immigrants. It was in this context that Parsons developed a systematic way of helping individuals to find appropriate work that still has much influence on the way in which career counseling is conducted today. Parsons' book *Choosing a Vocation*, which outlined his decision-making process, was published in 1909 after his death. Parsons theorized that there were three broad decision-making factors: (a) a clear understanding of oneself, including one's aptitudes, abilities, interests, and limitations; (b) a knowledge of the requirements, advantages, disadvantages, and prospects of jobs; and (c) the ability to reason regarding the relation of these two sets of facts. These three factors have had an enormous impact on how career counseling has been practiced during the century since it was originally published.

4. THEORIES OF CAREER DEVELOPMENT

Career development theories provide foundational knowledge from which to draw useful concepts to explain behavior. They offer a framework within which individual career behavior can be explained and hypotheses can be formed about the possible meaning of behavior. As such, they help career counselors to identify and understand clients' goals and problems within a theoretical framework. Since the inception of the field, career theory has been an important guiding force for the practice of career counseling. Early theories, such as those of Ginzberg, Bordin, Roe, and Super, all helped to provide theoretical approaches to career development. Ginzberg conceptualized the process of career development as being lifelong and subject to compromise, Bordin's conceptualization of career development was informed by a psychoanalytic view of human behavior. Roe built a theory based on Maslow's hierarchy of needs and personality types. Super conceptualized career development as a developmental process and not a one-time choice. All of these early theoretical contributions still have impacts on the way in which career counselors understand human behavior today.

Arguably, the theory that has spurred the most research, and has been used the most in practice, is that of Holland. Holland articulated his comprehensive trait-factor theory in his book *Choosing a Vocation*, which was published in 1973 and revised in 1985 and 1997. Holland's theory proposed that individuals' personalities and work environments can be categorized into one of six types: Realistic, Investigative, Artistic, Social, Enterprising, or Conventional. This RIASEC theory of career development maintains that individuals will search for environments that best fit their personalities and will derive more satisfaction in finding this fit. Holland's theory has been used extensively in the United States and abroad to provide a framework for career counseling.

More recently, a number of additional theories of career development have been proposed, including Lofquist and Dawis's theory of work adjustment, Krumboltz's social learning theory of career decision making, Gottfredson's theory of circumscription and compromise in career choice, and Lent Brown and Hackett's social-cognitive theory.

5. RESEARCH IN CAREER COUNSELING

The field of career development has been one of the most actively and rigorously researched fields within counseling psychology. The field has a great deal of information available indicating that career development services, such as workshops, classes, groups, computerized career information, and guidance systems, tend to be highly effective in helping individuals to become clearer and more confident about their career goals. Considerably less information is available specifically about the efficacy of career counseling. Even less is known about what specific aspects of the career counseling process lead to effective outcomes. A recent meta-analytic study conducted by Brown and Krane analyzed 62 studies and approximately 8000 participants in attempting to determine which interventions led to the greatest change. From these data, five specific components of career counseling were shown to contribute significantly to the effect size: written exercises, individualized interpretations of information, the provision of information on the world of work, opportunities for modeling, and the building of support for career choices in individuals' social networks. The authors noted that these five interventions collectively seemed to be associated with remarkable,

nearly linear increases in career choice effect size. Thus, as the methodological tools available to researchers are becoming more sophisticated, we are learning more about what specific interventions are most helpful in the career counseling process.

GLOSSARY

achievement test A procedure designed to measure an examinee's attainment of knowledge or skills.

cheating Any intentional action or behavior that violates the established rules governing the administration of a test or the completion of an assignment; cheating gives one student an unfair advantage over other students on a test or an assignment and decreases the accuracy of the intended inferences arising from a student's performance on a test or an assignment.

crib sheet A piece of paper or other material on which inappropriate or unauthorized material is written for use during a test; it is also known as a cheat sheet.

high-stakes test A test for which serious consequences are associated with performance.

honor code A formal statement or policy concerning the rights and responsibilities of students and teachers in academic settings as well as the penalties for failing to uphold those responsibilities; the statement may be limited to matters of academic integrity but may also deal with honesty, respect, and citizenship in the academic community more broadly.

plagiarism Representing, in written or oral expression, the words, thoughts, or ideas of another person without appropriate citation or referencing, usually for the purpose of intentionally misrepresenting such words, thoughts, or ideas as one's own.

proctoring The process of monitoring test takers during an examination; a proctor (usually the instructor in a classroom) observes examinees during a test to discourage cheating and document irregularities or suspicions of cheating, but the proctor can also provide legitimate assistance to test takers if special needs, questions, and the like arise during the test.

razoring The removal of material from a printed source document for the purpose of preventing others from gaining access to the source; the term comes from the use of a razor blade to excise pages from, for example, a book or journal held in a library reserve section.

surrogate One who takes a test in place of another.

validity The degree to which the conclusions yielded by any sample of behavior (e.g., test, assignment, quiz, term paper, observation, interview) are meaningful, accurate, and useful; it is the degree to which a student's performance results in decisions about the student that are "correct" or to which inferences about the student's knowledge, skill, or ability that are "on target."

Cheating in academics refers to actions on the part of students that violate the explicit rules or commonly accepted norms for examinations or assignments. Cheating occurs at all levels, from the primary grades though testing for licensure or certification in a profession. Although most research on the topic of

cheating has focused on inappropriate behavior on the part of those who take tests, cheating in academics can also include cheating by those who give tests. Reasonably accurate methods exist for detecting some types of cheating. Many strategies have also been proven to be effective for organizing instruction and assessment so that cheating can be prevented.

1. INTRODUCTION

Sound assessment practice involves the development and administration of high-quality instruments and procedures to measure student learning. Assessment instruments can include graded tests and assignments. Information that results from these instruments can be helpful to students themselves or to others who use the information for educational decision making such as teachers, administrators, and policymakers. Increasingly in education contexts, consequences are also associated with performance on assessments. When the associated consequences are relatively serious, the assessment is said to involve high stakes.

The stakes associated with an assessment can be serious or mild, and they can be positive or negative. For example, awarding scholarship money to a student who performed at an exceptional level on a college admissions test would be considered a serious positive consequence. Assigning an elementary student to a remedial reading program due to a low test score could be either a positive or a negative consequence, depending on whether or not the remedial program was effective and other factors. Withholding a diploma because a student failed a graduation examination would be a fairly serious negative consequence. As the importance of decision making increases, and as the stakes associated with assessment rise, the problem of cheating becomes more pronounced.

Studies of cheating by students indicate that the incidence of the behavior increases as students pass through the grade levels, with the greatest frequency at the high school and college levels. Research evidence indicates that approximately 90% of students admit to having cheated on a test or an assignment, and it is estimated that 3 to 5% of students cheat on a given test or assignment.

2. DEFINITIONS AND EXAMPLES

This article focuses on the kinds of cheating that occur in classroom situations. Cheating can occur on tests,

for example, when one test taker copies test answers from another test taker. Cheating may also occur on assignments, such as on term papers or projects, when a student inappropriately uses material taken from another source for the assignment.

Regardless of the situation, a general definition of cheating can be developed. Cheating can be defined as any intentional action or behavior that violates the established rules governing the administration of a test or the completion of an assignment, gives one student an unfair advantage over other students on a test or an assignment, or decreases the accuracy of the intended inferences arising from a student's performance on a test or an assignment.

Varieties of cheating by test takers can range from simple copying of another student's answers to more elaborate schemes. An examinee may use unauthorized materials, such as a cheat sheet, or may take advantage of the testing situation by requesting testing accommodations that are not necessary. Cheating on assignments may involve impermissible books, notes, or persons when the use of such aids is contrary to guidelines provided for an out-of-class assignment. Academic cheating also may include plagiarism, in which the original words, thoughts, or ideas of another person are used without appropriate citation or referencing (usually for the purpose of intentionally misrepresenting such words, thoughts, or ideas as one's own). Many Internet sources exist from which students can, either at no charge or for a fee, copy or download complete term papers or smaller portions of existing works. Finally, other forms of cheating exist in testing situations (e.g., when a person does not actually take a test himself or herself but rather relies on another person, called a confederate or surrogate, to do so) or on assignments when cheating may take the form of razoring (which involves the removal of material from a printed source document for the purpose of preventing others from gaining access to the source). More extensive lists of cheating methods were provided by Cizek in 1999 and 2003.

3. CHEATING AND VALIDITY

Validity is the single greatest concern in any assessment situation. The concept refers to the accuracy of the interpretations about examinees based on their performance on a test or an assignment. In technical terms, validity is the degree to which evidence supports the inferences made about a person's knowledge,

skill, or ability based on his or her observed performance. By definition, inferences are based on a less than ideal amount of information such as a sample of a student's knowledge or skill obtained via a test or term paper. Because it is often too costly or impractical to gather more information, inferences must be based on samples of behavior. Consequently, it is necessary to consider the accuracy of inferences based on the available evidence (e.g., test performance), that is, to consider validity. Any factor that attenuates the ability to make accurate inferences from the sample of performance threatens validity and jeopardizes the meaningfulness of conclusions based on the sample at hand. When cheating occurs, inaccurate inferences result.

4. PROFESSIONAL GUIDELINES ON CHEATING

Many educational institutions have developed honor codes to formalize expectations about academic integrity; to clearly define the types of actions that constitute cheating on tests, assignments, or other academic work; and to outline penalties for cheating. Test publishers usually produce carefully scripted directions for administering their tests and provide clear guidelines for what kind of behavior is permissible and what kind is not. Acceptable behavior and unacceptable behavior are also sometimes codified in states' administrative regulations or statutes. Assessment specialists, through their professional associations, have developed professional guidelines to inform test takers and test administrators regarding inappropriate practices. The most authoritative of these guidelines are found in the *Standards for Educational and Psychological Testing*, a document that focuses on testing. Among their provisions, the standards indicate that those involved in testing programs should

- protect the security of tests (Standard 11.7);
- inform examinees that it is inappropriate for them to have someone else take the test for them, disclose secure test materials, or engage in any other form of cheating (Standard 8.7);
- ensure that individuals who administer and score tests are proficient in administration procedures and understand the importance of adhering to directions provided by the test developer (Standard 13.10);
- ensure that test preparation activities and materials provided to students will not adversely affect the

validity of test score inferences (Standard 13.11); and

- maintain the integrity of test results by eliminating practices designed to raise test scores without improving students' real knowledge, skills, or abilities in the area tested (Standard 15.9).

5. DETECTING CHEATING

Attempts to detect cheating can be performed by observational/judgmental or statistical methods. Observational/Judgmental methods have the potential to detect cheating on academic assignments and tests. Statistical methods have been developed to detect a particular type of cheating (copying) on tests.

Observational/Judgmental methods rely more heavily on subjective human perceptions. For example, a student might enlist the aid of a surrogate to take an examination in his or her place. Human judgment is involved in detecting this form of cheating; exam proctors must be alert for test takers who do not appear familiar to them, must scrutinize examinees' identifications prior to the test, and so on. Judgment is also involved when handwriting samples from the student are compared with those of the surrogate to make a determination of whose handwriting appears on the test materials or when a student obtains an unusually large score gain from one test administration to another.

Judgment is also involved in the detecting of plagiarism on written assignments such as term papers. A number of techniques can be used to ascertain whether a student's written work is original or may have been plagiarized. Table I lists some common observational/judgmental methods for detecting this form of cheating. In addition to observational/judgmental methods, statistical methods and computer technology can be invoked to aid in the detection of cheating.

Basic search engines (e.g., Google, Yahoo) can be used to locate Internet sources from which plagiarized material may have been drawn. This method relies on an instructor entering a unique word (or, better yet, a unique phrase or string of words) from a student's paper to identify Internet sources containing the same string. Commercial (i.e., fee-based) Web sites devoted to the detection of plagiarism also exist. Most such sites require student work to be submitted electronically. Then, students' papers are compared with those in databases of student work maintained by the host of

TABLE I
Observational Indications of Potential Plagiarism

1. The writing style, language, vocabulary, tone, grammar, and/or other features of a student's writing are not commensurate with what the student usually produces.
2. There are awkward changes in verb tense, pronouns, structure, and/or organization of the paper. The writing is choppy. Sections or sentences in the paper seem out of place or do not relate to the overall topic of the paper.
3. Strange text, such as a date in the footer of a paper or a URL (Web site address) in a header, appears at the top or bottom of printed pages.
4. There is unusual or inconsistent formatting such as page layout, line spacing, margins, and/or pagination. The paper contains changes in font, pitch, color, and the like, suggesting that the paper may have been downloaded from the Internet or cut-and-pasted from another source.
5. The paper contains references to graphs, charts, accompanying material, citations, chapters, footnotes, and/or additional text that are not provided with the paper.
6. The paper includes allusions to ideas, persons, settings, and/or other elements with which the student is not likely familiar.
7. The paper contains citations or references to sources or materials to which the student is not likely to have access.
8. Citations or references are missing, inaccurate, or incomplete.
9. The student has difficulty summarizing his or her paper or in responding to simple questions about what he or she wrote.

Source. Adapted from Bates and Fain (2002, p. 1) and Cizek (2003a, chap. 4).

the site. An overall probability is produced for each student's work, indicating the overall degree of similarity between the student's paper and all of the other sources. Software for local use that essentially performs a similar function of searching for common phrasings can also be purchased.

Statistical methods are also available to gauge the probability of copying on multiple-choice tests. Information on these methods, including details regarding how to compute statistical indexes of cheating, was provided by Cizek in 1999 and by Sotaridona in 2003.

6. PREVENTING CHEATING

Many strategies exist for deterring cheating in academics. Many of these strategies are unique to the

particular type of cheating to be deterred (i.e., whether on a test or on a written assignment). Other strategies aim to foster higher levels of academic integrity in general. Table II provides a list of specific ways in which to prevent cheating on tests and written assignments.

In addition, at the college and university levels, many institutions have found that inappropriate behavior can be prevented by developing and disseminating explicit expectations about academic integrity. Such expectations, formalized in what are referred to as honor codes, help to promote a campus culture and community characterized by the valuing of ethical conduct. An excerpt of one such honor code is reproduced in Table III. The excerpt shown is limited to the portion of the code related to cheating, and a source reference is provided for accessing the full code.

TABLE II
Strategies for Preventing Cheating

1. Limit the amount of tests and assignments that "count" toward student grades. Foster an assessment climate in which students apprehend the value of accurate information on their strengths and weaknesses. Avoid using grades punitively.
2. Introduce students to the requirements of academic integrity explicitly and often. Provide concrete illustrations of inappropriate actions. Teach appropriate test preparation and citation practices.
3. Avoid assessment formats that make cheating easier. For example, reduce reliance on multiple-choice items in favor of constructed-response formats. Use alternate forms of tests in which test item positions are scrambled. Avoid "take home" tests. Avoid repeating term paper topics or test questions from year to year.
4. Keep test materials secure in advance of testing. Follow appropriate steps during testing such as requiring adequate spacing between test takers. Remain vigilant while proctoring.
5. Be fair and open about assessment. Provide students with adequate notice and description of examinations and adequate time to complete written assignments.
6. Inform students that statistical methods for detecting answer copying and technological aids for detecting plagiarism will be used.
7. Institute an honor code. Develop and disseminate policies on cheating. Implement penalties for academic dishonesty.

TABLE III
Sample Honor Code

A. General Responsibilities

It shall be the responsibility of every student at the University of North Carolina at Chapel Hill to

1. Obey and support the enforcement of the Honor Code;
2. refrain from lying, cheating, or stealing;
3. conduct themselves so as not to impair significantly the welfare or the educational opportunities of others in the university community; and
4. Refrain from conduct that impairs or may impair the capacity of university and associated personnel to perform their duties, manage resources, protect the safety and welfare of members of the university community, and maintain the integrity of the university.

Offenses proscribed by this section include, but shall not be limited to, those set out in Sections II.B and II.C.

B. Academic Dishonesty

It shall be the responsibility of every student enrolled at the University of North Carolina to support the principles of academic integrity and to refrain from all forms of academic dishonesty, including but not limited to the following:

1. Plagiarism in the form of deliberate or reckless representation of another's words, thoughts, or ideas as one's own without attribution in connection with submission of academic work, whether graded or otherwise
2. Falsification, fabrication, or misrepresentation of data, other information, or citations in connection with an academic assignment, whether graded or otherwise
3. Unauthorized assistance or unauthorized collaboration in connection with academic work, whether graded or otherwise
4. Cheating on examinations or other academic assignments, whether graded or otherwise, including but not limited to the following: (a) using unauthorized materials and methods (notes, books, electronic information, telephonic or other forms of electronic communication, or other sources or methods); (b) violating or subverting requirements governing administration of examinations or other academic assignments; (c) compromising the security of examinations or academic assignments; (d) representing another's work as one's own; or (e) engaging in other actions that compromise the integrity of the grading or evaluation process
5. Deliberately furnishing false information to members of the university community in connection with their efforts to prevent, investigate, or enforce university requirements regarding academic dishonesty
6. Forging, falsifying, or misusing university documents, records, identification cards, computers, or other resources so as to violate requirements regarding academic dishonesty
7. Violating other university policies that are designed to ensure that academic work conforms to requirements relating to academic integrity
8. Assisting or aiding another to engage in acts of academic dishonesty prohibited by Section II.B.

Cheating in Sport

Glyn C. Roberts, Yngvar Ommundsen, Pierre-Nicolas Lemyre and Blake W. Miller

Norwegian University of Sport Science, Oslo, Norway

1. Introduction
 2. The Context of Sport
 3. What Is Cheating?
 4. The Motivation to Cheat: Achievement Goals as a Determinant of Moral Action
 5. Dispositional Achievement Goals
 6. Perceived Motivational Climate and Determinants of Cheating
 7. What Can We Do about Cheating?
- Further Reading

Recent research reveals that understanding the achievement goal of a person may help to explain cheating in sport. Achievement goals have dispositional elements as well as situational determinants, and both have been associated with cheating and moral action in sport. The more ego involved the person, the more the person cheats. Reducing cheating may be achieved through coach education and by deemphasizing normative comparisons.

GLOSSARY

- achievement goals** Within an achievement context, the goals that give meaning to achievement striving.
- cheating** A quest to provide an unfair advantage over the opponent; cheating may be “unsportsmanlike” aggressive behavior or inappropriate moral action, but always with the intent to gain an advantage.
- dispositional goals** Achievement goals that are within a person, that is, an individual difference variable.
- ego involvement** When the goal of a person is to demonstrate superiority to peers.
- moral atmosphere** The collective norms of the team about whether or not to condone cheating.
- motivational climate** The perceived criteria of success and failure that a person perceives are manifest within an achievement context.
- task involvement** When the goal of a person is to achieve mastery or learning.

1. INTRODUCTION

Cheating in sports is endemic. Each week brings new revelations about cheating, from sprinters who take banned substances (e.g., Dwain Chambers, Carl Lewis, Kelly White) to endurance athletes who take performance-enhancing drugs (e.g., Roberta Jacobs, Richard Virenque, Pamela Chepchumba). But cheating is not limited to individual athletes; prestigious sport organizations have also been caught trying to bend the rules for their own advantage. Some of the most blatant examples of recent cases include the following. Six athletes from the Finnish Ski Federation were discovered to have taken performance-enhancing drugs with the blessing of the medical staff and were disqualified at the Lahti World Cup in 2001. The South Africa, Pakistan, and India cricket teams were found to have fixed matches in 2000. The Welsh Rugby Association recruited illegal players to play for Wales in 2000 by “discovering” fictitious Welsh grandparents for the players. Cyclists on sponsored teams

(e.g., the Festina cycling team) in the Tour de France were caught using banned substances in 2001 and 2002. Cheating has even polluted children's sports, with the most recent visible case being that of Little League pitcher Danny Almonte, who was 14 years of age when he was the winning pitcher for the Little League World Series (restricted to children 9–12 years of age) in 2001. Danny's father has been indicted for the fraud.

At the time of this writing, a huge cheating scandal involving track and field athletes was breaking in the United States. On October 16, 2003, the U.S. Anti-Doping Agency (USADA) released a statement describing the discovery of a new "designer steroid" that had been deliberately manufactured by BALCO laboratories in the United States to avoid detection by current testing procedures. The new steroid (tetrahydrogestrinone or THG) was discovered only after a prominent coach sent a syringe containing the substance to the USADA and named several prominent athletes who were using the steroid. The anti-doping laboratory at the University of California, Los Angeles, identified and developed a test for the substance, and the USADA retrospectively tested the samples from the U.S. Outdoor Track and Field Championships in 2003. Several positive sample results have emerged, and it has been decided that all of the samples from the 2003 World Championships in Paris are to be tested. Terry Madden, the USADA chief executive, stated that this is a case of intentional doping of the "worst sort" and that it involved a conspiracy involving chemists, coaches, and athletes in a deliberate attempt to defraud fellow competitors and the world public. The testing of both "A" samples and, if positive, subsequent "B" samples was ongoing at the time of this writing. In addition, Victor Conte, the founder of the BALCO laboratory that is at the heart of the scandal, was indicted to appear before a grand jury investigating the illegal distribution of a controlled substance. The scandal could involve many athletes and will tarnish many reputations and the sport. Among the athletes named thus far are U.S. shot put champion Kevin Roth, hammer thrower John McEwan, women's hammer throw champion Melissa Price, and middle distance runner Regina Jacobs, who all tested positive at the 2003 U.S. championships. The European sprint champion, the United Kingdom's Dwain Chambers, has also tested positive. Among other "clients" of BALCO laboratories who have been implicated are sprinters Marion Jones and Tim Montgomery, baseball star Barry Bonds, and the NFL's Bill Romanowski.

Not all cheating is as obvious. Each sport has its own manifestation of illegal or inappropriate activity. As an

example, professional soccer has what is termed the "professional foul" where players will sometimes pull an opponent's shirt to prevent or hinder progress with the ball. This is now so common that referees do not call it unless it is very blatant. Football players also "dive" when challenged for the ball, trying to draw a penalty. Baseball players cork their bats. The world's number one golfer, Tiger Woods, has accused many of his fellow professionals of using illegal drivers that give a "trampoline effect" to the ball. Cricket players tamper with the ball to make it "swing" more through the air. And so on,

Why do people cheat in sport? Many explanations have been given, and they are mainly economic (the rewards of being a successful elite athlete are huge), sociological (a breakdown in the moral fabric of society), and psychological (the focus of the current article). However, it is the act of competing that has been indicated the most. It is argued that competition, whether on the sport field, in the classroom, or in the boardroom, is the culprit. When people compete, especially in important contexts, people will cheat to achieve success. When winning is everything, they will do anything to win. But so many people who compete do not cheat, so it might not be competition per se that is the problem. An interesting question may then be asked: What are the determinants of cheating, and how are these manifested in sport contexts? The current authors' research over the past few years has investigated this issue and, like so many other researchers investigating cheating in sport, has looked at children's sport. What are some of the determinants of children engaging in inappropriate behavior in sport? First, one must look at the context of sport, and what it means for children, and then define what is meant by "cheating" before discussing the manifestation of cheating in sport.

2. THE CONTEXT OF SPORT

Performance in sport is clearly important for adult athletes; the rewards of competence can be significant. In addition, public interest in sport is high and is reflected in the column inches devoted to sport in the popular newspapers as well as in television airtime. It was estimated that one in four persons worldwide watched the final World Cup soccer match between Brazil and Germany on television in 2002. Thus, the entertainment value of sport is increasing for adults. The context is also important to children for different reasons.

Performing in sport contexts is assumed to be important in the socialization process of children toward

the development of appropriate moral behavior. In play, games, and sport, children are brought into contact with social order and the values inherent in society and are provided a context within which desirable social behavior is developed. The psychosocial and moral development of young participants is fostered when peer status, peer acceptance, and self-worth can be established and developed, and the adoption of various perspectives is enhanced. Sport is also assumed to provide a vehicle for learning to cooperate with teammates, negotiate and offer solutions to moral conflicts, develop self-control, display courage, and learn virtues such as fairness, team loyalty, persistence, and teamwork. Despite popular beliefs that sport builds character, this notion has been questioned. Research has shown that competition may promote antisocial behavior and reduce prosocial behavior.

The context of sports is becoming an increasingly important one for modern-day children. With the demise of children's game-playing culture, children are more and more likely to be involved with adult organized sport competition, even as young as 4 years of age (e.g., motocross in Belgium). In addition, research has demonstrated that the domain of competitive sport is a particularly important context for psychosocial development in that peer status, peer acceptance, and self-worth are established and developed. These social attributes are based on many factors, but one way in which a child can gain peer acceptance and status is to demonstrate competence in an activity valued by other children. One area of competence that is highly valued by children is sporting ability. In fact, because of the modern-day visibility of sport, being a good sport player appears to be a strong social asset for a child, especially in the case of boys. Thus, the context is an important one and is one where cheating to gain advantage or gain acceptance with one's peers can take place.

3. WHAT IS CHEATING?

In the area of sport moral action, especially with children, many variables have been investigated. Not all of them may be defined as cheating *per se*. For example, moral atmosphere has been included and refers to the cultural norms developed within a team about whether cheating is condoned or not. However, all of the variables may be defined as inappropriate behavior, at the very least, and range from poor "sportspersonship" to outright aggression so as to achieve a competitive advantage. Because cheating is a difficult concept to

pinpoint and define universally, it may be helpful to view cheating as a product or combination of several more or less moral concepts that are referred to often in the sport psychology literature. For example, cheating in sport has been viewed as a quest to provide an unfair advantage over the opponent. According to this definition, a number of concepts fall into the category of cheating in sport, for example, unsportspersonlike aggressive behavior, inappropriate moral functioning, and a team moral atmosphere where cheating is condoned.

Of all the virtues that sport supposedly fosters, sportspersonship is perhaps the most frequently cited. The virtue of sportspersonship is oriented toward maximizing the enjoyable experience of all participants. Although most people believe that they know what sportspersonship is, the development and understanding of the concept has suffered from the lack of a precise definition and an overreliance on broad theoretical approaches. In essence, a sport participant manifests sportspersonship when he or she tries to play well and strive for victory, avoids taking an unfair advantage over the opponent, and reacts graciously following either victory or defeat.

In an effort to generate a much-needed conceptual base to promote research, recent work from Vallerand and colleagues has contributed to a better understanding of the sportspersonship concept. Vallerand has adopted a social psychological view of sportspersonship that separates the latter from aggression and assumes a multidimensional definition consisting of five clear and practical dimensions: full commitment toward sport participation, respect for social conventions, respect and concern for the rules and officials, true respect and concern for the opponent, and negative approach toward sportspersonship. This definition and instrument has been used in sport to investigate sportspersonship. Research has used the scale; however, the negative dimension has never really worked out and is frequently not included. Therefore, when children respect the social conventions (e.g., shaking hands after a game), respect the rules and officials (e.g., not violating the rules or arguing with the referee), and respect the opponent (e.g., helping an opposing player up from the ground in football), they are considered to be high in sportspersonship.

Sportspersonship is but one dimension of social moral functioning in sport, and one model used to more fully investigate the issue is a model suggested by Rest in 1984. Rest proposed a four-component interactive model of sociomoral action that seems well suited when examining sociomoral aspects in

sport. The first component of the model deals with interpreting the sport situation by recognizing possible courses of moral action. The second component encompasses forming a moral judgment involving judgments about both the social legitimacy and moral legitimacy of inappropriate sport behavior. The third component involves deciding what one intends to do as a solution to the dilemma, and the fourth involves executing and implementing one's intended behavior. Behavior might include incidences of nonmoral actions (e.g., aggression) as well as sportpersonship behavior.

The process of making a moral decision may be influenced by many factors, including motivational factors, whereas actual behavior may be affected by distraction, fatigue, and factors that physically prevent someone from carrying out a plan of action. The interactive nature of the four processes means that factors proposed to act primarily on one process also influence the others indirectly. As an example, when a child is in a competitive context, many kinds of behavior are possible, including whether to cheat or not. A situation may develop where one could cheat to stop a player from scoring, but is it appropriate to do so? If doing so is judged as appropriate, does one intend to cheat to stop the player from scoring? Finally, does one actually cheat to stop the player from scoring? In this way, players go through the components of Rest's model.

In 1985, Shields and Bredemeier argued that a major factor influencing the construction of a moral judgment, and consequently moral behavior, in sport is the moral atmosphere of the team. To capture the perceived judgments by significant others as either approving or disapproving of one's moral actions, research has often included how the players perceived the moral atmosphere in terms of social moral team norms. Sport teams, like all groups, develop a moral atmosphere composed of collective norms that help to shape the moral actions of each group member. An example again is the professional foul in soccer. Sociomoral atmosphere, or perceived sociomoral team norms, has been measured by means of a questionnaire.

Another variable has been the perceived legitimacy of intentionally injurious acts. Participants are asked to imagine themselves competing in an important competitive context. Various intentionally injurious acts are described, and participants are asked to indicate to what degree they agree or disagree with the legitimacy of the actions described.

This is how moral functioning and cheating have been defined in research in sport, especially with children. But why do people cheat? One avenue for

exploring this issue has been to look at the motivation to cheat and has used concepts from motivation theory and research. The basic arguments behind this line of research are considered next.

4. THE MOTIVATION TO CHEAT: ACHIEVEMENT GOALS AS A DETERMINANT OF MORAL ACTION

The most promising avenue to investigate moral functioning and action in sport has been to use achievement goal theory. This framework assumes that achievement goals govern achievement beliefs and guide subsequent decision making and behavior in achievement contexts. It is argued that to understand the motivation of individuals, the function and meaning of the achievement behavior to the individual must be taken into account and the goal of action must be understood. It is clear that there may be multiple goals of action rather than just one. Thus, variation of behavior might not be the manifestation of high or low motivation per se; instead, it might be the expression of different perceptions of appropriate goals. An individual's investment of personal resources, such as effort, talent, and time in an activity as well as moral action, may be dependent on the achievement goal of the individual in that activity.

The goal of action in achievement goal theory is assumed to be the demonstration of competence. In 1989, Nicholls argued that two conceptions of ability manifest themselves in achievement contexts: an undifferentiated concept of ability (where ability and effort are perceived as the same concept by the individual or he or she chooses not to differentiate) and a differentiated concept of ability (where ability and effort are seen as independent concepts). Nicholls identified achievement behavior using the undifferentiated conception of ability as task involvement and identified achievement behavior using the differentiated conception of ability as ego involvement. The two conceptions of ability have different criteria by which individuals measure success. The goals of action are to meet those criteria by which success is assessed. When task involved, the goal of action is to develop mastery or improvement and the demonstration of ability is self-referenced. Success is realized when mastery or improvement has been attained. The goal of action for an ego-involved individual, on the other hand, is to demonstrate normative ability so as to outperform others. Success is realized when the performance of others is exceeded, especially when little effort is expended.

Whether one is engaged in a state of ego or task involvement is dependent on the dispositional orientation of the individual as well as situational factors. Consider the dispositional aspect first. It is assumed that individuals are predisposed to act in an ego- or task-involved manner. These predispositions are called achievement goal orientations. An individual who is task oriented is assumed to become task involved, or chooses to be task involved, so as to assess demonstrated competence in the achievement task. The individual evaluates personal performance to determine whether effort is expended and mastery is achieved; thus, the demonstration of ability is self-referenced and success is realized when mastery or improvement is demonstrated. In contrast, an individual who is ego oriented is assumed to become ego involved in the activity. The individual evaluates personal performance with reference to the performance of others; thus, the demonstration of ability is other-referenced and success is realized when the performance of others is exceeded, especially when little effort is expended.

Achievement goal theory holds that the state of motivational goal involvement that the individual adopts in a given achievement context is a function of both motivational dispositions and situational factors. An individual enters an achievement setting with the disposition tendency to be task and/or ego oriented (goal orientation), but the motivational dynamics of the context will also have a profound influence on the adopted goal of action, especially for children. If the sport context is characterized by a value placed on interpersonal competition and social comparison, the coach emphasizing winning and achieving outcomes, and a public recognition of the demonstration of ability, a performance climate prevails. This reinforces an individual's likelihood of being ego involved in that context. If, on the other hand, the context is characterized by learning and mastery of skills, trying hard to do one's best, and the coach using private evaluation of demonstrated ability, a mastery climate prevails. An individual is more likely to be task involved in that context. Therefore, being task or ego involved is the product of an interaction of personal dispositions and the perceived motivational climate. However, in the research literature, investigators typically look at one aspect or the other are rarely look at them in combination.

Shields and Bredemeier argued that situational influences may have a great effect on an athlete's moral action. Competitive ego-involving structures may focus the individual's attention on the self and, in the case of team sports, on those comprising the in-group as well. This may reduce the player's sensitivity to the welfare of

opposing players. Extensive involvement in competitive contexts may reduce the person's ability to show empathy, thereby reducing consideration for the needs of others faced with a moral dilemma. Indeed, several studies have shown that participation in competition is associated both with reduced sportpersonship and prosocial behavior and with increased antisocial behavior, hostility, and aggressiveness. However, it is argued here that it might not be competition in and of itself that induces sociomoral dysfunction on the individual and group levels. Rather, it might be the perceived motivational climate that may shape an athlete's moral functioning. Indeed, moral development theorists, such as Rest, agree that moral behavior is intentional motivated behavior. Thus, to predict sociomoral perceptions and actions, one must consider the motivational characteristics of the situation. First, dispositional influences on cheating are examined.

5. DISPOSITIONAL ACHIEVEMENT GOALS

When looking at the various important personal factors influencing people's behavior in sport, moral reasoning ability and achievement goal orientations have emerged as significant variables. An early research study found that moral reasoning in the context of sport is much more egocentric than moral reasoning in most situations in everyday life. Athletes, as compared with nonathletes, seem to change their basis for moral reasoning from non-sport- to sport-related activities. This type of reasoning seems to focus on self-interest and personal gain.

Research has shown that when athletes are task or ego oriented, they differ in various aspects of moral behavior as well as in views regarding what represents acceptable behavior in sport. For example, athletes who are primarily concerned with outperforming others (ego oriented) have been found to display less mature moral reasoning, tend to be low in sportpersonlike behavior, approve of cheating to win, and perceive intentionally injurious and aggressive acts in sport as legitimate. In contrast, among task-oriented athletes who tend to use self-referenced criteria to judge competence and feel successful when they have achieved mastery or improvement of the task, greater approval of sportpersonship, disagreement with cheating to win, and less acceptance of intentionally injurious acts have been observed.

Research has found that players who reported higher temptation to play unfairly and greater approval of

behavior designed to obtain an unfair advantage were more likely to be ego oriented. These players also perceived their coaches as being more ego involving than task involving. In addition, the athletes believed that teammates would play more unfairly and would have a higher rate of approval of behavior aimed at obtaining an unfair edge over the opponent. In a study investigating the influence of moral atmosphere (i.e., the collective team norms approving of cheating) on the moral reasoning of young female soccer players, players who were in a culture where aggression and unfair play were tolerated were more ego oriented. Furthermore, it has been found that ego-oriented players had lower levels of moral functioning, had greater approval of unsportsmanlike behavior, and judged that intentionally injurious acts are legitimate. Ego orientation has been related to unacceptable achievement strategies such as the use of aggression. Findings indicate that players high in ego orientation display more instrumental aggression than do participants with low ego orientation, suggesting that participants high in ego orientation may adopt a "win at all costs" attitude.

However, ego-involved individuals can also adopt adaptive achievement strategies. It is believed that when individuals are both ego involved and high in perceived ability, so long as the perception of high ability lasts, these individuals will seek challenging tasks, will revel in demonstrating their ability, and generally will not cheat. But when these individuals experience a change in their perception of ability, they are more likely to cheat so as to continue winning. Research has confirmed this in that high ego-, low task-oriented participants who are low in perceived ability are more likely to endorse cheating in sport than are high ego-, low task-oriented participants who are high in perceived ability. High task-oriented individuals are less likely to approve of cheating in sport than are any other sport participants, regardless of perceived ability.

An athlete high in ego orientation is assumed to believe that winning is the single most important thing when competing. When doubt about one's own ability exists, this may lead the young athlete to believe that it is harder to contribute to his or her team's success by using skills alone. The athlete can then be tempted to cheat so as to help the team win and gain peer acceptance. In some of the current authors' research over the years with young players in soccer, they have found that an ego achievement goal orientation is associated with poor sportpersonship and cheating when perception of ability is low. These findings suggest that young athletes are likely to cheat when they do not believe that they

can succeed by simply playing fair. How far one is willing to go to win is often seen as a positive attribute in the world of competitive sport. If one player is willing to get caught or be reprimanded by the officials while trying to intimidate or undermine the opponent, this athlete is likely to generate a positive response from his or her peers, parents, and coaches when playing on a team where winning is everything. Team loyalty can be demonstrated by going against the rules, particularly if the athlete does not get caught. The current authors have found that athletes with a high ego orientation show low respect for rules and officials as well as low respect for opponents.

When winning is everything and perception of ability is low, cheating and going against the rules may be judged to be acceptable so as to gain peer acceptance. This is true for both boys and girls. But boys cheat more. To illustrate this, two figures are included showing how boys and girls differ in degree if not in kind. These figures present data from the authors' own ongoing research involving young soccer players in the Norway Cup, the largest international competition for children in the world. The data show the impact of being high in ego orientation. In this particular example, the authors, using the Rest model to inform their questions, asked the players some questions about their experience with playing soccer. They wanted to see the relationships of the motivational variables on moral reasoning and moral action variables. [Figure 1](#) shows a canonical correlation chart of the responses of high-ego girls (ages 15–16 years). To be meaningful, the correlations should be greater than .30. As can be seen in the figure, when girls are ego involved, they judge inappropriate behavior as being appropriate, and the most important reason was negative; therefore, they were low in moral reasoning, they intended to cheat, and they judged injurious acts as being appropriate to win.

Not attaining significance, these girls had not cheated over the previous five games and considered the team atmosphere and the coaching climate as being relatively neutral. However, they were quite prepared to injure an opponent in the quest to win. Compare this with [Fig. 2](#), which shows a canonical correlation chart of the responses of high-ego boys. These boys judged inappropriate behavior as being appropriate, and the most important reason was clearly negative; therefore, they were low in moral reasoning, and all of the other variables are clearly positive.

This means the high-ego boys admitted that they had cheated over the previous five games, thought that the team atmosphere supported cheating to win, considered the coach as supporting cheating, and were quite

FIGURE 1 Girls: High ego, low task.

FIGURE 2 Boys: High ego, low task.

prepared to injure opponents in their desire to win. These data show clearly that high-ego players have more tolerance toward and support cheating to win, even to the extent of supporting injurious acts. Although the boys and girls thought and behaved in the same general way, boys are more extreme and do cheat more.

Clearly, being ego or task involved has implications for moral action in sport. The influence that the motivational climate has on moral thinking and action is considered next.

6. PERCEIVED MOTIVATIONAL CLIMATE AND DETERMINANTS OF CHEATING

Similar to the task- and ego-involving criteria to which an individual may be disposed, the situational aspects

of the competitive environment are also important. Although a number of significant others (e.g., teachers, parents, peers) can and do influence, to some extent, the type of motivational climate that is perceived, the coach is perhaps the most influential facilitator of task- or ego-involving criteria for the athlete. The bottom line here is that the criteria of success and failure that the coach brings into the situation are the criteria that the athlete adopts. The younger the athlete, the more likely it is that he or she will pay attention to the criteria of the coach. Indeed, there is evidence indicating that the criteria of what constitutes success and failure for the coach “washes out” the personal criteria of the young player. As such, the achievement goal that the coach imposes on the context becomes an important determinant of the behavior of the athlete.

In discussing the motivational climate, the terms “performance climate” (an ego-involving coach) and “mastery climate” (a task-involving coach) are used. If a performance climate prevails, the coach and the

athletes may come to view competition as a process of striving against others. The players may perceive pressure from the coach to perform well or be punished as well as pressure to outplay opponents and win so as to receive recognition and attention. Players may resort to cheating, violating rules, and behaving aggressively as a means of coping. In competition, a performance climate may generate a strong interteam rivalry. A hostile atmosphere toward opposing players may result, leading to the development of team norms or shared social moral perceptions among team members reflecting a derogatory and depersonalized picture of opposing players as mere obstacles to be overcome in the quest for victory by their own team.

The investigation of perceived motivational climate in relation to cheating is a relatively new research area among sport social scientists. The findings thus far indicate that perceived mastery and performance motivational climates created by coaches do affect cheating in systematic ways.

Players perceiving a strong mastery motivational climate reported that sportspersonlike behavior is important in competitive soccer. Players reported that it was important to value and respect the rules of the game and the officials who represented the rule structure. In addition, players noted the importance of respecting the social conventions found within the soccer environment when they perceived the coach as emphasizing mastery motivational criteria. In contrast, it has been shown that players who perceive a high performance climate indicate lower sportspersonship than do players who perceive a high mastery climate.

In general, the majority of research indicates that a perceived performance motivational climate is associated with cheating, whereas a perceived mastery motivational climate is associated with more positive

moral actions. This is true for college-level athletes as well as for younger athletes. In brief, perceptions of performance climate criteria were related to a lower level of moral understanding within the team, resulting in lower moral functioning illustrated by means of low moral judgment, a high intention to behave nonmorally, and low self-reported moral behavior.

Among high-level collegiate male and female basketball players, it has been found that players perceiving a performance motivational climate perceived a low moral atmosphere within their team that was related to lower moral functioning. Various perceptions of the motivational climate have been shown to be related to differing levels of moral functioning and perceptions of team moral atmosphere. Evidence illustrated in Fig. 3 shows that young players who perceive a strong mastery motivational climate indicated positive sportspersonship (i.e., had respect for opponents and officials and also respected social conventions), had positive moral reasoning, had a low intention to cheat, seldom engaged in cheating behavior, and considered the team norms and the atmosphere created by the coach to be anti-cheating.

In contrast, Fig. 4 shows a canonical correlation chart of the responses of girls in a performance-oriented climate. When girls are ego involved, they judged inappropriate behavior as being appropriate, and the most important reason was negative; therefore, they were low in moral reasoning, intended to cheat, had cheated during the previous five games, considered that the coach and teammates approved of cheating, and considered injurious acts appropriate to win. Again, the figure illustrates that even girls (and young female youth), when ego involved through a performance climate created by the coach, will increase their cheating.

FIGURE 3 Boys: Low performance, high mastery.

FIGURE 4 Girls: High performance, low mastery.

Gender differences have been found in the motivational climate literature consistently in that young male players react more strongly to performance climate criteria and are more prone to cheating compared with female players: Again, boys cheat more than do girls. However, the important point here is that regardless of gender, a strong coach-created performance motivational climate is related to low moral functioning, inappropriate behavior is judged to be appropriate, and players have lower moral reasoning, have a higher intention to cheat, and actually do cheat more. In addition, both male and female players identified their team moral atmosphere to be more supportive of cheating. These data show clearly that when players are ego or task involved, they think differently, have different ideas about cheating, and report different episodes of intention to cheat and actual cheating. Ego-involved players have more tolerance toward and support cheating to win, even to the extent of supporting injurious acts.

The research findings are quite consistent. When the coach emphasizes criteria of success and failure showing that he or she values winning above all else, athletes indicate that they tolerate cheating more and actually do cheat more than athletes who perceive their coach as emphasizing more mastery criteria of success and failure. This is true for elite athletes, at the professional and Olympic levels, as well as for child and youth sport participants. Clearly, the coach matters, but the major point here is that the coach does not have to endorse cheating per se; rather, it is simply that the coach who emphasizes winning above all else creates a motivational climate that the athletes interpret as being more accepting of cheating behavior.

7. WHAT CAN WE DO ABOUT CHEATING?

Some people deliberately cheat. There are enough cases in sport, in corporate business, and in everyday life demonstrating that some individuals and organizations simply cheat to gain an unfair advantage. There is little that can be done about these systematic cheats except to try to catch and punish them to the full extent possible. Whether that is through drug testing in sport, financial oversight in corporate business, and so on, regulations and oversight are needed to cull out the cheats. But cheating can be much more subtle and unintentional in many cases. It is this latter form of cheating that is addressed in these final remarks.

Competitive sport often places people in conflicting situations, where winning is emphasized and where fair play and justice are sometimes deemphasized. It would be wrong to attribute this to the competitive nature of sport. The research reported in this article suggests that the culprit is not competition in and of itself. Rather, the culprit may be the difference in salience of ego- and task-involving cues in the environment, whether through one's own disposition or through the cues emphasized by one's coach (or parent). It is these perceived criteria of success and failure that induce differential concern for moral action and cheating. A focus on winning may reinforce prejudice (i.e., "us against them") and lead to a more depersonalized view of opponents that, in turn, makes cheating more possible.

How can the development of good sportsmanship and sound moral reasoning be maximized, and how can cheating be prevented? Clearly, one way in which to help is to teach the coach to reinforce the importance of

task-involving achievement criteria in the competitive environment. This is important at all levels, especially in light of the degree of cheating going on in professional and Olympic sports. But this is more important for children's and youth sports. This does not mean that one cannot strive to win; rather, it means that we should apply different criteria to the meaning of winning and losing. By giving feedback to players on effort, hard work, and self-referenced increments in competence, more respect for rules, conventions, officials, opponents, and appropriate moral reasoning and action could be cultivated. One way in which to say this is that there are no problem athletes, just problem coaches (and parents). Coaches must be aware of the criteria of success and failure that they are emphasizing. If task-involving criteria are emphasized, cheating can be reduced and moral reasoning and action can be enhanced.

When focusing on children in the competitive sport experience, it is not just the coach who needs to be aware of the criteria being emphasized; parents are the most important source of information for the children. Indeed, it is often the parents who are most to blame in children's sports. However, coaching programs that address both parents and coaches now exist in most countries. The evidence is accumulating that strategies and instructional practices should be developed to facilitate the coach (and parents) in creating a task-involving coaching environment that is concerned with mastery criteria of success and failure. If there is concern about optimizing the motivation, psychosocial development, and moral functioning and action of children, the impact that teaching and coaching style have on these outcomes cannot be ignored.

However, coaches must realize that simply trying to enhance mastery criteria is often not enough. The ego-involving criteria are emphasized as well. Normative evaluation should not be used for athletes. Comparisons should be made with children's own past performance rather than with the performance of their peers. By giving feedback based on their own past performance and trying to give feedback to athletes privately rather than in an announcement to the whole team, coaches can do their best to maintain the motivation of the athletes and remove an important determinant of cheating in sport.

Will cheating ever be eliminated from sport? That is unlikely in elite sport when the rewards are so high. But in children's sport, attempting to reduce cheating is critical. Playing fair and recognizing justice for all should be a natural part of the sport experience. If the sport experience is the context in which children learn to relate to their peers, not only in sport but also for life, the criteria of success and failure inherent in the sport experience should be a critical concern.

GLOSSARY

best interests of the child doctrine The philosophy, now incorporated into the law in all 50 states, that in making decisions concerning custodial placement and parenting plans, the interests of the children should supersede those of the parents and/or others involved in the dispute.

evaluation of comparative custodial suitability A forensic psychological evaluation the primary focus of which is the relative strengths and deficiencies in the ability of parents to parent the specific children whose custodial placement is at issue.

forensic role Within the context of custody evaluations, a perspective and actions that are consistent with one's obligation to function as an impartial examiner and to gather information that bears upon specific issues before the court.

pendente lite A reference to a matter that one or both parties assert must be addressed by the court while the primary issues in litigation are still pending.

therapeutic role Within the context of custody evaluations, a perspective and actions that are consistent with one's obligation to assist those with whom one is professionally interacting.

This article begins with a historical overview of the manner in which child placement disputes have been adjudicated and a discussion of the best interests of the child standard. The outline of the factors that psychologists endeavor to assess includes a discussion of the methodological problems inherent in this form of assessment. The significant differences between therapeutic work with families and forensic assessment of families are explained. Because performing custody evaluations requires that psychologists work in a collaborative manner with attorneys and adapt to procedures with which mental health professionals are often unfamiliar, the adjustments that must be made are discussed. The article concludes by providing some perspectives on experts offered by two judges.

1. PSYCHOLOGY'S CONTRIBUTION TO UNDERSTANDING BEST INTERESTS

The historical context of custody evaluations begins with Roman law and the presumption of paternal preference. Children were viewed as the property of their fathers. A father had absolute power over his children. He was allowed to place his children into slave labor or sell them for profit. A child's mother had no legal rights. English common law also provided for absolute paternal power. Children were viewed as the property of the father and he had sole discretion over where the children lived, both during the

marriage and after a divorce. Mothers had restricted access to their children after divorce.

Though the reasoning varied, custodial placement decisions based primarily on generally accepted sex roles were the norm until 1970. In 1813, in deciding on the custodial placement of two children, ages 6 and 10, the Supreme Court of Pennsylvania declared: "It appears to us, that considering their tender age, they stand in need of that kind of assistance which can be afforded by none so well as a mother" [*Commonwealth v. Addicks and Lee*, 5 Binney's Rep. 520 (1813), at 521]. At approximately the same time, in Great Britain, what came to be referred to as the tender years doctrine dictated that children younger than age 7 required the care of their mothers. From age 7 on, the custodial responsibility for children would revert back to the father. As the work of fathers began to take them outside the home and as mothers became the primary caretakers, a preference for placement of children with their mothers developed. By the 1920s, a presumption in favor of the mother was clear in most American courts.

Comfort with the notion of a maternal preference was buttressed by Freud's then-popular theory that, among other things, stressed the unique role of mothers in the lives of children. Theories of bonding contributed further to the view that children needed to be with their mothers. Current research has demonstrated that infants form meaningful attachments to both parents by the middle of their first year; however, only recently has such research raised questions concerning the wisdom of a maternal preference.

In the 1960s, several social changes stimulated a reexamination of the maternal preference. These factors included an increase in the number of fathers wishing to maintain an active postdivorce role in the lives of their children, the entry into the workforce of large numbers of mothers, and an increased sensitivity to the discriminatory effects of placement decisions predicated on sex.

In 1970, the U.S. Congress passed the Uniform Marriage and Divorce Act, providing for a best interests of the child standard. The tide had turned from a focus on paternal or maternal preference or rights to a focus on what is best for the child. Simultaneously, psychology offered a revolutionary idea: The concept of the psychological parent was developed. Once society had decided that children, being the most innocent victims of divorce, should be protected as effectively as possible from its emotional consequences, the view emerged that mental health professionals could assist triers of fact in determining what parenting plan was most likely to best serve the interests of the children.

The best interests standard is not without its critics. It has been criticized as poorly defined, as too ambiguous, and as providing fodder for disputes and litigation. Mnookin has argued that the broad judicial discretion provided by the best interests standard leaves judges free to impose their personal biases and beliefs on their judicial determinations. The Supreme Court, in deciding *Troxel v. Granville* (a grandparents' visitation case), made note of the fact that the Washington Superior Court trial judge (whose decision was overturned) had deemed it appropriate to "look back at some personal experiences" [*Troxel v. Granville*, 530 U.S. 57 (2000), at 61].

The challenge is to develop a legal standard that is sensitive both to the social values of American culture and to the needs of the legal system. A legal standard addressing the best interests of the child should "offer effective and useful guidelines, so that similar cases are decided similarly without extralegal factors significantly affecting final dispositions" (Krauss & Sales, 2000, p. 845). A legally effective child custody standard would balance the needs of the family, the needs of society, the evolving social science research, the evolving case law precedents, and the changes in each family configuration while minimizing state intrusions into the functioning of the family.

In many states the criteria to be utilized in evaluating comparative custodial suitability are defined by statute. In states where criteria are not so defined, experts conducting evaluations of comparative custodial fitness bear an obligation to articulate the criteria that they will utilize in performing their assessments.

2. PSYCHOLOGICAL ASSESSMENT: WHAT CAN WE MEASURE?

In 1971, the Supreme Court handed down a decision in *Griggs et al. v. Duke Power Co.* (401 U.S. 424), a case that, on its face, had nothing whatsoever to do with children and custodial placement decisions. The *Griggs* case involved assessment in the selection, placement, and promotion of personnel. The court ruled that testing procedures must be demonstrably reasonable measures of (or predictors of) job performance. In the years since 1971, forensic psychologists involved in custody work have come to view the *Griggs* decision as an exhortation, urging us to focus our attention and our assessment efforts on functional abilities that bear directly on the issue before the court. Within the context of custody

work this suggests that we must endeavor to ascertain what attributes, behaviors, attitudes, and skills are reliably associated with effective parenting and confine ourselves to assessing those characteristics as they relate to the children who are the focus of the dispute.

Our problem is that the only assessment instruments with established reliability and validity provide data pertaining only to one or two of the criteria of potential interest to us. An instrument such as the MMPI-2, for example, may provide useful information concerning a test taker's general mental/emotional health, but that leaves much to be assessed about the individual's parenting. LaFortune and Carpenter (1998, p. 222) list the seven most frequently used assessment instruments that "focus on parenting skill and the parent-child relationship" and that are "touted by their authors as helpful in clinical determinations of parental fitness." LaFortune and Carpenter declare: "[T]he validity of these measures is unestablished at best and seriously flawed at worst" (p. 222). Although the hope is expressed that improvements in these instruments may make them useful in the future, the authors conclude that their use at present "cannot be recommended" (p. 222).

Although frequency of use by surveyed mental health professionals is not an acceptable measure of either the reliability or the validity of an assessment instrument, a disturbingly high proportion of custody evaluators use instruments that are psychometrically deficient but that are popular, largely because of successful marketing. Additionally, some clinicians have brought to forensic work psychodiagnostic assessment instruments generally considered useful in health care settings but ill suited to the evidentiary demands of forensic work. In a therapy setting, a psychodiagnostic assessment marks the beginning of an ongoing relationship in the course of which there will be opportunities for subsequent reassessment. In a forensic setting, the report in which one's assessment is described marks the end of a relationship. No opportunities to reassess are provided. Because of this critical difference between clinical assessment and forensic assessment, it cannot be presumed that instruments popular among clinicians are suitable in forensic work.

Consider the following, from the Standards for Educational and Psychological Testing (American Education Research Association *et al.*, 1999): Tests are to be accompanied by documentation that will provide test users with "the information needed to make sound judgments about the nature and quality of the test, the resulting scores, and the interpretations based on the test scores" (p. 67). Elsewhere, the

authors of the Standards opine: "The greater the potential impact on test takers, for good or ill, the greater the need to identify and satisfy the relevant standards" (p. 112).

The authors of the Standards have called attention to the fact that "[w]hen directions to examinees, testing conditions, and scoring procedures follow the same detailed procedures, the test is said to be standardized. Without such standardization, the accuracy and comparability of score interpretations would be reduced" (p. 61). Many of those currently performing evaluations of comparative custodial suitability came to this work via clinical psychology, where being helpful is not viewed as an impediment to assessment. Moreland, a former member of the NCS staff and the MMPI-2 restandardization team, observed that "in responding to questions, examiners may inadvertently hint at the nonpathological answer when the test taker is someone whose position they favor (whether it be a custody case, injury case, or whatever)." He added: "[N]either NCS nor the Eyde group has told test givers how to deal with questions from test takers" (e-mail from Kevin Moreland, August 22, 1996).

In the vast majority of custody disputes, it is presumed by all involved that both parents are suitable. The court's task, with advisory input from the mental health professional, is to decide whether, in addition to being capable, the two parents can coparent effectively. If they can, a joint custodial arrangement may be appropriate; if they cannot, one of these two suitable parents must be designated as the primary custodian. If a primary custodian must be designated, then the court must decide which of two presumably suitable parents is more suitable. Psychologists, and those who seek our advisory input in custodial placement disputes, must recognize that we have no way of evaluating the validity of our recommendations because we have no way of knowing what would have occurred if the nonfavored parent had, instead, been selected as the primary custodian. Otto *et al.* (2003) observed that "research in this area will always be constrained by the inability to use true experimental designs to address the most prominent questions related to custody" (p. 203).

The foregoing paragraphs have an unmistakably pessimistic tone. Some might argue that we do not do custody evaluations well and that if we cannot do them well, we should not do them at all. It is reasonable to presume that as increasingly more psychologists become involved in assessing comparative custodial fitness and share with their colleagues their ideas for improving our procedures, we will become increasingly

more proficient. Deciding not to do custody evaluations is not the answer.

3. THE MARRIAGE OF CLINICAL SKILLS AND FORENSIC PRECISION

Most psychologists currently practicing or preparing to practice forensic psychology obtained their original training in clinical psychology. Forensic work is built on solid clinical training and experience; however, to function effectively as a forensic psychologist, the therapeutic mind-set must be altered significantly. It is also important to recognize that there is, in the words of Greenberg and Shuman (1997), an "irreconcilable conflict between therapeutic and forensic roles" (p. 50). A psychologist who is serving or who has served in a therapeutic capacity with any of those involved in a custody dispute should not function as the evaluator. Similarly, an evaluator should not offer therapy or counseling services to those whom he or she has evaluated.

In a forensic setting we seek answers to questions that have been posed (either directly or implicitly) by the court. We are not attempting to determine the etiology of a litigant's problems, nor are we attempting to set therapeutic goals and formulate treatment plans. Instead of communicating warmth, we communicate skepticism. Although that may sound harsh, it is important that litigants be reminded that information offered by them will not simply be written down in our notes and accepted at face value. Reasonable attempts will be made by us to verify information given to us. Section VI.F of the *Specialty Guidelines for Forensic Psychologists* (Committee on Ethical Guidelines for Forensic Psychologists, 1991) reminds forensic psychologists that "[w]here circumstances reasonably permit, forensic psychologists seek to obtain independent and personal verification of data relied upon." Ceci and Hembrooke (1998, p. 4) have expressed the view that "the uniquely human qualities that compel us to want to help are the very qualities that can make us poor experts."

Some of the most serious problems that forensic psychologists create for themselves stem from an inability or unwillingness to control the impulse to think like and act like "helpers" when they are obligated, by virtue of their forensic task, to function as examiners. Shuman (1993, p. 298) has opined that the techniques customarily employed by mental health professionals to establish a therapeutic alliance "are entirely inappropriate in

a court-ordered examination." Pruett and Solnit (1998, p. 126) express the view that "empathic skills must be constrained in a manner unusual for clinical practice but essential for fair, ethical, evaluative interaction."

The prevailing presumption in clinical work is that those who appear before us honestly share with us their perceptions of themselves and those with whom they interact. There is a tendency to presume, further, that discrepancies between a client's descriptions and objective reality are attributable, primarily, to the operation of various perception- and memory-distorting phenomena of which the client is not consciously aware. Only limited thought is given to the possibility of deliberate, calculated lying.

Individuals being examined within the context of custody disputes are strongly motivated to present themselves as being better adjusted than they know themselves to be. An examination that might be deemed adequate in a clinical context might be viewed as inadequate in a forensic context. Regardless of the assessment instruments utilized, a forensic examiner must operate more like an investigator than a sympathetic and supportive listener. In particular, custody evaluators cannot be passive recipients of offered information. We must use clinical skills to elicit information and actively seek, both from the litigants and from appropriate collaterals, any information that might reasonably be viewed as pertinent. Data collected by Ackerman and Ackerman suggest that approximately 28% of the evaluative time expended by those responding to a survey was devoted to information verification (obtaining information from documents, disinterested collateral sources, and other nonparties). Bow and Quinnell found that 98% of evaluators review documents relevant to the case, 86% interview therapists, 78% interview teachers, and 52% interview physicians and/or pediatricians.

4. DANCING WITH ATTORNEYS WITHOUT TRIPPING

In the field of custody work, most of the missteps that occur in interactions between forensic psychologists and attorneys relate to conflicting obligations. Such conflicts are easy to understand when psychologists are endeavoring to function as impartial examiners. Clashes are often unanticipated when psychologists have been retained by attorneys to function as their consultants or to offer expert testimony. Even when functioning in the consultant role, however, psychologists' ethical

obligations differ from those of the attorneys who have retained them and choreography can still be a challenge.

It is not uncommon for judges and attorneys to ask that a psychologist functioning as impartial evaluator alter his or her customary data collection sequence in the name of expediency or offer interim recommendations to assist the court in resolving a *pendente lite* issue. With regard to data collection, there is a logical progression to the information-gathering aspect of a custodial fitness evaluation, and although some modifications are acceptable, others are not. Data obtained through the administration to the parties of psychological tests and information secured by means of various questionnaires inevitably suggest areas of inquiry. It is inadvisable to conclude one's evaluative sessions with the litigants without having in hand test data and the questionnaires.

Standard 9.01 (a) of the psychologists' ethics code (American Psychological Association, 2002) declares: "Psychologists base the opinions contained in their recommendations, reports, and diagnostic or evaluative statements, including forensic testimony, on information and techniques sufficient to substantiate their findings." In the absence of sufficient information, recommendations should not be offered. All involved should also be mindful of the fact that parenting plans set in place in response to specific and immediate concerns alter family dynamics in ways that are not readily predictable and that may not be in the best interests of the children.

Court appointment does not guarantee evaluator competence. Neither does competence assure findings and recommendations with which all involved will be pleased. Where an expert's opinions have not been formulated through the utilization of appropriate procedures and are not supported by reliable data, exposing these deficiencies is a critically important function of an opposing expert.

The *Specialty Guidelines for Forensic Psychologists* (Committee on Ethical Guidelines for Forensic Psychologists, 1991) closes with a reminder (contained in section VII.F) that "[f]orensic psychologists are aware that their essential role as expert to the court is to assist the trier of fact to understand the evidence or to determine a fact in issue." Psychologists retained as consultants to attorneys or retained to offer expert testimony are, despite their collaborative relationships with those who have employed them, obligated to promote understanding and to decline participation in partisan attempts to distort or misrepresent evidence. Just as those whom we evaluate should be provided with information concerning our policies and procedures, so, too,

should attorneys who retain us be provided with such information. Information provided in advance prevents problems.

5. FOLLOWING THE RAINBOW

Standard 2.01 (c) of the psychologists' ethics code states, in part: "Psychologists planning to provide services . . . new to them undertake relevant education, training, supervised experience, consultation, or study." Section 2.01 (e) states, in part: "In those emerging areas in which generally recognized standards for preparatory training do not yet exist, psychologists nevertheless take reasonable steps to ensure the competence of their work" (p. 1064). In 2002, the American Psychological Association formally designated forensic psychology as a specialty. The obligation of psychologists trained in clinical psychology to professionally prepare themselves for forensic work if they plan to offer forensic psychological services is clear yet occasionally ignored.

The performance of an evaluation of comparative custodial suitability is, by definition, a forensic psychological endeavor. In our view, such evaluations should be guided by the forensic model. Earlier, we alluded to the Supreme Court's expressed disapproval of a trial court judge's decision to "look back at some personal experiences" [*Troxel v. Granville*, 530 U.S. 57 (2000), at 61] in formulating his opinion in a visitation dispute. The opinion formulation process to which the judge made direct reference is, more often, unarticulated. There is reason for concern that psychologists, whose services have been sought because of their presumed expertise, occasionally reflect on personal experiences, values, and beliefs in formulating their opinions. What makes an opinion an expert opinion is not the professional credentials of the individual whose lips form the words or whose keyboard is used to type them. What makes an opinion an expert opinion is the manner in which the opinion was formulated. Professional credentials are necessary but not sufficient.

An expert opinion is formulated utilizing the accumulated knowledge and the recognized procedures of the expert's field. If the accumulated knowledge of the expert's field was not utilized, the opinion expressed is not an expert opinion. It is a personal opinion, albeit one being expressed by an expert. Judge Alex Kozinski has astutely observed that the task facing triers of fact, when expert testimony has been offered, "is to analyze not what the experts say, but what basis they have for saying

it" [*Daubert v. Merrell Dow Pharmaceuticals, Inc.* (on remand), 43 F.3d. 1311 (9th Cir. 1995), at 1316]. The Honorable Stephen Hjelt, the presiding Administrative Law Judge for the California Office of Administrative Hearings in San Diego, in what might best be described as an open letter to psychologists, opined that our "profession has strong roots as a discipline that has a foundation in the scientific method. However, some of you simply stopped using it" (Hjelt, 2000, p. 12). We close by urging psychologists, attorneys, and judges to consider the words of judges Kozinski and Hjelt. Psychologists should use their training in methodology, cross-examining attorneys should demand that testifying experts articulate the bases for their opinions, and judges should consider the data that form the basis for expert opinions and not be gullible consumers of recommendations offered by experts.

GLOSSARY

cultures of relatedness Collectivistic societies where interpersonal distances are small between connected selves.

heritability The portion of variability in a trait that is passed to offspring via genes; high heritability is often understood to mean high genetic causality.

mechanistic model A behaviorist approach that interprets “environment” in a very limited sense as proximal stimuli.

organismic model An approach that emphasizes biologically based maturation, ignoring the context of development.

scaffolding Temporary support and guidance in problem solving.

Human development occurs in a cultural context. Obvious as this statement may be, its realization in developmental science is far from adequate. Most mainstream research and theory that derives from the Western (particularly American) academic centers and informs the field tends to approach human development in and of its own, without much attention to its cultural aspects. This state of affairs has implications for how

child development is construed, how it is assessed, and what is done (if anything) to enhance it. This article presents the current knowledge regarding the interface of culture and child development, with the main processes and dynamics involved, and also provides a brief overview of the scholarship on the subject. The main theoretical conceptualizations regarding child development, as well as their implications in significant spheres of applied fields, are reviewed.

1. STUDY OF CHILD DEVELOPMENT IN PSYCHOLOGY

A main issue in the psychological study of child development is the scarcity of a contextual approach. The prominence of the mechanistic and organismic models in developmental psychology and the stress on the individual as the unit of analysis have worked as deterrents to contextual conceptualizations of child development. The mechanistic model, used by behaviorism, has construed “environment” in a very limited sense as proximal stimuli. The organismic model has stressed biologically based maturation, ignoring the context of development. These perspectives are of both historical and contemporary influence. Recent advances in cognitive neuroscience, genetic research, and the like have further strengthened the “biological shift.” The focus has been on the individual organism as a product of these two major influences—more recently, as a combination of the two. Thus, a vast

majority of current psychological research on child development is conducted in the laboratory and does not take the larger cultural context into account.

Notwithstanding this state of affairs, there is also a rich tradition of research and thinking in child development, particularly in anthropology, that takes culture seriously. Introducing culture into child development has been done, starting mainly during the second half of the 20th century, first in anthropology and then in ecological, cross-cultural, and cultural psychology. Although this work remained rather marginal for some decades, it is beginning to be better recognized, to increase in volume, and to leave its mark on mainstream research and conceptualizations in developmental psychology. One reason for this changing orientation is the fact that research informed by cultural context is now being done in modern nations, including those in the Western world, rather than in isolated small human groups, as was the case with classic anthropological work. So, it is seen as more relevant by psychologists. A second reason is the fact that Western societies, especially the United States where there is the greatest amount of research production, have become multicultural societies. The growing cultural diversity has again made culture more relevant in the psychological study of development.

1.1. Study of Child Development Within Culture

Research on child development that takes culture seriously is being done within two different paradigms. One of these, known as cross-cultural psychology, uses a comparative approach in which theory testing is of high priority. Cross-cultural comparative methodology works as a corrective to the rather ethnocentric assumption of the pan-human generality of findings obtained in unicultural studies. The view here is that the findings may in fact have universal generality, but this has to be demonstrated rather than assumed. Indeed, the theoretical basis for a comparative methodology is the “universalism” of psychological processes, although their manifestations in behavior differ due to cultural factors. The methods/instruments used are similar to those used in unicultural psychological studies of development; however, the issue of equivalence in measurement emerges as much more significant in cross-cultural methodology.

The other paradigm is cultural psychology, which claims that cultural context gives meaning; thus, human behavior is context specific and should be

studied within culture, not comparatively. For example, topics such as the cultural organization of human development within family and society and the cultural construction of intelligence are studied. This is akin to an anthropological perspective stressing the uniqueness of each cultural context. Accordingly, research tends to be based on observations within context and descriptive qualitative analysis rather than on experimentation and standardized measures with a comparative orientation that are typical in cross-cultural research. For example, observational studies have been conducted extensively within the tradition of “everyday cognition” or “informal learning” by children of culturally relevant skills such as tailoring, woodcarving, weaving, pottery, and other handicrafts as well as street mathematics.

The two paradigms have also been called *etic* and *emic*, in analogy with phonetics and phonemics in linguistics. Phonetics studies general aspects of sounds in languages, whereas phonemics studies sounds in a particular language. The different perspectives underlying cultural and cross-cultural psychology and the *etic* and *emic* approaches are posited as conflicting; however, they both contribute to our understanding. They both have emerged as correctives to the “culture-blind” orientation of mainstream developmental psychology’s organismic and mechanistic paradigms. However, they both entail some risks when taken to an extreme. The comparative cross-cultural approach can claim “false universals,” whereas the cultural approach can assume “false uniqueness” (of each cultural context). The challenge is to combine the benefits of each in understanding the unity and diversity within the dynamics of culture and child development.

1.2. Life Stages and Culture

Over the past few decades, the study of human development has moved from a focus on childhood to a focus on the life span. The span of development is seen to be continuous and to cover the whole spectrum, from prenatal period to old age and death. This approach renders culture even more relevant because cultural differences emerge quite significantly during the various phases of the life span. Thus, although there tends to be a great deal of commonality in the meaning attributed to, and the socially described role of the growing human during, infancy and early childhood, cultural variations start and increase progressively during the subsequent stages of middle and later childhood, adolescence, young and later adulthood, and old age. For example, early anthropological work showed that adolescence

and gender roles during adolescence in some preliterate societies are quite different from those in Western technological societies. Even when less diverse socioeconomic cultural contexts are compared, such as more affluent/urban and less affluent/rural ones, the roles of both adolescents and children in family and society are found to differ. In particular, a much greater proportion of children and adolescents work, carrying out household chores or family business, and are economically productive in less affluent/rural and more traditional society. For example, the fact that children in Africa spend less time in “play” and more time in “work,” as compared with children in the United States, can be attributed to many factors such as the necessities of less affluent lifestyles but also the cultural meaning of childhood and children’s work. Nsamenang claimed that child work in West Africa is a social learning process for adult roles and, therefore, an inherent part of development. From a Western human rights perspective, however, child work can be seen as child “labor”—and, therefore, child abuse—especially if it interferes with formal education. This is a case in point for the various cultural meanings accompanying different lifestyles that can be a source of debate or even conflict.

Thus, cultural meanings associated with different life stages reflect lifestyles, social norms, and social values. Old age is another life stage that is defined and understood variously. Whereas old people in Western technological societies tend to lose social status and experience some isolation from the community of young people, old people in many traditional societies remain very much integrated within family and community and are respected for their life experience, knowledge, and wisdom. They also tend to be more active in important domestic and communal roles involving imparting of traditions to the young, moderating dispute settlements, and the like.

Thus, culturally informed life span perspectives show that age does not have the same meaning across space and time. What is universal is possibly the tendency of all cultures to use age as a basis for defining the individual and assigning him or her with certain roles, responsibilities and privileges. With this in mind, this article focuses on the life stage of childhood in the cultural context.

2. DEVELOPMENT IN CONTEXT

The context of child development includes numerous levels of influences, all interrelated with and embedded within one another. One way of conceptualizing

contextual variables is in terms of their degree of comprehensiveness as encompassing systems. This ecological perspective has been influential in the study of child development in the cultural context. For example, Bronfenbrenner differentiated among four levels, increasing in complexity and comprehensiveness from micro-, to meso-, to exo-, to macrosystems. Determining which of these ecological systems is to figure in the study of child development at any particular time is an empirical issue. An important component of the macro-system of the ecology of child development is societal values regarding children that are reflected in parental beliefs, values, and child-rearing orientations.

The recognition of the significant implications of the ecological perspective for child-rearing orientations and the resultant child outcomes have led to concepts such as “ethnotheories” or “naive theories” (e.g., LeVine’s theory of parental goals). Super and Harkness proposed the concept of the “developmental niche,” consisting of the physical and social setting, child care and child rearing, and the psychology of the caretaker, to explain the cultural structuring of child development. Similarly, the “ecocultural niche” (suggested by Weisner), and the “developmental microniche” (suggested by Worthman) have been proposed as organizing concepts to model the relationships of biology, behavior, and culture in shaping human development. Other theoretical models have also entailed an ecological/cultural contextual framework, such as Berry’s “ecocultural framework,” further combined with ecological systems theory by Georgas and with the developmental niche by Dasen.

An ecological perspective also calls for situating parental beliefs and child-rearing orientations within the socioeconomic and social structural context. This is important to understand why certain belief systems show systematic variation across different parental populations. The answer often lies in the underlying functional relations. Ecological perspectives have also figured in other analyses. For example, bringing the temporal dimension into an ecological perspective in forming a sociological life events approach, Elder studied intergenerational relations and adolescent adjustment and development at various historical periods. Similarly, concepts of developmental pathways and “canalization” over an epigenetic landscape were used by Waddington to analyze variations and self-stabilizing constraints that restrain the variations in the organism–environment system as it changes and evolves over time.

These conceptualizations aim to deal systematically with the myriad spatial and temporal environmental influences that provide developmental pathways for

the individual. Nevertheless, the individual not only is acted on but also acts on the environment so as to create its own developmental pathway that is unique yet also has common characteristics with others. This view is stressed particularly by European-based theories of individualization.

2.1. The Value of Children and Family as Developmental Niche

Study of parental values and child-rearing orientations can serve as an example of an ecological approach to development in the cultural context. Values attributed to children and how childhood is conceptualized provide important clues as to the place of children in the family and society. A cross-cultural study on the Value of Children (VOC), conducted during the 1970s and currently being replicated in several countries, points in particular to the economic/utilitarian and psychological values attributed to children. The economic/utilitarian value is stressed in sociocultural contexts where children's material contributions to the family are significant. This often takes the form of contributing to family income while young and providing elderly parents with old-age security during later years. Psychological VOC, on the other hand, is stressed in contexts where children entail more economic costs than economic assets. These dynamic relations among ecological factors, family/parental values, and child outcomes are dealt with by another ecological theory, namely the "family change model" (proposed by Kagitcibasi).

In sociocultural contexts of low affluence, rural/agrarian/low-socioeconomic status standing where children in fact contribute to the family's material well-being, the economic/utilitarian VOC is salient, child work is common both in and out of the house, and the family is characterized by intergenerational material interdependencies. This is the family model of "interdependence." In contrast, in more affluent contexts where children are in school and are costly to raise, the psychological VOC is salient, child work is negligible, and intergenerational material interdependencies are weak. This is the family model of "independence." The interdependent pattern is more prevalent in collectivistic cultures or "cultures of relatedness" with closely knit human relations. The independent pattern is more typical of the individualistic societies or "cultures of separateness." Thus, there is a general correspondence among societal conceptions of childhood, parental values, family patterns, and children's actual lifestyles.

In the family model of interdependence, there is obedience-oriented child rearing that does not promote the development of autonomy. This is because the independence of children is not valued and might even be seen as a threat to the family livelihood because independent offspring may look after their own self-interests rather than those of the family. Intergenerational interdependence is manifested through the family life cycle first as the dependence of the children on their parents, with this dependence being reversed later on as the dependence of the elderly parents on their adult offspring for their livelihood.

A contrasting pattern is seen in the family model of independence, characteristic of the Western (mostly American) middle-class nuclear family, at least in professed ideals. Here, child rearing is oriented toward engendering self-reliance and autonomy, and independence is also valued between generations, where objective social welfare systems and affluence render family interdependence unnecessary or even dysfunctional. Individuation-separation is considered a requisite for healthy human development and is also reinforced by (popular) psychological teaching.

It is commonly assumed (e.g., by modernization theory) that there is a shift from the model of interdependence to the model of independence with urbanization and economic development. However, recent research shows that the changes in family interaction patterns often do not follow such a linear route. In collectivistic cultures of relatedness where interpersonal distances are small between connected selves, individuals and families do not shift toward individualistic separateness with urbanization and economic development. Connectedness continues, although mainly in the realm of psychological interdependencies, while material interdependencies weaken with changing lifestyles. This leads to a third pattern proposed by Kagitcibasi, the "family model of psychological interdependence." In some ways, it is different from both the traditional (rural) family characterized by total interdependence and the individualistic (urban) family characterized by independence.

Child rearing involves control rather than permissiveness because the goal is not individualistic separation. However, autonomy also emerges in child rearing, mainly for two reasons. First, autonomy of the child is no longer seen as a danger because elderly parents are no longer dependent on their grown-up offspring for their material livelihood. Second, autonomy of the growing person is functional in urban lifestyles where, for example, decision making (rather than obedience) is required in school and in more specialized jobs.

2.2. Development of the Self

Thus, the family is the developmental niche for the self. Studying the family provides insights into understanding the self, in particular how and why the different types of self develop. For example, a distinction is made between the independent self and the interdependent self, and the cognitive and behavioral concomitants or consequences of these two types of self are examined. Thus, current work on culture and self focuses on cross-cultural variability, particularly along the dimension of independence–interdependence. However, why and how these different types of self develop is not well understood except in reference to macrosocietal characteristics such as individualism and collectivism.

Family is the significant mediating variable here that sheds light on the functional underpinnings of self development. In the family model of interdependence the “related self” develops and is interdependent with others. In the family model of independence, the “separate self” develops and is independent. The third family model of psychological interdependence is more complex because it entails both autonomy and connectedness in child rearing, with the resultant “autonomous-related self” (proposed by Kagitcibasi). The coexistence of autonomy with connectedness is important because the two are often seen to be antithetical in psychology. Under the influence of psychoanalytic thinking, particularly object relations theory and the separation–individuation hypothesis, separation is considered to be a requisite of autonomy in human development. Therefore, the implication is that connected selves cannot be adequately autonomous. This is a central debate, particularly in understanding adolescence. A psychoanalytically oriented individualistic perspective, such as that proposed by Steinberg and Silverberg, considers adolescence to be a “second separation–individuation process” where detachment from parents is seen as a requisite for the development of autonomy. Others, such as Ryan and colleagues, suggest that individuation during adolescence is facilitated not by detachment but rather by attachment. Recently, there also has been some recognition of the compatibility of relatedness and autonomy in the adolescent and adult attachment literature. The autonomous-related self challenges the individualistic assumption. It also goes beyond the dualistic conceptualization of the independent self versus the interdependent self that is prevalent in cross-cultural psychology.

Current research provides support for the compatibility of autonomy and relatedness, indeed pointing to their

combination as being a psychologically more healthy state that satisfies the two basic human needs for autonomy and connection (merging). The family model of psychological interdependence also finds research support in both the Western and non-Western contexts. For example, a more positive relationship is found between autonomy and relatedness than between autonomy and separateness in both Korean and American samples; positive links, rather than negative links, are found between relatedness to parents and autonomy in adolescents in the United States; combined autonomy and control orientation is noted among Chinese and Korean parents; parental autonomy goals do not imply separateness, and achievement values are associated with parental collectivism (rather than individualism), among Turkish parents in Germany; family interdependencies coexist with some individualistic values in Hong Kong; and Chinese and Chinese American parents are found to endorse both relatedness and autonomy, together with high control of and closeness with their children.

Parental orientations are of crucial importance in leading to diverse developmental outcomes. Systematic variations are noted even in parents’ orientations to infants, providing evidence that the various developmental pathways and their combinations may have their roots all the way back to infancy and are reinforced throughout the life span. Such research, informed by cultural and cross-cultural perspectives, opens up new vistas in the development of the self that can shed light on the interface of culture, parenting, and the individual through time.

3. DEVELOPMENT OF COMPETENCE

Child rearing is goal oriented, although this is mostly not made explicit. Often, the goal is competence in the sense that socialization, by definition, implies becoming a competent member of a social group. Competence in this perspective refers to what is culturally valued, thereby showing variation across cultures. This sphere of child development is the meeting ground for the development of the self and cognitive development.

In more traditional contexts, particularly with closely knit human ties and interdependent family systems, cultural conceptualizations of cognitive competence include a strong social component. Because much research from Africa has pointed to this, it has been called “African social intelligence”; however, it is much more widespread, particularly in traditional

collectivistic cultures of relatedness with closely knit human ties. It reflects cultural valuing of social responsibility and sensitivity to others' needs and expectations. Obedience orientation in child rearing, discussed earlier, is also involved here because it engenders dependent children who grow up to be loyal adult offspring. Independence and separation are not socialization goals.

Research also shows that, particularly in nonindustrialized rural/agrarian contexts of low levels of affluence, children develop practical skills that serve the family and reflect material dependence on children's work. For example, from early on, children do household chores, take care of animals and babies, and even cook food for the family—tasks in which most urban middle-class children would perform poorly. However, the same children often do poorly in simple cognitive tasks with which urban middle-class children have no difficulty. Clearly, children's cognitive competence in culturally valued domains gets promoted, whereas development in other domains lags behind if it is recognized at all. For example, Serpell showed that "folk" conceptions of intelligence in a Zambian village differed significantly from what is measured by intelligence tests, even culturally sensitive ones. Dasen found in Ivory Coast (West Africa) that intelligence involved mainly social and practical skills (e.g., "being good with hands").

3.1. Environmental Change

An issue in the development of competence in cultural context is social change. The channeling of competence toward culturally valued domains is adaptive so long as there is stability in lifestyles and societal demands. A problem emerges, however, in contexts of social change when adaptive mechanisms get challenged by modifications in lifestyles. Such modifications often accompany social structural and economic changes, especially urbanization and migration. For example, rural-to-urban mobility in developing countries is of immense proportions, also feeding into international migration. Although the young population (10–19 years of age) in developing countries was mainly rural in 1990 (approximately 600 million rural vs 300 million urban), the rural and urban populations of youth are expected to become equal before 2015. Thus, this significant global human mobility calls for a better understanding of what is adaptive and what is maladaptive in the cultural construction of children's developmental niches in contexts of social change.

For example, research on ethnic minorities in North America and Europe, mostly migrants from other parts of the world, points to misfits between parental beliefs

and values and to new environmental demands emerging from urban living conditions, particularly schools. In the face of social change and mobility, the question of whether there is an optimal fit between (traditional) child-rearing orientations and children's developmental trajectories becomes relevant. Such a question challenges cultural relativism, which assumes that what is culturally valued is by definition the right channel of child socialization. The matter turns into an empirical issue open to investigation by research. Such research calls for the possibility of using common (minimal) standards of child development and competence. It also points to the potential of applied work involving intervention.

3.2. Cognitive Development: Piaget and Vygotsky

A great deal of developmental research in the cultural context has focused on cognitive development. A general conclusion is that basic cognitive processes appear to have cross-cultural similarity; however, their manifestation in behavior shows variability given the diversities in cultural/environmental factors that may serve as constraints or reinforcers. The distinction between capacity and performance comes to the fore, as does the issue of culturally sensitive assessment of cognitive competence.

Most theory in psychology, and also in developmental psychology, claims universality, particularly with the weight of the organismic perspective mentioned previously. This is true for Piagetian theory, the generality of which has been subjected to a great deal of cross-cultural empirical testing with variable results. The most important cross-cultural support for the theory is given to the sequencing of stages of cognitive development. Although the particular ages at which the stages or substages are attained, or whether they are attained, show cross-cultural variability, reversal of stage sequence is never found. Beyond this, the first stage of sensorimotor intelligence is found to be a "strong" universal, shown in all studies with infants. The preoperational period is also considered to be a candidate for a strong universal. Even during these early periods, however, differences emerge, for example, in terms of whether objects or social stimuli are handled or attended to more (apparently due to the different types of stimuli, language use, and maternal responsiveness to which infants and young children are subjected in different cultures).

During the period of concrete operations, cultural differences become more important such that in some cultures, some children fail to engage in concrete

operations even when they reach adolescence. Dasen suggested that the qualitative characteristics of concrete operational development (reasoning types) are universal but that the rate of development in certain domains, particularly quantification and spatial reasoning, is influenced by environmental factors. Finally, individuals in many societies never achieve the formal operational stage of cognitive development. Schooling is the main factor that plays a role in whether formal operations are mastered. Actually, this factor is not confined to the nonindustrialized, non-Western contexts. Not all adults in Western technological society achieve this type of thinking. When confronted with this research evidence, Piaget accepted the role of experience and culture for the development of formal operational thinking.

Vygotsky's sociocultural theory of development takes human development out of the confines of the individual and into the cultural and historical realms. As such, it has been important for contextualist perspectives, particularly those of cultural psychologists. Vygotsky stressed the role played by culture, language, and the child's "zone of proximal development" in cognitive development. This is not a stage theory, but the evolution of speech through "social," "egocentric," and "inner" speech periods is sequential. Research on infant-mother interaction across several cultural groups, and informed by Vygotskian thinking, pointed to cultural differences, particularly in various types of maternal responsiveness and speech. Later, the child is aided by the adult through verbal interaction and instruction to reach beyond the current level of competence. The theory that proposes a continuous process of interaction between persons and sociocultural factors is used as a framework in "everyday learning" or "apprenticeship" situations involving "scaffolding" (i.e., temporary support and guidance in problem solving) by an adult. However, it is also criticized as vague and not conducive to measurement or hypothesis testing. As is also apparent from this glimpse of the two most significant theories of cognitive development, diversity and commonality across cultures challenge developmental theory.

4. NATURE-NURTURE DEBATE AND PLASTICITY

Cross-cultural research can help to provide insights into some of the basic issues in child development. This is mainly because a cross-cultural developmental approach uncovers a greater range of variation than does a single-culture study. With increased coverage of diversity, a

wider perspective emerges according to which what is typical and what is atypical might need to be redefined. It also becomes more possible to distinguish between biological and environmental influences. That is, the greater the commonality found across varied cultural contexts, the greater the likelihood of a biological basis for a developmental process, whereas a finding of increased diversity across cultures implies environmental causality.

The perennial nature-nurture debate is a case in point. Although there is much greater sophistication in the treatment of the issue today compared with the earlier, rather simplistic comparisons, the issue stands unresolved. In several spheres, including temperament, personality, intelligence, and gender identity, the nature and malleability of child development can be better understood if cultural context is taken into consideration. "Heritability" refers to the portion of variability in a trait that results from heredity. As such, high heritability is often understood to mean high genetic causality and, thus, a negligible role for the environment. Yet even with extremely high heritability, the environment can still have a powerful influence. For example, a surge in the heights of second-generation Japanese children raised in the United States was reported. The heritability in this group was more than .90, yet the American-reared sons were substantially taller than they would have been if they had been reared in Japan. Similarly, it is reported that the heights of young adult males in Japan increased by approximately 3½ inches since World War II. If a trait as highly heritable as height can show such fluctuations in relatively short time periods and across societies, other traits with lower levels of heritability, such as intelligence and personality, can change as well.

A currently popular view stressing biological determination is Scarr's genotype-phenotype theory, which holds that each individual picks and chooses from a range of environments those that best fit his or her genetic potential/orientations. Thus, the theory claims that genetic endowment creates the environments that individuals choose for themselves. When cultural context is taken seriously, however, the limitations of the theory become obvious. The theory assumes that people have equal opportunity or options from which to choose, yet a great many people in the world are not in a position to choose much at all. Environmental opportunities vary greatly; particularly in deprived environments, the genetic human potentials might not be realized. Thus, heritability for intelligence, for example, would be expected to be lower in deprived conditions than the .50 estimated for the general population

and would be expected to be higher in “good” environments than in “poor” ones because the former provide the resources for the biological potential to be realized.

Indeed a great deal of research points both to lower levels of measured intellectual performance and to other indicators of poor competence such as school failure in socioeconomically deprived environments. Other evidence regarding the powerful influence of the context of development and the plasticity of human development comes from studies of adoption after privation and the effects of schooling.

An early study reported massive intelligence quotient (IQ) gains in children born to low-IQ mothers after they were given up for adoption into environmentally enriched middle-class homes. Although children’s IQs still correlated with those of their biological mothers, indicating genetic influence, they were much higher than the mothers’ IQs and even higher than those of the general population. This study was criticized for its methodology, but its findings were corroborated by later research. For example, recent work with Romanian adoptees from orphanages after the fall of the Ceausescu regime points to the crucial importance of both early environmental deprivation and plasticity of human development. It was found that severely malnourished children (below the third percentile in head circumference, body size, and developmental level) recovered to normal development by 4 years of age if they were adopted into English homes before 6 months of age. Those who were adopted later, however, did not fare as well.

There is debate concerning the long-term effects of early deprivation. Some consider the deleterious effects to be critical and long-lasting, even referring to the first 2 years as possibly a “critical period” in human development. Others are less certain due to the limited capacity of infants to process their experiences cognitively and/or due to plasticity, particularly with regard to catching up in physical growth. Nevertheless, there appears to be consensus that whatever the genetic potential, environment, particularly during the early years, has an important impact on human development and that even quite high values of heritability still leave plenty of room for environmental enhancement or reduction of human potential.

5. IMPLICATIONS FOR APPLICATION

Beyond “saving” children from deprivation through adoption, there are other more common implications

for application of the significant cultural/environmental impact on human development. Some examples of implications for application, involving advocacy and program- and policy-relevant research, would help to put the issues and their possible solutions into perspective.

5.1. Developmental Norms

Growth norms for infants and children have been established by pediatricians. Some of these have a great deal of cross-cultural validity. However, developmental norms paralleling physical growth norms are largely missing and are badly needed for assessment, screening, and detection of developmental risks. With better public health measures such as immunizations, significant increases have been achieved in the rates of infant and child survival globally. However, the circumstances that used to put infants at risk for death continue to put the survivors at risk for arrested or delayed development. Thus, the question of what happens to those who survive assumes great importance. With new policy shifts focusing on early childhood care and development, developmental psychologists are now being called on for their expertise. This is required especially for the cross-culturally valid conceptualization and assessment of human development.

Interactive conceptualization of nutrition, health, and psychosocial development, with each one acting on the other two, is proposed to better represent the dynamic processes of child development in the cultural context. For example, the effectiveness of health and nutrition programs can be increased by combining them with early childhood stimulation and education. The role of the proximal environment, particularly child care, is of importance here as a mediator of the macro-level influences. Thus, within the same poverty situations, some children thrive, whereas most others stay behind. Mother–child (or caretaker–child) interaction emerges as an important “shield” factor in promoting the child’s resilience, conceptualized as “positive deviance.” Here, supporting and training the mother or caretaker goes a long way toward leading to better child outcomes.

In dealing with disadvantaged contexts of child development, culturally valid assessment tools and developmental norms are crucially important. The challenge is to develop child development indicators that have cross-cultural validity to function as “standards” of development and also have cultural validity. Environmental indicators are also of crucial importance and are even less well established cross-culturally. For example, research points to the positive effects of maternal literacy

and education on child survival, longer intervals between pregnancies, better child physical growth, and more developmentally facilitative maternal child-rearing patterns. A concept such as “optimal parenting” becomes relevant here. When made applicable to large numbers of children and parents, such knowledge can be used for detection and screening of risk cases and for establishing and promoting the environmental factors conducive to healthy child development.

5.2. Schooling

Schooling is another case in point. A great deal of evidence points to the significant contributions of education, particularly schooling to societal development. Of greater relevance for psychology is the contribution of schooling for cognitive development. For example, Ceci showed that each additional month that a student remains in school may increase his or her IQ score above what would be expected if the student had dropped out. Other research provides similar evidence. Furthermore, a causal relationship is implicated from education to IQ, rather than the other way around, on the basis of higher-IQ children choosing to stay in school longer, as claimed by genotype–phenotype theory mentioned previously. There are different types of evidence supporting this causal relationship, including the effects of intermittent school attendance, delayed school entrance, length of school year, summer vacations, and early-year birth dates.

Given the overwhelming evidence regarding the societal and individual benefits of schooling, there needs to be strong advocacy for increased schooling for all, particularly for girls. Access to schooling is behind schedule in most of the world. For example, during the 1990s, when overall school enrollment reached 92% in North America, it remained at a mere 42% in Sub-Saharan Africa. Although it is developmental psychological research that reveals the positive effects of schooling on cognitive competence and human potential development, psychologists play only a marginal role in efforts to make “education for all” a reality in the world. At the same time, schools should be improved so as to entail better pedagogy and both culturally relevant and globally shared knowledge. Psychologists have a role to play here as well. For example, Stevenson and colleagues studied the cultural contexts of schooling and its cognitive products, focusing on the values and practices of Japanese, Chinese, and American schools and parents, with significantly different achievement outcomes for

children. The implications for educational policy and practice are far-reaching.

5.3. Early Enrichment

The importance of early experience for the development of competence is well recognized, notwithstanding the significance of organismic factors. Therefore, concerted efforts have been expended to provide deprived children with early enrichment in attempting to enhance their ability to benefit from formal schooling. “School readiness” is defined in terms of the child’s activity level, social competence, psychological preparedness, and cognitive abilities, including preliteracy and prenumeracy skills. It is also reflected in the positive orientation and support of the child’s family.

Research and applications during early childhood education abound in North America and Europe but are few and far between in developing countries. An important issue is whether a “center-based” or a “home/community-based” contextual approach is to be used (a related distinction is that between a child-focused and a parent-focused orientation). A general conclusion that can be drawn from research in various cultural contexts is that if the child’s family environment can provide the child with the necessary stimulation, a center-based, child-focused approach is effective; otherwise, parental involvement is needed to improve the home environment. A home-based contextual approach has the potential to create lasting effects that would continue to support the child even after the completion of the early enrichment program, as evidenced by longitudinal research. It also tends to have multiple goals and multiple effects in supporting and changing the home environment, particularly the parents, together with the child. Given the crucial importance of the proximal environment and particularly of parenting, a contextual and culturally sensitive early enrichment can go a long way toward increasing the possibility that children from disadvantaged backgrounds can enter adulthood on a more equal footing with those from relatively advantaged backgrounds.

5.4. Problems in Development

Various problems in child development arise from environments that fall far short of presenting an optimal fit with children’s developmental trajectories. Most of these emerge in social–cultural–economic deprivation (discussed earlier). Even more serious developmental problems may be encountered in especially difficult

circumstances such as war, family violence, child abuse and neglect, abject poverty involving malnutrition, debilitating and fatal morbidity (e.g., HIV/AIDS), and homelessness (e.g., street children). Under such difficult circumstances, beyond arrests in physical and cognitive/language development, emotional and social development also suffers greatly with possible psychopathology. Beyond medical and other research and interventions, there is a need for research that examines the cultural aspects involved such as societal values, parental views of children's needs, and parental behaviors and priorities for survival. Culturally sensitive assessment of the situation and interventions that are informed by cultural knowledge would be expected to have a greater chance for success. In particular, cultural strengths, such as closely knit human ties and social support mechanisms, could be identified and buttressed further, whereas vulnerabilities and weaknesses could be ameliorated. Thus, especially in the most difficult circumstances, a cultural/contextual approach is valuable. This is an important area of applied developmental psychology.

6. CONCLUSION

Child development occurs in culture and has to be studied in cultural context. Such a cultural/ecological perspective is necessary for both scientific and applied work. Understanding, assessing, and possibly enhancing child development requires that both a "whole child" perspective, attending to different spheres of development, and a contextual perspective be used. In so doing, both the unity and diversity of human development across cultures need to be recognized. Finally, developmental scientists should strive to go beyond understanding child development to use this understanding optimally in enhancing human development and well-being within and across cultures.

GLOSSARY

direct questions Yes/No or short-answer questions that probe for particular details about an experienced or witnessed event; questions can range from nonleading to suggestive, depending on how the question is phrased and the type of information that is included.

free recall questions Vague general prompts requesting a narrative description of prior events; prompts provide minimal cues or information about what should be recalled.

script A general knowledge structure that represents information from a class of similar events; it is a description of the typical features of repeated events.

structured interviews Scripted interview prompts and questions that are designed to obtain as much narrative information from children and to be as minimally leading as possible.

suggestibility Susceptibility to errors when describing witnessed or experienced events; it can be caused by internal factors (e.g., biases) or external factors (e.g., questioning technique).

Since the 1980s, there has been a virtual explosion of studies concerning children's eyewitness abilities and

participation in legal proceedings. The studies, along with considerable public, legal, and legislative attention, were motivated by a number of phenomena. One was a growing awareness of the widespread prevalence of maltreatment, especially child sexual abuse. Large U.S. national surveys revealed that many more individuals were reporting unwanted sexual experiences as children than had been recognized previously, yet few perpetrators were successfully prosecuted criminally. In response, increased efforts were made to identify victims of maltreatment and facilitate the prosecution of perpetrators of crimes against children. A second contributing factor involved revisions in statutes (e.g., competency requirements) that reduced barriers to admitting children's testimony as evidence in court. By reducing such barriers, the number of child victims/witnesses becoming involved in legal cases increased dramatically. Unfortunately, little was known about how to elicit accurate information (e.g., about abuse) from children. Legal professionals and scientists, as well as the public, focused on the consequences of failing to identify a victimized child rather than on the potential for false reports of a crime. A third phenomenon during the 1980s, however, altered the public's and researchers' focus on false allegations. Specifically, several high-profile legal cases that involved scores of children alleging sexual assault in their day care facilities took place. The children's allegations included fantastic and impossible claims and often emerged only after the children had been subjected to repeated, highly suggestive interviews. These children's reports, and the

cases in general, raised serious concerns about the reliability of children's memory abilities. Questions about how to protect children from harm and ensure that those who commit crimes against children are punished, while at the same time guarding against false allegations of abuse, were brought to the forefront of public, legal, and scientific attention. Research on children's memory, suggestibility, and false memories, as well as on children's participation in legal cases, has sought to answer these questions. The present article focuses on this research. First, research concerning factors that influence children's memory accuracy and susceptibility to false suggestions is presented. Second, the effects of participation in legal proceedings on children's well-being are discussed. Third, a brief overview of new directions in the field is provided. The article is limited in scope to findings that are most applicable to legal cases, are particularly well established, and have received considerable attention. It is also limited to discussion of child victims/witnesses. A large and growing body of literature now focuses on child defendants, and it is not possible to review both areas in a single brief article.

1. FACTORS THAT INFLUENCE CHILDREN'S TESTIMONY

Hundreds of studies have now been conducted concerning the reliability of children's eyewitness abilities. A number of factors have been identified that have implications for children's memory and suggestibility. Those discussed here can be heuristically divided into child, to-be-remembered event, and interview characteristics.

1.1. Child Characteristics

Numerous characteristics of children can influence their eyewitness abilities. The most well-studied characteristic is age, and the most consistent finding across research involves age differences in performance. With advancing age, children remember more information, are more accurate, are less suggestible, and make fewer false event reports. Both cognitive and social factors underlie age differences. Cognitively, older children are better able to conduct memory searches, know what is important to recount, and know how to cue their own memories. They also have more experiences and greater general knowledge, and this helps them to encode, interpret, and later remember information. Socially, older

children are more aware that adults can make mistakes, and this reduces their willingness to report false information suggested by adults as having occurred.

Other characteristics, in addition to age, have also been studied as predictors of children's memory and suggestibility. These include cognitive factors (e.g., intelligence, language, inhibitory control) and socioemotional factors (e.g., temperament, emotional reactivity, attachment). With regard to cognitive factors, although findings have not always been consistent, higher intelligence, greater language understanding, and better inhibitory control are generally associated with improved memory and reduced suggestibility, even when children's age is statistically controlled. With regard to socioemotional factors, outgoing temperament, low emotional reactivity, and secure attachment are often related to better memory, especially for stressful experiences.

Although research concerning child characteristics is important theoretically and provides considerable insight into processes underlying accuracies and inaccuracies in children's memory and suggestibility, it is difficult to apply to legal contexts. In particular, it is not possible to use any of the aforementioned characteristics, alone or in combination, as a litmus test to determine whether to accept or reject a particular child's eyewitness account. Nonetheless, the research may help to identify children who need special precautions taken when they are questioned about forensically relevant matters. Armed with information about factors that predict performance in individual children, interviewers may be better able to alter their questioning procedures to ensure that each child is interviewed in the most appropriate manner possible.

1.2. To-Be-Remembered Event Characteristics

Numerous factors associated with a to-be-remembered event may influence children's memory and suggestibility. Three factors that have received considerable attention are the stressfulness of the to-be-remembered event, the number of times that an event occurred, and children's level of involvement.

For some time, researchers have attempted to determine whether stress helps or hurts children's memory. Studies have focused on children's memory for mildly arousing laboratory-based events (e.g., fire alarms) as well as for highly distressing, salient, naturally occurring experiences (e.g., medical procedures, natural disasters). Although results have not revealed any

uniform positive or negative effect of stress on memory, some general conclusions are possible. First, children, like adults, remember emotional events better than they do neutral events. Thus, although the effects of varying levels of distress on memory remain unclear, stressful events appear to be more memorable than nonstressful neutral events. Second, memory for central details of an event (e.g., details directly associated with the cause of the stress) is often better than memory for peripheral details (e.g., information unrelated to the cause of the stress). It should be noted, however, that what is considered central to a child is not necessarily the same as what is considered central to an adult. For instance, a parent's departure during a medical procedure may be especially salient, and hence central, to a child even though the parent's departure is unrelated factually to the medical procedure. Third, the effects of stress on memory vary across children such that for some children (e.g., securely attached children) stress helps memory, whereas for other children (e.g., shy or insecurely attached children) stress inhibits memory. Researchers have begun to investigate interactions between stress and child characteristics as joint predictors of memory and suggestibility. The results of these new studies will continue to elucidate when and how stress affects children's performance.

The number of times an event is experienced can affect children's memory, although the direction of the effect varies depending on the type of to-be-remembered information. When an event is experienced repeatedly, children form scripts, which are mental representations of what "usually" happens or the common recurring features of the event. When asked to recount what happened during a repeated event, children can use these scripts to help them describe what usually happens. Thus, scripts enhance memory for the common repeated components. Unfortunately, children may fail to report nonrepeated details because these details are not included in the script of what usually occurs. Children may also have difficulty discriminating between repeated events and report details that are consistent with what usually occurs, even if those details did not occur during one particular incident.

A third event-relevant characteristic is children's participatory role. Children's memory is better for events in which they participated than for events that they merely witnessed. Active participation often results in more elaborate encoding and enhanced understanding of an event, both of which facilitate recall. Accordingly, children may often be better witnesses about events that they personally experienced than about events that

they only witnessed, although some witnessed events, such as those that are especially relevant personally or are particularly salient or stressful, can also be remembered quite well.

1.3. Interview Characteristics

Much of the research concerning children's eyewitness testimony has focused on how characteristics of the interview affect performance. Results have been applied directly to legal contexts. For instance, several criminal convictions have been overturned because the interviews with alleged child victims were conducted in a manner that has been shown, in empirical research, to lead to errors and entirely false event reports. Also, interviewers are now often taught appropriate interviewing tactics and which tactics to avoid when questioning alleged child victims/witnesses.

How questions are phrased can affect the completeness and accuracy of children's reports. Questions are often divided into "free recall" and "direct" questions. Free recall questions are vague general statements prompting a child to recount, in narrative form, a past event (e.g., "Tell me what happened when . . ."). Direct questions include nonleading, leading, and suggestive questions. Nonleading questions do not imply incorrect information or a particular response (e.g., "What color was the car?"). Leading questions imply a particular response (e.g., "Was the car red?"). Suggestive questions contain false embedded information (e.g., "What was the man wearing when he entered the room?" when in fact there was no man) or explicitly imply which answer should be given ("He entered the room first, didn't he?" when the man did not in fact enter first).

Free recall questions are less controversial than direct questions because children's free recall responses are typically quite accurate. That is, children rarely provide incorrect information when asked, in an open-ended manner, to recount a particular event. The major drawback to free recall, however, is that children's reports are often incomplete. Children might not know what is important to recount. They also might have difficulty in forming cogent narrative answers, even when they remember event details.

To obtain additional information, direct questions that probe for specific information are often needed. Such questions indeed increase the amount of information that children provide; however, the questions, especially those that are suggestive, also increase errors. Children may answer in a way that they believe the interviewer desires, they might not be comfortable

indicating that they do not know an answer, they may develop a “yeah”- or “nay”-saying response bias, or they may accept the interviewer’s suggestions as fact. Each of these increases errors, and in some circumstances it may lead children to claim that entirely false events occurred.

Importantly, although children’s free recall reports are generally accurate but incomplete and children’s responses to direct questions are less accurate, two exceptions to these trends must be mentioned. First, accuracy of free recall can be compromised if, prior to asking free recall questions, children are exposed to false suggestive information. For instance, before an interview, a parent or an interviewer might imply to a child that an alleged perpetrator did something bad or a child might learn from other children what happened during an alleged event. These preinterview sources of false suggestions lead to increased errors in children’s responses to both free recall and direct questions. Second, when no abuse occurred, children tend to be more accurate when answering abuse-related direct questions (e.g., “Did he take pictures of you when you were in the bathroom?,” “Did he touch your bottom?” [asked to children who merely experienced a play interaction with an adult]) than when answering non-abuse-related questions. Thus, children’s willingness to err in response to direct questions varies depending on the content of those questions.

Highly leading interview instructions can have a dramatic effect on children’s memory and suggestibility. Such instructions include asking children to imagine or pretend that a particular event occurred or introducing false stereotypic information about an event or individual(s). When these instructions are given before or during an interview, children will often alter their statements about an individual’s activities or change their interpretation of an event and recount information that is consistent with the leading instructions. In addition, when children are explicitly told that an event occurred and are given information about what happened, a sizable minority will repeat the information as having happened even if the event is false. Interestingly, children are less likely to assent that false negative events (e.g., falling off a tricycle and getting stitches) occurred than to assent that false positive events (e.g., going on a hot air balloon ride) occurred, although some children nonetheless assent to both positive and negative events. What remains of theoretical interest is the extent to which children believe that the false events took place versus the extent to which they are simply acquiescing to an interviewer’s suggestions.

Question repetition, both within and across interviews, has been especially controversial. Some claim

that simply repeating questions about untrue information causes false reports in children. However, such a phenomenon has not yet been confirmed empirically. Instead, the effects of repeated questions vary as a function of the type of question, whether questions are repeated within or across interviews, and preinterview instructions. Within an interview, particularly young (e.g., preschool-age) children often change their responses when asked repeated direct (e.g., yes/no) questions. They tend to interpret the repetition as an indication that their first response was incorrect. In contrast, when questions are repeated across interviews, at least when no highly leading instructions have been provided, earlier interviews can actually have a buffering effect, reminding children of an original event and reducing errors in later interviews. Finally, when repeated interviews are combined with highly leading interview instructions such as those described previously, a high percentage of children (often one-third or more) will make false reports that are consistent with the instructions.

1.4. Summary

A variety of factors have been studied as predictors of accuracies and inaccuracies in children’s memory and eyewitness abilities. Some findings (e.g., those concerning age differences in performance, the accuracy of children’s free recall reports, the deleterious effects of highly suggestive interview questions and instructions) have been consistently found in empirical research and are now met with minimal controversy when applied to legal settings. Other findings (e.g., those involving effects of stress on memory or interview repetition), however, have been more variable and are not amenable to broad straightforward conclusions or applications to legal contexts. That is, whether many factors (e.g., repeated interviews, stress, participation) help or hurt children’s eyewitness abilities depends on a number of considerations, such as how questions are asked and the type of memory being probed. These considerations need to be taken into account when attempting to evaluate child victims’/witnesses’ reports.

2. CHILDREN’S INVOLVEMENT IN THE LEGAL SYSTEM

Although most research concerning children’s testimony has focused on the accuracy of children’s eyewitness

abilities, studies also have investigated the effects of legal involvement on children and the use of innovative practices to facilitate children's participation in legal cases. Some psychologists and legal scholars contend that children suffer "secondary" victimization by participating in a legal system that was not designed for, and can be quite intimidating to, children. Such individuals advocate altering standard courtroom procedures (e.g., allowing children to testify without a defendant present) to reduce children's distress. Other scholars, however, maintain that, because all witnesses can be distressed during a legal case, distress should not be used as the basis for abandoning defendants' fundamental rights or changing standard legal practice.

A few studies have investigated the effects of legal involvement on children. Most noteworthy are studies of the effects on child sexual abuse victims. Findings indicate that some children are adversely affected by legal involvement in terms of increased distress and behavior problems following their legal cases. Factors that increase a child's risk of adverse effects include testifying multiple times, testifying while facing the defendant, not having maternal support during the case, and not having corroborative evidence confirming the abuse allegation. However, not all children appear to be adversely affected, and adverse effects appear more often following criminal involvement than following juvenile or family court involvement. Furthermore, the extent to which adverse effects are maintained over long time periods has only recently begun to be investigated.

As mentioned previously, some advocate altering standard legal procedures to facilitate children's participation in legal cases. A related line of research has investigated the use of these alterations and their effects on children's distress and case outcomes. Innovative techniques include those that affect pre-court interviews with children (e.g., multidisciplinary centers, videotaping interviews) and those that affect in-court practices (e.g., admitting children's out-of-court statements [hearsay] as evidence, allowing children to testify via closed-circuit television testimony). Although there is support for the use of the innovations, and the constitutionality of their use has been upheld by some U.S. courts, their actual use appears to be limited. In particular, surveys of prosecutor and judicial behaviors indicate that techniques that alter in-court practices are rarely used, primarily due to concerns that decisions will be overturned. Techniques that alter how children are interviewed are also rated as too costly for widespread use. Despite the limited use of innovations, however, they appear to be effective

in reducing children's distress. Also, studies of jurors' decision making have revealed relatively few differences in case outcomes based on whether children testify live or children's statements are presented in some other format (e.g., hearsay is presented, children testify via closed-circuit television). Finally, the use of several innovations, such as videotaped testimony and closed-circuit television testimony, is standard in other countries (e.g., Great Britain). Perhaps as awareness of both the benefits of the innovations and the lack of adverse effects on case outcomes grows, the innovations will be used more frequently in the United States as they are in other countries.

3. CONCLUSIONS

Numerous characteristics, including those both intrinsic (e.g., age) and extrinsic (e.g., stress of a to-be-remembered event, interviewer demeanor, testifying in court) to children, have implications for children's ability to recount past experiences accurately and for their ability to cope with involvement in the legal system. Although this article has highlighted some of the better established and particularly noteworthy findings and controversies, it is by no means exhaustive. Furthermore, several exciting new directions in research continue to refine understanding of the conditions under which children's testimony is more likely to be accurate and how to facilitate children's participation in legal cases. These new directions focus on how characteristics of children interact with contextual characteristics to affect their memory and suggestibility and on the development and testing of formal interview protocols that can be used in forensic contexts to ensure that children are questioned in the most appropriate manner. With regard to interactions between children and contextual characteristics, it is likely that individual children respond very differently to particular events, such as stressful experiences, and these different responses may affect how individual children later remember the events. With regard to interview training protocols, simply providing forensic interviewers with background knowledge (e.g., about the hazards of leading questions) and general training does not improve how actual interviews are conducted. Thus, researchers have begun to develop specific guidelines and structured protocols that interviewers can use when questioning alleged child victims/witnesses. Although these new protocols, which are more widely accepted in other countries (e.g., Great Britain, Israel), are currently being tested in the United

States, they already appear to be effective in increasing the amount of narrative information provided (e.g., in response to free recall questions) and in helping interviewers to avoid the most problematic questioning tactics. These protocols may also decrease the number of times children need to be questioned, thereby reducing distress that can result from being interviewed multiple times about alleged crimes.

As new psychological research is conducted, and as previously reported findings are confirmed and extended, it will be imperative to continue to educate those involved in actual forensic contexts regarding abilities and limitations of child witnesses. Not only will this knowledge advance scientific understanding of children's memory capabilities and suggestibility, but it will also benefit both alleged victims/witnesses and defendants in legal cases involving children.

GLOSSARY

behaviorism The term originated with the work of Watson. Behaviorism was a movement in psychology that argued that mental events were impossible to observe and measure. It was claimed that psychology was only the study of observable behavior. Until the 1960s, this was the dominant approach to learning.

cognitivism An approach in psychology that was born in 1956. It began as a reaction to behaviorism. It proposed that human information and storing processes were very important in the process of learning.

conditioned or conditional response (CR) Any response that is learned by conditioning.

conditioned or conditional stimulus (CS) Any stimulus that, through conditioning, ultimately evokes a conditioned response. The conditioned response is originally a neutral stimulus.

contiguity The quality of two events occurring relatively closely in time. Conditioning will only occur if events or stimuli (CS-US) follow each other.

contingency The relationship between two events in which one depends on the other. Contingency refers to the

probability that when the CS occurs, the US is likely to follow.

unconditioned or unconditional response (UR) Any response elicited spontaneously by an unconditioned stimulus, without any prior learning or conditioning.

unconditioned or unconditional stimulus (US) Any stimulus that elicits a response without any previous learning.

The simplest associative mechanism, whereby organisms learn to produce new responses to stimuli and learn about relations between stimuli or events, is classical, or Pavlovian, conditioning. In classical conditioning, a neutral stimulus is repeatedly paired with another stimulus, called an unconditioned stimulus (US), that naturally elicits a certain response, called an unconditioned response (UR). After repeated trials, the neutral stimulus becomes a conditioned stimulus (CS) and evokes the same or a similar response, now called the conditioned response (CR). Most of the concepts presented in this article were developed by Pavlov. However, it also examines how original classical conditioning has been modified. Although the basic conditioning paradigm emerged 100 years ago, its comprehension and conceptualization are still developing.

1. FROM PAVLOV TO THE PRESENT

Russian physiologist I. Pavlov (1849–1936) was one of the pioneers in research on classical conditioning. His investigations, carried out at the end of the 19th

century, form the axis of associative learning. Pavlov was interested in the digestive system and, through these studies, he observed that dogs, the subjects of his experiments, anticipated the salivation response when they saw food. Subsequently, Pavlov presented a light or the ticking of a metronome [conditioned stimulus (CS)] for a number of seconds before the delivery of food [unconditioned stimulus (US)]. At first, the animal would show little reaction to the light but, as conditioning progressed, the dog salivated during the CS even when no food was delivered. This response was defined as the conditioned response. Hence, research on classical conditioning began. Soviet psychology has changed in many ways since the death of Pavlov in 1936, and many of these changes brought it closer to American psychology. One way in which the general theory of Pavlovian conditioning developed similarly in the two countries was via the incorporation of cognitive variables. The originally simple Pavlovian paradigm was expanded and reinterpreted through the efforts of many American researchers. American learning theorists developed alternative methods for estimating the strength of the association between a CS and a US. They also identified new Pavlovian phenomena and suggested new explanations of the basic mechanisms underlying the conditioning produced by use of Pavlovian procedures. Although Pavlov's writings were widely disseminated in the United States, most of the criticism of his ideas was expressed in 1950 by J. A. Konorski in Poland. Konorski and Miller, Polish physiologists, began the first cognitive analysis of classical conditioning, the forerunner of the work by R. A. Rescorla and A. R. Wagner (American psychologists) and A. Dickinson and H. J. Mackintosh (English psychologists).

In the 1950s, some clinical psychologists—such as J. Wolpe (in South Africa), H. J. Eysenck (in the United Kingdom), and B. F. Skinner (in the United States)—began to treat psychological disorders with a technology based on learning principles, aiming to substitute pathological behavior for a normal one. This movement, known as behavior modification, was based on both classical and operant conditioning and reinforced the popularity of these techniques among clinicians.

Significant changes on theoretical views upon this phenomenon were introduced by Rescorla and Wagner in 1972, whose model assumed that organisms, in their interaction with the environment, form causal expectations that allow them to predict relations between events. From this perspective, learning would consist

of the acquisition of information about the causal organization of the environment. In order to acquire this information, associations between elements are established. However, it is not sufficient for the elements to be contiguous so that an animal will associate them, as Pavlov proposed; it is also necessary for the elements to provide information about a causal relation. In fact, the central concept is the notion of contingency and the way in which it is represented in the animal's mind. This new "cognitive associationism" accepted the existence of both cognitive processes and associative mechanisms in the mind and rapidly gained wide support among learning experimentalists.

Although in some cases the organism seems to be conditioned only on grounds of CS-US "contiguity," in many other cases learning seems to allow the organism to predict US arrival from the CS appearance; this would be due to a "contingency relationship" that is expressed in terms of probability; if the probability of the appearance of the US is the same in the presence and in the absence of the CS, contingency will be null and no conditioning will occur. On the contrary, if the probability of the US appearing in the presence of the CS is greater than the probability of it appearing without the CS, then conditioning occurs. Therefore, classical conditioning is defined as the capacity of organisms to detect and learn about the predictive relation between signals and important events. Currently, classical conditioning is not considered to be simple and automatic learning about the establishment of CS-US relations but rather a complex process in which numerous responses intervene, not just glandular and visceral responses, as was thought at first. It also depends on the relevance of the CS and the US, the presence of other stimuli during conditioning, how surprising the US may be, and other variables.

Lastly, the growth of connectionist modeling has renewed interest in classical conditioning as a fruitful method for studying associative learning.

2. BASIC CONDITIONING PROCEDURE

The procedure of classical conditioning consists of the repeated presentation of two stimuli in temporal contiguity. First, a neutral stimulus (NS) is presented—that is, a stimulus that does not elicit regular responses or responses similar to the unconditioned response (UR). Immediately after that, the US is presented.

NS (a bell) → OR (orientation response)

US (presence of food in the dog's mouth) → UR (salivary response)

CS (a bell) → CR (salivary response)

FIGURE 1 Diagram of the sequence of events in classical conditioning.

Because of this pairing, the NS will become a CS and, therefore, will be capable of provoking a conditioned response (CR) similar to the UR that, initially, only the US could elicit (Fig. 1).

On the initial trials, only the US will elicit the salivation response. However, as the conditioning trials continue, the dog will begin to salivate as soon as the CS is presented. In salivary conditioning, the CR and the UR are both salivation. However, in many other conditioning situations, the CR is very different from the UR. According to Pavlov, the animals learn the connection between stimulus and response (CS–UR). Currently, it is understood that animals learn the connection between stimuli.

3. BASIC PROCESSES

Some basic processes that affect all sorts of conditioning learning have been identified. They include the following:

1. Acquisition: the gradual increase in strength of CR, linking the two stimuli (CS followed by the US).
2. Extinction: the reduction and eventual disappearance of the CR at the CS onset, after repeated presentations of CS without being followed by US.
3. Generalization: when a CR is linked to a CS, the same CR is elicited by other CSs in proportion to their similarity to the original CS.
4. Discrimination: occurs when subjects have been trained to respond in the presence of one stimulus but not in the presence of another.

4. EXPERIMENTAL PROCEDURES

4.1. Appetitive Conditioning

Appetitive conditioning is a modality in which the US (and CS) will originate a positive (approaching, consummative) behavior in the organism.

4.2. Aversive Conditioning

In aversive conditioning, the US and CS have negative properties and will generate an escape or evitation behavior. Aversion to some taste (Garcia effect) showed the possibility of obtaining long aversive reactions to some CS taste that, after being linked to some US with strong aversive digestive qualities, would generate an evitation response after a long interstimuli interval. Learning taste aversion plays an essential role in the selection of food because it prevents the ingestion of toxic foods. It has also helped to understand and treat food aversions in people suffering from cancer and undergoing chemotherapy.

5. EXCITATORY CONDITIONING

Excitatory conditioning occurs because the CS allows the subject to predict when the US will occur. In excitatory conditioning, there is a positive relation between the CS and the US. The excitatory stimulus (CS+) becomes a stimulus that elicits a CR after its association with the US. Traditionally, classical conditioning research has focused on this kind of conditioning.

6. INHIBITORY CONDITIONING

Inhibitory conditioning occurs because the CS allows the subject to predict that no US will be presented; that is, an inhibitory conditioned stimulus (CS-) signals the absence of an unconditioned stimulus (either positive or aversive), provoking the inhibition of the CR in the organism. This kind of conditioning was studied by Pavlov, and there has been a renewed interest that continues today.

One of the clearest examples of this procedure is the one presented by M. Domjan: A red traffic light (CS+) signals the potential danger (US), which is the car. If a policeman indicates that we can cross the street (CS-) despite the red light, he is signaling that there is no danger (US). Inhibitory stimuli, such as “out of order” or “do not cross” signs, provide useful information.

7. WHAT INFLUENCES CLASSICAL CONDITIONING?

The capacity of stimuli to become associated is modified by many phenomena, such as the CS–US interval, spatial

contiguity between stimuli, the similarity of the CS and the US, the intertrial interval, the characteristics of the CS and the US (intensity, novelty, and duration), or previous experience of the CS (latent inhibition), the simultaneous presence of other more salient stimuli (overshadowing), or more informative stimuli (blocking).

7.1. CS–US Interval

The interstimulus interval is the time between the appearance of the CS and the appearance of the US. It is one of the critical factors that determine the development of conditioning. Different CS–US interstimulus intervals are usually employed.

Simultaneous conditioning describes the situation in which the CS and the US begin at the same time. Delayed conditioning occurs when the onset of the CS precedes the US onset. Trace conditioning occurs when the CS and US are separated by some interval in which neither of them is present. The US is not presented until after the CS has ended. Backward conditioning occurs when the CS is presented after the US. This procedure casts doubt on the principle of stimulus contiguity because although the CS and the US are presented in inverse order, the association should be equally efficient.

The simultaneous and backward conditioning procedures produce poorer conditioning in comparison to delayed and trace procedures. However, today, due to the use of more sophisticated measurements than those traditionally employed, all the procedures can produce efficient conditioning.

8. APPLICATIONS

Classical conditioning is relevant to behavior outside the laboratory in daily life and plays a key role in understanding the origins and treatment of clinical disorders. In humans, classical conditioning can account for such complex phenomena as an individual's emotional reaction to a particular song or perfume based on a past experience with which it is associated; the song or perfume is a CS that elicits a pleasant emotional response because it was associated with a friend in the past. Classical conditioning is also involved in many different types of fears or phobias, which can occur through generalization.

Pioneering work on this type of phenomena was carried out by J. B. Watson and collaborators in the 1920s. They were able to condition a generalized phobia

to animals and a white furry object in a young child, “Albert” (creating a learned neurotic reaction), and also to extinguish a phobia in another child, “Peter,” through a learning procedure (carried out by Mary C. Jones). Both cases have been considered pioneering work in the behavior modification field.

8.1. Everyday Human Behavior

8.1.1. Classical Conditioning and Emotional Response

Recent reanalyses have evidenced the relevance of individual differences and cognitive variables. People who are more anxious in general develop phobias from experiences that do not produce fear in others.

Fears can be learned by multiple means that include direct Pavlovian conditioning, but the Pavlovian paradigm, with the revisions of the neoconditioning theory, continues to be one of the most influential theories on phobic anxiety. All fears or phobias do not seem to be explainable by simple Pavlovian conditioning, although many may be. Many phobias are reported to be the result of indirect or cognitive learning, including learning by observation and by information transfer. Classical conditioning has also been useful to explain panic attacks.

8.1.2. Classical Conditioning and Food Aversion

Food aversions are a serious clinical problem, especially those developed by association with the nausea produced by chemotherapy for cancer, which may later interfere with eating many foods. Applying modern knowledge of the classical conditioning process, treatment usually consists of trying to prevent the aversion by minimizing the predictability relationship of the CS and the US (nausea). Giving the patients a food with a highly salient, novel taste in novel surroundings results in blocking, and the novel cues overshadow the tastes of more familiar foods. The result is a strong aversion to cues that will not be present after chemotherapy is finished. This is helpful and causes no problems because there is little development of conditioned nausea to familiar foods when eaten at home.

8.2. Clinical Treatment

Behavior therapy, based on the principles of classical conditioning, has been used to eliminate or replace behavior, to eliminate the emotional responses of fear

and anxiety, and as treatment for nocturnal enuresis, alcoholism, and so on.

8.2.1. Systematic Desensitization Therapy

As behavioral methods developed over time, a behavior therapy technique called systematic desensitization was devised based broadly on the classical conditioning model. Undesirable responses, such as phobic fear reactions, can be counterconditioned by the systematic desensitization technique. This technique inhibits expressions of fear by encouraging clients to face the feared CS and thus allowing extinction to occur. In systematic desensitization, anxiety is associated with a positive response, usually relaxation. Systematic desensitization is a procedure in which the patient is gradually exposed to the phobic object; training in progressive relaxation is an effective and efficient treatment for phobias.

8.2.2. Implosive (Flooding) Therapy

One approach to treating phobias with classical conditioning was originally called implosive therapy (flooding). It is used to extinguish the conditioned fear response by presenting the CS alone, repeatedly, and intensely. The phobic individual experiences the CS, and all the conditioned fear is elicited, but no aversive US follows, nothing bad happens to the subject in the presence of the CS, and so the conditioned fear of the CS disappears.

Clinical Assessment

Irving B. Weiner

University of South Florida, Tampa, Florida, USA

1. Nature and Purpose of Clinical Assessment
 2. Sources of Information in Clinical Assessment
 3. Issues in Clinical Assessment
 4. Future Directions
- Further Reading

Clinical assessment is a procedure in which various forms of information drawn from interviews, behavioral observations, standardized tests, collateral reports, and historical documents are integrated to facilitate decisions about diagnosis and treatment planning.

GLOSSARY

- deception* A conscious and deliberate attempt to appear less disturbed and more capable than is actually the case; it is also known as “faking good.”
- idiographic* A way of describing people according to their individual and unique characteristics.
- malingering* A conscious and deliberate attempt to appear more disturbed and less capable than is actually the case; it is also known as “faking bad.”
- nomothetic* A way of categorizing people according to characteristics they share in common with other people.
- performance-based measures* Assessment instruments that sample how people respond when given a task to do.
- self-report inventories* Assessment instruments that sample how people describe themselves when asked to indicate whether, or to what extent, various statements apply to them.
- standardized tests* Formal measuring instruments that consist of a specific set of stimuli and instructions and that are always presented to respondents in the same way.
- structured interviews* Interviews based primarily on a preset schedule of specific questions.
- unstructured interviews* Interviews consisting primarily of open-ended inquiries and comments.

1. NATURE AND PURPOSE OF CLINICAL ASSESSMENT

Clinical assessment consists of collecting various kinds of information about the nature of people to facilitate arriving at certain kinds of decisions intended to promote the welfare of persons being assessed. These decisions most commonly address interrelated issues of differential diagnosis and treatment planning, and they typically are reached in consultation with persons who have been assessed concerning what would be in their best interest.

1.1. Differential Diagnosis

Treatment of persons with physical or psychological problems proceeds best when the nature and origins of these problems can be identified with reasonable certainty. Adequate differential diagnosis includes both nomothetic and idiographic components. The nomothetic component consists of categorizing the type of disorder a person has and noting the kinds of characteristics the person shares in common with other people who have the same disorder. The idiographic

component consists of specifying the particular life experiences that have given rise to the disorder in this individual case and identifying current circumstances that appear to be perpetuating the disorder.

1.2. Treatment Planning

Differential diagnostic information derived from clinical assessments guides treatment planning in four key respects. First, the category of disorder with which a person is diagnosed calls attention to modes of treatment that have been shown to be effective in treating people with the same or a similar category of disorder. Second, the diagnosed severity of a person's disorder indicates whether treatment can be provided adequately on an outpatient basis or instead requires a hospital or other residential setting. Third, diagnostic information about past and present events in a person's life often points to topics and goals on which the treatment sessions should focus. Fourth, in addition to identifying critical treatment topics and goals, diagnostic information can alert therapists to patient characteristics that might slow progress in the treatment, at least until these potential obstacles to progress have been minimized or overcome.

2. SOURCES OF INFORMATION IN CLINICAL ASSESSMENT

Clinical assessment is a multifaceted process in which information is drawn from diverse sources. These sources of information include interviews, behavioral observations, standardized tests, collateral reports, and historical documents. The data obtained from these sources sometimes converge, and in such cases the confirmatory information they provide broadens the base of the assessment process and lends certainty to inferences drawn from it.

In other instances, diverse sources of information may diverge, for example, when a man being interviewed describes himself as a laid back person who is easy to live with, whereas his wife (a collateral informant) describes him as an irritable and demanding person who is nearly impossible to live with. Instances of divergent data from different sources often help clinical assessors to sharpen their decision making by identifying why these divergences have occurred and determining which sources have yielded the most reliable and useful information. Ordinarily, prior to collecting assessment data, it is difficult to anticipate which sources of information will converge (and thus be redundant) and

which will diverge (and thus deepen understanding of the person being assessed).

2.1. Interviews

Mental health specialists who conduct clinical assessment interviews ask patients questions and invite them to talk about their symptoms and problems, any previous treatment they have received, their family backgrounds, and their developmental, educational, occupational, and social histories. Depending on the preferences of the clinician and the capacities of the respondent, these interviews may be relatively structured or relatively unstructured. Relatively structured assessment interviews are based primarily on a preset schedule of specific questions (e.g., "How many brothers and sisters do you have?," "Do you have trouble sleeping at night?"). Relatively unstructured interviews, in contrast, consist primarily of open-ended inquiries and comments (e.g., "What was growing up like for you?," "You seem a little anxious right now"). In actual practice, most clinical assessment interviewers combine some open-ended inquiries with various specific questions intended to clarify items of information.

2.2. Behavioral Observations

Clinical assessors learn a great deal about people from observing how they sit, stand, walk, gesture, show their feelings, and express themselves in words. These observations are made mostly while conducting assessment interviews, but clinicians sometimes have opportunities to observe people in other contexts as well, for example, as patients in a residential treatment setting or as inmates in a correctional facility.

Regardless of their context, behavioral observations can take a variety of forms. For example, clinicians working with families may take note of how family members talk to each other during a family group interview or how they interact during a home visit, each of which is a sample of fairly natural behavior. Alternatively, clinicians may watch and listen to how family members collaborate when they are given some task to do or are asked to decide on a single set of answers to a questionnaire, each of which is an artificially contrived situation.

2.3. Standardized Tests

Standardized tests are formal measuring instruments that consist of a specific set of stimuli and instructions and that are always presented to respondents in the same

way. The systematized materials and procedures that characterize standardized tests make it possible to collect normative reference data concerning how certain groups of people (e.g., men, women, children, Americans, Japanese) are likely to respond to these tests on average.

The standardized tests commonly used in clinical assessments are categorized as being either self-report inventories or performance-based measures. Self-report inventories sample how people describe themselves when asked to indicate whether, or to what extent, various statements apply to them (e.g., “I worry quite a bit over possible misfortunes,” “In school, I was sometimes sent to the principal for bad behavior”). Performance-based measures sample how people respond when given a task to do (e.g., putting blocks together to make various designs, describing what a series of inkblots look like). Conjoint use of self-report inventories (what people say about themselves) and performance-based measures (how people go about doing assigned tasks) typically maximizes the scope and utility of the assessment data obtained with standardized testing.

2.4. Collateral Reports

In addition to interviewing, observing, and testing people being evaluated, clinical assessors may obtain collateral information from other individuals who know them or have observed them. Collateral informants are most commonly family members, but they may also include friends, teachers, and employers. Collateral reports usually enhance the scope and reliability of clinical assessments, especially when the people being assessed are unable or reluctant to talk freely or to cooperate fully with testing procedures.

At times, however, mistaken impressions on the part of collateral informants may detract from the accuracy of their reports, which turn out to be less dependable than what the people being assessed have to say. Informants' reports may also be of questionable reliability if personal issues they have with the people being assessed bias their perspectives. Clinical assessors may also confront instances in which people being evaluated exercise their rights to confidentiality by denying access to informants other than themselves or to historical documents.

2.5. Historical Documents

Historical documents provide real accounts of events in people's lives for which their own recollections may be vague or distorted. School, medical, military, and criminal records (when available) enhance the dependability

of clinical assessments by documenting life experiences that people may be reluctant to talk about or unable to remember clearly. In addition, when there is concern that people being assessed have suffered some decline in mental or emotional capacity from previously higher levels of functioning, historical documents can provide a valuable baseline for comparison. This is especially the case when the past records include clinical assessments.

3. ISSUES IN CLINICAL ASSESSMENT

Contemporary clinical assessments must typically take account of four issues, especially with respect to collecting and using standardized test data. First, are the test results reliable and valid? Second, could the test results reflect malingering or deception on the part of the respondent? Third, are the test findings applicable in light of the respondent's cultural context? Fourth, can one make appropriate use of computer-based test interpretations?

3.1. Reliability and Validity

The reliability and validity of test results refer to whether the results are dependable, that is, whether they provide an accurate measurement of whatever they are measuring. The reliability of tests is most commonly estimated by examining the internal consistency of their items or by determining the retest stability of the scores they generate. The validity of tests refers to how much is known about what they do in fact measure, as determined by the extent to which their scores correlate with other phenomena such as a diagnosed condition and a favorable response to a particular form of treatment.

Currently available clinical assessment instruments vary in their demonstrated reliability and validity, and examiners must be cautious about relying on measures that are limited in these respects. On balance, however, research findings indicate that most of the tests commonly used in clinical assessment, when administered and interpreted properly, meet the criteria for acceptable reliability and validity.

3.2. Malingering and Deception

Malingering among persons being assessed consists of a conscious and deliberate attempt to appear more

disturbed and less capable than is actually the case. Malingering, also known as “faking bad,” commonly emerges as an effort to minimize being held responsible for some misconduct (e.g., being found not guilty of a crime) or to maximize being held deserving of receiving some type of recompense (e.g., being awarded damages for an alleged injury).

Deception, in contrast, consists of attempting to appear less disturbed and more capable than is actually the case. Deception, also known as “faking good,” usually arises as an attempt to gain some benefit (e.g., being employed in a position of responsibility) or to avoid losing some privilege (e.g., being deprived of child custody or visitation rights).

Clinical assessors can draw on various guidelines for identifying malingering and deception on the basis of interview behavior and responses to standardized tests. Based on criteria related to consistency versus inconsistency, these guidelines include specific kinds of interview questions, validity scales on standardized tests, and certain standardized tests designed specifically to reveal efforts to fake bad or fake good. Used in conjunction with data from observational, collateral, and historical sources, these interview and test measures are usually effective in detecting malingering and deception. Nevertheless, research findings indicate that resourceful and motivated respondents, especially when they have been coached with respect to what they should say and how they should conduct themselves, can succeed in misleading even experienced examiners.

3.3. Cross-Cultural Contexts

Cross-cultural clinical assessment generally proceeds in two phases. The first phase consists of drawing on sources of assessment information to identify the nature of an individual’s psychological characteristics. The second phase consists of determining the implications of these psychological characteristics within the person’s cultural context. With respect to collecting information, some assessment methods are relatively culture free (e.g., copying a design from memory). Other assessment methods, especially those involving language (e.g., interviews, self-report inventories), are relatively culture bound. To obtain reliable results, particularly with culture-bound methods, assessment data should be collected by an examiner or with a test form in a language with which the person being examined is thoroughly familiar.

Following collection of the data in cross-cultural assessment, the process of interpreting these data should be attuned as much as possible to available normative

standards within groups to which the person being examined belongs. On the other hand, normative cross-cultural differences in assessment findings, such as scores on some test variable, may indicate an actual difference between cultures in the psychological characteristic measured by that variable rather than a need to adjust standards for interpreting the variable. In the case of standardized tests, in fact, many variables identify psychological characteristics in the same way regardless of the person’s cultural context.

The main challenge in doing adequate cross-cultural assessment arises during the second phase of the process, that is, when clinicians must estimate the implications of a person’s identified psychological characteristics for how the person is likely to function in his or her daily life. In some instances, psychological characteristics are likely to have universal implications. For example, being out of touch with reality will ordinarily interfere with adequate adjustment in any social, cultural, ethnic, or national surroundings. In most instances, however, the implications of psychological characteristics are likely to depend on their sociocultural context. For example, whether being a passive, dependent, group-oriented, and self-sacrificing person promotes effective functioning and a sense of well-being will depend on whether the person is part of a society that values these personality characteristics or that instead is embedded in a family, neighborhood, or societal context that values assertiveness, self-reliance, and ambitious striving for personal self-fulfillment.

3.4. Computer-Based Test Interpretation

Computer software programs are available for most standardized and widely used clinical assessment instruments. The data entry for these programs consists of the score for each test item or response, and the output typically includes (a) a list of these scores; (b) a set of indexes, summary scores, and profiles calculated on the basis of the test scores; and (c) a narrative report concerning the interpretive significance of these indexes, summary scores, and profiles. This narrative report is the key feature of what is commonly called computer-based test interpretation (CBTI).

Self-report inventories also lend themselves to a computerized test administration in which the test items and the alternative responses to them (e.g., “agree strongly,” “agree,” “disagree,” “disagree strongly”) appear on the screen. Computerized administration of

performance-based measures has not yet been shown to be practicable, however, owing to the fact that the response data are observational, infinite in their variety, and frequently interactive (in the sense that responses may require certain kinds of inquiry to clarify how they should be scored).

Computerized testing programs usually reduce scoring and calculation errors and also save time in recording and arraying the various indexes, summary scores, and profiles that provide the basis for test interpretation. Computerization also facilitates the interpretive process itself by virtue of a computer's complete scanning and perfect memory. A good CBTI program does not overlook any encoded implications the data are believed to have for psychological characteristics of the person being assessed.

On the other hand, CBTI is limited by its unavoidable nomothetic focus. Computer-generated interpretive statements describe features of a test protocol and present inferences that are applicable to people in general who show the same or similar test features. These statements do not necessarily describe the person being assessed, nor do they identify idiographic ways in which the person differs from most people who show certain similar test scores. Consequently, because of human individuality, CBTI narrative reports nearly always include some statements that do not apply to the respondent or that are inconsistent with other statements.

Accordingly, informed and professionally responsible computerized testing requires thorough knowledge of how and why test scores generate certain interpretive statements. Sophisticated clinical application of computer-generated test interpretation also requires appreciation of what a computer-generated report implies in the context of each respondent's personal history and current life circumstances. Unfortunately, CBTI programs can be obtained and used by persons with little or no knowledge of the tests on which they are based, especially in the case of self-report software that conducts the test administration, and with little appreciation of how and why to translate the nomothetic statements in computer-generated reports into the idiographic statements that are essential for an adequate clinical report.

4. FUTURE DIRECTIONS

Research findings have validated a large number and a wide variety of clinical assessment methods as providers of accurate and dependable information about the psychological characteristics of people. This information

has, in turn, been shown to be helpful to mental health professionals in making decisions about differential diagnosis and treatment planning. However, little is yet known about the long-term impact of decisions made on the basis of clinical assessment findings. Are people better off as a result of having been assessed than they would have been otherwise? Do assessment-based decisions enhance the quality of life that people are able to enjoy? These questions set an important agenda for further directions in clinical assessment research that should emphasize follow-up studies of the long-term effectiveness of assessment procedures.

GLOSSARY

analytic thinking The type of thinking that focuses on the object (instead of context) and the categories to which the object belongs. Analytic thinkers rely on rules and formal logic in understanding the world. This type of thinking is more prevalent among Westerners, particularly European North Americans.

correspondence bias (fundamental attribution error) The tendency to overemphasize a person's dispositions and to downplay the importance of the situation when explaining behaviors.

entity theory of intelligence The belief that intelligence is fixed and unchangeable.

holistic thinking The type of thinking that emphasizes context and relationships, and makes relatively little use of categories and formal logic. This way of thinking is prevalent among East Asians.

incremental theory of intelligence The belief that intelligence is mutable and can be changed.

independent self A type of self-construal, or self-concept, in which the self is perceived as a distinct entity that has a unique combination of traits, abilities, and other inner attributes. The independent self acts in accordance with his or her private thoughts and emotions rather than in a manner that is motivated by the thoughts and emotions of others.

interdependent self A type of self-construal in which the self is seen in relation to others, and the self is motivated to create and maintain interpersonal relationships with these relevant others. People with interdependent selves generally place the needs and goals of their in-group above their own.

perspective taking The ability to take the point of view of another person.

Culture refers to shared values, beliefs, and norms among a group of people who most often speak the same language and live in proximity. Cognition is defined as the process and products of human perception, learning, memory, and reasoning. Culture affects many aspects of cognition, and cognitive tendencies also guide the propagation of culture. This article provides an introduction to understanding how culture interacts with cognitive processes at basic and social levels from the perspective of cultural psychology. We discuss how culture affects the way that people perceive themselves, categorize information, and make social inferences. Moreover, we address how decision

making, memories, and communication and reasoning styles may be influenced by our cultural backgrounds.

1. SELF

In 1991, Markus and Kitayama outlined two types of self-concepts or self-construals: independent and interdependent. An independent self is perceived as a distinct entity who has a unique combination of traits, abilities, and other inner attributes. Moreover, the independent self acts in accordance with his or her private thoughts and emotions rather than in a manner that is motivated by the thoughts and emotions of others. It is worth noting that the study of the self has largely taken a “monocultural approach” that has originated in the West. Because North Americans predominantly have independent self-construals, it is not surprising that North American psychologists have adopted an approach that treats the self as an independent entity. When researchers, however, examined how the self is construed in other cultures, they discovered that independent self-construals were not as prevalent as in North America. Indeed, interdependent selves are found to be quite common among some other cultural groups, such as Asians. People with interdependent selves see themselves in relation to others and are motivated to create and maintain harmonious interpersonal relationships with these relevant others. Although people with interdependent selves hold internal attributes, they also understand the importance of context in shaping these inner attributes. Consequently, they are less likely to act in accordance with their thoughts, emotions, and other attributes, especially when such behavior affects relevant others. Thus, interdependent selves are guided by the way the self is related to others. According to Markus and Kitayama, interdependent selves are predominant in Chinese, Japanese, Hispanic, Filipino, African, and Hindu populations, and independent selves are predominant in Western populations.

The distinction between independent and interdependent selves followed Triandis’s work on individualism and collectivism, which has received tremendous attention in the cross-cultural psychology literature. Individualist selves place their own personal goals above their groups’ goals, whereas collectivists give priority to their groups’ goals over their own. It is worth noting that research suggests that individualism and collectivism are not opposite dimensions. In 2002, Oyserman and colleagues conducted a meta-analysis

examining individualism and collectivism across numerous cultures and found that people who are high in one dimension (e.g., collectivism) are not necessarily low in the other dimension (e.g., individualism). For example, European North Americans tended to be high in individualism yet were not less collectivistic than Japanese or Korean samples.

2. ATTENTION AND PERCEPTION

Culture affects how we perceive the world and where we focus our attention. Particularly, it shapes the extent to which we attend to the central object or to the field. In addition, differential attention may affect people’s subsequent cognitive performances. To test cross-cultural differences in perception, researchers have used the rod-and-frame test (RFT) among other tests. RFT is made of a box (also called a frame) and a black line (also called a rod) at the end of the box; the frame and the rod can be turned independently of each other. When European American and Asian participants were asked to make perceptual judgments about the position of the rod, Li-Jun Ji and colleagues found that the position of the frame affected Asians’ perceptions of the rod more than Americans’ perceptions. In other words, European Americans were better than Asians at disassociating the object from the background and hence were more field independent. Conversely, Asians tended to make perceptual judgments based on the relationship between the object and the background and hence were more field dependent. In 1976, Berry argued that cognitive styles (such as field dependence and independence) are related to one’s lifestyle. In particular, he found that sedentary agriculturalists were inclined to have a field-dependent cognitive style, and nomadic hunters and gatherers were more likely to have a field-independent cognitive style.

Similarly, Masuda and Nisbett presented European American and Japanese participants with an ocean scene on a computer screen. They found that Japanese participants paid attention to the background objects more than European Americans did (although Japanese participants did not necessarily pay less attention to the central object than did European Americans). As a result, Japanese participants were able to recall more details about the background than were European Americans. Such differential sensitivity to the background or the context has been found to facilitate performance on certain tasks but debilitate performance on other tasks. When the context remains constant, it

provides a helpful cue for Japanese participants to recognize the central object. When the context changes, however, it becomes difficult for Japanese participants to correctly identify the central object because of a possible cognitive binding between the central object and the background. On the other hand, changes in context do not have as much impact on European American participants, who generally pay little attention to the context anyway. Similarly, when a cognitive task requires disassociation between the object and the background, the task is easier for European North Americans than for East Asians. European North Americans are more likely to focus their attention on the central object and are better at ignoring the context in comparison to many Asians.

3. REASONING STYLES

For the past decade, Nisbett and colleagues have conducted a series of empirical studies on reasoning across cultures, which demonstrate that culture shapes people's thinking and reasoning styles in general. Specifically, many Westerners, particularly European North Americans, adopt an analytic system of thought. That is, they focus on the object (instead of context) and the categories to which the object belongs, and they rely on rules and formal logic in understanding the world. In contrast, East Asians tend to think holistically such that they emphasize context and relationships between objects. Moreover, they rely more on intuition and experience and make relatively little use of categories and formal logic compared to Westerners.

In a study conducted by Norenzayan and colleagues, Korean and European American participants were asked to rate the extent to which various arguments were convincing. Participants were presented with either typical arguments (e.g., "All birds have ulnar arteries. Therefore, all eagles have ulnar arteries.") or atypical arguments (e.g., "All birds have ulnar arteries. Therefore, all penguins have ulnar arteries."). Koreans were more inclined to rely on their experiences and to indicate that typical arguments were more convincing than atypical arguments. On the other hand, European Americans, who tend to rely on formal logic and think analytically, saw both arguments as equally convincing. Similarly, when Korean and European American participants were asked to rate the logical validity of valid and invalid arguments that lead to either plausible or implausible conclusions, cultural differences emerged. In particular, Koreans were more likely

than European Americans to report that arguments that had plausible conclusions were more logically valid than arguments that had implausible conclusions.

According to Peng and Nisbett, differences in the reasoning styles between the East and the West also affect the way people think about contradictions. Chinese are much more likely than Westerners to seek compromising solutions when presented with opposing views. For example, European Americans who are told that (i) felines eat fish or (ii) felines do not eat fish often favor one argument at the expense of the other. That is, Westerners often report that one of the options is correct and the other is incorrect. Chinese respondents, however, tend to seek a solution that reconciles the two options. In this manner, Chinese tolerate apparent contradiction in an effort to find the "Middle Way." Similar cultural differences emerge when people attempt to resolve social conflicts. American and Chinese participants were presented with two scenarios that describe everyday conflicts (i.e., a conflict between a mother and daughter and a conflict that pitted focusing on school versus having fun). Peng and Nisbett found that, in general, Americans tended to favor one side of the conflict at the expense of the other (e.g., mothers need to respect their daughters' autonomy more), and Chinese generally favored a compromising solution (e.g., both parties need to better understand each other).

4. CATEGORIZATION

In order to make sense of the world that is full of infinite information, we classify and categorize information in a way that can be culturally bound. For instance, Lopez, Atran, Coley, Medin, and Smith found that European Americans and Itzaj categorize mammals in ways that are similar in some situations yet different in others. The Itzaj are Mayans who live in the Peten rain forest region in Guatemala. They spend considerable time interacting with their environment, such as engaging in hunting activities or agriculture. In some regards, both European Americans and Itzaj have developed similar classification systems for mammals. For example, both cultural groups classify opossums in the same category as porcupines, even though opossums are marsupials and are in a class that is completely distinct from porcupines. In other respects, Itzaj are more likely than European Americans to classify mammals on the basis of ecological properties, such as behavior and habitat. For example, Itzaj classify

animals that dwell in trees together, whereas European Americans do not.

Deeper cultural differences emerge when people are asked to classify a variety of information. For example, European American participants tend to category things based on their category memberships, such as grouping “banana” and “orange” together because they are both fruits. Chinese children and Chinese University students tend to group things based on their functional relationships with each other, such as grouping “banana” and “monkey” together because monkeys eat bananas. According to Mishra, this latter type of grouping is also present in other cultures, such as the Birhor, Asur, and Oraon of India. Among European North Americans, however, this latter form of categorization is only found among children and is considered less sophisticated.

When categorizing information, East Asians rely more on intuitive experience, whereas European Americans rely more on formal rules. Generally, European Americans tend to assign objects to categories based on properties that fit the rule. For them, understanding, describing, and explaining objects involve classifying and seeking fundamental physical causes. Conversely, East Asians see an object as it relates to its context and the relationships among various objects. Because Asians historically did not generally perceive and classify objects as being distinct entities, they sought practical knowledge rather than developed formal rules or models.

5. INTERPERSONAL PERCEPTION AND MEMORY

Given that other people are a significant part of Asians’ self-definitions, Asians also tend to pay more attention to other people’s behaviors and emotions. They are expected to remember other people’s preferences, read other people’s minds, and anticipate the needs of others. This finding is related to the fact that Asians tend to be less direct than North Americans in expressing themselves.

Accordingly, European North Americans and Asians also differ in the way they remember information. Indeed, East Asians pay more attention to and remember more behaviors of their friends than do North Americans. When asked to recall and describe situations where they provided support to a friend, Japanese spend more time discussing the situations of their

friends than their own actions. Conversely, European Americans describe their own actions more than their friends’ situations. Furthermore, Japanese accounts of helping behavior tend to correspond more closely to their friends account compared to European Americans. Interestingly, there was little or no consensus between American participants and their friends regarding the nature of support that is exchanged in their relationship.

A special case of interpersonal perception is perspective taking. Perspective taking refers to the ability to take the point of view of another person. In a conversation, East Asians (such as Japanese and Chinese) sometimes identify themselves from another person’s perspective. For example, a Japanese mother might call herself “Oka-san” (mother) in conversation with her child. The self is experienced through the other’s perspective and his or her role in that relationship (e.g., mother–child). In other words, Asians tend to experience their own actions from the points of view of others. Similar differences have also been found in memory research. Research by Qi Wang has found that East Asians’ memories tend to focus on other people or groups, whereas European North Americans’ autobiographical memories tend to be self-focused and vivid. In one study, Asian North Americans were more likely to remember past episodes from a third-person’s point of view, in which their memories included themselves. In contrast, European North Americans remembered the past episodes as they originally saw them; thus, the episodes they remembered tended not to include themselves. In addition to focusing on differential information when reporting autobiographical memories, European Americans tend to recount more emotional memories than do Chinese.

6. SOCIAL INFERENCE

Cultural differences are also found in social inference. Research suggests that Asians emphasize the context more than Westerners when explaining social events. For example, Asians tend to attribute the cause of behaviors to situational factors, whereas North Americans tend to attribute the same behaviors to personal factors. A well-known finding in North American culture is that people often fail to take contextual information into account when they judge the causes of others’ behaviors. This phenomenon is called the correspondence bias, which is also known as the fundamental attribution error. In the classic paradigm,

participants are shown one of two types of essays: One essay expresses a favorable attitude toward a particular issue (e.g., capital punishment), and the other essay expresses an unfavorable attitude toward the issue. Participants are informed that the person who wrote the essay was able to choose which side of the issue he or she would like to discuss (i.e., choice condition) or was instructed to endorse a particular point of view (i.e., no choice condition). Next, the experimenter asks the participants to indicate the true attitude of the person who wrote the essay. Surprisingly, European Americans tend to judge the target person's attitude as corresponding to the view expressed in the essay, even when they know the target person did not have a choice. Consistent with an analytic thinking style, European Americans pay attention to the focal object (i.e., the essay writer) and erroneously believe that the person is independent from the situation. In contrast, Asians are more likely to recognize the situational constraints on the person's behavior when such constraints are made salient.

7. DECISION MAKING

Historically, there has been a dearth of research on how culture influences decision making. Recently, however, researchers have begun to give this area more attention. Much of this burgeoning research has focused on differences between East Asians and European Americans.

East Asians and European Americans tend to make decisions using different information. In one study, Incheol Choi and colleagues provided Korean and European American respondents with vignettes describing a target's prosocial and deviant behaviors. Participants were also given a list indicating possible reasons that might or might not explain the causes of the target's behaviors. Koreans considered generally more information than Westerners when asked to explain the target's behaviors. Likewise, other researchers have found that East Asians are more inclined to use historical information when making judgments about the present compared to Westerners. These cultural differences have been attributed to the different underlying theories people hold, in which East Asians have more complex and holistic theories than Westerners. In this manner, East Asians believe that many factors can interact to cause a particular outcome, whereas Westerners tend to believe that fewer factors can lead to a given outcome.

Culture can also affect the extent to which decision makers are willing to take risks. For example, Chinese are more likely to take financial risks than European Americans, although Chinese are more risk averse when they make medical or academic decisions. One possible explanation for these domain-specific patterns of risk taking is that Chinese have greater social ties (including family and friends) than European Americans, which can provide a "cushion" for any negative consequences associated with risk taking in financial domains.

Culture can also influence how confident an individual feels about his or her decisions or judgments. Typically, North Americans tend to make overly confident judgments. For example, after a general knowledge test, Americans are likely to judge that they are correct more often than they actually are correct. Yates and colleagues also found such overconfidence among Chinese, even though they did not find that Japanese made overly confident judgments. There are also different values associated with decision styles in different cultures. For example, decisiveness is not valued in Japan as much as it is in the United States or in China. These findings suggest that there are differences even between East Asian cultures, which call for further research.

8. LANGUAGE AND COMMUNICATION STYLE

Language is deeply interconnected with culture. On the one hand, language carries cultural meanings and values. On the other hand, language also transforms culture. Language functions as a tool that enables an individual to focus on certain aspects of the world. Research has found that Japanese pay greater attention to contextual factors during communication compared to European North Americans. For example, Japanese and Chinese do not use the first-person pronoun in some situations. When a teacher is talking to her students, she calls herself "teacher," and when she is talking to her child she refers to herself as "mother." In many English-speaking Western countries, however, the language focuses on the self, which promotes the idea that people are separate entities that are independent from their context. For example, in English people refer to themselves as "I" in almost every context. Moreover, English speakers usually do not drop personal pronouns when they are speaking.

Researchers have examined how language activates cultural identity. For example, Mike Ross and colleagues found that Chinese students in Canada reported interdependent self-perceptions when responding in the Chinese language. Interestingly, when asked to report their self-perceptions in English, they responded in a more westernized way. That is, they tended to see themselves as being more independent than interdependent. Likewise, Li-Jun Ji and colleagues found that Chinese bilinguals who learned English at a relatively late age categorized objects in a more relational (and Chinese) way when tested in Chinese than when tested in English. Thus, it appears that bilinguals' self-perceptions and cognition are closely related to language.

What is the role of language cross-culturally? According to Kim, talking is connected to thinking more in Western culture than in East Asian culture. When Asian Americans and Westerners were asked to think-aloud while solving reasoning problems, talking impaired Asian Americans' performances but enhanced the performances of European Americans. In the West, articulating one's thoughts and conveying such information to others enables the speaker to organize his or her thoughts. In contrast, verbal self-presentation is not encouraged among many Asians; thus, articulation of one's ideas does not occur naturally and actually hinders the reasoning process.

9. INTELLIGENCE

Jean Piaget had a considerable impact on the field of cognitive psychology and on intelligence research. He was the first psychologist to empirically measure the cognitive development of children over time. In this manner, he examined how the experiences of children are qualitatively different than adults. He advocated that the cognitive development takes place in four main stages that are universal regardless of culture (i.e., sensorimotor intelligence, preoperational, concrete operations, and formal operations). For instance, in the sensorimotor intelligence stage, children acquire mental representations, learn to imitate, and discover that objects continue to exist even when they are not in perceptual view. Much of Piaget's research has been criticized for a number of reasons. First, many sociocultural researchers do not support Piaget's universalist approach to cognition and maintain that development can take many routes rather than a single direction. Second, researchers contend that Piaget's notion of stages overlooks contextual factors that

shape an individual's development. Third, some researchers have argued that Piaget's stages are ethnocentric, in which people from cultures that do not develop in accordance with Piaget's stages are perceived as lacking in intelligence. Thus, these researchers see the theory as lacking generalizability. Although Piaget's research has played an important role in intelligence and cognitive development research, it appears that his theory is limited.

The history of defining and measuring intelligence has largely taken place in the West. When researchers began examining whether intelligence as defined by Western science could be applied to other cultures, they realized that other cultural groups often had different notions of what constituted intelligence. For example, the Trobriand Islanders may regard superior navigational skills as a key characteristic of an intelligent man. The !Kung of the Kalahari desert may define intelligence as the ability to spot sources of water. In China, intelligence may be viewed as knowing when and how to use language properly, such as knowing when (and when not) to speak. For Hindus, transcendental knowledge may be viewed as highly as practical knowledge. It appears that cultures define intelligence differently and that these differences stem from contrasting ecological and social experiences.

Not only can culture lead to diverse definitions of intelligence but also culture can influence the way individuals develop and maintain implicit theories concerning the malleability of intelligence. Dweck, Hong, Chiu, and colleagues argue that people hold either an "incremental theory" of intelligence or an "entity theory" of intelligence. Entity theorists believe that intelligence is fixed and unchangeable. For instance, European Americans tend to hold an entity theory. Consequently, they do not generally try to improve their performance on intelligence tasks when they have performed poorly because they generally believe that increased effort will have little effect on improving future performance. On the other hand, incremental theorists believe that intelligence is mutable and can be changed. East Asians tend to hold an incremental theory toward intelligence. Accordingly, they try to improve their performance on intelligence tests because they believe that increased effort leads to better performance.

Different definitions of intelligence make it difficult to develop a test of intelligence that can be used in all cultures. In addition, experience with Western cultures can sometimes have a considerable impact on test performance because most available intelligence tests

are developed in the West. For example, Australian Aboriginals who have more interactions with people from European backgrounds tend to perform better on standardized intelligence tests than Aboriginals from more isolated communities. In addition, some research suggests that performance on cognitive tasks is related to familiarity with testing materials. Children in Zambia often build intricate cars from wire, whereas children from England often draw pictures using pencils and crayons. Thus, Zambian children are more familiar with the medium of wire and English children are more familiar with paper-and-pencil mediums. Serpell found that Zambian children performed better than English children on a task that involved assembling a pattern using wire. Conversely, English children performed better than Zambian children on tasks that involved paper and pencils.

10. CONCLUSIONS

Research on culture and cognition has enriched our understanding of human behavior and has improved the quality of psychological theories by including people from non-Western cultures. This flourishing area of research has many great implications. Culture fosters people to think in different ways, and these differences may lead to misunderstandings and hostilities, from the long-lasting clashes between Jews and Arabs to the recent conflict between the U.S.-led coalition and Iraq. A world that appreciates and understands people from diverse backgrounds may help resolve existing and future conflicts.

Knowledge of culture and cognition may also help to smooth interactions at interpersonal levels. With increased globalization, the world becomes smaller and cross-cultural interactions become more frequent. Understanding how your colleagues from other cultures may view the world and reason differently than you do will help you to enhance your multicultural partnerships and collaborations. Examples of failing to recognize cultural differences in cognition can be found in business. For example, in a joint-venture company, making internal attributions for success by a

European American could be perceived as arrogant by a Chinese, whereas making external attributions for failure by a Chinese might be perceived as irresponsible by the European American. Ignorance of each other's thinking styles is likely to lead to negative interpersonal experiences and could even have negative consequences on the business outcome.

Understanding cultural differences in cognition can also play an important role in education. For example, teachers who deal with students from different cultural backgrounds would benefit from knowing more about how culture influences cognition. Some teachers may encourage students to verbalize their thoughts as a means of helping them develop their ideas. Although this approach to teaching may benefit Western students, students from other cultural backgrounds may actually be hindered by such an approach.

Understanding the relationship between culture and cognition enhances our understanding of the world, and we can benefit from such knowledge in different aspects of our lives.

GLOSSARY

cognition (or “*intellectual functioning*”) Global intelligence or a mental capacity that consists of several specific abilities; an IQ (for intelligence quotient) test such as versions of the Wechsler Adult Intelligence Scale (WAIS) are examples.

cross-sectional studies A type of research that studies age-associated changes in different individuals who are grouped by age; for example, the decline in cognitive functions might be measured over the life span by comparing the scores of individuals in age groups of 20, 40, 60, and 80 years.

crystallized abilities (or “*verbal*” or “*left hemisphere*” aptitudes) Aptitudes that are largely dependent on acquired knowledge and formal education and that develop rapidly during the first 20 years of life; vocabulary is an example.

dedifferentiation The relative decline in specific aptitudes from decade to decade that is nested within a greater decline in global intellectual functioning in normal older adults.

fluid abilities (or “*performance*” or “*right hemisphere*” aptitudes) Aptitudes that are largely independent of acquired knowledge and education and that are influenced

by biological factors and the integrity of the central nervous system; block design is an example.

immune system The body’s complex and multidimensional defense against invading bacteria, viruses, other pathogenic microorganisms, and tumors; it also assists in the repair of damaged tissue after injury and creates specific antibodies to combat diseases.

longitudinal studies A type of research that studies age-related changes in the same participants who are reexamined several times over their lifetimes.

MicroCog A computerized test of intellectual functioning that consists of 13 subtests measuring both crystallized and fluid abilities; it was administered to 1002 physicians (ages 25–92 years) and 561 normal respondents.

neuroimaging Imaging technology that enables investigators to observe how the brain functions when it carries out specific intellectual tasks; single photon emission computed tomography (SPECT), positron emission tomography (PET), and functional magnetic resonance imaging (fMRI) are examples.

optimal cognitive agers (OCAs) Those older individuals whose cognitive test scores are statistically similar to those in midlife.

psychoneuroimmunology The study of how the central nervous system is influenced by psychological and social factors.

Public Law 99-592 The law that eliminated age-based mandatory retirement for workers in the United States; it became effective January 1, 1994, and excludes only a small number of occupations (e.g., Federal Bureau of Investigation agents, airline pilots).

variability (or “*variance*” or “*standard deviation*”) How widely dispersed, from top to bottom, the individual scores within an age group may be.

Interest in cognitive aging has grown substantially during the past 25 years. For instance, the divisions of the American Psychological Association (APA) expanding most rapidly during this period have been those with a strong interest in aging such as aging and neuropsychology, a field that examines cognitive impairments associated with aging (e.g., Alzheimer's disease). Responding to the growing interest in Alzheimer's disease and other conditions afflicting numbers of older people, the U.S. Congress designated the 1990s as the "Decade of the Brain." It might be said that this interest applies especially to "older" brains. Funds are being invested at record high levels to increase the understanding and amelioration of the effects of age on intellectual vigor as well as on physical health. These efforts may be more important today than ever before. The reasons for this are demographic, legislative, physical, and economic.

1. INTRODUCTION

1.1. Demographic Trends

America is graying. At the start of the new millennium, one of every seven U.S. citizens was over 65 years of age. By 2025, this proportion will be one of every five. The group of those age 85 years or over, currently numbering in excess of 3 million, is the fastest-growing segment of the population. This increase in the numbers of elders is not a uniquely American phenomenon. By 2025, those age 65 years or over in Japan will double. The People's Republic of China, Korea, and Malaysia anticipate a tripling of this age group. There is little benefit in a longer lifetime if the quality of health and mental acuity are greatly diminished during these added years. The budget of the National Institute on Aging has tripled during the past decade. Substantial portions of that agency's funds are earmarked for research to reduce the incidence of Alzheimer's disease and other forms of cognitive impairment and to enhance intellectual vitality during the later years.

1.2. Legislative Changes

Compelling workers to retire due to age was banned in the United States by Public Law 99-592 as of January 1, 1994. With the exception of a small number of occupations, such as Federal Bureau of Investigation agents and airline pilots, this law eliminated age-based mandatory retirement for nearly everyone. A primary reason for

passage of this law was that many studies had found that a large number of older individuals can match the physical and mental vigor of their younger colleagues. Because variability increases with age, it is necessary to differentiate between functional age and chronological age among seniors. Currently, organizations and professions are struggling with the implementation of objective and fair methods for retaining their older physically and cognitively vigorous employees while creating scenarios for encouraging the retirement of those whose abilities have declined to the point that their job performance is compromised.

1.3. Increased Physical and Cognitive Vigor

Despite the growing trend toward obesity in the United States, the physical and cognitive vigor of a large proportion of 60-, 70-, and even 80-year-olds today is superior to that of their parents and grandparents of the same age generations ago. Research confirms these observations. A 1997 report by the National Academy of Sciences showed a dramatic increase in the proportion of Americans over 65 years of age who are able to care for themselves. Reasons offered to account for these gains include reductions in drinking and smoking, better diets, weight loss, control of blood pressure, and use of aspirin to reduce heart attacks and strokes. Also, modern medicine has been chipping away at physical conditions that greatly affect cognition, including medications for diabetes, hypertension, and heart problems as well as advances in cardiac surgery and neurosurgery. Better physical health is strongly correlated with higher levels of intellectual functioning among older individuals.

1.4. Economic Needs

One unanticipated benefit of Public Law 99-592 is that the American economy will need its aging "baby-boomers"—those born during the 1946–1964 era—to work well past what used to be the normal retirement age into the first quarter of the 21st century. The reason is that the labor pool is shrinking due to the "baby-bust" generation—those born during the 1965–1977 era—now entering the workforce. Because their yearly birth pools were much smaller than those during the previous 20 years of the baby boom, the labor force will experience a shortfall in those age groups that organizations have traditionally relied on to form the backbone of their workforces, that is, those 30 to 44 years of age.

By 2009, there will be 10.6% fewer men and women in that age group than there were a decade earlier. Census projections estimate that there will not be as many people in that age group as there were in 2000 until 2025. A source of workers that could fill this projected labor shortage are men and women in their 60s and early 70s. Fully 70% of the baby boomers, now at midlife, say that they want to stay on their jobs after reaching 65 years of age. A large proportion of these individuals are mentally and physically fit to continue working if opportunities are made available.

2. COGNITIVE CHANGES ACROSS THE LIFE SPAN

What happens to cognitive abilities over the life span? Which aptitudes are impaired most dramatically, and which are most likely to be spared? How much variability is there among people of a given age as they grow older? This section examines global changes in cognition through the life cycle and trace the age-associated pattern of decline among particular aptitudes, paying close attention to the degree to which some are impaired or spared. It also discusses evidence in support of increasing differentiation of cognitive functions with advancing age.

2.1. Overall Cognitive Changes through the Life Span

Figure 1 shows the decline in Full Scale IQ from 30 to 75-plus years of age on an earlier version of the Wechsler

Adult Intelligence Scale (WAIS). The curve is derived by comparing the average of the scaled scores for each older age group decade with the norms for 25- to 34-year-olds. Overall, cognitive scores slope gently downward until 60 years of age. At that point, the level of intellectual functioning of the average 60-year-old is only 10% less than that of the average 30-year-old. But then the cognitive decline accelerates. During the next decade, the overall IQ drops 9%. The scores of those age 75 years or over are 11% lower than those of 70-year-olds.

A limitation of these data is that the WAIS respondents were not matched for characteristics (other than age) that affect cognitive changes over the life span. These other characteristics are educational level, social class background, and access to health care. Those who have more education, are wealthier, and are able to avail themselves of adequate medical services usually score higher on cognitive tests than do their less fortunate age mates. Studies that have rigorously matched age groups on these characteristics have found that the shape of the curves of overall cognitive decline is similar but that the test scores are higher at every age for those with more advantages.

2.2. Decline of Specific Aptitudes through the Life Span

Although overall intellectual functioning declines predictably from 30 years of age onward, the downward progression of individual aptitudes varies greatly. For instance, the various versions of the WAIS all have found that the Verbal IQ scores slope downward far more gradually than do the Performance IQ scores. For

FIGURE 1 Average WAIS Full Scale IQ scores for older age groups compared with 25- to 34-year-olds. Adapted from Kaufman, A. S. (1990). *Assessing adolescent and adult intelligence*. Boston: Allyn & Bacon.

instance, scores on the Verbal IQ decline 10% from 30 to 70 years of age, whereas scores on the Performance IQ drop 25% during this same period.

The types of abilities in the WAIS Verbal and Performance sections explain why there is so much difference in the rate of decline. The Verbal IQ score is based largely on crystallized abilities. In contrast, the Performance IQ subtests are composed of largely fluid aptitudes. Research by Salthouse and colleagues has demonstrated that fluid aptitudes, such as processing speed and working memory, are greatly impaired by aging. Tests involving processing speed typically require solving complex problems under time pressure. Being required to learn a number–symbol code and then to enter the proper number next to a list of symbols is an example. Working memory involves storing an important piece of information while working on another task. Backward number recall is an example.

Age differences in processing speed and working memory apply much more to complex tasks than to simpler ones. For instance, little difference occurs between younger and older adults on analogies of low and medium difficulty under time pressure. Where the performance of older test takers falls off, relative to that of young adults, is on the hardest of the analogies (e.g., “Fission is to splitting as fusion is to _____”) under stressful time limits. The differences are shown in Fig. 2.

Research reports summarized by Heaton and colleagues in 1981 show other aptitudes whose scores decline earlier and more steeply with increasing age. Timed spatial recall, reasoning, and verbal memory after delay are examples. In contrast, attention, word knowledge, and calculation skills remain relatively stable and are largely spared by the aging process.

All age groups have more difficulty with tasks requiring dual-task or divided attention. The increased incidence of automobile accidents among drivers using cell phones is an example. As people age, their dual-task performance declines rapidly. Over the past three decades, scientific studies have consistently reported that younger adults outperform older adults on many different tests of dual-task attention, for example, classifying a list of words appearing on a computer screen as verbs or nouns while simultaneously listening to a string of numbers and pushing a button when hearing two odd numbers in a row.

Although there is clear evidence of substantial disparity in the rate of decline of specific aptitudes, a number of studies have reported data showing dedifferentiation of cognitive functions with advancing age. That is, in normal older adults, the decline in specific aptitudes from decade to decade is embedded within a greater decline in global intellectual functioning. The evidence is stronger in cross-sectional data and among test scores based on accuracy alone. Longitudinal studies and test results combining speed with accuracy show weaker but similar patterns. Explanations for this phenomenon vary. One theory is that dedifferentiation is simply a symptom of cognitive decline. Another view, based on imaging studies, is that older adults compensate for diminished skills by drawing resources from other areas of the brain that are not normally activated during mental tasks.

2.3. Alzheimer’s Disease

If the 1990s was indeed the Decade of the Brain, it could also be said that the 1980s was the decade when Alzheimer’s disease (AD) and other forms of dementia began to attract public attention as potential

FIGURE 2 Effect of time pressure on analogy scores by difficulty level. Adapted from Salthouse, T. A. (1992). Why adult age differences increase with task complexity. *Developmental Psychology*, 28, 905–919.

threats to those entering the decades beyond middle age. The Alzheimer's Disease and Related Disorders Association was founded in 1980. In that same year, according to Lexis/Nexis (an electronic database for media publications), major U.S. newspapers mentioned AD or dementia twice. In the year 2000, there were 250 separate pieces about AD or dementia.

AD was first described by a German psychiatrist, Alois Alzheimer, in 1907. His first case was a 50-year-old woman whose memory and other cognitive functions deteriorated rapidly over a 5-year period before she died. An autopsy found abnormal brain structures that are referred to as neurofibrillary tangles, and neuritic plaques. As this case demonstrates, the relatively young onset differentiates AD from senile dementia. Today, health care specialists distinguish between presenile AD (prior to 65 years of age) and senile AD (age 65 years or over).

The criteria for AD include a gradual decline in at least two intellectual functions (e.g., attention, memory, language, reasoning, spatial ability) that are sufficient to significantly impair social relationships and/or performance at work. This decline cannot be explained by head trauma, neurological conditions, ill health, severe psychiatric symptoms, or drug/alcohol abuse. The cognitive deterioration also may be associated with depression, emotional outbursts, and/or apathy. It is not unusual to find AD occurring in individuals who otherwise are in good health.

At the start of the new millennium, there were an estimated 5 million people in the United States with AD or other forms of dementia. Prevalence estimates vary, however, and depend on the criteria used for making the diagnosis. For instance, a research team in England rated 100 elderly, community-dwelling volunteers using seven different sets of diagnostic criteria for AD. They found that between 3 and 63% of this population would be judged as "having" AD, depending on which standards were applied. A survey of the incidence of AD among older people in seven countries found proportions ranging from 1.9 to 52.7% of the population. One explanation for the disparate findings on the frequency of AD is the differences in the way in which the condition was assessed. Diagnoses that used tests that included measures of both crystallized and fluid abilities produced more consistent estimates. Applying these test-based standards, AD appears to afflict approximately 3% of 65- to 69-year-olds, 6% of 70- to 74-year-olds, and 11% of 75- to 79-year-olds. Beyond 80 years of age, the proportion of AD rises sharply.

3. AGE-RELATED VARIABILITY

Studies of age-related changes in cognitive functions have concentrated on what are called "measures of central tendency," which are most often the mean or average scores. Figures 1 and 2 are illustrations of this approach. Typically, the mean scores of 30-year-olds are compared with the averages of groups of those in older decades. The downward slope of these age group means is then reported. What has been overlooked by focusing on averages alone is what happens to the variability of the individual scores with each advancing decade. The increasing variability with age found in the cross-sectional study of the cognitive aging of 1002 physicians using a computerized test, MicroCog, is an example.

Figure 3 shows the percentage of decline in MicroCog total score in each age group after 40 years. This is compared with the percentage growth of the variability for each decade during this same period. It can be seen that the standard deviations of the age groups rise much more rapidly than the mean scores decline. At 70 years of age, the average physician's MicroCog total score was 13% lower than that of the typical 40-year-old. But the variability of the scores for these 70-year-olds was 57% greater than that for their younger colleagues.

Growing variability within advancing age groups is not specific to these data. Summaries of other studies of age-associated changes in cognition have reported that four of every five studies found that variance within each age group increased with advancing age. These findings occurred equally in both cross-sectional and longitudinal research.

The practical value of being aware of this growing age group variability is that it indicates that a number of older individuals continue to function as well as those in their prime. These older individuals might be called optimal cognitive agers (OCAs).

4. EVIDENCE FOR OPTIMAL COGNITIVE AGING

Newspapers and magazines often feature stories of elders who have been productive and successful until very late in life. Novelists James Michener and Barbara Cartland were still writing into their 90s. Heart transplant pioneer Michael DeBakey, South African political leader Nelson Mandela, musician Lionel Hampton, and humanitarian Mother Teresa worked productively in their 80s. Grandma Moses did not begin painting until

FIGURE 3 Percentage changes in MicroCog total score and variability from 40 years of age: 1002 Physicians. Reprinted by permission of the publishers from *Profiles in Cognitive Aging* by Douglas H. Powell in collaboration with Dean Whitla, Cambridge, MA: Harvard University Press, Copyright © 1994 by the President and Fellows of Harvard College.

she was 78 years old and continued well beyond her 100th birthday.

Social scientists are sometimes skeptical of such examples, wondering whether these people are merely statistical anomalies rather than representative of the vast majority of their age mates. However, empirical evidence now confirms the presence of large numbers of elders who continue to function cognitively at a level similar to those in midlife. This group of individuals, the OCAs, can be distinguished from their contemporaries by applying statistical standards.

Consider the following example. The MicroCog study described earlier obtained cognitive test scores on a large number of physicians from 25 to 92 years of age. Suppose that we wanted to know what proportion of older physicians were OCAs. We could use those doctors in their prime (say, 45–54 years of age) as a comparison group and then set a statistical threshold for optimal cognitive aging. For example, we might choose a cutting score of the 10th percentile, approximately -1.3 standard deviation, of those 45 to 54 years of age. In other words, for doctors to qualify as OCAs by this standard, their scores on MicroCog must be higher than the bottom 10% of those in midlife. The percentages of physicians age 65 years or over who meet this statistical standard are shown in Table I.

These data confirm what informal observation has told us: A large number of people continue to function at a high level cognitively well beyond 65 years of age. Nearly three-quarters of the 65- to 69-year-old physicians, and half of the 70- to 74-year-old physicians, scored as well on this cognitive test as did those in their prime. One-quarter (25%) of 75- to 79-year-old physicians, and

TABLE I
Proportions of Older Physicians with MicoCog Scores above the 10th Percentile of 45- to 54-Year-Old Physicians

Age group	Percentage above 10th percentile
65–69 years	73.2
70–74 years	50.0
75–79 years	25.0
80+ years	10.4

Source. Adapted from Powell, D. H., in collaboration with Whitla, D. K. (1994). *Profiles in cognitive aging*. Cambridge, MA: Harvard University Press.

slightly more than 10% of those beyond 80 years of age, performed as well as the reference group. These data are not specific to physicians. Similar proportions were found among nonphysician respondents in this study.

Although there are advantages to using respondents matched for education, social class, and access to health care for these calculations, nearly any cognitive test data set that reports individual test scores by age group through the life span can be analyzed to yield the percentage of older participants who are OCAs.

5. CORRELATES OF OPTIMAL COGNITIVE AGING

What distinguishes these OCAs from their contemporaries whose cognitive decline follows the average downward trend for their age group? Are there behaviors

within individuals' control that are correlated with optimal cognitive aging? If so, identifying these factors may contribute to behavioral changes that can improve the quality of these later years for many people.

But first, another question must be asked: What are the relative contributions of heredity and environment to the quality of cognitive aging? Research finds that heredity does play a strong role in the acquisition, maintenance, and decline of most human qualities. It is also true that environmental forces exert a strong effect. Swedish scientists tested 80-year-old identical twins who had been separated at birth and raised in different home environments. The researchers estimated that approximately 60% of the variance (i.e., factors contributing to the similarity of cognitive ability) was genetic and that the rest was related to environmental influences. Reports from dozens of other twin studies have estimated that heredity accounts for 50 to 60% of what goes into mental ability. So, it seems that somewhere between 40 and 50% of the factors influencing the quality of cognitive aging is related to environmental influences, that is, factors that are partly within the control of each individual.

This section summarizes those behaviors that are correlated with optimal cognitive aging and that are within individuals' control to varying degrees. These include activities that have been demonstrated to be directly related to higher levels of cognition in older adults. Also, this section describes a number of activities that indirectly benefit cognition because they are associated with better physical health. Finally, the section discusses selective optimization with compensation as a strategy for minimizing the inevitable negative effects of cognitive aging.

5.1. Activities That Directly Benefit Cognition

Activities that directly benefit cognition include regular exercise, mental enrichment, active social networks, and cognitive training. Of all the activities that could be recommended to maintain cognitive vitality, regular exercise has the greatest positive effect. This is because exercise strengthens the cardiovascular system, which maintains necessary blood flow to the brain. Cardiovascular disease is a major cause of cognitive impairment among individuals of any age. Meta-analyses of research over the past 40 years have found that younger and older individuals working out for 30 minutes or more every other day for at least 3 months perform at a higher

level on tests of attention, memory, spatial ability, processing speed, and reasoning than do their sedentary neighbors. Of interest is that those individuals whose regimen combines strength/flexibility and aerobic training obtain slightly higher cognitive scores than do those who engage in aerobic or strength/flexibility exercise alone.

Physical and mental vigor can be improved until quite late in life. An illustration of the power of these programs was strength training for 90-year-olds at the Hebrew Rehabilitation Center for the Aged in Boston. After just 8 weeks of regular workouts, these nonagenarians increased their muscle strength by 174% and increased their walking speed by 48%. Although pre- and postcognitive tests were not given, it is likely that improved intellectual vitality accompanied the physical gains. Baylor Medical School researchers found that physically active women and men in their late 60s had greater cerebral blood flow that resulted in higher cognitive test scores than those of their inactive contemporaries.

Mental enrichment stimulates cognitive functions. K. Warner Schaie, the director of the Seattle Longitudinal Study, and his coworkers identified factors that they believe are correlated with maintaining high levels of mental vigor well into later life. These include being open to new and stimulating experiences and having close relationships with individuals who have strong intellectual abilities. Scientific support for this thinking has come from the laboratory of Marian Diamond at the University of California, Berkeley. She was among the first to discover that laboratory animals that were raised in a more complex and challenging environment, along with other animals, developed a thicker frontal cortex than did those that lived in normal but unstimulating cages. She discovered that this occurred in both young and middle-aged animals. The increased thickness was because the existing brain cells in the cortex produced more connections (called dendrite branching) in response to outside stimulation.

A research team at the University of California, Los Angeles, confirmed these findings with humans. The researchers looked at the brains of 20 adults at autopsy. Then, they correlated the size of the nerve cells in the brains' cortexes with the activities reported by these individuals prior to death. They found that the cortexes of those older people who were more mentally and socially active were thicker than those of individuals who were not.

Social support has long been known to be correlated with physical health, but until recently little attention had been paid to its effect on cognition. Scientists from the MacArthur Studies of Successful

Aging studied the impact of social networks on a battery of aptitude tests given to 70- to 79-year-olds. They found that those who had more emotional support obtained higher test scores. At follow-up testing nearly 8 years later, higher retest aptitude scores were moderately correlated with having had greater social support. Other research has found that having larger and more diverse social networks and having more frequent contact with friends and family are related to less cognitive decline.

The question of whether age-related cognitive decline can be reversed through training has raised the interests of specialists in gerontology for the past quarter-century or so. Overall, it appears that most normally functioning individuals in the “young-old” years (approximately 60–75 years of age) and many of those who are older have the capacity to enhance their mental capabilities through practice. One example is the improvement made by participants in the Seattle Longitudinal Study who received 5 hours of training when they were 67, 74, and 81 years old. On average, the two younger groups improved their reasoning and spatial abilities to the levels of their test scores of 14 years earlier. Octogenarians were able to improve their performance to the level of 7 years earlier.

Follow-up studies of cognitive training have found that only those mental skills selected for remediation improved. Those not targeted for tutorial work remained the same as when the instruction began. Thus, if the goal of the program was to better remember a list of words, the participants did not wind up also exhibiting stronger calculation skills at the end of training.

Surveys of the published reports on cognitive training have found that many different methods produce positive results. Older participants at the Max Planck Institute in Berlin who spent 5 hours studying self-help books on improving fluid (spatial) abilities performed as well on tests as did those who had 5 hours of training. These gains were maintained on tests 6 months later. Similar results have been achieved with a wide range of other interventions, with some of them being quite indirect. For instance, members of groups that practiced transcendental meditation regularly improved their scores on cognitive tests far more than did those who did not.

So far, the effects of the training are largely untested in real life. After completing a course on memory improvement, is a woman better able to recall a list of errands she must run? After cognitive training, can a man more easily remember where he left his car in a supermarket parking lot?

5.2. Activities That Indirectly Benefit Cognition

Intellectual functions are indirectly influenced by a number of activities that enhance physical health. In an otherwise reasonably healthy aging population, these include behaviors that benefit cardiovascular functions and strengthen the immune system.

In addition to regular exercise, two crucial contributors to cardiovascular health are weight control and blood pressure management. Obesity is a growing problem in the United States. Depending on which criteria are applied, the proportion of overweight adults in the United States currently varies from 37 to 67%. By any standard, the percentage of obese adults has nearly doubled during the past 40 years. Excess weight is associated with greater risk for diabetes, hypertension, and cardiovascular disease—three conditions that adversely affect cognition. Obesity increases with age, partly because fewer calories are required to support normal activity with advancing years and partly because many older adults are physically inactive. In the year 2000, 35% of American older adults reported that they had engaged in no physical activity during the previous month.

Controlling blood pressure reduces the risk of cardiovascular disease and stroke. Participants in the Framingham Longitudinal Study with untreated hypertension scored lower on cognitive tests than did those with normal blood pressure. Increased diastolic blood pressure had particularly negative consequences for intelligence. The intellectual consequences of high blood pressure are far more serious for younger people. Hypertensives under 40 years of age had far lower scores on cognitive tests of attention, memory, mental flexibility, and reasoning than did age-matched normal individuals. Beginning to control high blood pressure early has substantial cognitive and physical advantages.

Physical vitality and cognitive vitality are greatly affected by the efficiency of the immune system. The immune system declines with age. Just as with age-related cognition, however, considerable variability occurs in immune system functions among older people. Until the past decade, it was assumed that the immune system functioned independently of psychosocial influences. Over the past 10 years, however, evidence has accumulated that the immune system is significantly influenced by mental states. This has led to increasing scientific interest in what is called psychoneuroimmunology. Of particular interest is the influence of stress on the suppression of the immune

system given that this, in turn, can adversely affect health and cognition.

How much stress individuals confront, how well this stress is managed, and what other resources individuals can draw on to ameliorate the impact of negative events and bring comfort into their lives all are found to be correlated with health status. For example, more than 400 adult volunteers in Pittsburgh, Pennsylvania, were given nose drops containing a common cold virus. Not surprisingly, a large number of the volunteers developed severe colds soon afterward. But not everyone developed colds, and the severity levels of the colds varied widely. These scientists also measured the total amount of stress that these individuals had to deal with during the past year. Then, they compared these data with the susceptibility to, and the severity of, the colds. They found that individuals with more stress in their lives developed colds far more often, and with more severity, than did those whose stress scores were below average.

Elevated stress-related emotions of anxiety, depression, and anger correlate with lower scores on mental tests. This may be because high levels of stress diminish intellectual resources. An illustration is the finding that neuronal loss in the hippocampus area of the brain was moderately correlated with the number of months in combat in the war in Vietnam. The negative effect of stress emotions appears to be greatest on fluid abilities. For example, higher levels of anxiety have been demonstrated to be associated with lower scores on aptitudes such as analogies, picture memory, and block design.

5.3. Selective Optimization with Compensation

One of the most promising strategies for minimizing the impact of aging on cognitive performance is selective optimization with compensation. Developed by Baltes and coworkers, the essential ingredients in this approach are broken down into three steps. The first step is selection, that is, giving up some activities to concentrate the available mental energies on those remaining activities. The activities that continue to have priority are usually selected due to skills, motivations, and opportunities. An aging physician who wishes to remain active might be an example. In midlife, the physician has a busy practice and also teaches medical students. He simultaneously does clinical research, serves on professional committees and boards, and does consulting work. By his early 60s, the physician may begin to focus his mental energies on those patients and types of

activities that he likes best, cutting back on those professional responsibilities in which his interest is waning. So, the physician keeps working at his practice but takes no new patients, and he continues his teaching and research but gives up committee work and consulting. At 70 years of age, the physician may limit his professional activities to teaching and research.

The next ingredient is optimization. This means doing everything possible to maximize one's performance at those things that one chooses to do by anticipating the potential negative effects of cognitive aging. For example, the physician may begin to limit his practice to those patients who he believes he can treat most effectively, referring the others to colleagues. Keeping up with the recent developments in medicine and taking short courses to maintain and upgrade his medical skills become priority items. The physician may try to work "smarter," that is, using computerized expert analyses and digital libraries more readily as opposed to trying to keep all of this information in his head. Optimization requires more time for preparation. For an older physician, this might entail carefully reviewing the chart of a patient in advance of an appointment rather than counting on his ability to get a picture of the medical history by a quick scan while seeing the patient. The aging physician also begins to dictate notes right after seeing the patient instead of waiting until the end of the day or later in the week to do so. In his 60s, the physician must accept the reality that far more time needs to be set aside to prepare lectures than was the case a decade earlier.

Compensation is doing everything that can be done to bolster fading abilities. Eyeglasses and hearing aids, to see and listen as well as possible, are examples from the physical standpoint. From the cognitive standpoint, compensation can include doing one task at a time and recognizing the effect of circadian rhythm (day-night cycle) and glucose/caffeine on cognition. The still working older physician compensates by avoiding dual-task activities such as making notes in a patient's chart while talking about another patient on the telephone. Cognitive compensation might include putting to use an understanding of his personal circadian cycle. The average older person's mental functions are stronger in the morning than later in the day, so the physician may schedule his most difficult patients in the morning and schedule less challenging professional activities in the afternoon. Finally, the physician may compensate for diminished mental acuity in the late afternoon with a cup of coffee and a cookie. For most healthy older individuals, moderate amounts of caffeine and glucose enhance attention and memory for a short time.

6. LOOKING AHEAD

Judging from the remarkable progress and growth of interest in all aspects of aging during the past quarter-century, there is little doubt that this will continue to be an area of expanding scientific and academic interest, as well as an area of considerable opportunity, during the decades ahead.

Several relatively recent developments make cognitive aging an especially interesting subspecialty within the field of aging. For instance, developments in neuroimaging technology over the past decade or so have enabled investigators to see in real time how the brain functions when carrying out specific intellectual tasks, to visualize the differences between the brain structures of younger individuals and those of older individuals, and to observe how the brain is compromised by conditions such as AD. Neuroimaging techniques have made possible a quantum leap in understanding the relationship between the brain and behavior. A new discipline, called cognitive neuroscience, draws deeply from this technology. At the time of this writing, the field is attracting the interest of some of the most influential thinkers in the social sciences and medicine.

Another important development has been the availability of findings from longitudinal studies of human development through much of the life span. Examples of these longitudinal studies include the Oakland/Berkeley Growth and Guidance Studies, the Terman Study of Children With High Ability, the Grant Study of Adult Development, the Seattle Longitudinal Study, and the Duke Longitudinal Studies. Some of these were begun during the 1920s and 1930s, whereas others started during the third quarter of the 20th century. Although many of these studies have limited generalizability because their participant pools are not representative of the U.S. population in terms of gender, education, social class, and race, they still provide an increased understanding of the aging human body and mind. As the participants from these investigations are moving into their later years, this research has begun to bear fruit. The numerous books and articles published about these studies have contributed much to the understanding of cognitive aging.

But these publications do not nearly exhaust the opportunities to learn much more about cognitive aging. The raw data from many of these longitudinal studies—the actual responses from each participant every time he or she was examined—are currently archived and are available for analysis. For instance, the Henry A. Murray Research Center for the Study of Lives

at Harvard University contains nearly 300 complete data sets from these longitudinal studies as well as other cross-sectional research that is better balanced for demographic variables. The rapid growth in data storage technology and computer memory and speed makes it possible today to access the raw data from these aging studies and to examine them using a computer in the privacy of a distant laboratory, professorial office, or student's room. Today's scholars can examine this vast storehouse of information, posing new questions, formulating new hypotheses, and looking for new answers in the responses of participants studied generations earlier.

The verity of any research finding is strengthened when it is demonstrated across studies, across generations, across geographical regions, and across investigators. Sophisticated statistical packages and advances in meta-analyses make it possible to compare findings from several studies at once. For instance, a student working on his or her thesis may want to know whether the findings from cross-sectional studies about the significant correlation between more social support and less cognitive decline also could be confirmed by looking at these same relationships in longitudinal studies of earlier epochs. The archived raw data can be easily loaded into the student's computer for analysis of this new question.

Finally, because substantial scientific interest in cognitive aging is relatively new, much interesting work begs attention. Following are two examples. First, what are the characteristics of people who benefit most from cognitive training? What are the mediating effects of variables such as education, motivation, temperament, and degree of impairment? Do people with more education and higher levels of motivation, who are more extraverted and less intellectually impaired, benefit more from cognitive training? Or, is it just the opposite—do those people with less education and lower levels of motivation, and who are less extraverted and more intellectually impaired, make greater gains following training?

The second example is Public Law 99-592. Its passage solved one problem but exposed another. What standards will replace the arbitrary age limits of 55, 60, or 65 years to determine when someone is no longer able to do the job? Because of the currently shrinking labor pool, valid and fair procedures are urgently needed to determine whether an older person continues to have the skills necessary to perform competently in an occupation. So far, no techniques have been developed that have the necessary sensitivity to identify only those individuals with true cognitive

impairment without falsely identifying others who, in fact, do not suffer from cognitive impairment.

Knowledge about cognitive aging has accrued rapidly during the past 25 years or so. More is on the way. As these new findings accumulate, they raise the probability that all individuals, through their behaviors in small increments, will be able to positively influence a significant portion of the cognitive quality of their later lives.

GLOSSARY

affect A person's mood or state of mind such as depression or happiness.

agitation Inappropriate verbal, vocal, or motor activity that is not judged by an outside observer to result directly from the needs or confusion of the individual; these behaviors have been labeled problem behaviors, disruptive behaviors, challenging behaviors, disturbing behaviors, behavioral problems, and agitation, all terms that are used interchangeably.

functional status—ADL The ability of a person to complete activities of daily living (ADL), that is, activities required for personal self-maintenance; some of these activities include bathing, dressing, grooming, feeding, and toileting.

self-affirmation The enhancement of the sense of selfhood/personhood; it can be achieved through things such as meaningful activities, social interactions, and successful accomplishment of objectives.

Cognitive and behavioral interventions for persons with dementia include a large range of tools used to enhance cognitive, behavioral, and affective functioning as well as self-maintenance. Such interventions should follow a detailed analysis of the problems, goals, and abilities of these persons. The interventions are described under the following categories: cognitive, behavioral, self-affirming, sensory, social contact, structured activities, environmental, medical/nursing care, and staff/caregiver training and management. Although these interventions have shown promise in prior research, the field of investigation is still in the early stages, and larger controlled intervention studies are needed. Furthermore, research is needed to clarify the process of intervention and which intervention ingredients are crucial for success. These studies would lead the way to effectiveness and cost analyses.

1. INTRODUCTION

The scope of cognitive and behavioral interventions for persons with dementia can be conceptualized from a narrow or a wide perspective. The narrow perspective includes only interventions traditionally referred to as

cognitive behavioral, including reinforcement techniques and cognitive restructuring. A wider perspective includes a range of techniques based on different theoretical frameworks and disciplines, many of which are used either to prevent or to substitute for use of psychoactive medication. This article uses the latter approach, with the goal of clarifying the wide range of techniques available to clinicians in enhancing the quality of life of persons with dementia.

The various intervention techniques that are used with persons with dementia can be organized along several dimensions: the function of the intervention, the theoretical framework serving as a basis for the intervention, the type of activity undertaken during the intervention, and the population subgroups for whom a technique is appropriate. Interventions should be ranked by their effectiveness within a subgroup for certain goals with specific outcome criteria. Some of these dimensions are reviewed briefly in what follows.

2. PURPOSE OF INTERVENTIONS

Cognitive and behavioral interventions are used for improving functions in many domains, including the following:

- Cognitive goals include enhancement of memory as measured by memory tests, enhancement of memory for daily tasks, enhancement of ability to communicate, an increase in task engagement, an increase in orientation to time and place, and a decrease in overall cognitive decline.
- Functional goals usually involve an increase in independence or in participation in the performance of activities of daily living (ADL) (e.g., dressing, eating, toileting) and a decrease in risk of falling.
- Affective goals include a decrease in negative affect (e.g., depression, anxiety) and an increase in positive affect (e.g., pleasure, contentment).
- Behavior change involves a decrease in problem behaviors (agitation) such as aggressive behaviors, repetitive nonaggressive and restless behaviors, and repetitive verbal/vocal behaviors. Such behaviors are frequently indicative of discontent in persons with dementia and may also be disruptive to caregivers.
- In terms of self-affirmation, a loss of sense of self and of identity is a common characteristic of dementia. Even when the inner sense of self may remain intact, the socially defined self is often diminished by the decline in social, work, and leisure roles. Therefore,

some interventions target enhancement of the sense of selfhood/personhood in dementia.

3. THEORETICAL FRAMEWORKS

Many theoretical frameworks underlie cognitive and behavioral interventions. Some of the basic concepts used in these frameworks are described in what follows.

3.1. Cognitive

Research on cognitive processes differentiates between explicit and implicit memory. Explicit memory requires the ability to produce the memorized material and usually involves conscious knowledge of the material. In contrast, implicit memory affects behavior but does not involve awareness of the memory. Explicit memory is usually lost earlier in the dementia process than is implicit memory. Procedural memory involving everyday activities frequently involves implicit memory. Therefore, some simple procedures can be learned during the early and middle stages of dementia even when there is no awareness of the learning process.

3.2. Behavioral Theory

Behavioral theory asserts that behavior manifestation is affected by its antecedents and consequences. Environmental stimuli can become associated with a behavior and trigger it, whereas consequences such as reinforcement can affect the likelihood of the behavior's manifestation. To change a behavior, the contingencies between a behavior and its consequences need to be changed, for example, withdrawal of reinforcement or introduction of reinforcement for different behaviors under different circumstances. Alternatively, an intervention can alter the environmental stimulus that triggers the behavior.

3.3. Cognitive and Behavioral Theories of Depressed Affect

Cognitive and behavioral theories of depressed affect include (a) cognitive theory that ascertains that depression is a consequence of negative and distorted cognitions about oneself (based on work by Beck and Ellis), (b) theory that claims that depression involves learned helplessness and a sense of loss of control (based on Seligman's work), and (c) theory that depression relates

to an insufficient level of reinforcements or pleasurable experiences (based on Lewinsohn's work).

3.4. Unmet Needs Theory

The unmet needs theory asserts that people with dementia manifest inappropriate behavior due to unmet needs. The theory claims that people with dementia have the same needs as do other people. These needs, which are generally summarized under Maslow's hierarchy of needs, include physiological, safety, love and belonging, esteem, and self-actualization needs, with the latter sometimes being manifested as a need for cognitive stimulation or for meaningful activity. According to this theory, these needs frequently go unrecognized by caregivers, and even when they are recognized, these needs are often not satisfied because caregivers do not understand their significance or do not know how to address them. The unmet needs result in inappropriate behavior in one of several mechanisms. First, the inappropriate behavior may be a call for help due to the unmet need. Second, the inappropriate behavior may be an attempt by the person with dementia to respond to his or her need (e.g., self-stimulation as a response to sensory deprivation). Finally, the inappropriate behavior may be a direct result of the unmet need (e.g., screaming due to pain).

3.5. Humanistic Theory

Humanistic theory maintains that a person's subjective understanding of his or her experiences is more important than objective reality.

3.6. Stages of Human Development

Erikson described eight stages of human development culminating in the eighth stage (age 65 years or over), described as "Integrity versus Despair," in which a person looks back at accomplishments and ahead to the unknowns of death and feels either fulfilled or saddened. Feil added a ninth stage to Erikson's developmental framework that she termed "resolution versus vegetation." It is viewed as an opportunity to resolve conflict and achieve a sense of integrity before death.

4. TYPES OF INTERVENTIONS

This section includes a descriptive list of interventions used with people with dementia. In understanding the

interventions on this list, several underlying principles need to be clarified.

4.1. General Issues in Considering Types of Interventions

- An intervention should follow a thorough assessment such as a functional analysis that examines the nature of the behavior as well as possible causes, antecedents, and consequences. The assessment should also include information about past stresses, identity, habits, and preferences as well as current medical and psychosocial status. This assessment would guide the understanding of the etiology of presented symptoms as well as realistic goals and options for treatment. Once an intervention is implemented, it should be evaluated. If it does not meet the goals, a different treatment alternative should be taken. Such alternatives might be a different intervention or might involve a different aspect of the intervention (e.g., different timing, differing amounts [dosage], different presentation style, different therapist).
- The list of interventions is not exhaustive but provides examples of the currently available interventions. Interventions are in the process of being developed and tested, so the list is an evolving body of knowledge.
- Interventions often have multiple purposes, and there are multiple options for interventions in any functional domain (see Table I). For example, cognitive interventions can be used for improving cognition, function, behavior, and/or affect.
- The descriptions in what follows provide only a general concept of the various interventions. However, each type of intervention can be considered as a whole range of possible interventions and, therefore, can be delivered in many different ways. It is the specific operational details that may make any treatment effective.
- The manner in which an intervention is presented can be crucial for its success.
- An important issue in understanding the utility of interventions is discerning the active ingredient of the interventions. Two interventions might seem quite different, yet the potent factor in both may be the opportunity to interact with a supportive person. The understanding of the underlying differences among interventions should be a focus for future research.
- Matching interventions to the person and the purpose is important. Cognitive and behavioral interventions cannot be applied uniformly to all persons with dementia. Interventions are appropriate for specific

TABLE I
Nonpharmacologic Interventions: Examples of Type of Intervention by Goal

<i>Goal/type</i>	<i>Treatment modalities</i>	<i>Environmental</i>
Enhance cognitive performance	Cognitive remediation/memory training Spaced retrieval Reality orientation Cognitive tasks, such as reading group activities or sorting activities	Memory books (Bourgeois et al., 2001; Brooker & Duce, 2000) Use of signs and pictures to enhance orientation
Enhance functional performance	Independence promoting strategies (Beck, 1998; Namazi, Gwinnup, & Zadorozny, 1994) Prompted (Schnelle, 1990) and scheduled voiding (Jarvis, 1981)	Increased cue visibility. Change lighting levels (Beck & Heacock, 1988; Koss & Gilmore, 1998) Increase toilet visibility, raise toilet seat
Enhance self-perception	Reminiscence therapy (Gagnon, 1997; Hoerster et al., 2001) Validation therapy (Morton & Bleathman, 1991; Toseland et al., 1997) Self-identity based interventions	Provide objects (e.g., furniture, photographs) that were meaningful in the past
Enhance pleasure	Interventions based on past or present pleasant activities Sensory interventions Structured activities	Provide objects (e.g., pictures, piano) that were liked in the past
Decrease behavior problems	Sensory interventions Behavioral interventions Social contact interventions Structured activities Staff training Environmental interventions Medical/Nursing care interventions Combination therapies (Cohen-Mansfield, 2001)	Allow access to a secure outdoor garden

Table © Cohen-Mansfield (2004).

goals and need to be matched to individuals based on their cognitive and sensory abilities as well as on their identities, habits, and preferences. In addition to tailoring the type of intervention to the person and their specific needs, the content of the intervention, such as the type of music that is played, needs to be matched to the person's preferences. This need to individualize treatments makes both research and practice more complex.

4.2. Cognitive Interventions

4.2.1. Memory Training

Positive results have been described for memory training with older persons. However, these are usually conducted with persons with either no memory impairment or mild cognitive impairment. Interventions reported for

persons with dementia usually involve more support and less reliance on the person than traditional memory training methods. Interventions such as mnemonics are therefore usually inappropriate for this population. However, positive results have been demonstrated in small studies that involved daily cognitive stimulation by caregivers and with a computerized cognitive remediation system created by Butti and colleagues.

4.2.2. Cognitive Restructuring

Cognitive interventions based on Beck's and Ellis's work have been used to treat depressed persons with mild levels of dementia. These interventions involve cognitive restructuring, that is, challenging or changing distorted thought processes and thoughts that cause depressed affect.

4.2.3. Task Simplification/Cognitive Prosthesis

The most common and straightforward cognitive methods involve task breakdown, enhanced instruction, modeling, rehearsal, cueing, and gradual approximations of a task. These principles apply across different domains. The notion of simplifying tasks can also be applied across daily activities such as by providing consistency in caregiver assignment (this helps to orient older persons across different tasks). Similarly, many environmental interventions have been used to simplify orientation such as placing items that are frequently needed in a permanent location, using labels and signs, wearing a large wristwatch, and placing a card with important information in a pocket.

4.2.4. Memory Books

Memory books are booklets with autobiographical, daily schedule, and problem resolution information. When nursing assistants were trained to use the memory books, nursing home residents showed improvement in conversation and affect.

4.2.5. Spaced Retrieval for Procedural Memory

Spaced retrieval is a memory training technique that involves repeated rehearsal, with testing occurring over gradually increasing time intervals. For example, the resident may be trained to check whether his or her glasses are being worn. The resident would first be asked to check immediately after instruction, then after 20 seconds, after 40 seconds, after 1 minute, after 2 minutes, and so on. In this way, people with dementia are able to learn procedures so as to consistently check their calendars. This procedural learning is essential for independent functioning and is based on the use of procedural implicit memory, which is retained until the later stages of dementia.

4.2.6. Reality Orientation

Reality orientation is an intervention in which staff members present orienting information, including information about time, place, and person, to persons with dementia. Such information may be conveyed in special group sessions, which may include discussion of current events or may be ongoing in interactions between (usually formal) caregivers and persons with dementia.

4.2.7. Cognitive Tasks

Cognitive tasks include both group and individual activities that involve use of cognitive and memory skills. Group examples include “question-asking readings” in which a group reads a relatively low-reading level script that is typed in large font and high contrast and that is accompanied by questions typed on cards that allow participants to discuss related topics. Another group memory task is “memory bingo,” in which participants have bingo-type cards with endings of popular sayings. For each card, the group facilitator reads the beginning of the saying, and participants use long-term memory to complete the sentence and use recognition skills to find it on the card in front of them. The sayings can also be used to stimulate discussion. Individual cognitive tasks include activities such as card or object sorting by category.

4.3. Behavioral Interventions

4.3.1. Differential Reinforcement

Differential reinforcement may involve positive reinforcement contingent on nonagitated behavior or “time out” (e.g., moving the person to a quiet area when agitated) or “restriction” (e.g., denying the person goods [e.g., candy], activities, or access to a location or another person when agitated).

4.3.2. Stimulus Control

Stimulus control is based on behavior being emitted under specific antecedent conditions and not others. Stimulus control involves changing the stimuli that tend to trigger a behavior, so that the behavior will be less likely to be triggered, or changing the association between the antecedent stimulus and the behavior by changing contingencies depending on the presence of various antecedent stimuli. Camouflaging exit doors and placing stop signs on them, along with training that the stop sign means stop and walk away, are examples of the use of stimulus control.

4.3.3. Maximizing Control

Helplessness has been shown to relate to depressed affect, whereas control is associated with well-being. Providing residents with opportunities to exercise control can involve having a door that they can open to an outdoor area, having a plant that they can care for, or allowing them to make decisions about meals, clothes, and the like.

4.3.4. Increasing Levels of Pleasant Activities or Noncontingent Reinforcements

Clarifying which activities or experiences are reinforcing to individuals with dementia and providing these activities or experiences is a method that has been used to treat depressed affect in persons with dementia.

4.4. Self-Affirming Interventions

4.4.1. Reminiscence Therapy

Reminiscence therapy encourages persons with dementia to recall their pasts. Sessions may use audio-visual aids such as old family photos and other objects. Reminiscence can enhance patients' sense of identity and sense of worth and/or general well-being, and may also stimulate memory processes.

4.4.2. Validation Therapy

Validation therapy, developed by Feil, involves communication with a therapist who accepts the disorientation of the person with dementia and validates his or her feelings. The assumption is that the person returns to unfinished conflicts in the past, around which a meaningful conversation can take place addressing the emotions that are important for the elderly person rather than trying to correct the disorientation. Thus, it fits within the perspective of humanistic theory. Validation therapy can take place in one-on-one treatment or in a group.

4.5. Sensory Interventions

4.5.1. Massage/Touch

Massage or therapeutic touch has been used to decrease behavior problems in people with dementia. Touch is sometimes considered a form of communication when verbal communication is no longer available. In many of the articles reporting on massage therapy, the procedures took approximately 5 minutes and were performed once or twice a day.

4.5.2. Music and White Noise

Music has been used for decreasing behavior problems and for improving cognition or function. Music has been used to relax patients during meals or bathing or as a means of providing sensory stimulation to people who are understimulated. Music interventions take many forms, including listening to a music tape, playing

musical games, dancing, moving to music, and singing. Prior to using music therapy, hearing would need to be checked, and an amplifier, headphone, or hearing aid might need to be used. Music is more effective when it is individualized to match the person's preferences. White noise has also been used to induce relaxation, thereby improving sleep and decreasing restlessness.

4.5.3. Sensory Stimulation

Sensory stimulation involves the presentation of stimuli that affect different sensory modalities, including hearing, touching, seeing, and smelling. Therefore, it can include elements of the massage and music interventions described previously as well as aromatherapy, moving lights, pictures, and the like. The "Snoezelen" sensory stimulation program, which was developed in The Netherlands and includes a variety of relaxing stimuli, is also a type of sensory stimulation.

4.6. Social Contact Interventions

Loneliness is highly correlated with depressed affect, and being alone has been shown to relate to behavioral problems. The best intervention for loneliness is positive interaction with a person who is meaningful to the elderly person. However, this is often not feasible. Therefore, a variety of alternative social interventions have been developed. In addition to the following social contact interventions, most group activities, including cognitive ones, can be used as vehicles to promote social contacts.

4.6.1. One-on-One Interaction

One-on-one interaction is a potent intervention for loneliness and behavior problems. It can be conducted with relatives, paid caregivers, or volunteers.

4.6.2. Pets/Dolls

Pet therapy often involves visits with a dog that last from a half-hour to an hour. However, other pets (e.g., a cat, fish) can be used as well. Even plush stuffed animals have been used successfully, as have robotic pets. Dolls have also been used to simulate companions, since they can be viewed as real babies. Pet therapy not only involves interaction with the pet but also serves as a topic for interaction with other people.

4.6.3. Stimulated Interaction/Family Videos/Interaction Videos

Simulated presence therapy uses an audiotape to simulate phone interactions. The tape contains a relative's portion of a telephone conversation and leaves pauses that allow the older person to respond to the relative's questions. Family videotapes also simulate interaction by having a loved one talking to the person with dementia. These videotapes have been found to produce engagement and decrease agitation in persons with dementia. Interaction videos are those in which the persons on the videos, usually professionals, interact with the persons with dementia, often recalling information from the past or inviting the persons with dementia to sing along, using long-term memory for well-known songs.

4.7. Structured Activities

4.7.1. Indoor Activities

Structured activities are used to improve affect and decrease behavior problems. They can take many forms and include activities that Buettner termed "simple pleasures," including both group and individual activities. The activities may involve manipulation (e.g., ball throwing), nurturing (e.g., watering a plant), sorting, cooking, sewing, or engaging in sensory intervention as described previously (e.g., music, tactile stimulation with a fabric book). The content of activities may be based on information regarding which activities were or are reinforcing to the individual.

4.7.2. Outdoor Activities

Outdoor walks and physical activities are forms of structured activities that have the potential to improve function and affect and to decrease problem behaviors. Outdoor walks may take place in the company of a caregiver and so may also involve a social component, or they may occur in a secure outdoor area involving an environmental intervention. Outdoor walks are often limited by weather conditions.

4.8. Adapted/Enhanced Environmental Interventions

Environmental interventions can be used for multiple goals such as to decrease or accommodate behavior

problems, to enhance functional status, and to increase orientation.

Environments for increasing functional ability have included different levels of environmental adaptation, from decreasing clutter to providing grab bars or handrails. The following are specific types of adaptation or enhancements.

4.8.1. Visibility of Cues Needed for Activities of Daily Living

The importance of visibility has been demonstrated in several research studies. For example, use of toilets increased when toilets were more visible, and eating behavior improved with better light and increased contrast between plates and the table.

4.8.2. Seating in Motion

Rocking chairs and gliding swings have been used for relaxation, improved affect, stimulation, and reduced physical agitation.

4.8.3. Homelike Ambience

Homelike furnishings in the institutional setting and enhanced ambience can affect many aspects of well-being for both patients and their caregivers.

4.8.4. Reduced Falls

Decreasing bed height, placing mattresses on the floor, using hip protectors, improving light on the way to the bathroom, and improving call systems all can help to decrease the risk of injury due to falling.

4.8.5. Privacy and Intrusion Deterrence

To prevent trespassing into other people's rooms or through emergency exit doors, doors and doorknobs can be camouflaged with cloth panels or murals, thereby disguising the doors. In addition, providing alternative doors, which can be controlled by the patient and permit movement into another secured area, can be useful in reducing trespassing.

4.8.6. Clear Labels and Signs

Clearly labeled signs with large font and high contrast can be used to increase orientation. Nursing homes can also use boxes with pictures of residents taken in

the past, or other memorabilia that is meaningful to them, to help orient residents in finding their rooms. Clear labels on public toilets are useful in decreasing incontinence.

4.8.7. Wandering Areas

Places that allow people to walk in a safe environment can be created either indoors or outdoors. These usually involve some type of walking loop that allows for walking but does not have an exit door that might allow for egress into an insecure area. In contrast, exit doors that can be opened by residents and allow them control of their own exit to another secure area can be therapeutic.

4.8.8. Peace and Quiet

Reduced stimulation environments, such as quiet rooms with soft colors, an absence of paging systems, and only a few objects, have been reported to be helpful. Reduced stimulation interventions may use neutral colors on pictures and walls and a consistent daily routine, with no televisions, radios, or telephones (except one phone for emergencies).

4.8.9. Nature Environments

Natural environments, including pictures of fish and/or sounds of bird songs or bubbling brooks, have been used to decrease agitation in the shower. Visual, auditory, and olfactory stimuli have been used to make nursing home corridors feel like home or like a natural outdoor environment, thereby improving resident and staff well-being and decreasing trespassing and exit-seeking behaviors.

4.9. Medical/Nursing Care Interventions

Although medical and nursing care interventions would not usually be considered cognitive or behavioral treatments, they are included here because it is the behavioral assessment that is used to reveal the underlying etiology of negative affect or behavior problems that allows a medical or nursing intervention to relieve the condition. Therefore, interventions such as light therapy to improve sleep, pain management, reduction of discomfort by improved seating or positioning, and removal of physical restraints all have

been associated with improvement in behavior. Similarly, the provision of eyeglasses or hearing aids can be an important intervention for treating sensory deprivation and loneliness as well as the ensuing depressed affect and problem behaviors.

A behavioral approach may also guide nursing interventions directly in helping elderly persons to achieve maximal functional levels. One example is that of cognitive interventions that include cueing and task breakdown. Another example involves toileting management protocols. Two types of toileting protocols have been described. In scheduled or timed voiding toileting, patients are taken to the toilet either at fixed times (usually every 2 hours) or on a schedule that is based on their voiding pattern. Prompted voiding involves asking residents on a regular basis whether they need assistance with toileting. Patients are helped when they indicate such a need. Both types of protocols can be effective in reducing incontinence.

4.10. Staff/Caregiver Training and Management

Staff training programs can take many forms and focus on any of the interventions outlined previously. Many focus on improved understanding of older persons and the impact of the disease and on improving verbal and nonverbal communications with persons suffering from dementia. Given that good communication skills are crucial for proper assessment of a problem area and for delivery of any intervention, training for such communication is the basis of good caregiving. Examples of methods for simplifying and clarifying communication using both verbal and nonverbal communication channels were provided by Beck and Heacock in 1988. Changing caregiver behavior through training is a complex and difficult challenge and often requires ongoing instruction, modeling, monitoring, feedback, and support of the caregiver. Therefore, in institutional settings, staff training is closely tied to management.

4.11. Combination Therapies

Good care involves using combinations of the available interventions and tailoring them to the needs, abilities, and preferences of the older person. In addition, many intervention programs combine elements from various intervention modalities.

5. EFFICACY, EFFECTIVENESS, AND UTILITY

There are two basic questions concerning interventions. First, are interventions effective? Second, what is the cost of interventions? There is insufficient research to answer either question, although partial answers have been suggested. One study reported the benefits of validation therapy for reducing aggressive behavior, and another reported on the benefits of reality orientation on orientation and affect, in comparison with control groups. However, in a review of reality orientation, validation therapy, and reminiscence therapy, Gagnon concluded that reality orientation and validity therapy do not produce sufficient change to justify their costs. Cohen-Mansfield reviewed 83 studies of nonpharmacological interventions for inappropriate behaviors in dementia and described the majority as reporting a positive, but not always significant, impact. Many of the studies included small samples and other methodological limitations, most often resulting from limited funding for this type of research.

There are few studies that have examined the question of cost. One study by Rovner and colleagues implemented an intervention that included daily group-structured activities, reduction of psychotropic medications, and weekly educational rounds with staff members. They calculated the cost of the 6-month intervention program at \$8.94 per patient per day. Another study by Schnelle *et al.* examined ways in which to improve nursing practices concerning exercise and incontinence care and concluded that current staffing levels are inadequate to provide good care.

Given the early stage of research in this field, there is an urgent need to increase our understanding about the following basic questions. Which interventions are efficacious for which individuals? Which aspects of an intervention are necessary for it to be efficacious? What are the active ingredients, or principles at work, in various interventions? Which personal characteristics (e.g., gender, culture, prior stress) need to be considered when matching an intervention with a person? Process variables (e.g., the person who is delivering the intervention, the timing of the intervention) and their significance need to be elucidated. Only after we have answers to these basic questions can the questions of effectiveness and costs be addressed properly.

3. How Cognitive Skills Can Be Trained and the Impact of Training
4. Conclusion
Further Reading

Cognitive skills are basic and higher order mental abilities, such as attention, information processing, memory, executive functioning, and reasoning, that interact with sensory and perceptual systems to determine success in performing daily activities. Older adults are at risk for cognitive decline but may benefit from strategies to maintain cognitive skills and from training programs to enhance certain skills.

GLOSSARY

divided attention The ability to split a person's attentional focus or to maintain vigilance with respect to two or more objects or activities.

executive function A set of higher order cognitive abilities primarily associated with frontal and prefrontal structures of the brain; it involves planning, organizes information, inhibits responses, and orchestrates mental resources.

hippocampus A subcortical structure of the brain that is key for memory function and is specifically involved in encoding new information, a vital first step for subsequent recall.

mild cognitive impairment (MCI) A term used to describe individuals with focal memory impairments but no evidence of frank impairment in other cognitive domains and no evidence of impaired daily functioning; MCI is often thought of as a preclinical stage of dementia.

transfer of training The capacity for training-induced improvements in cognitive skills to translate into improved performance of cognitively demanding activities.

1. COGNITIVE SKILLS AND THEIR IMPORTANCE FOR DAILY FUNCTIONING

The ability to think, remember, and reason allows people to negotiate the world in which they live, whether it be planning the steps in cooking a meal, remembering to take their medications on time, deciding how to spend their money, or reacting quickly to avoid hitting a dog in the road. People's cognitive abilities provide them with the flexibility to engage in a number of unique and demanding situations. Declines in any of these abilities can subsequently diminish the ability to function in day-to-day life. Cognitive abilities that tend to decline with age, with potential impact on the ability to perform everyday tasks, include attention, speed of processing, memory, executive functioning, and reasoning. These abilities interact with sensory and

perceptual systems to determine performance in daily life.

1.1. Sensation and Perception

Information processing must begin with acquiring the information in the first place. Thus, age-related changes in sensory–perceptual abilities (e.g., poorer vision, hearing) can influence older adults' ability to perform measures of cognitive ability as well as everyday activities. For the most part, older adults can compensate for age-related sensory decline through corrective lenses and /or hearing aids. Older adults also compensate for degraded sensory information through cognitive strategies in which they use the context of a situation (e.g., conversation, other words in a sentence, situational cues) to understand what is being presented. However, impairments in sensory processing can lead not only to poorer performance on cognitive tests, and perhaps a false impression of cognitive impairment, but also to restrictions in everyday activities such as driving. Such restrictions may, in turn, lead to increased depression and/or the need for formal care.

1.2. Attention

Attention encompasses a rather broad range of abilities, from simply orienting (e.g., turning attention toward a sudden noise), to sustained attention or vigilance (e.g., maintaining focus over an extended period of time). Divided attention is quite commonly used in everyday contexts and occurs when people try to do two things at the same time. This ability may or may not decline with age, depending on the individual and the difficulty of the two tasks being performed at the same time. The use of cell phones while driving is an example of a divided attention task that can be fairly difficult. There is mounting evidence that crash risk is elevated for drivers of all ages while using cell phones, and this risk may increase with age. In general, research indicates that older drivers are susceptible to decrements in driving performance when increased demands are placed on attention, whether it be cell phones or multiple events occurring at a congested intersection. Selective attention, or the ability to pay attention to relevant information while ignoring irrelevant information, is also germane in this context. It has generally been found that the detrimental effect of irrelevant information, or distraction, is higher for older adults.

1.3. Speed of Processing

Speed of processing, or the ability to perceive and process information quickly, is one of the first cognitive abilities to decline with age. Over the past decade or so, many studies have demonstrated relationships between cognitive processing speed and everyday function in older adults. Various indexes of mobility have been linked to processing speed impairments in older adults with and without dementia. For example, reductions in life space, or the extent of a person's travel in his or her environment inside and outside the home, have been associated with impairments in processing speed. Furthermore, multiple studies have demonstrated that processing speed impairment is an excellent predictor of increased crash involvement in older drivers and is an even stronger predictor of injurious crashes. Reduced processing speed also is related to slower performance of instrumental activities of daily living (IADLs) such as looking up a telephone number, finding items on a crowded shelf, and reading medication labels.

1.4. Memory

Memory is one of people's most obvious cognitive abilities. Of all the mental abilities, people report complaints about this ability more often than about any other ability, probably because it is fundamental to most everyday tasks. Also, memory decline can be obvious when a person is attempting to recall necessary information such as telling a doctor what medications he or she is taking or trying to remember a phone number. Although activation of both cortical and subcortical areas of the brain is necessary for good memory functioning, the hippocampus, a subcortical structure, has the primary responsibility of encoding new information, a vital first step for subsequent recall of the information. As seen with Alzheimer's disease, when the hippocampus is severely damaged, profound memory loss is experienced. Although some normal age-related decline in memory does occur with age, such changes generally do not severely affect daily functioning to the same degree as found in a dementia such as Alzheimer's disease. Regardless, age-related memory declines have been found to influence activities of daily living (ADLs), whether they be forgetting to adhere to medical appointments or not remembering to pay bills. Research has linked memory declines to self-reported impairment with daily shopping, preparing a hot meal, housecleaning, managing finances, and completing forms.

1.5. Executive Function

One of the most complex cognitive abilities is executive function, which includes people's ability to plan, organize information, inhibit responses, think abstractly, and reallocate mental resources. This ability is primarily associated with the frontal lobes of the brain and is known to decline with age. Executive functioning is necessary to complete tasks that require complex behavior or have multiple steps. For instance, executive functioning is useful in paying bills because this task requires planning (e.g., determining how much money to transfer from a savings account to a checking account), calculating how much money remains in the checking account after paying the bills, and (in many cases) deciding what is the least amount that can be paid to prioritize money to other uses. Thus, financial capacity can be impaired in individuals with executive dysfunction, as is seen in adults with Alzheimer's disease. However, dysfunction in executive abilities can also affect less cognitively demanding activities. For example, scientists have found that lower levels of executive functioning are related to impairment in the ability to perform other IADLs such as medication management, even among noninstitutionalized retirees.

1.6. Reasoning

Reasoning is another complex cognitive ability affected by aging. This ability is similar to executive functioning; in fact, damage to the frontal lobes also impairs the ability to reason. Unlike executive functioning, reasoning focuses on using logical constructs, knowledge, and principles to extrapolate a solution to a problem. Reasoning is a sophisticated problem-solving skill that requires both memory and executive functioning. Reasoning is used in a variety of real-world tasks, ranging from medical decisions to driving behavior. Thus, declines in reasoning ability can impair decision making in a variety of real-world scenarios. As with other cognitive skills, reasoning ability has been found to predict IADL performance. Scientists have found that inductive reasoning is important for figuring out problems associated with everyday tasks such as shopping and managing money. In fact, researchers have found that as inductive reasoning is enhanced, everyday problem solving also improves.

1.7. Cognitive Impairment

Whereas age-related declines in cognition and function may be relatively subtle and selective in normal aging, the declines experienced by individuals with mild

cognitive impairment (MCI) or dementia are more pronounced and become pervasive over time.

MCI is a term used to describe individuals with focal memory impairments but no evidence of frank impairment in other cognitive domains and no evidence of impaired daily functioning. MCI is often thought of as a preclinical stage of dementia. Approximately 5 to 15% of adults age 65 years or over may be affected by MCI. Individuals with MCI, by virtue of their memory impairments and their risk of progression to dementia, are at high risk for declines in the abilities needed to function effectively and independently in society. These individuals are likely to experience a gradual loss of functional skills of a magnitude that lies somewhere between the subtle decrements associated with normal aging and the much more obvious deficits associated with dementia. Little has been done to directly evaluate the impact of cognitive changes in MCI on the performance of everyday tasks. A critical question is how changes in memory and other cognitive abilities influence the performance of everyday tasks over the period of time that, for many individuals, will mark the transition from MCI to dementia. To date, no one has mapped cognitively demanding everyday activities to component cognitive abilities in MCI. Thus, it is difficult to determine whether some tasks of daily life are dependent on specific abilities or how levels of ability influence functional performance. A clearer understanding of this relationship within the MCI population is needed.

Dementia includes a category of diseases, such as Alzheimer's disease, characterized by more severe cognitive impairments that hamper a person's ability to perform everyday tasks. The incidence of dementia rises with age. For example, only approximately 5% of adults over 65 years of age have Alzheimer's disease, whereas 10 to 20% of adults over 80 years of age are affected, and estimates have indicated that as many as 40% of adults age 85 years or over suffer from the disease. Research in the field of cognitive aging has demonstrated that the deterioration of cognitive function that occurs with dementia contributes to a decline in the performance of everyday activities. Research has also shown a clear link between declining everyday function (e.g., managing finances, grocery shopping, driving) and subsequent hospitalizations, need for care, and death.

2. HOW COGNITIVE SKILLS MAY BE MAINTAINED

Cognitive decline in numerous areas can result in difficulty in performing tasks important for everyday life and

for maintaining independence throughout old age. Thus, an important question to consider is, "How can individuals maintain cognitive abilities and avoid cognitive decline?" Several factors have been related to sustained cognitive function with age, including education level, physical activity level, pulmonary health, and feelings of self-efficacy. By and large, healthy and active lifestyles that include proper diet and exercise, prevention of disease, and the avoidance of trauma all are important for sustaining cognitive capacity with advancing age.

Higher education levels are associated with better cognitive performance during older adulthood. Education level affects cognitive function both directly, through enhancing brain function, and indirectly, through individuals with more education being more likely to participate in intellectually stimulating activities that, in turn, preserve cognitive abilities.

Physical activity has various benefits for older adults and positively affects cognitive function in a variety of ways. For example, physical activity has been shown to decrease depression (which can cause cognitive deficits, particularly for older adults) and to increase overall physical health and improve quality of life. Strenuous exercise directly benefits brain and central nervous system functioning, which are vital to maintaining cognitive abilities. Accordingly, aerobically active individuals perform better on measures of working memory, reasoning, and speed of processing than do those who exhibit more sedentary behavior.

In addition to exercise, many facets of physical health have been related to cognitive function. For example, a specific physiological measure, pulmonary peak expiratory flow rate, has been found to be predictive of sustained cognitive ability with age. This physiological index is related to cardiovascular health and physical activity level. Studies have noted in particular that preserved vascular and cardiovascular health is vital for cognitive function. For example, decreased cerebral blood flow is associated with poor cognitive performance. Furthermore, poor cardiovascular health is associated with increased incidence of stroke, a leading cause of cognitive impairment. In the Seattle Longitudinal Study (SLS), absence of cardiovascular disease was linked to better reasoning ability and speed of processing performance for older adults. A number of other diseases, such as diabetes, emphysema, and Parkinson's disease, can also result in cognitive deficits. In general, the fewer chronic diseases a person has, the better his or her chances of maintaining cognitive abilities with advancing age.

Overall, a healthy lifestyle is important not only for physical health but also for mental health. Obesity has been related to higher incidence of many chronic

diseases, which in turn are related to cognitive decline. Cigarette smoking and excessive alcohol consumption both have been linked to higher incidence of stroke, a leading cause of cognitive impairment, as well as to many other poor health outcomes, thereby negatively affecting cognition. Furthermore, alcoholism can be directly detrimental to cognitive function. Most obviously, traumatic head injury results in cognitive impairment and is associated with increased incidence of dementia later in life. Therefore, simple preventive behavior, such as using seat belts combined with air bags while in automobiles and using helmets while riding on motorcycles, bicycles, or scooters, is advised.

In addition to physical health and healthy lifestyles, psychological well-being is important for preserving cognitive function. An individual's attitude can affect his or her cognitive performance with age. For example, self-efficacy, a positive evaluation of one's own cognitive capabilities, is related to better cognitive performance. Individuals in the SLS who rated their personalities as "flexible" during mid-life were found to be at reduced risk for cognitive decline in later life. Furthermore, individuals who indicated satisfaction with their life accomplishments during middle age performed better on cognitive measures in later life.

Sustained social activity also is associated with better cognitive performance. For example, researchers have found that those who engage in social, domestic, and leisure pursuits are less likely to have cognitive impairment. Similarly, the SLS indicated that older adults who had high socioeconomic status and were socially active experienced the least cognitive decline over a 7- to 14-year period. Risk of cognitive decline was lessened for individuals who read extensively, traveled, attended cultural events, were involved in clubs and professional associations, and pursued continuing education opportunities. Extensive social networks and support systems, including intact families, have also been related to better cognitive functioning with age. Conversely, depression has been identified as a psychological/biological cause of decreased cognitive function. Particularly for older adults, depression can manifest itself as cognitive impairment.

3. HOW COGNITIVE SKILLS CAN BE TRAINED AND THE IMPACT OF TRAINING

3.1. Cognitive Training

Given that cognitive abilities can and do decline with age, often resulting in difficulty in performing everyday

tasks, the possibility of cognitive training to prevent, slow, or reverse age-related cognitive decline has been investigated. A growing number of studies now support the protective effects of intellectual stimulation on cognitive abilities for older adults without dementia. Early studies in the area of cognitive training were conducted within the Adult Development and Enrichment Project (ADEPT) and the SLS. Both of these studies provided 5 hours of strategy training, preceded and followed by cognitive assessment. Significant cognitive training gains were observed in both studies for the specific abilities that were trained.

A large randomized clinical trial, Advanced Cognitive Training for Independent and Vital Elderly (ACTIVE), recently evaluated the impact of three promising cognitive interventions—speed of processing training, memory training, and reasoning training—on the maintenance of both cognitive and day-to-day abilities in community-living older adults. The study showed that for all three interventions, there were significant and specific improvements in cognitive ability as well as an increased benefit of additional booster training. The amount of training gain for cognitive abilities was equal to or greater than the amount of decline that would be expected in older adults without dementia over 4 to 14 years of aging in the absence of any training.

3.2. Durability of Training

In the ACTIVE study, among those individuals who experienced immediate cognitive improvements, training gains were found to persist for at least a 2-year follow-up period for all three interventions. Prior cognitive training studies have also pointed to the durability of training effects, with maintenance of reasoning training demonstrated at even 7 years after original training. Those older adults in the SLS who received reasoning booster training were found to substantially outperform their initial baseline levels 7 years later. Although studies of memory training have consistently shown that memory improvement can be maintained 1 week to 6 months, results on the durability of training beyond 6 months are less consistent. Some investigators have reported a significant decrease in memory performance and a substantial decrease in mnemonic strategy use over a 3-year interval in a memory training group. Multifactorial memory training programs, such as those incorporating psychomotor training in addition to memory training, have resulted in maintenance of memory improvement extending to 3½ years.

Maintenance of speed of processing training effects has not been evaluated extensively beyond the ACTIVE study, which demonstrated maintenance for at least 2 years. In an early training study, speed training effects were found to persist over a 6-month period. Furthermore, participants in the older age group (>60 years) performed at the same level following training as the middle age group (40–59 years) had performed at baseline. In a subsequent study among older adults, training effects were found to persist over 18 months and remained significantly better than baseline. Thus, in general, cognitive training studies have supported the durability of training effects.

3.3. Transfer of Training

Given that cognitive training can result in improvements of targeted cognitive skills, can these cognitive improvements transfer to improvements in performance of everyday activities? Older adults are constantly faced with learning new things such as skills for using computers, home medical devices, automated teller machines, videocassette recorders, and job-related skills. In addition, older adults would benefit from preservation of functional abilities that were most likely acquired at a younger age (e.g., driving, other IADLs). Although the onset of decline occurs for many cognitive abilities during a person's 60s, the onset of decline for everyday abilities typically occurs during the 70s or later. Obviously, functional competence is multidimensional, relying on multiple cognitive abilities. Consequently, assessment of functional competence/everyday abilities has included multiple methods, including global measures, performance-based measures, and self-report measures.

An example of a cognitively demanding task of daily living is the Everyday Problems Test (EPT), which assesses a person's ability to interact with 14 everyday situations (e.g., doubling a recipe, interpreting transportation schedules, understanding a Medicare benefit chart). Similarly, the Observed Tasks of Daily Living (OTDL) assessment presents tasks in three domains: medication use, financial management, and telephone use. Participants are asked to perform actions required to solve everyday tasks (e.g., searching medication label for side effects, making change). Performance on these measures has been related to multiple basic cognitive abilities; therefore, it may improve with cognitive training.

Other measures of everyday ability emphasize the speed of responding to real-world stimuli. For

example, slower processing abilities can present a risk with respect to safe driving. The speed of processing research has examined age differences in the Useful Field of View (a collection of speeded tasks evaluated in the ACTIVE clinical trial) as well as the benefits of speed of processing training to both cognitive abilities and everyday tasks. Prior training research found that improved speed of processing resulted in improved braking times in a driving simulator in addition to significantly reducing the number of dangerous maneuvers made by drivers during an open-road driving evaluation and maintaining the extent of people's driving over an 18-month period. Self-reported difficulty in driving, driving avoidance, and reducing the extent of people's driving all have been found to be associated with slower processing speed. Despite the fact that individuals with impairments appear to self-regulate their driving performance by reducing their exposure to challenging driving situations, studies have shown that these modifications have not been sufficient to eliminate their increased risk of crash involvement. Another measure, the Timed IADL (TIADL) test, provides an index of the time needed to successfully complete five tasks (e.g., finding a number in a telephone book, finding specific items of food on a grocery shelf). The time needed to complete the TIADL tasks is similarly reduced following speed of processing training among older individuals with impaired processing speed. Thus, speed of processing training has been found to generalize to important everyday abilities in addition to boosting cognitive ability.

4. CONCLUSION

Clearly, there are many aspects of cognition that can potentially decline as a part of the aging process, and some of these declines can affect performance of

everyday tasks. There is a growing body of literature demonstrating that these declines can be prevented or slowed through changes in lifestyle. Progress also has been made in the area of cognitive training, indicating that cognitive decline is not necessarily irreversible during older age and that interventions may allow longer maintenance of cognitive function into older age. Furthermore, the fact that many cognitive declines are amenable to moderating effects implies that the independence and mobility of individuals can be extended into later life. In short, the outlook for preventing, delaying, or reversing the onset of age-related cognitive decline is bright.

GLOSSARY

adaptive control of thought (ACT) An influential unified theory of cognition based on a symbolic architecture of the mind, developed by John Anderson. This theory had several different versions; one of the most influential is known as ACT*.

automatic and controlled processes A cognitive process is said to be automatic when its functioning may be triggered by the mere presence of a stimulus, without need for conscious attention. It is called a controlled process when its functioning depends upon conscious attention.

bottom-up and top-down processing Cognitive processing takes place in a bottom-up manner when the direction of the information processing flow goes from simple (or low level) to complex (or higher level) processes. Top-down processing goes in the opposite direction and refers to the influence of high level on lower level processes.

cognitive neuroscience An interdisciplinary enterprise in which cognitive psychology, neuroscience, and computer science cooperate in order to study and understand the relationship between mind and brain; considered a subdivision of cognitive science.

cognitive science An interdisciplinary enterprise in which different branches of scientific knowledge dedicated to

the study of cognition merge. Six disciplines are involved: psychology, computer science, linguistics, philosophy, anthropology, and neuroscience.

connectionism An approach within cognitive science contending that information processing takes place through the interactions of a large number of simple processing elements called units, each sending excitatory and inhibitory signals to other units. Parallel processing and distributed representations are the main characteristics of connectionist (also called PDP) models.

information processing An approach to the study of cognition that considers the human mind as a symbol-manipulating system similar to a computer. Cognition can be divided into a series of stages; at each stage, certain particular operations are performed on incoming information. The eventual performance of the system is thought to be the outcome of this series of stages and operations.

levels of explanation Different viewpoints from where the behavior of a complex information processing system may be considered, described, and eventually explained.

local and distributed representations A representation is said to be local if there is a one-to-one correspondence between entities in the represented world and elements in the representation. In a distributed representation, each entity is represented by a pattern of activity distributed over many elements in the representation, and each element is involved in representing many different entities of the represented world.

neural networks Sets of elementary, neuron-like information-processing units related to each other by excitatory or inhibitory connections. Neural networks form the basic structure of connectionist architectures.

physical symbol system A system consisting of physical symbols. A physical symbol is a physical entity able to

designate or refer to another entity that is the *meaning* of the symbol. Physical symbols form the basic structure of symbolic architectures.

serial and parallel processing Information processing is organized in a serial way when processes are carried out one after another, each taking as input the output of the previous one and beginning operation when the preceding process has finished. When processes are organized in parallel, they operate simultaneously and their input is independent of the output of other processes.

situated cognition A nonrepresentational approach within cognitive science contending that mind, body, and environment are coupled systems, dynamically interacting with each other. Hence, they should not be studied as isolated systems; rather, their mutual interactions should be the main goal of cognitive science.

Soar A general cognitive symbolic architecture for developing systems that exhibit intelligent behavior. It was created by John Laird, Paul Rosenbloom, and Allen Newell.

In the broad sense of the term, cognitivism encompasses all those theoretical approaches that consider the study of the human mind and its constituent processes as the main objective of psychological science. In this sense, psychology, as an experimental enterprise, was cognitive from its very beginning. For example, W. Wundt considered the task of psychology to be the analysis of conscious processes into its constituent elements, and many chapters in William James' book *The Principles of Psychology* were dedicated to analyze processes such as attention, memory, and consciousness, the core cognitive processes. In a more strict sense, cognitivism refers to a particular theoretical approach to studying cognitive processes that originated as a reaction against behaviorism in the midst of the 20th century and is known as the information-processing approach. This article primarily concentrates on the origin and subsequent development of this approach, though attention is also paid to other cognitive views influencing psychological research.

1. COGNITIVISM DURING THE BEHAVIORIST ERA

From a cognitive point of view, the contribution of behaviorism to our knowledge of psychological processes was almost restricted to the realms of learning, motivation, and emotion. Little if any concern was shown about cognitive processes such as perception, attention, memory, and consciousness in the writings

of Hull or Skinner. Even when they made a foray into the territories of thought (C. Hull) or language (B. Skinner), their nonrepresentational approach turned out to be too restricted and had little influence on subsequent research. Among behaviorists, E. Tolman was one of the few who did not show disdain for using terms and concepts with a cognitive flavor. Even in his case, however, those terms did not refer to processes to be studied for their own interest; rather, they were conceptualized as intervening variables useful to predict behavior.

It should be mentioned, however, that behaviorism did provide a lasting contribution to cognitive and psychological research in general. Emphasis on the measurement of variables, the careful design of experiments, and the wide-ranging use of objective scientific methods is part and parcel of the invaluable legacy of behaviorism. Thanks to this methodological heritage, modern cognitivism could establish itself on a solid scientific foothold.

Despite the general sway of behaviorism during the second quarter of the 20th century in the United States, interest in cognitive research remained active within restricted domains of psychological inquiry. This was particularly so in Europe, where the influence of behaviorism took longer to be felt and was never as strong as it was in the United States. The following streams of investigation deserve to be pointed out:

1. The contribution of Gestalt psychologists to the development of perceptual theory.
2. Research on concept formation, problem solving, and thinking by researchers such as Edouard Claparède, Wolfgang Köhler, and Frederic Bartlett.
3. The sociohistorical approach to cognitive development carried out in Russia by Lev Semenovitch Vygotsky.
4. Jean Piaget's research program on cognitive development and genetic epistemology in Switzerland. Piaget was one of the first thinkers to realize the interdisciplinary nature of cognitive research. In 1955 he founded the International Center for Genetic Epistemology in Geneva, where scientists from different disciplines tried to set up the foundations of a true cognitive science. Piaget influence on cognitive development and educational psychology is still noticeable today; research along his line of thinking is an integral part of contemporary cognitive research.
5. It is important to recognize that, in some areas of psychology, behaviorism never played the dominant role it did within experimental psychology. References

to mind and mentalistic concepts never disappeared from social and clinical psychology. Authors such as Kurt Lewin, Leon Festinger, Erich Fromm, Carl Rogers, and Abraham Maslow are only a few among the many who did not adhere to the dominant behavioristic approach.

All these streams of investigation paved the way for what has come to be known as the cognitive revolution.

2. THE INFORMATION-PROCESSING APPROACH

Cognitivism, as it was articulated within the information-processing approach, was from its beginning the result of multiple lines of thought coming from different scientific disciplines. Within psychology, there was a profound dissatisfaction with behaviorism as a method of tackling complex human behavior. World War II compelled psychologists to face practical problems, such as the manipulation of aircraft, radar, and other highly technical devices involving multiple stimuli and responses and posing heavy demands on human operators. In these situations, concepts from the animal learning labs had little application, so psychologists turned to communication engineering and information theory for help. The human operator was conceptualized as an information transmitter and decision maker, and research on selective attention followed as a matter of course.

In 1959, the linguist Noam Chomsky published a devastating review of Skinner's book *Verbal Behavior*; his review was also an attack on other behavioristic accounts of language. As an alternative to studying linguistic performance, Chomsky emphasized linguistic competence, knowledge about the rules of grammar that the native speaker of a language owns. Under Chomsky's influence, psychologists became interested in the cognitive processes responsible for the structural aspects of human language. Subsequently, the significance of linguistic structures for our understanding of memory and thought was increasingly acknowledged.

The most determining influence, however, came from the realm of computer science. Computers are general purpose machines that can be programmed to perform any well-defined task. As information-processing systems, they are able to receive, store, transform, and retrieve information. A computer performance may be analyzed at the physical level of circuits used to implement the

system (hardware), but there is a different, more abstract program level (software) that lends itself as an adequate analogy for the human mind. Programs are sets of instructions ready to act upon data; they may take diverse sequences of actions depending upon different conditions. As both instructions and data are stored in the same symbolic form, programs can also act upon themselves in a recursive manner, changing their own instructions if the task demands it.

When computers first appeared, they were largely considered to be mathematical devices, number-manipulating machines that would make calculations easier. But it soon became apparent that they were able to deal not only with numbers but also, more generally, with symbols. Thus, computers came to be conceptualized as symbol-manipulating systems. Computers can take symbolic input, recode it, store it, retrieve it, make decisions based on the recoded information, and produce symbolic output. These operations closely resemble mental processes and offer a precise and mechanistic way of thinking about them. Hence the computer became the best metaphor to lead the scientific research of the human mind.

There is general agreement that the critical time period giving a boost to cognitivism took place between 1954 and 1960. In 1956, a summer seminar took place at Dartmouth, where Allen Newell, Herbert Simon, and other major workers on artificial intelligence gathered to establish a research program for the new discipline interested in building programs able to generate intelligent behavior. In 1958, another summer seminar was organized by Newell and Simon at the RAND Corporation in Santa Monica in order to acquaint psychologists with computer simulation techniques and their application to the study of cognitive processes. In 1960, the Center for Cognitive Studies was created at Harvard, where Jerome Bruner and George Miller served as a point of reference for the new cognitive psychology.

3. COGNITIVE SCIENCE

The time from 1960 to approximately 1976 was a consolidation period for cognitive psychology. Processes such as attention, memory, language, and thought moved to the forefront of psychological research. In 1967, Ulric Neisser published a textbook, titled *Cognitive Psychology*, that served as a reference for the psychological research that was being done within the new cognitive framework. The heuristic value of the computer analogy was widely accepted, though it was

not understood the same way by all researchers. For some, the computer was just a metaphor that helped to conceptualize human mind as an information-processing system. For others, however, the computer was much more than a metaphor; they assumed that both the computer and the mind were examples of a type of system with specific properties. In 1976, Newell and Simon proposed the term physical symbol system as a name for this type of system and as a fundamental concept for a general and unifying approach to cognition that came to be known as cognitive science. That same year, the Sloan Foundation became interested in this approach and created an interdisciplinary research program to explore its possibilities. In 1977, the journal *Cognitive Science* was founded, and the Cognitive Science Society followed 2 years later. Nowadays cognitive science has been established as an academic discipline in several universities in different countries.

Cognitive science was an interdisciplinary enterprise in which different branches of scientific knowledge dedicated to the study of cognition merged. Originally, there were six disciplines involved, namely, psychology, computer science, linguistics, philosophy, anthropology, and neuroscience. Each had developed a particular way of looking at cognition, and some already had productive bilateral relations that had given rise to new fields of cognitive research, as was the case for psycholinguistics or computational linguistics. Nevertheless, there was the shared belief that progress within each discipline largely depended upon progress in the rest of them. Today, links between the six disciplines exist, though some are stronger than others, and new fields of research, as is the case for cognitive neuroscience, have emerged.

4. TENETS OF COGNITIVISM

4.1. Levels of Explanation

Cognitivism is not reductionist; it maintains that complex information-processing systems, such as the computer or the human mind, cannot be understood as a simple extrapolation of the properties of its elementary components. To understand a complex system, we have to take into consideration the fact that its behavior can be described at different levels of abstraction, each related to particular questions that may be asked about the system. If an explanation is conceptualized as an answer to a specific question, then we must be open to expect different explanations depending upon

the description level associated to the question. The classical view of cognitive science distinguishes at least three different levels of analysis, named according to David Marr terminology.

4.1.1. The Computational Level

The computational level is the level of abstract problem analysis and refers to what the system does and why. At this level, explaining why people or computers do something requires pointing to their goals and objectives and to the strategies and means to carry them out. Take, as a simple example, the case of a calculator able to perform number addition. An explanation of what the machine does and why should be found in arithmetic theory, because the task to be performed by the system has to comply with the principles of this theory.

4.1.2. The Algorithmic Level

The algorithmic level is the program level in which a representation for coding the system's input and output should be specified, together with an algorithm providing the appropriate output for a given input. This level refers to how the system brings about its task. It is also called the symbol level, because the goals established at the computational level are encoded by symbolic expressions. In the case of the calculator from the example above, explaining how the system resolves an addition has to do with the representation used to encode numbers (Arabic, Roman, or binary, for instance) and the specific algorithm employed, for example, adding the units first and carrying to the tens if the sum exceeds 9.

4.1.3. The Level of Physical Implementation

The level of physical implementation is concerned with the particular technology used to physically realize the system. In our example, an explanation at this level would point to the working of electronic circuits, but electronic circuits are not the only way to implement an addition machine. Old cash registers, for example, were not electronic but mechanical; however, they could use the same algorithm as an electronic calculator to perform addition.

These three levels are frequently related and influence each other; for example, the choice of electronic circuits to build an addition machine may favor a binary over a decimal representation of numbers. However, it is convenient to note that, because the

three levels are not necessarily bound, some phenomena may find an explanation at only one or two of them. Above all, it should be noted that it is pointless to search for only one valid explanation of the behavior of complex information-processing systems. An explanation only makes sense in relation to a question referred to a particular level of analysis. Therefore, we need explanations at different levels in order to understand complex information-processing systems.

4.2. Systems Approach

Cognitivism views human cognition as an activity emerging from the interaction of a system of components. Though the search for components is considered a valuable aspect of the scientific activity, cognitivism emphasizes the significance of structure and functional architecture for our understanding of the mind.

From the beginning, cognitive psychology made wide use of flowchart models as a means of specifying the component processes involved in a particular situation. D. Broadbent's model was one of the first to specify the attention and memory components needed to explain human behavior in situations in which a person has to select one out of several different streams of information, as exemplified by a cocktail party, where a person has to follow one among many surrounding conversations. At first, models tended to be bound to specific tasks or situations, but soon interest for building general models became dominant. The model of human memory advanced by R. Atkinson and R. Shiffrin in 1968 is a good example of this trend. These authors were able to develop a memory model consisting of three different components, namely, sensory registers, short-term memory, and long-term memory. Extensive previous research had been carried out on each of these components, but Atkinson and Shiffrin managed to put them together within a general framework that was influential for years. Memory research also offers a good illustration of the analytic procedure that cognitive research employed to determine the components of a cognitive system. Five years after the model of Atkinson and Shiffrin was published, E. Tulving argued in favor of the partition of long-term memory into an episodic component and a semantic component. Later, in the 1980s, it was proposed that both episodic and semantic memory were part of a declarative or explicit component of memory having to do with conscious knowledge, but research also focused on an implicit, largely unconscious component of memory dealing with knowledge

related to cognitive, motor, and perceptual skills. Though there is no general agreement about the psychological reality of all these components and some authors consider the increasing number of them as a plain violation of the scientific principle of parsimony, a large group of psychologists views this tendency as a result of many years of analytic research and as a valuable way to make contact with brain research.

With the advent of cognitive science, the term cognitive architecture came to be used as a way to indicate that the structure of the cognitive system had some sort of primitive and permanent character. Search for this character divided the field of cognitive science into two conflicting views. On the one hand, the classical view considered the concept of the physical symbol as the building block of cognitive architecture and defined a cognitive system as a physical symbol system. On the other hand, a new connectionist view considered the concept of the neural network to be the basic unit of analysis for understanding the human cognitive system.

A physical symbol is a physical entity able to designate or refer to another entity that is the meaning of that symbol. For centuries this capacity to refer to something else was thought to belong only to the realm of ideas, and an idea was considered to be nonmaterial. As mentioned previously, the computer became a model for the human mind when scientists became aware that a computer was a symbol-manipulating machine rather than a machine dealing only with numbers. The physical symbol concept, by attributing to physical entities the capacity of having meaning, became a key concept in bridging the gap between brain and mind. In turn, a physical symbol system was defined as a system constituted by physical symbols. The adaptive control of thought (ACT) and the Soar systems, developed by John Anderson and Allen Newell, respectively, are two of the most influential current symbolic architectures.

The connectionist view represented an attempt to associate cognitive science with brain theory. Though the origin of the concept neural network goes back to Donald Hebb, and some interesting work on neural networks had already been done during the first years of cognitivism, the impulse that brought connectionism to the fore took place in the mid-1980s. Connectionists tried to build information-processing systems that were neurally inspired and called computation on such a system brain-style computation because they thought that the primitive concepts of a cognitive model should resemble the primitive units of the brain, neurons.

A neural network is composed of a set of elementary, neuron-like processing units connected to each other

in a specific way. The different strengths of the connections among units defines a pattern of connectivity that may change through experience according to a particular learning rule. An activation rule determines the way different inputs to a unit combine to determine the unit's state of activation, and an output function is in charge of mapping the unit state of activation into output. The only other component of a neural network is an environment within which the system can operate. Systems of this kind have been successfully used to explain performance on cognitive tasks as well as to model cognitive processes. For some time there were major disputes between defenders of symbolic and connectionist architectures. Nowadays, the arguments have abated, and many cognitive scientists make free use of both symbolic and neural network architectures depending upon the problem at hand. Neural networks seem best suited to model knowledge dependent on long, repetitive practice, as is usually the case in implicit knowledge. On the other hand, symbolic architectures appear preferable for modeling high-level cognitive processes such as reasoning or thought.

4.3. Representation

One of the main characteristics defining a particular system as cognitive is its capacity to reinstate a prior experience in the absence of a current external stimulus. We say that such a system owns the capacity to represent its environment.

Interest in mental representation as such was not a relevant feature of the first cognitive models. As discussed previously, they mainly dealt with mental structure and its components. Reference to mental representation was implicit in the use of terms such as encoding and recoding, but interest in the mental code itself had to wait until the early 1970s.

To understand what representation is we should differentiate the representing world from the represented world. The representing world has to somehow imitate the represented world, though not every possible aspect of the latter must be reflected in the former. For any representation, the following three features must be specified:

1. What aspects of the represented world are chosen to be encoded;
2. What elements of the representing world are doing the encoding;
3. What the correspondence is between the two worlds.

Research on mental images and memory brought to the forefront the very problem of mental representation. Was the representation responsible for mental images different from abstract semantic or syntactic representations? Were there analogical representations? These questions divided the field of cognitive psychology in two halves, one for and the other against analogical representations, a debate that still continues, although recent research in cognitive neuroscience seems to favor their existence. In the field of semantic memory, a plethora of representational formats for abstract knowledge were advanced within the framework of symbolic architectures. Prototypes, semantic features, semantic networks, schemata, and production systems were some of the main formats employed, but none attained general acceptance. Some investigators tried to build semantic representations based on a handful of primitive structures, but most models using symbolic architectures turned to local representations. In a local representation, there is a one-to-one correspondence between entities in the represented world and elements in the representing world.

Connectionist systems use distributed representations. In a distributed representation, each entity is represented by a pattern of activity distributed over many elements in the representing world, and each element represents many different entities. Distributed representations have proved to be very effective in dealing with aspects of cognition that were difficult to implement on symbolic architectures. Content-addressable and reconstructive memories, ability to generalize automatically to novel situations, and capacity to be modified according to a changing environment are genuine achievements of distributed architectures.

Cognitive science, symbolic cognitive science in particular, has been criticized for the way it has elaborated the notion of representation. Criticisms range from denying a particular characteristic of the representation, like that of being symbolic or abstract, to calling the entire notion into question. A common trait for these views is their concern about treating mind, body, and environment as coupled systems, dynamically interacting with each other; hence the term situated cognition is often used for this approach. It emphasizes that representations undergo continuous changes in tune with changes in the environment and encourages research on the changing patterns of behavior over time, using nonlinear differential equations to do the modeling. From this point of view, the best way to construct cognitive models is to build real agents. So far, the main contributions of this viewpoint

are to be found in the fields of perception and motor processes. To what extent this approach may be useful in understanding higher cognitive processes remains to be seen.

4.4. Process

Processes are operations acting on a representation either to generate it or to transform it in some way. They may be involved in translating external input into a particular representation, modifying the representation itself, or generating output. A process may be considered a function mapping an input to an output.

Interest in elementary mental operations goes back to the Dutch physiologist F.C. Donders in 1868. He assumed that the time spent by an agent performing a task could be divided into a series of stages, each of which corresponded to an elementary component process of the task. By using simple tasks, supposedly consisting of few elementary components, and subtracting the time spent in performing one task from the time corresponding to the next more complex one (with an extra elementary component), Donders thought to have isolated the time for simple cognitive processes such as detection or discrimination. Two assumptions relevant for cognitive psychology underlay Donders' experimental program: the existence of elementary mental operations and their serial organization as component processes of a complex task.

The information-processing approach has tended to rely on the assumption that a small number of elementary mental operations are sufficient to specify the complexity of human cognitive performance. However, there is little agreement about what the elementary operations are and about the ultimate level of description appropriate for an elementary operation. Connectionist models offer an alternative because they use only activation and inhibition as elementary processes acting on neuron-like elementary units, but many researchers prefer descriptions in more intuitive terms referring to information-processing stages.

A central issue for information-processing theories is the way in which mental processes are assembled in order to perform a task. Early cognitive models assumed a serial organization of processes; they were carried out one after another, each process taking as input the output of the previous one, and starting operation when the preceding process had finished. It soon became apparent that many cognitive processes in perception, memory, and other cognitive areas could not be understood on the basis of serial

organization only; rather, they seemed to operate simultaneously, that is, in parallel. Parallel functioning of processes is typically associated with division of labor and modularity. A module, much like a subroutine in a computer program, is made up of a set of operations carrying out a particular assignment in the service of a larger task. It has been much debated whether the entire human mind or only some cognitive processes are modularly arranged. Nevertheless, there seems to be general agreement that modularity is a characteristic of low- rather than high-level cognitive processes. Connectionism has made parallel processing a distinctive feature of its approach. The term parallel distributed processing, often used as an alternative name for connectionism, highlights the two defining characteristics of this view, namely, distributed representation and parallel processing. Even so, many connectionist models group their simple, neuron-like units into layers, thus allowing for some serial organization of information processing stages.

An additional dimension introducing differences within cognitive theory has to do with the direction of the processing flow. Some theories and models emphasize bottom-up processing, in which the entire job is carried out by algorithms acting on input data to build increasingly complex representations. David Marr's influential theory of vision is a good example of a cognitive theory built from a bottom-up point of view. On the other hand, top-down processing emphasizes the feedback influence that complex cognitive component processes, such as goals, beliefs, and knowledge, exert on the functioning of simpler ones. A process is said to be data driven when its working is independent of feedback influences from goals, intentions, or other higher level processing stages. A process depending upon these influences is said to be conceptually driven. The most powerful cognitive models are usually interactive, meaning that they include both bottom-up and top-down processing.

Another frequently used classification of cognitive processes is the division between automatic and controlled processes. An automatic process usually refers to a sequence of component subprocesses that is triggered by a particular input. The sequence may include both bottom-up and top-down processing. An automatic process may be built-in as part of the physical implementation of a system, or its components may be assembled as a result of practice. Thus, to the extent that automaticity depends on practice, it should be considered a gradual rather than an all-or-none property for processes. On the other hand, when a new sequence of component

processes is required, top-down attentional influences are needed to do the assembling. In this case, the sequence is called a controlled process, meaning that it is under attentional control. Automaticity and dependence upon attentional control are complementary characteristics of mental processes; the more automatic a process is, the less attentional control it needs to act. Distinguishing between automatic and controlled processes has become very useful in psychological research. This distinction partially overlaps with that between explicit and implicit or between conscious and unconscious processes. Further research on this area will likely reveal fundamental characteristics of the human cognitive system.

4.5. Methods

Cognitivism brought to psychology new research methods and new ways of approaching more traditional ones. Reaction time came to be one of the main dependent variables used to understand cognitive processes. As mentioned before, Donders' subtractive method and more sophisticated later developments, like S. Sternberg's additive factors method, served as a guide in that reaction time was not studied by itself, but as an index for making inferences about nonobservable processes. Accuracy measures were also developed with the same purpose. In 1954, signal-detection theory was applied to perception by W. Tanner and J. Swets, providing indexes of perceptual functioning uncontaminated by the observer's decision biases. Subsequently, signal detection was also applied to memory and became a valuable tool for studying diagnostic systems.

Modeling cognitive processes was a research method characteristic of the cognitive approach. Mathematical as well as flow-chart models were widely used in the early days, but computer models, either symbolic or connectionist, were soon considered the high road to understanding cognitive processes. Computer modeling helped psychologists become aware of cognitive processing intricacy and forced them to be specific about the mechanisms involved in a particular task.

Recently, methods from the realm of neuroscience have been incorporated into cognitive research. These days, electrophysiological and brain-imaging techniques allow online recording of brain activity while a person is performing specific cognitive tasks. These technological advances provide a unique opportunity to relate brain activity to cognitive performance and to establish connections between cognitive constructs and brain

structures and processes. An entirely new and promising field of research, known as cognitive neuroscience, has appeared, bringing new horizons for cognitive research.

5. COGNITIVIST INFLUENCE

The influence of cognitivism pervades every field of psychological research and spreads to the entire realm of social sciences. The term cognitive, considered vague and nonscientific during the behaviorist era, has now become respectable and scientific. Different approaches within cognitive science provide new ways of thinking about mental processes and intelligence. The study of human intelligence, once restricted to the statistical analysis of psychological tests, has now expanded to the working of mental machinery. The intelligence factors isolated by means of factor analysis are being studied in relation to cognitive constructs, thus bridging a long-lasting gap between differential and experimental psychology. As almost every article in this encyclopedia shows, cognitive factors are frequently mentioned as relevant causes in the explanation of different practical situations. We learn about cognitive ergonomics, cognitive behavior modification, cognitive neuropsychology, and other cognitive enterprises as truly influential approaches within applied psychology. Each one deserves to be treated separately.

Collective Action

Bert Klandermans

Free University of Amsterdam, Amsterdam, The Netherlands

1. What Is Collective Political Action?
2. Why Do People Participate in Collective Political Action?
Further Reading

GLOSSARY

collective action frames Sets of collective beliefs that serve to create a frame of mind in which participation in collective action appears meaningful.

collective identity A place shared with other people.

collective incentives Incentives that relate to achievement of the movement's goals and the extent to which participation in a specific activity contributes to goal achievement.

erosion of support The process whereby people lose their sympathy for the movement in the course of a mobilization campaign.

free rider A person who refrains from participation, assuming that he or she will reap the benefits of the collective action anyway.

grievances Experiences of illegitimate inequality, feelings of relative deprivation, feelings of injustice, and/or moral indignation about some state of affairs.

identity Participation as an expression of identification with a group.

ideology Participation as a search for meaning and an expression of one's views.

instrumentality Participation as an attempt to influence the social and political environments.

mobilization The transformation of potential participants (sympathizers) into participants.

nonconversion of support The failure to convert sympathizers into participants because organizers failed to target them or were unable to motivate them.

personal identity The set of places that a person occupies in society.

selective incentives Incentives that relate to costs and benefits that differentiate between participants and nonparticipants.

On February 15, 2003, millions of people took to the streets in hundreds of cities in 60 countries throughout the world. In what was probably the largest collective action ever staged in human history, they protested against the imminent war in Iraq. Men and women of all ages expressed their aversion to the planned invasion. They were mobilized through the media, through organizations in which they were members, and by people who knew them. They came alone or with family and/or friends. They detested their government if it supported the war or applauded their government if it opposed the war. Obviously, these were not random samples of the population that walked the streets. The vast majority of the participants placed themselves at the left end of the political spectrum. They were predominantly white-collar workers or students who were highly educated. They were people who were interested in politics, and many had taken

part in demonstrations previously. The antiwar demonstrations were examples of an increasingly common form of political behavior, namely, collective action. What is collective action, why do people participate in such action, and how are these people mobilized? This article addresses these questions. Although the concept of collective action has a broader use, the article restricts itself to collective political action.

1. WHAT IS COLLECTIVE POLITICAL ACTION?

Collective political actions are challenges by people with common purposes and solidarity in interaction with elites and authorities. This definition includes two key elements that deserve some elaboration. First, collective political actions are challenges. They concern disruptive direct action against elites, authorities, other groups, or cultural codes. There is an obvious reason why this is the case. Collective political action is typically staged by people who lack access to politics. If they had access, there would be no need for the action. However, disruption forces authorities to pay attention to the claims brought forward. Second, collective political actions concern people with a common purpose and solidarity. Participants rally behind common claims. They want authorities to do something—to change a state of affairs or to undo changes. Such common claims are rooted in feelings of collective identity and solidarity. If these challenges gain sustainability, they constitute a social movement.

Collective political action has become much more frequent over recent decades. For example, in 1975, 22% of people in Britain signed at least one petition; in 1990, the figure was 75%. In 1974, 9% of people in Britain participated in at least one demonstration; in 1990, the figure was 25%. Between 1979 and 1993, the number of protest events in the French city of Marseille more than doubled, from 183 to 395 events per annum. During that same period, considerable increases in protest events in Germany were reported, a result that was confirmed in 1995 by Kriesi and colleagues' now classic study on new social movements in Europe. At the same time, diffusion to broader sectors of the population was witnessed. Across age groups and gender lines, from the left to the right, among workers and students, and in Western and non-Western societies alike, collective political action has become a common phenomenon.

2. WHY DO PEOPLE PARTICIPATE IN COLLECTIVE POLITICAL ACTION?

The social psychology of protest suggests three fundamental motives for participation in collective political action in that people may want to (a) change their circumstances, (b) act as members of their group, and/or (c) give meaning to their world and express their views and feelings. This article suggests that these three motives together account for most of the motivation to participate in collective political action in a society refers to these motives as instrumentality, identity, and ideology. Instrumentality refers to participation as an attempt to influence the social and political environment. Identity refers to participation as an expression of identification with a group. Ideology refers to participation as a search for meaning and an expression of one's views. This article does not suggest that these are mutually exclusive motives or are competing views on collective action participation, although some parties in the debates in the literature seem to have taken that position. However, this article concurs with those who argue that approaches that neglect any of these three motives are fundamentally flawed. To be sure, individual participants may participate due to a single motive, but all three motives are needed to understand why people take part in collective political action. Of course, that raises the question of how the three motives interact in fostering participation. The article elaborates on this in the following discussion of the motivation to participate.

2.1. The Motivation to Participate in Collective Action

2.1.1. Instrumentality

Instrumentality begins with dissatisfaction, be it the experience of illegitimate inequality, feelings of relative deprivation, feelings of injustice, moral indignation about some state of affairs, or a so-called suddenly imposed grievance, that is, an event imposed on people (e.g., highway construction in the neighborhood). Social psychological grievance theories, such as relative deprivation theory and social justice theory, have tried to specify how and why grievances develop. Despite the fact that grievances are at the roots of collective political action, they have not featured prominently in social movement literature since the early 1970s. Resource mobilization theory and political process theory, the

two approaches that have dominated the field since those days, have always taken as their point of departure that grievances are ubiquitous and that the key question in action participation research is not so much why people are aggrieved as it is why aggrieved people participate. The instrumentality paradigm holds that participants are people who believe that they can change their social and political environments at affordable costs.

The perceived costs and benefits of collective action can be distinguished in selective and collective incentives. Selective incentives relate to costs and benefits that differentiate between participants and nonparticipants. People are spending time and/or money only if they participate, people run the risk of being beaten up by the police only if they participate, people's friends will blame them for not participating only if they stay home, and so on. Sometimes, movement organizations try to make participation more attractive by providing selective benefits (e.g., a popular music group, a train ticket to the city where the demonstration is held, a T-shirt). Authorities or opponents, for their part, can try to make participation less attractive by imposing costs on participants. Collective incentives are related to achievement of the movement's goals and the extent to which participation in a specific activity contributes to goal achievement. Obviously, it is not enough for a goal to be important to a person. What is also needed is some likelihood of success. The problem with collective action is that it is difficult to know to what extent an activity will have any influence on authorities. In any event, chances are low that an activity will have any impact if only a few people participate. Therefore, the likelihood of success depends on the expected behavior of others. If too few people participate, it is unlikely that the activity will make any difference. As a consequence, expectations about the behavior of others play an important role in the decision to participate. If someone expects that only a few people will participate, that person's motivation to participate will be low. In a way, the expectation about other people's behavior functions as a self-fulfilling prophecy. If people believe that few people will participate, they will not be motivated to participate and, thus, will help make their own expectation come true.

Instrumentality presupposes an effective movement that is able to enforce some wanted changes or at least to mobilize substantial support. Making an objective assessment of a movement's impact is not an easy task, but movement organizations will try to convey the image of an effective political force. They can do so

by pointing to the impact they have had in the past or to the powerful allies they have. Of course, they may lack all of these, but they might be able to show other signs of movement strength. A movement may command a large constituency as witnessed by turnouts at demonstrations, by membership figures, or by large donations. It may be composed of strong organizations with strong charismatic leaders who have gained respect. Instrumentality also implies the provision of selective incentives. Movements may vary considerably in the selective incentives for participation they provide. Obviously, this is also a matter of the resources that a movement commands. Surprisingly little comparative information is available on the resources that movements have at their disposal. In a similar vein, systematic documentation is lacking on the ways in which the larger political system and the alliances and opponents of movement organizations influence movement participation. In 1978, Tilly coined the now classic terms "repression" and "facilitation" to distinguish between political systems that increase and decrease the costs of participation. Indeed, repressive political environments may increase the costs of participation considerably. People may lose friends, they may risk their jobs or otherwise jeopardize their sources of income, they may be jailed, and they may even lose their lives.

Viewed from an instrumental perspective, a solution to the dilemma of collective action must be found. It was through the work of Olson that students of movement participation became aware of the problem. In 1968, Olson published his *The Logic of Collective Action*. The core of the book was the argument that rational actors will not contribute to the production of a collective good unless selective incentives persuade them to do so. Collective goods are characterized by "jointness of supply." That is, if they are made available to one person, they become available to everybody irrespective of whether people have contributed to the production of the collective good (e.g., a law against discrimination, measures against pollution). Therefore, according to Olson, a rational actor will choose to take a free ride unless selective incentives (i.e., costs or benefits that are made contingent on participation in the production of the collective good) prevent him or her from doing so. Olson's argument was soon applied to social movement participation. It helped to explain why so often people do not participate in social movements despite their interest in the achievement of the movements' goals. Movement scholars argued that movement goals typically are collective goods. If a goal

is achieved, people will enjoy the benefits irrespective of whether they have participated in the effort. In view of a goal for which achievement is uncertain but for which benefits—if they materialize—can be reaped anyway, rational actors will take a free ride.

However, social movement scholars quickly discovered that reality is more complex than Olson's simple model suggests. The problem with Olson's logic of collective action is that it provides an explanation for why people do not participate but fares poorly in explaining why people do participate. Moreover, Olson's solution that people participate for selective incentives is fundamentally flawed because it does not give a satisfactory answer to the question of where the resources needed to provide selective incentives come from. If these resources must be collected from individual citizens, the same collective action dilemma arises again. This is not to say that selective incentives are irrelevant; however, in the final instance, they cannot solve the collective action dilemma. In other words, if collective and selective incentives do not provide a sufficient explanation of movement participation, what else might make the difference? A recurring criticism was that Olson's model assumes that individuals make their decisions in isolation, that is, as if there are no other people with whom they consult, with whom they feel solidarity, and by whom they are kept to their promises. This pointed to the significance of collective identity as a factor in movement participation.

2.1.2. Identity

It soon became clear that instrumentality, or movement participation to achieve some external goal (social or political change), was not the only reason to participate. After all, many external goals are reached only in the long run if at all. Similarly, when it comes to material benefits, costs frequently outweigh benefits. Apparently, there is more involved in being a movement participant than perceived costs and benefits. Indeed, one of those motives relates to belonging to a valued group.

Identity can be described succinctly as a place in society. People occupy many different places in society. They are students, housewives, soccer players, politicians, farmers, and so on. Some of those places are exclusive, that is, occupied by only a small number of people (e.g., the members of a soccer team). Others are inclusive and encompass large numbers of people (e.g., Europeans). Some places are mutually exclusive (e.g., male/female, employed/unemployed), some are nested (e.g., French/Dutch/German vs European), and some

are crosscutting (e.g., female and student). All of these different roles and positions that a person occupies form his or her personal identity. At the same time, every place a person occupies is shared with other people. The author of this article is not the only professor of social psychology, nor is he the only Dutch or the only European. He shares these identities with other people, a fact that turns them into collective identities. Thus, a collective identity is a place that is shared with other people. This implies that personal identity is always collective identity at the same time. Personal identity is general, referring to a variety of places in society, whereas collective identity is always specific, referring to a specific place.

Most of the time, collective identities remain latent. Self-categorization theory hypothesizes that an individual may act as a unique person (i.e., display his or her personal identity) or as a member of a specific group (i.e., display one of the many collective identities he or she has depending on contextual circumstances). Contextual factors may bring personal or collective identity to the fore. Obviously, this is often not a matter of free choice. Circumstances may force a collective identity into awareness whether people like it or not. The Yugoslavian and South African histories have illustrated this dramatically, and there are other equally or even more dramatic examples throughout human history. But collective identities can also become significant in less extreme circumstances. For example, consider the possible effect of an announcement that a waste incinerator is planned next to a certain neighborhood. Chances are that within very little time, the collective identity of the people living in that neighborhood will become salient.

Self-categorization theory proposes that the more people identify with a category, the more they are prepared to employ a social category in their self-definition. Identification with a group makes people more prepared to act as a member of that group. This assertion refers, of course, to identity strength. Social identity literature tends to neglect that real-world identities vary in strength. But identifying more or less strongly with a group may make a real difference, especially in political contexts. Moreover, strong identities may be less affected by context. Following this reasoning, we may expect that strong identities make it more likely that people act on behalf of their group. The basic hypothesis regarding collective identity and movement participation is fairly straightforward. A strong identification with a group increases the likelihood of participation in collective political action on

behalf of that group. The available empirical evidence supports this assumption overwhelmingly.

Movements offer the opportunity to act on behalf of one's group. This is most attractive if people identify strongly with their group. The more farmers identify with other farmers, the more appealing it is to take part in farmers' protests. The more women identify with other women, the more inviting it is to participate in the women's movement. The more gay people identify with other gay people, the more they are attracted by the possibility of taking part in the gay movement. In addition to the opportunity to act on behalf of the group, collective political action participation offers the opportunity to identify with the movement's cause, the people in the movement, the movement organization, the group in which one is participating, and/or the leader of the movement. Not all of these sources of identification are always equally appealing. Movement leaders can be more or less charismatic, and the people in the movement or in someone's group can be more or less attractive. Moreover, movements and movement organizations may be, and in fact often are, controversial. Hence, becoming a participant in a movement organization does not mean taking a respected identity on oneself—quite the contrary. Within the movement's framework, of course, this is completely different. There, the militant does have the status that society is denying him or her. And for the militant, of course, in-group/out-group dynamics may turn the movement organization or group into a far more attractive group than any other group "out there" that is opposing the movement. Indeed, it is not uncommon for militants to refer to their movement organization as a second family, that is, as a substitute for the social and associative life that society is no longer offering them. Movement organizations not only supply sources of identification but also offer all kinds of opportunities to enjoy and celebrate the collective identity—marches, rituals, songs, meetings, signs, symbols, common codes, and so on.

2.1.3. Ideology

The third motive—wanting to express one's views—refers at the same time to a long-standing theme in the social movement literature and to a recent development. In classic studies of social movements, the distinction was made between instrumental and expressive movements or protests. During those days, instrumental movements were seen as movements that aimed at some external goal (e.g., implementation of citizenship rights). Expressive movements, on the other hand, were

movements that had no external goals and for which participation was a goal in itself (e.g., expression of anger in response to experienced injustice). Movement scholars felt increasingly uncomfortable with the distinction because it was thought that most movements had both instrumental and expressive aspects and that the emphasis on the two could change over time. Therefore, the distinction lost its use. Recently, however, the idea that people might participate in movements to express their views has received renewed attention. Attention arose this time from movement scholars who were unhappy with the overly structural approach of resource mobilization and political process theory. These scholars began to put an emphasis on the creative, cultural, and emotional aspects of social movements such as music, symbols, rituals, narratives, and moral indignation. People are angry, develop feelings of moral indignation about some state of affairs or some government decision, and wish to make these feelings known. They participate in social movements not only to enforce political change but also to gain dignity in their lives through struggle and moral expression.

Ideology has a significant affective component. Acting on one's ideology is deemed to be one of the fundamental motives of action participation and is necessarily charged with emotion. Appraisal and action are socially constructed. That is, they are formed in interpersonal interaction, especially in the case of politically relevant emotions. Cultural and historical factors play an important role in the interpretation of the state of affairs by which politically relevant emotions are generated. Obviously, appraisal can be manipulated. Activists work hard to create moral outrage and anger and to provide a target against which these can be vented. They must weave together a moral, cognitive, and emotional package of attitudes. But emotions also play an important role in the ongoing activities of movements. The literature distinguishes two kinds of collective emotions—reciprocal emotions and shared emotions—that reinforce each other. Each measure of shared outrage against an injustice reinforces the reciprocal emotion of fondness for others precisely because they feel the same way. Conversely, mutual affection is a context in which newly shared emotions are easily created. Anger and indignation are emotions that are related to a specific appraisal of the situation. At the same time, people might be puzzled by some aspects of reality and may try to understand what is going on. They may look for others with similar experiences, and a social movement may provide an environment in which to exchange experiences, tell their stories, and express their ideologies.

Social movements play a significant role in the diffusion of ideas and values. In 1998, Rochon made the important distinction between “critical communities” (where new ideas and values are developed) and “social movements” (which are interested in winning social and political acceptance for those ideas and values). “In the hands of movement leaders, the ideas of critical communities become ideological frames,” stated Rochon, who continues to argue that social movements are not simply extensions of critical communities. After all, not all ideas developed in critical communities are equally suited to motivate collective action. Social movement organizations, then, are carriers of meaning. Through processes such as consensus mobilization and framing, they seek to propagate their definitions of the situations to the public at large. A study of flyers produced by the various groups and organizations involved in the protests against the International Monetary Fund and the World Bank in Berlin, Germany, is an excellent example in this respect. The study showed how links were constructed between the ideological frame of the organizers of the demonstration and those of the participating organizations so as to create a shared definition of the situation. In the social movement literature, such definitions of situations have been labeled “collective action frames.”

Social movements do not invent ideas from scratch; rather, they borrow from the history of ideas. They build on an ideological heritage as they relate their claims to broader themes and values in society. In so doing, they relate to societal debates that have histories of their own, and those histories are usually much longer than those of the movements themselves. In 1992, Gamson referred to the “themes” and “counterthemes” that, in his view, exist in every society. One such pair of a theme and counter-theme that Gamson mentioned is that of “self-reliance” versus “mutuality,” that is, the belief that individuals must take care of themselves versus the belief that society is responsible for its less fortunate members. Klandermans has demonstrated how, in The Netherlands, these two beliefs became the icons that galvanized debate and spurred protest over disability payments. Self-reliance became the theme of those who favored restrictions in disability payment, whereas mutuality was the theme of those who defended the existing system.

2.2. The Transformation of Potentiality into Action

People who are potentially prepared to take part in collective action do not automatically participate.

Potential must be transformed into action. This is in fact what most mobilization campaigns are about—targeting potential participants and turning them into actual participants. Obviously, a campaign will never be 100% successful in that regard. In the course of a campaign, people may lose their sympathy for the movement. Klandermans has labeled this “erosion,” a phenomenon that is more likely to occur if counter-movements and/or authorities are mounting counter-campaigns. On the other hand, organizers might fail to convert sympathizers into participants because they fail to target or motivate them. Klandermans has called this “nonconversion.” The rest of this section focuses on targeting.

Targeting sympathizers involves finding answers to two strategic questions: “Who are the sympathizers?” and “How can they be reached?” Every attempt to persuade must find answers to these two questions. Indeed, sophisticated movement organizations such as Greenpeace have learned to employ many of the strategies that have been developed in advertising. Social networks are of crucial importance in this regard. Movement organizations have two options here in that they can (a) try to co-opt existing networks or (b) build new networks. Both strategies are mobilization efforts in themselves. Co-optation is the easier strategy of the two because it builds on existing commitments to organizations and networks that are part of the movement organization’s alliance system. However, there are risks. The co-opted organizations may use the campaigns for their own ends, or their leadership may—for whatever reason—decide not to collaborate. The latter makes it more difficult for the rank-and-file to cooperate. Yet co-opting existing networks, such as churches, unions, political parties, and youth organizations, is frequently applied, if only because doing so implies an answer to both strategic questions. On the one hand, it works from the assumption that most members of the movement organization sympathize with the movement. On the other hand, it assumes that these sympathizers can be reached through the organization’s networks.

Building new networks implies recruiting people who are willing to spend considerable amounts of time for a prolonged period as movement activists. Therefore, it will require more effort on the part of the organization than will co-opting existing networks. But once the new networks are established, they will be more reliable. The recruitment of movement activists is a process that is determined, on the one hand, by factors that influence who is being asked and, on the

other, by factors that influence who agrees to serve as activists when asked. As for the first type of factors, a crucial determinant is someone's position in networks linked to the movement organization or, more specifically, to the movement organizer who is undertaking the recruitment effort. Movement organizers tend to recruit first among the people they know, and this often suffices. After all, they do not need many activists. They need a few to maintain the networks, and once they have those few, the return on having additional activists diminishes rapidly. Indeed, it has been argued that long-term activism is one form of activism that must cope with free-rider behavior. The latter point is important when deciding whether to serve as an activist or not. Klandermans has maintained that the people who are asked to serve as activists understand perfectly well that they are giving a free ride to most of the sympathizers to the movement, but they are prepared to do so because they care. Only people who really care a lot are prepared to sacrifice for the others. They make the effort because they believe that "If [they] don't do it, nobody else will." Klandermans has asserted that only people who strongly support the movement's ideology, and who feel responsible for maintaining and proselytising the movement and its ideology, are prepared to make the effort of serving as movement activists.

GLOSSARY

anomalous trichromatism Group of color blindness pathologies caused by disturbances in the functionality of a certain type of cone; there are three types of anomalous trichromatism: protanomaly (when the problem is related to the cones that are more sensitive to long wavelengths), deuteranomaly (when the alteration is related to the cones that are more sensitive to medium wavelengths), and tritanomaly (when the alteration is related to the cones that are more sensitive to short wavelengths).

color blindness Term used to name a set of color perception anomalies; the term is not totally accurate because most color-blind people do not have “black and white” vision but rather experience a more or less reduced gamut of chromatic sensations.

daltonisms (red–green pathologies) Term used to name the group of color blindness associated with the X chromosome; it includes two varieties of protan alterations (protanopia and protanomaly) and two varieties of deutan alterations (deuteranopia and deuteranomaly).

dichromatisms Group of color blindness pathologies caused by the absence of functionality in a certain cone type

(usually, the cones do not have the proper photopigment); protanopia is the dichromatism related to problems in the cones that are more sensitive to long wavelengths, deuteranopia is the dichromatism related to the cones that are more sensitive to medium wavelengths, and tritanopia is the dichromatism related to the cones that are more sensitive to short wavelengths.

metamers Stimuli that, being physically different, produce an identical chromatic experience.

monochromatisms Group of color blindness pathologies; monochromats have functionality in only one specific type of photoreceptor, and they lack color perception.

opsin Protein present in the receptor photopigments.

scotopic vision The customary vision in normal-sighted people at night; it is mediated by the retina rods and does not allow color perception (and, consequently, is a monochromatic type of vision).

The scientific definition of color blindness is explained, emphasizing that this denomination is not only applied to people without color experiences (monochromats) but also to all with no-common color experiences (dichromats and anomalous trichromats). Clinical nomenclature in color-blind diagnosis is described, specifying the causal origin of each color-blind type. The different action types available to applied psychologists to help color-blind people are described (diagnosis, perceptual problems detection, use of specific information, creation-selection of accurate materials, etc.).

1. INTRODUCTION

The existence of metamer stimuli (i.e., physically different but perceptually identical) has psychological implications that are essential to understand the functional logic of color perception in both normal-sighted and color-blind people. Figure 1 shows the spectracolorimetric measurement of two metamers. The upper portion (Fig. 1A) is a physical description of the light reflected by a white shirt. The

middle portion (Fig. 1B) corresponds to the light from this object as reproduced on a conventional television screen. It is easy to observe considerable differences between these two physical stimuli that, nonetheless, produce the same perceptual experience (“white”).

The existence of metamers casts serious doubts on what could be called the “commonsense theory of color perception and color blindness.” This theory can be summarized in the following three ideas:

1. Color is a physical property of light (e.g., the light reflected by blood is red, the light reflected by a lawn is green).

2. The function of our visual system consists exclusively of detecting such properties from the stimulation that reaches the retina.

3. Color blindness would derive from the visual system’s limitations to detect the presence of some color (e.g., difficulty in detecting the presence of red).

From the viewpoint of the commonsense theory, the existence of metamers implies that all humans are color-blind because they experience the same color in response to physically different stimuli. It must be emphasized that such stimuli generate different color experiences when presented to other animal species (e.g., the stimuli from Figs. 1A and 1B are not metamers for bees and pigeons). Consequently, it can be concluded that the essential difference between normal-sighted and color-blind people is quantitative and not qualitative: All of them have metamers, but color-blind people have more or them. Although this conclusion is correct, a different conclusion can be inferred regarding the main premise of the commonsense theory because color is not a physical property of light. Instead, it is a property of the perceptual response generated in reaction to light, as was explicitly stated by Isaac Newton in his book *Optics*: “The rays, to speak properly, are not coloured. In them there is nothing else than a certain power and disposition to stir up a sensation of this or that colour.”

Following Newton’s ideas, the next section reveals the nature of the “certain power and disposition” present in physical stimuli and, even more important, how our visual system produces “a sensation of this or that colour” in response to them. Subsequently, it will be easy to conclude that the most important difference between normal-sighted and color-blind people is that the latter have a reduced capacity to detect energetic imbalances in light and, consequently, to produce color experiences.

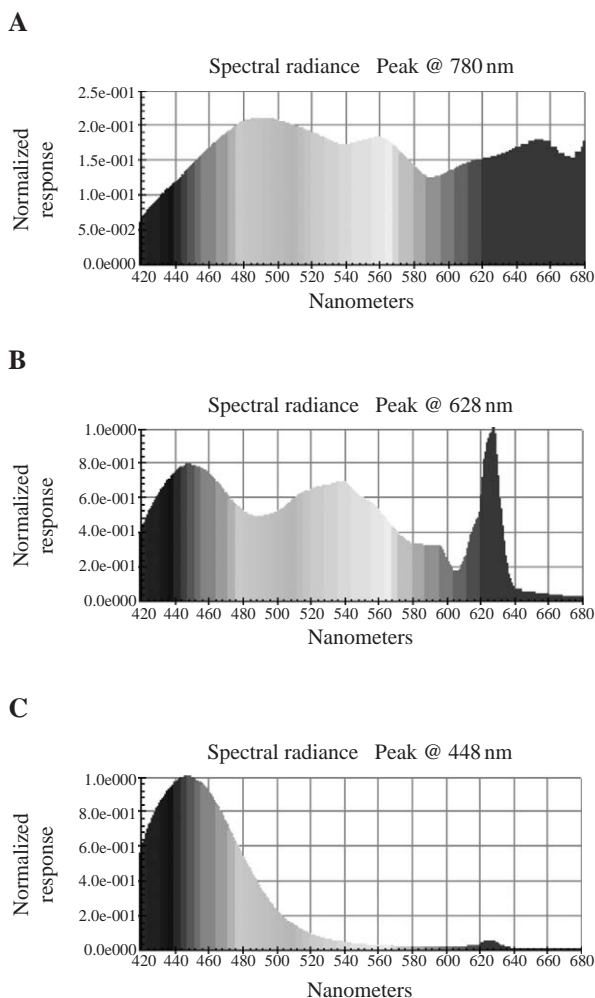

FIGURE 1 Spectracolorimetric measurements of three stimuli. Horizontal axis indicates the wavelength in nanometers (1 nm = 10^{-9} meters). Vertical axis indicates the relative quantity of energy. (A) White shirt. (B) White shirt on a television screen. (C) Primary blue screen.

2. USING THE ANOMALOSCOPE TO DIAGNOSE: PHOTORECEPTORS AND TYPES OF COLOR BLINDNESS

Color perception is the result of a complex visual processing sequence, initiated in the retina photoreceptors, that involves a large number of brain centers. Consequently, any anomaly in this sequence can generate some type of color blindness. However, most of the problems related to color perception are caused by some functional anomaly in a photoreceptor type. Consequently, this analysis centers on these anomalies.

There are two types of photoreceptors in the human retina: cones and rods. Cones are especially relevant to understanding color perception and can be divided into three types (continuous curves in Fig. 2), depending on the relative position of their spectral sensitivity curves. In the standardized scientific nomenclature, these types are called “L” (long), “M” (medium), and “S” (short), depending on the portion of the spectrum that produces larger responses for each type of cone. Taking into account the relative curve position and counting from right to left, the clinical nomenclature calls the three cone types “proto,” “deutera,” and “trita,” respectively (corresponding to the Greek words for “first,” “second,” and “third”). Recent genetic evidence indicates that, at least for the L and M cones, the spectral response curves

present minor interindividual differences among normal-sighted people (discontinuous curves in Fig. 2).

The analysis of cone responses is useful to understand (a) the origin of metamers, (b) their more widespread presence among color-blind people and the various types of color blindness, and (c) how they could be diagnosed using an anomaloscope. Each of these aspects is considered in turn.

2.1. The Origin of Metamers

Despite their physical differences, the two metamers in Figs. 1A and 1B share an essential characteristic: They both present important energy accumulations in the three spectrum portions (long, medium, and short). That is why both stimuli generate high responses in the three cone types. Cone response similarity is the cause of the achromatic sensation generated (“white”). On the other hand, the stimulus represented in Fig. 1C accumulates energy in only one spectrum portion (the short one) and, consequently, generates an imbalance in the relative responses of the three cone types (the S cones have a larger response). This imbalance causes a chromatic sensation (“blue”). To summarize, first, the energetically unbalanced stimuli (more energy in any spectrum portion) tend to generate imbalances in the relative responses of the three cone types and, consequently, the generation of hue

FIGURE 2 Cone spectral sensitivity curves. Horizontal axis indicates the wavelength in nanometers. Vertical axis indicates the relative sensitivities of the cones. S = cones most sensitive to short wavelengths; M = cones most sensitive to medium wavelengths; L = cones most sensitive to long wavelengths.

experiences (e.g., blue, green, purple). Second, the specific hue experienced depends on the type of imbalance detected by the cones. Third, all physical stimuli that generate the same pattern of response in the cones are metamers. For example, all stimuli that produce the same predominance of the S cones over the other cones will generate the same blue perception, and all stimuli that produce high and similar responses in the three cone types will generate the same white perception.

People with only one photoreceptor type lack the ability to detect energetic imbalances and are called “monochromats.” Their vision is very similar to that experienced by normal-sighted people when watching a black and white film. The psychophysical characteristic of these individuals is that, by performing the necessary intensity adjustments, they can experience any pair of wavelengths as metamers. Equation (1) synthesizes the cause of this fact. As can be observed, the response (R) in the type of cone available depends on the relative wavelength visual efficacy (EF_λ) and physical intensity (I_λ) of the stimulus:

$$R = EF_\lambda \cdot I_\lambda. \quad (1)$$

2.2. Metamers and Types of Color-Blind People

The term “scotopic vision” refers to the kind of vision mediated by rods. When the illumination level is reduced and the cones become inoperative, vision depends on the rods and all humans become monochromats because they see with only one type of photoreceptor. Consequently, all of the variations have a quantitative characteristic and can be described using Eq. (1). Monochromatic vision is the only type of vision available to people who lack cones (rod monochromats). In addition, these individuals have severe acuity problems (similar to normal-sighted people at night, they cannot detect subtle details) and must use sunglasses permanently to reduce the amount of light reaching their eyes. Also considered monochromats are individuals with only one cone type (the S cone), although they do not have photophobia or acuity problems.

Strictly speaking, only monochromats should be called “color-blind” people because they are the only ones whose visual world is similar to that of normal-sighted people when watching a black and white film. However, monochromats comprise only a small portion of the people who are usually called color-blind.

People lacking a certain type of cone are dichromats. In the clinical taxonomy, this condition is indicated by

using the suffix “anope” after the cone denomination. Thus, people lacking L cones (protanopes) are protanopes, people lacking M cones are deuteranopes, and people lacking S cones are tritanopes. To reach a better understanding of dichromats’ color limitations, a brief description of the most prestigious diagnostic test, the Nagel analytic anomaloscope, is presented.

2.3. Diagnosing Dichromatism and Anomalous Trichromatism with an Anomaloscope

The Nagel anomaloscope uses three monochromatic stimuli of 546, 589, and 670 nm (vertical lines in Fig. 3). These values are out of the operative range of the S cones (not represented in Fig. 3). Consequently, the next analysis can focus on the other two cone types: the M cones (thick left curve in Fig. 3) and the L cone (thick right curve in Fig. 3).

The anomaloscope shows a circle divided into two halves. One half is used to present the reference stimulus, a monochromatic stimulus with a wavelength of 589 nm (represented by the central vertical line in Fig. 3). To make the explanation simpler, assume that presentation of the reference stimulus generates similar activation levels in both cone types (L and M) and that, because of this, a yellow experience is generated. The second half of the circle presents a mixture of 546- and 670-nm light (represented, respectively, by the left and right vertical lines in Fig. 3). For a normal-sighted person, a 546-nm monochromatic stimulus generates more response in the M cones than in the L cones and, consequently, the perception of green. On the other hand, the 670-nm monochromatic light is experienced as reddish because it generates a larger response in the L cones than in the M cones.

The use of a Nagel anomaloscope requires adjusting the quantities of both mixture components (the greenish and the reddish light) to match the reference stimulus. For a normal-sighted person, this means that the mixture should similarly activate the M and L cones and, therefore, produce the same yellow experience as does the reference stimulus. These adjustments are performed very precisely because every variation in the relative quantities of the mixture components will produce a greenish or reddish hue and, consequently, an easily noticeable difference in relation to the reference color.

When carrying out Nagel anomaloscope adjustments, the more common dichromat types (protanopes and

FIGURE 3 Anomaloscope stimuli and cone spectral curves. Horizontal axis indicates the wavelength in nanometers. Vertical axis indicates the relative sensitivities of the cones. M = cones most sensitive to medium wavelengths; L = cones most sensitive to long wavelengths; D = curve that substitutes one of the two previous ones in anomalous trichromats.

deuteranopes) are not as consistent as normal-sighted people. This is because the three stimuli used act on the same cone type, that is, the only one they have (remember that S cones are irrelevant to this analysis). Consequently, the situation is very similar to the one described by Eq. (1); the response (R) generated by the reference stimulus can be metamized by any of the two mixture stimuli presented individually, or by any combination of both mixture stimuli (given the accurate quantities).

Anomalous trichromats are the next group of color-blind people to be considered. This group consists of all people who, like normal-sighted people, have three cone types in their retinas (this is why they are trichromats) but whose spectral curve responses are somewhat different from those represented in Fig. 2 (this is why they are anomalous). The most important consequence of this is that anomalous trichromats perceive as metamers certain stimuli perceived as different by normal-sighted people.

Nowadays, it is commonly assumed that the anomalous trichromat's limitations in differentiating colors, and the peculiar way in which these are perceived, derive from an exaggerated overlapping of the spectral response curves of two cone types. To understand why, the D curve in Fig. 3 must be used to substitute one of the two continuous curves (the M or L curve). With the new pair of curves, the relative differences in the response of both cone types to any stimulus are reduced, as is the ability to discriminate colors—the more overlapping there is, the less ability

to discriminate. At the limit, a full overlapping of curves would make both cone types functionally equivalent, and these people would behave like dichromats.

3. CAUSES OF COLOR BLINDNESS

Most color blindness is genetic in origin. In this group, the alterations associated with problems in the L cones (protanopia and protanomalies) or in the M cones (deuteranopia and deuteranomalies) are collectively called “daltonisms” or “red–green problems.” These problems affect many more men (5–10%) than women (<0.9%) because they are associated with genetic alterations in recessively transmitted X chromosomes. Consequently, men will express red–green problems when there are anomalies in the only X chromosome they have. On the other hand, a woman must have problems in both X chromosomes to be daltonic. With only one affected chromosome, they will show a normal use of colors but can transmit the red–green disturbance to their offspring.

The most important gene in relation to the opsin characteristic of S cones is not located in sexual chromosomes; instead, it is located in the seventh pair of chromosomes. Consequently, problems associated with these cones have a similar incidence in men and women. These types of color blindness are transmitted dominantly, but they affect a very small number of people (<0.05%).

TABLE I
Comparison of Acquired and Congenital Color Vision Deficiencies

<i>Acquired color vision defect</i>	<i>Congenital color vision defect</i>
Onset after birth	Onset at birth
Monocular differences in the type and severity of the defect occur frequently	Both eyes are equally affected
Color alterations are frequently associated with other visual problems such as low acuity and reductions in the useful visual field	The visual problems are specific to color perception; there are no problems with acuity (except in rod monochromatism) or visual field
The type and severity of the deficiency fluctuate	The type and severity of the defect are the same throughout life
The type of defect might not be easy to classify; combined or non-specific defects occur frequently	The type of defect can be classified precisely
Predominantly either protan or deutan	Predominantly tritan
Higher incidence in males	Same incidence in both sexes

Although the chromosomes associated with rod monochromatism have not yet been identified, this type of problem is known to be transmitted recessively. Consequently, the affected gene must be located in both chromosomes to produce problem expression.

Defective color vision can be acquired by any kind of agent with the capacity to disturb the normal functioning of the visual system—the result of ocular pathology, intracranial injury, the use of therapeutic drugs, aging, and so on. Frequently, color disturbances are initial symptoms of pathologies and can be used for early detection, indicating when therapeutic measures should begin or when they should be discontinued. Table I reviews the most important differences between acquired and congenital color deficiencies.

4. COLOR BLINDNESS AND PSYCHOLOGICAL INTERVENTION

4.1. Problems and Solutions: A Case of Protanopia

Mr. X works as an editor for a famous Spanish scientific dissemination journal. This activity is not severely handicapped by color blindness, according to various studies. Mr. X was diagnosed as a protanope some years ago. Although his perceptual limitations made it difficult for him to perform tasks in the same way as other people do, he had no problems after carrying out some modifications in his work environment. His past difficulty in correcting page galley proofs and the way

in which he “solved” this problem are an example. This protanope used to receive printed pages on which the errors to be corrected were indicated by red pencil marks. For a normal-sighted person, locating red marks is a very easy task because they “pop up” over the black letter background. However, for Mr. X, dark red and black colors are very similar (nearly metamers), so red marks did not “pop up” from his perspective. Consequently, he missed many error marks. How did he prevent this situation? Very simply: by using a color that would stand out over the background of black letters. In his case, blue ink was a very appropriate solution.

The kind of difficulty described in the previous paragraph has been experienced for centuries. To avoid them, people usually adopt one of two alternatives. Either color-blind people are denied access to some tasks and/or activities, or some task modifications are carried out to make them accessible to color-blind people. In any case, neither of these alternatives is viable in the absence of an accurate chromatic vision diagnosis.

4.2. Detecting and Diagnosing Color Blindness: A Two-Step Strategy

Pseudoisochromatic tests (Fig. 4) use stimuli that are very similar in color (“isochromatic”) for color-blind people but not for normal-sighted people (“pseudo”). For example, in the famous Ishihara test (Fig. 4A), color-blind people have difficulty in reading the number presented in each plate. This is because they do not perceive enough differences between the points that form the number and the background. Another similar

FIGURE 4 Two examples of pseudoisochromatic plates (originals are colored). (A) Ishihara test (observer’s task is to identify the number). (B) TIDA test (observer’s task is to select the little monkeys similar in color to the big monkeys).

example is provided by a test, called the “TIDA,” to detect color-blind children. In this case (Fig. 4B), color-blind individuals of the red–green type select some greenish and reddish monkeys from the bottom line as being similar (“belonging to the same family”) to the larger gray monkeys presented in the upper line.

Because they are easily constructed and applied, there are many pseudoisochromatic tests available for using during the first stage of the diagnostic process to detect the presence of color blindness. However, their use must be complemented, during a second stage, with an anomaloscope to get the most accurate

diagnosis. Among the pseudoisochromatic tests capable of detecting a red–green anomaly are the following: the Ishihara test; the Dvorine test; the Hardy, Rand, and Rittler (HRR test); the D-15 test; and the City University Color Vision Test. The latter three tests are also useful for detecting tritan anomalies and for grading the severity of the color perception problem.

Anomaloscopes show users a circle divided into two halves. One half is used to present the reference stimulus and must be metamered in the other half by a stimulus mixture. As indicated previously, to detect and differentiate red–green problems, a Nagel match must be used.

This kind of match uses a reference stimulus of 589 nm (yellow for a normal-sighted person) and an adjustable stimulus mixture made up of 546 nm (green for a normal-sighted person) and 670 nm (red for a normal-sighted person). To detect and differentiate among tritan problems, the Moreland match must be used. This uses a reference stimulus made up of a mixture of 480 nm (greenish blue for a normal-sighted person) and 580 nm (yellow for a normal-sighted person) and an adjustable stimulus mixture made up of 436 nm (blue for a normal-sighted person) and 490 nm (bluish green for a normal-sighted person).

4.3. After Diagnosis: Trying to Compensate for Perceptual Limitations

Gaining awareness of people's color blindness and perceptual limitations is the first step in the process of obtaining psychological help. With this knowledge, color-blind people can avoid incorrect attributions about the causes of their perceptual difficulties, and just as important, they obtain a first cue to adopt compensatory interventions. More concretely, and returning to the case discussed earlier, Mr. X's awareness of his perceptual peculiarities prevented him from attributing his difficulty in locating red marks to cognitive or motivational factors. He never thought that his difficulties were due to an attentional deficit. Eventually, he realized that his problems were the consequence of his difficulty in differentiating the dark red ink marks from the black letters, and so he was able to suggest the use of blue ink.

Knowing that a person is color-blind, the psychologist should look for, and try to compensate for, the following two kinds of problems:

- Difficulty in performing figure–background segmentations
- Difficulty in using the basic chromatic categories

4.3.1. Figure–Background Segmentation Difficulties

Many computer users are familiar with the following situation. Initially, they used a common application (e.g., Microsoft PowerPoint) to present a colored written message on a colored background (e.g., yellow letters on a green background). Of course, this message is easy to read on the original screen because the letters used have an adequate lightness contrast with the background.

However, when another screen is used to present the same message (e.g., a large screen used in a classroom), the message becomes very difficult to read due to a reduction in the lightness contrast. The cause of this problem is simply that the same document, as well as the same software specification, produces different colors on different screens.

A problem very similar to the one just described is relatively frequent for some types of color-blind people because, when looking at some stimuli, they experience lightness contrasts that are different from those experienced by normal-sighted people. For example, protanopes perceive reddish backgrounds as darker and, consequently, have difficulty in reading black letters on reddish backgrounds. They also have difficulty in detecting when a red light is on because they perceive it as less brilliant than do normal-sighted people.

Color-blind people not only have figure–background segmentation problems derived from their peculiar lightness perception, but a similar type of problems also may be a consequence of their restricted gamut of chromatic experiences. To understand the origin of this type of difficulty, consult Fig. 3 again and remember that, for some dichromats, the three stimuli used by the anomaloscope affect the responses of only one cone type. Consequently, when presented with the precise physical intensity (see Eq. 1), the exact same color experience is produced in these people, although normal-sighted people would perceive very different hues (green, yellow, and green) in response to these stimuli.

4.3.2. Problems Related to the Use of Basic Chromatic Categories

The expression “basic chromatic categories” is used to name the linguistic categories consistently used among speakers of a certain language. For the languages in most developed countries (e.g., English, Spanish, Japanese), there are 11 categories. These are identified in English by the following terms: red, green, blue, yellow, white, black, brown, orange, purple, pink, and gray. To say that these categories are used consistently means that, for example, if an observer is required to select the prototype of one of these categories, he or she will select the same one, or a very similar one, on different occasions. These choices will also be very similar to the equivalent choices performed by other normal-sighted people.

Previously, the singular adjustments performed by color-blind people in a Nagel anomaloscope were described. Specifically, it was indicated that stimuli

belonging, for normal-sighted people, to the red, green, and yellow categories can be metamers for red–green dichromats. Taking this into account, and also considering that color-blind people generally have an increased number of metamers, it is logical to expect color-blind people to have severe difficulties when using basic chromatic categories. In contrast to this expectation, research carried out with 30 dichromat children (protanopes and deuteranopes) provided the results presented in Fig. 5. The children achieved an important level of “hits” when required to name prototypical exemplars of the 11 basic Spanish chromatic categories. Moreover, for five basic categories (yellow, green, blue, red, and white), their hit percentage was more than 85%.

Why is there such disparity between, on the one hand, the low discriminative level shown by color-blind people in response to the stimuli used by diagnostic tests and, on the other, their relatively high capacity to name prototypes? What is the practical relevance of this fact? These questions are addressed in turn.

The main difference between the stimuli used in an anomaloscope and the stimuli provided by everyday chromatic surfaces is the range of available intensities. For example, when using a Nagel anomaloscope, the wavelengths that a normal-sighted person perceives as green (546 nm), yellow (589), and red (670 nm) can be presented with a broad range of physical intensities. Consequently, differences in the capacity to activate

cone responses can be compensated by intensity variations (see Eq. 1). This compensation is not possible with surface colors in which the response intensity (perceived lightness) is very closely related to the specific wavelengths reflected. So, for red–green dichromats, the yellow prototype is always perceived with a higher lightness than is the green or red prototype. Of course, this also helps these individuals to avoid naming confusions. This does not occur when no prototypical exemplars of the basic categories are used (e.g., pale green), in response to which more naming errors are produced.

Because many everyday chromatic stimuli are close to the basic chromatic category prototypes, color-blind people can frequently name a color correctly (Fig. 5). Consequently, for example, many teachers frequently do not agree with the results provided by the standardized chromatic vision evaluation procedure because these results are always worse than children’s real capacity to name and differentiate everyday chromatic materials. Taking this into consideration, should we conclude that chromatic evaluation is useless? The answer is clearly no because color blindness detection alerts one to the problems with figure–background segregation discussed previously and, logically, because these individuals continue to have more trouble in naming and using color categories than do normal-sighted people, even when prototype exemplars are used (Fig. 5).

FIGURE 5 Percentage of correct naming responses to basic Spanish category prototypes. Black bars, dichromats’ responses; white bars, controls’ responses.

GLOSSARY

ecological In psychology, an emphasis on the importance of the environmental context in understanding individual behavior and social problems.

prevention Interventions that aim to reduce the occurrence of physical or psychological disorders and social problems.

promotion Interventions that aim to enhance psychological well-being and the quality of community life.

social action Interventions that strategically exert influence at the grassroots level to enhance access to resources for disadvantaged groups.

Community psychology is concerned with the relationship between individuals and their social and community environments. Community psychologists contribute to the public welfare through collaborative interventions that prevent psychological and social problems, promote personal and community well-being, and empower disadvantaged citizens and groups.

1. INTRODUCTION

The field of community psychology developed during the mid-1960s as a reaction against the limitations of traditional intrapsychological approaches to research and social problems. In contrast, the developers of the field emphasized the importance of social contexts and social environments in understanding behavior and social problems, envisioned a strengths-based approach rather than a deficits-based approach to research and action, and emphasized the importance of the prevention of problems rather than the treatment of problems after the fact. Community psychology shares with sociology an emphasis on the influence of structural features of the environment on human behavior, but the former differs from the latter research discipline in its greater emphasis on action and individual experience. Community psychology shares with social work a focus on helping individuals in a community context, but the former differs from the latter applied field of practice in its greater emphasis on empirical research, systems-level change, and prevention.

Community psychologists are involved in research and action focused on the entire spectrum of contemporary issues facing citizens and communities. These include educational reform, homelessness, domestic violence, intergroup conflict, substance abuse, teenage pregnancy, poverty, child abuse, youth violence, racial and sexual discrimination, coping with life stress, community capacity building, and enhancing psychological sense of community. Applied research on these issues draws on a wide

range of research methods, including needs assessment, qualitative interviews, quantitative field research, focus groups, evaluation research, and action research. Similarly, the range of intervention approaches through which community psychologists address social problems is broad and includes program development, consultation, community coalition building, social action, community development, and social policy advocacy.

Distinctive aspects of community psychology include its guiding values, its ecological multilevel framework, and its focus on prevention, promotion of well-being, group empowerment, and community change. Each of these is described in this article.

2. GUIDING VALUES

Community psychologists emphasize the distinctive nature of the values that guide their work. The following seven guiding values can be discerned.

2.1. Individual Wellness: The Physical, Psychological, Social, and Spiritual Health of Citizens

Unlike clinical psychologists, community psychologists do not focus on the etiology and remediation of mental illness; rather, they focus on understanding the factors that contribute to well-being and healthy development and on the associated development of programs that prevent the development of physical and psychological problems.

2.2. Sense of Community: Citizens' Sense of Belonging to a Larger Group

Community psychologists view the decline of community cohesion as a major contributor to individual and social problems and the enhancement of a sense of community as a key contributor to individual wellness and community vitality.

2.3. Social Justice and Empowerment: The Equitable Distribution of Economic, Political, and Psychological Resources in Society

Community psychologists are concerned with addressing the pressing social issues of the day and in particular with empowering marginalized groups through enhancing

their access to economic, political, and psychological resources.

2.4. Citizen Participation: The Active Involvement of Citizens in All Aspects of Community Life

Community psychologists are wary of expert-driven, top-down solutions for the problems that communities face, viewing such approaches as too often ineffective and as contributors to citizen alienation and dependence. In contrast, community psychologists view citizen involvement as the antidote necessary to bring about community revitalization and solutions to pressing social problems.

2.5. Collaboration and Community Strengths: Working Together with Citizens and Groups in the Community and Building on Their Strengths

As proponents of a strengths-based perspective, community psychologists view citizens and community groups as the sources of solutions to community problems. Working together as partners allows the respective strengths of both community members and community psychologists to contribute to community betterment.

2.6. Respect for Human Diversity: Genuine Appreciation of Human Differences Such as Differences in Ethnicity, Gender, Sexual Orientation, Religion, Age, Physical Disability, and Social Class

Community psychologists are critical of social paradigms that view those who are "different" from the mainstream as the cause of the problems they face in society. In direct contrast, community psychologists affirm diversity as a public good and an invaluable resource.

2.7. Empirical Grounding: The Research Basis for Efforts to Make a Positive Difference in Communities and the Larger Society

Community psychologists view systematic evidence as the key to understanding individual and social problems and view such understanding as central to

effective program development, community action, and social policy.

Taken as a whole, these seven values reflect the field's joint commitment to research and action, its focus both on bettering the lives of individuals and on bringing about broader social change, and its emphasis on working with, for, and in the community. Individual community psychologists, however, vary greatly on the relative importance placed on each of the guiding values, with resultant differences in preferred approaches to community work. For example, academic researchers emphasize the importance of research and publication, whereas applied community practitioners emphasize the value of action and hands-on community involvement. Community psychologists oriented to individual wellness emphasize the development of local programs to prevent problems and assist those in need, whereas those oriented to social justice and empowerment often articulate the need for higher level social change efforts to transform social norms and to redistribute social and economic resources. Strongly quantitative community psychology researchers emphasize traditional research values of rigorous design and measurement validity, whereas those more oriented to social justice issues emphasize discovery-oriented qualitative, participatory, and action research methods.

3. ECOLOGICAL MULTILEVEL FRAMEWORK

The guiding conceptual framework of community psychology is social ecology, which emphasizes that an understanding of human behavior must always encompass the social environment in which it is embedded. Within the social environment, multiple levels of analysis can be distinguished, including the individual, the microsystem (e.g., family, classroom, social network), the organization, the community, and the macrosystem (e.g., cultural norms; the larger society). Research at the individual level of analysis might focus, for example, on the relationship between psychological well-being and level of perceived social support in a sample of inner-city youth. At the microsystem level of analysis, a researcher might study the relationship between the social climate of self-help groups and group effectiveness. Evaluating the impact of a comprehensive, community-wide teenage pregnancy prevention program on incidence rates of teenage pregnancy in communities that either received or did not receive the

intervention is an example of research at the community level of analysis. Additional examples of research topics at various levels of analysis are depicted in Table I.

Central to the ecological paradigm is the principle of ecological interrelatedness. Lower levels of analysis are embedded within higher levels and are directly influenced by, and can also influence, these higher levels. Thus, the role of the environment in causing individual and social problems is emphasized. Indeed, community psychology arose in part as a reaction against views that "blamed the victims," such as lower income populations and ethnic minorities, for problems that community psychologists view as stemming from larger community and societal forces.

Indeed, given the complex social problems with which the field is concerned, community psychologists believe that multiple levels of analysis should ideally be encompassed in community research and action. Take, for example, the case of youth violence in urban areas. A community psychology approach to addressing that problem, based on the ecological perspective, would naturally call for interventions at multiple levels. These might include interpersonal problem-solving and

TABLE I
Ecological Levels of Analysis in Community Research

Level	Sample research topics
Individual	Psychosocial predictors of well-being, competency-enhancing prevention programs, psychological empowerment, resilience, individual indicators of community problems
Microsystem	Family cohesion, social networks, peer groups, classroom social climate, teacher expectations, self-help group processes, neighborhood effects
Organization	Organizational characteristics of empowering community settings, whole school reform, faith-based organizations, voluntary associations, block associations
Community	Community coalitions for drug abuse prevention, community-wide health promotion, psychological sense of community, community readiness for change
Macrosystem	Social-political forces, cultural beliefs, social movements, strengths-based social policy

Adapted from Dalton, Elias, & Wandersman (Table 1.1, p. 13).

conflict resolution skills training at the individual level, family support programs at the microsystem level, whole school reform of urban schools at the organizational level, a campaign to alter cultural norms about violence and masculinity at the community level, and a strengths-based antipoverty initiative at the federal level. Although a given research or intervention project of any individual community psychologist will not realistically be able to encompass all ecological levels in any social problem area, the field as a whole aspires to conduct research and interventions that encompass the entire spectrum of ecological levels.

4. COMMUNITY RESEARCH METHODS

Community psychology researchers employ a wide range of research methods to examine community phenomena of interest. These encompass both qualitative and quantitative methods as well as research designs ranging from experimental program evaluation to action research.

Qualitative methods are especially useful for generating in-depth descriptions of a phenomenon, an understanding of context, new insights, and opportunities for the “voice” of marginalized populations to be heard. Methods include qualitative interviewing, participant observation, and focus groups. Interviews can be coded systematically using sophisticated qualitative software programs. Participant observation allows in-depth examination of a particular group or community setting, with a focus on uncovering the worldview and meaning system of members. Focus groups facilitate the generation of common themes that emerge as a result of discussion in the group context.

Quantitative methods are used for varied purposes in community psychology, including hypothesis testing, needs assessment, and program evaluation. Hypothesis testing research may focus on community samples of individuals, on samples of groups or organizations, or (increasingly in multilevel research) on individuals, families, and groups nested in a sample of organizations, neighborhoods, or communities. Needs assessment provides systematic descriptive information concerning the nature and level of local needs in a setting or community and serves as a basis for collaborative planning of interventions. Program evaluation examines the extent to which interventions are achieving their intended outcomes and the factors

contributing to observed outcomes, using experimental or quasi-experimental research designs.

Increasingly, community researchers combine qualitative and quantitative methods within a single study. This approach allows for building on the strengths of each research method. Furthermore, to address community phenomena, there is increasing focus on interdisciplinary research that incorporates research methods from other fields. Examples include community ethnography (anthropology), geographic information systems (geography), community case study (community sociology), and epidemiology (public health).

Consistent with the community psychology values of citizen participation and collaboration as well as building on community strengths, partnerships are often developed between community researchers and populations under study. Investigators engage those being studied as active collaborators in defining the research question, helping to develop appropriate research instruments, designing and implementing research procedures, and interpreting and disseminating research findings. In some cases, helping local groups or organizations to develop their own research capacities may be one of the intended outcomes of the research process, as is the case in empowerment evaluation.

Community psychology espouses adventuresome research methods appropriate to the research question at hand, even if these methods are not conventional in nature. In many research contexts, the researcher is viewed not as an objective, fully detached observer but rather as an individual whose values influence the scientific enterprise in important ways. Furthermore, consistent with this perspective, the researcher's relationship with those studied is seen as part of the larger social ecology of the phenomenon under investigation.

5. COMMUNITY RESEARCH AREAS

Community psychologists examine a wide range of topics in community-based research. Four illustrative research areas are briefly described in what follows.

5.1. Social Problems

One broad area of community research centers on pressing social problems such as discrimination, poverty, education of minority students, substance use, HIV/AIDS, and homelessness. Much of this research focuses on marginalized groups in society such as ethnic minorities and lower income populations. Community

psychologists examine factors that contribute to the specific social problem under focus. Individual, family, and environmental variables are encompassed in this research. For example, in the urban education area, community psychology researchers have examined the roles of family support, teacher expectations, the transition to middle school, the social climate and culture of schools, and neighborhood poverty. The results of research in each social problem area provide a basis for intervention approaches to address the particular social problem.

5.2. Stress and Mental Health

A second long-standing focus of community psychology research examines the interrelationships among stress, coping, social support, and psychological well-being. Life stressors examined run the gamut from acute stressors (e.g., death of a parent) to ongoing stressors (e.g., poverty). Research in this area has revealed various personal and environmental factors that help individuals to cope with stress, including spirituality, interpersonal problem-solving skills, and social support from friends, family, and mentors. This body of research has suggested important foci for psychological and environmental interventions that aim to prevent negative outcomes of stress and enhance resilience in the face of adversity.

5.3. Community and Quality of Life

A third area of research examines the role of community settings in contributing to the quality of individual and community life. This research encompasses settings such as voluntary associations, block associations, faith-based organizations, and self-help groups. These settings provide a meaningful niche in which citizens find meaning, support, and opportunities to contribute to the well-being of others and the larger community. Research on community settings indicates that certain organizational characteristics, such as cohesion, support systems, opportunity role structure, and leadership, have been found to be related to member well-being and psychological empowerment.

5.4. Sense of Community

A fourth illustrative area of community psychology research centers on psychological sense of community. This refers to the sense of belonging or connectedness to a larger group. Sense of community is important both in relational communities defined by shared

goals and activities (e.g., church, professional association) and in geographical communities (e.g., neighborhood, city, nation). Researchers have delineated four underlying dimensions to sense of community: membership, influence, integration and fulfillment of needs, and shared emotional connection. The individual and environmental correlates of sense of community, subgroup differences, and changes over time represent important topics of research in this area.

The importance of context and the importance of diversity are cross-cutting themes in many areas of community psychology research. Depending on the dangerousness of neighborhood context, for example, parenting style or psychological sense of community has been found to be more or less adaptive. Ethnic groups differ in terms of life contexts and challenges, culturally embedded values and meaning systems, and access to resources and services. Findings related to distinctiveness of context and diversity provide a critical foundation for the development of context-sensitive and culturally competent interventions.

In addition to theory generation and hypothesis testing research, many community psychologists conduct evaluation research. This research sometimes focuses on interventions developed by the investigator but more frequently examines various community-based programs developed by others. Evaluation research examines program outcomes, the quality of implementation of programs, and the theory-based processes through which program efforts occur.

Importantly, research in community psychology often builds on theory and findings from other subfields of psychology. Developmental psychology provides critical underpinnings for community psychology research on children's coping, support, and well-being. Social psychological theory contributes to community psychology work in the areas of discrimination, oppression, and empowerment. Health psychology models help to guide community psychology work in the areas of health promotion and disease prevention. Cultural psychology provides important theoretical models and perspectives for community psychology work on ethnic identity, coping, and ethnic minority populations.

In comparable fashion, disciplines outside of psychology influence community psychology theory and research. Public health has a major influence in the area of prevention and health promotion. Anthropology's focus on cultural norms, practices, and worldviews has broadened community psychology models to encompass the culture of settings and cultural narratives of community members. More generally, across the gamut of social

problem domains, there are major theoretical paradigms and accumulated research findings from other fields of direct relevance (e.g., sociology of education, community sociology, urban affairs, criminology, economics, law, social history).

Conversely, many community psychology models and perspectives have influenced other subareas of psychology and allied researchers in other disciplines. For example, prevention has become an important domain of investigation in other applied areas of psychology, including developmental psychology, applied social psychology, health psychology, and clinical psychology. Similarly, the importance of community-based research, ecological context, the strengths-based paradigm, qualitative research, and varied community psychology findings in specific social problem areas has influenced investigators in multiple areas of psychology as well as those in allied social science disciplines.

6. PREVENTION AND PROMOTION

In contrast to helping individuals after serious problems have developed, community psychologists seek to prevent the initial occurrence of problems. Primary preventive interventions aim to reduce the number of new cases (i.e., incidence) of a wide range of physical illnesses and psychological problems, including HIV/AIDS, substance abuse, and depression. Universal preventive interventions seek to do so while focusing broadly on a general population (e.g., all students in a school or school system). Selective preventive interventions focus strategically on the subset of individuals at above average risk for developing a disorder or problem due to either environmental factors (e.g., alcoholic parent, concentrated poverty) or personal factors (e.g., school difficulty). Indicated prevention programs focus specifically on individuals at high risk for developing a disorder or problem, usually those showing early symptoms of the disorder or problem.

Prevention programs have been developed for every stage of the life span. However, most prevention programs focus on infants, children, and youth, based on the principle that early intervention is the most likely means to prevent later programs. For example, Nurse Home Visitor programs provide low-income, single new mothers with support, child-rearing information and skills, and linkages to community-based resources as a means to prevent child abuse and poor child outcomes. Head Start and related preschool programs help low-income preschoolers to learn basic school-

related social and cognitive skills commonly present in their middle-class counterparts, thereby preparing those served to make a positive transition to formal schooling.

Prevention programs in public schools provide at-risk children with important coping skills and social support. Programs for middle and high school youth often focus on prevention of specific social problems such as substance abuse, school dropout, and teenage pregnancy, for example, by providing refusal skills to counteract negative peer pressure, information that underscores the implications of poor choices, and meaningful positive activities (e.g., community service) in which to engage.

Prevention specialists increasingly emphasize the importance of comprehensive, community-wide, and multilevel interventions. In the case of a program to prevent school dropout among urban youth, for example, a comprehensive preventive intervention might address multiple risk factors related to dropout, such as students' academic skills and knowledge, coping skills, engagement in creative or prosocial activities, and adult social support, rather than only one of these (and other) contributing factors. A multilevel approach in the academic performance domain, for example, might include an individual tutoring component, enhancement of the cultural competence of teachers, and schoolwide changes to provide a more supportive and caring school climate rather than an intervention at only one of these levels. Finally, a community-wide intervention could mobilize students, teachers, parents, nonprofit organizations, businesses, and the media. Given the difficulty of making a difference in pressing social problems, comprehensive, multilevel, and community-wide programs are more likely to provide the intensity and multiplicity of impact necessary to counter the multiple factors contributing to problem development.

Promotion of wellness interventions seeks to enhance psychosocial competencies and development, as well as the overall quality of individual and community life, rather than aim specifically (as preventive interventions do) at reducing rates of a specific disorder or problem. Intervention programs that contribute to normative child development, enhance children's resilience to adverse circumstances, and/or strengthen parenting skills are examples of promotion interventions at the individual level of analysis. Efforts to enhance psychological sense of community, intergroup relationships, and/or neighborhood revitalization are examples of promotion interventions at the microsystem or community level.

Outcome research has demonstrated the effectiveness of a range of prevention and promotion programs. However, these programs often are developed by university-based investigators under the ideal conditions of large amounts of grant funding and a singular focus on program success. A major challenge in the prevention area has been to effectively sustain programs after grant funding ends and to effectively disseminate programs to new sites and communities lacking the resources and special conditions that were present for initial program development. Given these challenges, the study of factors leading to effective program implementation, dissemination, and adoption is receiving additional focus. Some of the key variables found to be important include strong agreement on program goals among the various stakeholders, linkage of the program goals to the basic mission of the setting, clear and strong program leadership, and adequate implementation of core program components and principles.

7. SOCIAL ACTION AND COMMUNITY CHANGE

An additional important domain of community psychology interventions relates to social justice and empowerment. Social action and community change aim to enhance levels of economic, social, and psychological resources for individuals and groups lacking power in society. A range of methods are employed.

Grassroots organizing efforts bring together citizens and community groups in low-income neighborhoods to pressure elected officials to allocate additional funding for basic individual and community needs. Organizing efforts may involve recruiting individual citizens or working with extant community groups, such as inner-city churches, that have preexisting access to large numbers of citizens. Community psychologists involved in grassroots organizing efforts bring to bear their group skills and empowerment perspective along with linkages to resources and research bases that can be used by those leading the organizing efforts.

Community coalition development brings together groups from multiple sectors of the community to devise plans for addressing a specific community need. Groups represented often include local government, business, human service agencies, citizen associations, and faith-based organizations. Community

psychologists can serve as coalition conveners, resource experts in specific substantive areas, technical support providers, and/or evaluators.

Action research addresses local community problems through collaboration with community groups centered on local community needs. Projects may be initiated by community psychologists interested in a particular community problem or by community groups that approach community psychologists for help in addressing a need specific to their groups or the community. Consistent with an empowerment perspective, the research and action pursued have direct utility for self-defined local community needs.

Finally, community psychologists have become increasingly involved in social policy advocacy. Some community psychologists bring policy-relevant research to the attention of policymakers through congressional hearings, dissemination of reports, and/or congressional briefings. Others work full-time in the policy sector as congressional aides or policy analysts in the executive branch of government. Finally, a small number of community psychologists have become policymakers in elected positions, including local school board members and city council members.

In their social action and community change work, community psychologists necessarily work with a wide range of citizens, community groups, organizational staff and directors, and elected officials. The values of the field, including the focus on empowerment, collaboration, and community strengths, serve as important guides in this arena.

GLOSSARY

cafeteria plan A system in which organization members get the opportunity to trade some labor conditions for others to design a package with the highest personal utility; work time may be traded for leisure time, cash may be traded for additional health insurance, and so forth.

fringe benefits A term that refers to secondary and tertiary labor conditions; primary conditions cover direct compensation and provisions on work time, holidays, and vacations, secondary conditions concern health insurance and other types of social security, and tertiary conditions are specific to a company (e.g., car lease rates).

incidental pay A system that provides a supervisor with the opportunity to rapidly express recognition for a job extremely well done, for effort beyond the call of duty, and the like; rewards are often small (e.g., a free lunch, a dinner for two, a paid conference).

job evaluation A systematic procedure for describing the standard content of a job as well its standard conditions; depending on the system's particular characteristics, job descriptions are analyzed and evaluated.

merit rating A system of performance appraisal based on qualitative characteristics of individual workers (e.g., creativity, diligence, care for clients); the appraisal outcome

is rewarded (usually annually) with an extra step on the job's salary scale or with a separate bonus.

performance-related pay A category of pay systems in which work outcomes are tied to pay; outcomes may bear on individual or team contributions to work, the achieved results, and/or departmental or organizational effectiveness indexes (e.g., sales volume, profits, customer satisfaction).

reflection theory on compensation A theory in which compensation is considered to be a major domain relevant to a person's self-identity; compensation reflects information in four areas and resulting in four different meanings: motivational properties, relative position, control, and spending.

Compensation is a major domain within human resource management to which several disciplines contribute. Psychological approaches to financial compensation focus on the motivational force of pay, its potential to get organization members to learn new abilities and skills, and the conditions for perceiving pay systems and practices as fair. In industrialized countries, the structure of compensation in profit and nonprofit organizations is quite comparable. Two important components of compensation—job evaluation (which often determines base pay) and performance-related pay—are considered more closely. Research indicates, for instance, that job evaluation tends to grasp one common factor (extent of required education), whereas employees may perceive the evaluation outcome as a harness. Performance-related pay appears to be a rather vulnerable kind of system, particularly when performance appraisal is based on qualitative characteristics. Frequently, employees do not

perceive a relationship between the appraisal result and the awarded bonus amount. When quantified critical performance factors are applied, this relationship becomes more clear. Also, rather small differences in pay affect the behavior at work more often than do large differences in pay.

1. PSYCHOLOGICAL PERSPECTIVES

Managers and employees in an organization often wonder whether its compensation systems and strategies affect the work behaviors of the organization's members, individually as well as in teams, and the performance results of the organization at large. Psychologically, this theme can be addressed in more than one way. One approach is in terms of the conditions that make compensation more or less motivating, often relative to the motivating potential of other work characteristics. Characteristically, the motivational force of compensation is inferred from the organization members' level of effort, achieved performance, degree of satisfaction, and opportunities for personal development as well as from the effectiveness of cooperative efforts. A slightly different approach concerns the extent to which compensation facilitates the learning of new abilities and skills rather than stimulating employees to maintain their former habitual working patterns. This second approach is also basic to the decision, in cases of complex processes of organization change, as to whether alterations in compensation should precede or follow these. A third approach is distinguishable as managers face, for instance, the need to cut costs and are considering whether another compensation package might help them to achieve this. In such cases, an important perspective is the fairness with which this may be brought about, both in the procedures followed and in the quality of the end result. Here again, it is vital to consider the conditions under which compensation affects performance results.

These (and other) psychological perspectives are becoming more meaningful as they are considered within the frameworks of particular compensation systems. Although there are huge differences among pay forms and systems, there is a comparable compensation design across industrialized countries. This design is outlined in the next section. Then, two main categories of systems—job evaluation and pay for performance—are discussed from the viewpoint of how psychological insights may help to better understand recurring problems.

2. THE DESIGN OF COMPENSATION

Although there are great differences among industrialized countries in the amount of pay provided for particular jobs, the structure of compensation is quite comparable throughout the major part of the world. It is designed on the basis of most or all of the components described in what follows.

2.1. Base Pay

The base pay component reflects the value of a job to an organization often with respect to the particular labor market of a country or region. In many cases, systems of job evaluation are used to appraise and order the value of most or all available jobs within an organization. These relative job values are subsequently categorized in classes to which particular wage and salary scales are tied. In other cases, managers monitor the salaries that are paid in referent organizations for particular jobs and apply these to achieve "market conformity." Job values embody, to a large extent, how scarce particular abilities and skills—or competencies—are within a (national) labor market. Thus, base pay recognizes the (scarcity of) qualifications of a worker to fulfill a specific set of tasks.

2.2. Performance-Related Pay

The performance-related pay component bears on the appraisal of job performance. Characteristically, specific targets or standards are set, and these have to be met or passed before a particular bonus is awarded. When the quantity of work performance was dominant, targets applied to the number of "pieces" made (piece rate system) or the amount of time required to perform a particular task (tariff system). Current standards relate more often to performance quality, team effectiveness, sales value, client satisfaction, and the like. Through performance-related pay, employees are recognized for what they do (and don't do) in their work and are often thought to be stimulated to improve their performance.

2.3. Fringe Benefits

The fringe benefits component reflects the labor conditions that apply to members of an organization. In Europe, fringe benefits usually relate to a collective labor agreement (within the framework of a country's social security policy) and include both secondary (e.g., health insurance programs) and tertiary conditions (e.g., a

company's car lease program). In the United States, fringe benefits packages are much more organization specific, mirroring entrepreneurial and managerial views on appropriate provisions. Usually, their coverage is much more modest than in European countries. When a cafeteria plan is applied, organization members get the opportunity to select, on a regular basis (often annually), alternative labor conditions, trading less attractive options for more attractive ones. Fringe benefits mirror the views of entrepreneurs and union leaders (and society as well) on the required level of minimal security in work and life.

2.4. Incidental Pay

When deciding on matters of pay, managers in most countries must take into account various laws, regulations, and the specific organization's tradition of established practices. This host of rules might make it very hard to quickly express recognition to employees who have performed beyond expectations, put in many more hours than agreed on to speed up deliveries, and so forth. Incidental pay provides managers with the opportunity to reward some employees directly when applicable. Usually, the awards are small (e.g., a lunch for two, a dinner party). However, incidental pay might also involve larger awards (e.g., a paid conference).

Countries differ to a large extent regarding the proportional amount of base pay within their organizations. In some countries, base pay may amount to more than 90% of an employee's salary, whereas in other countries, base pay may cover approximately 50% of the salary. Moreover, opinions vary concerning the degree to which organization members' incomes should be based on their performance and sensitive to the volatility of (consumer) markets. Because job evaluation (base pay) and pay for performance have an incisive effect on managers' and employees' behaviors at work, these two components are addressed in more detail in what follows.

3. JOB EVALUATION

There are many different systems of job evaluation in use. Common to most systems is that key jobs are described according to their content and accompanying standard work conditions and are subsequently analyzed and appraised in terms of a job evaluation system's characteristics (e.g., required knowledge, problem solving, supervision). Frequently, a point rating procedure, in which numerical values are assigned to the main job features, is

applied. The sum total of these values constitutes the "job value." This approach is, to some extent, derived from the technique of job analysis, a well-known subject area within work psychology. Through job analysis, the work elements of a job (e.g., cutting; sewing) are carefully analyzed in terms of those worker characteristics that are required for successful job performance (e.g., abilities, skills, personality factors). The objective of any job analysis system is to grasp the essence of a job in terms of a variety of distinct "worker" and/or "work" qualifications.

Would the latter objective also hold for job evaluation? Research shows that these systems usually measure one common factor: extent of required education. In practice, several (professional) groups in organizations tend to stress the relevance of particular job qualities (e.g., leadership behavior, manual dexterity and sensitivity for specific tools in production work) that are believed to have been underrated in a particular job evaluation system. But factor-analytic studies show that even when a job evaluation system is "extended" to include such particular job qualities, second and/or third factors—if they can be identified at all—have much in common with the first (general education) factor. In other words: job evaluation measures the educational background required for adequate decision making in a job. Although the concepts and wording of job characteristics in various job evaluation systems might seem to differ from one another, they tap into the same construct. This is also exemplified through the custom, in several countries, of using a simple arithmetic formula to translate job value scores from one system of job evaluation into the scores of another system.

Obviously, these procedures for determining job value and base pay level do have important implications. First, the process of translating work descriptions or characteristics into worker attributes is quite vulnerable because it requires psychological expert knowledge to determine the variety of attributes (e.g., abilities, aptitudes, skills) relevant to adequately perform a particular job. Research has shown repeatedly that ratings may be biased in various respects due to the "halo effect," gender discrimination, implicit personality theory, and the like. This theory refers to a pattern among attributes that a particular rater believes exists. One example might be that somebody scoring high on emotional distance is thought to excel in analytical thinking, have a "helicopter view," and engage in a structuring leadership style because the rater assumes such a pattern to be "logical."

Second, regardless of an individual worker's personal conception of his or her job's main content, that job's

value is determined mainly by the level and nature of the required educational background. Consequently, a worker may perceive the evaluation of his or her job as not representing the worker's ideas about the job's actual content but rather as being the outcome of a bureaucratic exercise. Related to this is a third issue: Job evaluation may be experienced as a "harness" (because it measures one factor nearly exclusively), especially when a fine-grained salary structure is tied to the job value structure. This characteristic often makes it difficult and time-consuming to adjust job value and base salary to changed conditions. Flexible procedures have been designed to accommodate these needs.

Fourth, the larger the base pay proportion, the more organization members may perceive their pay as meaningful to satisfying important personal needs, according to the reflection theory on compensation. This theory holds that pay acquires meaning as it conveys information relevant to the self-concept of a person. Four meanings are distinguished: motivational properties, relative position, control, and spending. However, meaningfulness often diminishes as employees reach the high end of their salary scale without having much expectation of improving their level of pay. This implies that although base pay may motivate employees initially to stay in their jobs and to maintain at least an acceptable level of performance, this motivational force may wear out the longer employees remain in their jobs without noticeable changes in their level of pay.

4. PERFORMANCE-RELATED PAY

Research data and practical experience reveal that the introduction of a performance-related pay system is a time-consuming and rather complicated exercise. Evidently, performance-related pay may be successful in an organization, but there are also many instances where it fails to produce its intended effects. Many factors have to be considered, the most salient ones of which concern yardsticks of performance appraisal, antecedent conditions, size of pay differences, and some contingency variables (e.g., secrecy).

4.1. Performance Appraisal: Qualitative Versus Quantitative Yardsticks

In many companies, qualitative characteristics are used for the appraisal of individual performance such as

creativity, innovation, and customer orientation. These are often alternatively called behavioral yardsticks, personality statements, or competencies. A major problem is their abstract and often heterogeneous nature, without a direct relationship to observable work behaviors. They require a supervisor to "translate" daily and less frequent work events and actions into the framework of abstract person concepts without paying due attention to the interaction between the work situation and individual attributes. Thus, the use of these qualitative yardsticks is very much subject to bias. Because performance appraisal often occurs rather infrequently—(e.g., semiannually, annually), this method of appraising individual performance is vulnerable in practice. Because this performance appraisal result is tied to pay (either as a step on the salary scale or as a bonus), each department's supervisor is usually assigned a particular budget to control salary costs. The supervisor may award each employee with an equal share in the budget. However, performance-related pay is intended to reward differences in performance differentially. Characteristically, a normal distribution curve is applied to effectuate this, as Fig. 1 shows.

Figure 1 reveals that the great majority of employees earn an average bonus, whereas a few receive either a low bonus or a high bonus. Now assume that a supervisor wants to assign a relatively high bonus to some employees whose performance was beyond expectations. The restrictions posed by the budget necessitate that the supervisor assign a relatively low bonus to several other employees even though their performance often would not require this kind of intervention. How

FIGURE 1 Normal distribution curve.

FIGURE 2 Instrumentality perceptions according to expectancy theory and an absent “line of sight” as merit rating is applied.

should the supervisor get this message across? This example illustrates why research data on this system of merit rating (or competence pay) show time and again that employees hardly perceive a relationship between their performance appraisal result and their bonus. There is hardly any “line of sight,” as Fig. 2 illustrates.

Figure 2 shows a core component of the expectancy theory on work motivation. Accordingly, the motivation to perform occurs as an individual perceives a relationship between his or her effort and performance level (expectancy) as well as a link between his or her performance level and one or more outcomes (instrumentality) that are attractive (valence). The figure highlights the principle of instrumentality and the often lacking line of sight—between the appraisal result and the resulting pay amount—as merit rating is applied. Not surprisingly, employees appear to be dissatisfied with their pay and consider the system (as well as the results it produces) to be unfair. The bonuses hardly recognize employees’ performance contributions, and supervisors often wonder whether the bonuses can ever motivate employees to perform better.

There is no recipe for success. But when quantitative yardsticks are used, performance appraisal is a much less vulnerable process. Such yardsticks relate to outcomes of performance or to the pursuit of particular behavioral actions (e.g., prescribed behavior patterns in risky work situations). Performance outcomes can be set through defining a job’s critical performance factors—two or three characteristics that represent the essence of a job (or job family) such as the number of billable training hours (for professional trainers) or the rate of recurring errors (for equipment repairers). Defining these factors is time-consuming; however, they can also be used for education and training, personal development, and career planning and can also be the focus of leadership behavior. Because critical performance factors should be vital to a job and sensitive to the job incumbents’ decisions and actions, they lend themselves to performance pay as well. Research and practical experience show that their line of sight is usually adequate.

4.2. Antecedent Conditions

A performance-related pay system requires a careful phase of preparation. At least the following four conditions should be met.

4.2.1. Study of Work

Through analyzing work processes within a unit or department, it should become clear whether work activities are adequately tuned to each other, work methods are well chosen, and the workforce is sufficiently trained. Within this context, critical performance factors may be set.

4.2.2. Norm Setting

For each performance factor, a specific target ought to be set. Research on goal-setting theory has revealed that difficult and specific goals (for individual tasks with single goals) lead to high performance as employees accept these targets and are provided with frequent feedback.

4.2.3. Performance–Pay Link

Performance-related pay may be awarded when a target has just been met, is clearly within reach, or has been surpassed. The performance–pay link may be proportional or either less or more than proportional. Expectancy theory would recommend rewarding achieved results as frequently as possible.

4.2.4. Control by Employees

Mutual trust appears to be one of the cornerstones for getting performance-related pay under way. Employees (and managers) concerned should be involved in implementing a new system—in its design, in its introduction, and/or in its daily administration. The more employees believe that they are in control of a system, the more they tend to evaluate the system as fair.

4.3. Size of Pay Differences

Suppose that the salary an employee earned this month is several euros or dollars less than the amount he made last month. Chances are great that the employee will notify the salary administration department. However, if the employee's most recent paycheck would have shown a slightly higher salary than before, he probably would not have inquired about the difference. Upward and downward pay differences are not each other's reverse in their behavioral effects. Some studies show that a pay increase of less than 3% is usually not perceived as significant by individual employees (regardless of the level of their previous earnings). A pay increase of 5% or more is considered to be worthwhile "to go for," for instance, through better performance. However, if performance-related pay is applied, the size of the bonus appears not to be as important as the performance–bonus link per se.

Yet people at work often tend to compare themselves with others regarding their contributions to the work and the rewards they receive in return. Social comparison theory and equity theory have revealed that persons tend to compare their contributions–reward ratios with those of others who are in the most comparable situations (i.e., a referent). An employee who is comparing a valuable, relatively scarce attribute (e.g., his or her pay) with a referent wants to come out just a little bit higher. Such an outcome is quite motivating. But it hurts when the outcome is that the employee comes out a little bit lower. It is small differences that count.

4.4. Some Contingencies

Compensation systems and strategies operate within the social and cultural climate of an organization (and within the society at large). Consequently, many factors have been shown to affect compensation, one of which is pay secrecy. Many employers are quite open about their pay practices, whereas many others prefer to keep these secret. Whatever the arguments for such secrecy, it has an impact on the climate of trust and does not prevent organization members from making earnings comparisons among themselves. Research data show that such comparisons are unavoidably based on incomplete information, which may result in the misperception that the difference with the earnings of immediate subordinates is too small and that the difference with the earnings of superiors is too large. This may cause pay dissatisfaction. However, it is important

to differentiate among three levels of "progressively open" information: the compensation system, its salary scales, and the level of individual earnings.

Also, differences in personality variables may be important. For example, individuals with higher scores on self-efficacy are more in favor of performance-related pay. Also, the higher the negative affect (i.e., the tendency to focus on negative life experiences that causes feelings of guilt and shame), the more disadvantageous effects a performance-related pay system will have.

5. CONCLUSION

Compensation in organizations provides a good example of multidisciplinary concerns. Compared with sociological, business administrative, and (especially) economic contributions, more psychological expertise would be most welcome. Recent work on the relationship between an organization's general business strategy and its compensation strategy calls for better theories (and more research) on the choice of particular pay patterns. Psychology may profit greatly from the groundwork laid in other disciplines.

might not be the result of a rating error but rather might reflect true levels of performance on the job.

Competence at work refers to the general evaluation of how individual employees (or teams of employees) contribute to the overall goals of the organization. Most typically, this evaluation is based on the judgments of some person (most often a direct supervisor), and formal evaluations are accompanied by documented ratings as well as feedback and discussion about ways in which to improve. Assessments of competence are often the basis for decisions about pay raises and promotions, but they can also be used as criterion measures against which to validate selection techniques. Underlying many of the purposes is the need to assess competence so as to help employees improve their performance on the job.

GLOSSARY

contextual performance Behaviors exhibited by employees that are not part of their formal job requirements but that contribute to overall organizational effectiveness; examples include volunteering for assignments, working with enthusiasm, and helping others at work.

frame of reference training A type of training in which raters are taught the definitions of various scale points on the rating scale rather than being taught to eliminate rating errors; the goal is to increase the accuracy of the ratings provided.

halo error A rating "error" manifesting itself as a high degree of consistency across ratings in various aspects of the job; this is assumed to occur due to a belief that good performance in one part of the job influences performance in other parts of the job, but eventually it became clear that this consistency might not be an error at all.

incident diary A log or record kept by the rater, noting all incidents of good and poor performance exhibited by an employee during a period of evaluation.

leniency error Another rating "error," in this case manifesting itself as ratings consistently above the rating scale mean value; eventually, it became clear that this too

1. THE CONCEPT OF COMPETENCE AT WORK

An organization, whether private or public sector, hires employees to help the organization reach its goals. It is unusual, however, for every person hired to contribute to those goals equally, so it is important that we be able to assess the contribution of each employee (or group of employees) in the organization. There are a number of reasons why it is important that we are able to assess contributions in this way. One reason that is critical for employee selection is that we must be able to develop a

criterion measure against which to validate selection techniques. That is, for legal as well as practical reasons, it is important to know that the persons selected with a given technique will be those most likely to contribute to the organization's goals. But from a broader organizational perspective, we must be able to assess competence so that we can help employees to improve and expand the contributions they make to organizational goals. This is possible if we can assess relative strengths and weaknesses and then provide feedback about how to correct those weaknesses, and if we can demonstrate how improvements are tied to rewards such as pay increases, so that we can reward the employees accordingly. This requires that (a) we can define competence and the nature of that contribution and (b) we can assign some score or value to the contribution of each employee such that we can make some type of comparison across time and across employees.

The most traditional approach to defining competence at work is based on job analysis. That is, the purpose of job analysis is to specify what an employee is expected to do on the job, and the definition of competence on the job should probably be related to those requirements. But it is difficult to define competencies on the basis of specific tasks or operations carried out by employees. Such an approach would become extremely cumbersome given that we rarely have multiple employees on different jobs performing similar tasks. Thus, it makes more sense to define competencies in terms of more broadly defined contributions that underlie multiple tasks. As a result, in many cases, competencies are defined in terms of traits or characteristics of individuals that are believed to lead to success on a number of jobs. Furthermore, although a major portion of an employee's contribution will probably come in areas related to his or her job requirements, an employee can certainly make other types of contributions as well.

Any organization has certain tasks that must be carried out for the good of the organization such as employees being willing to help each other solve problems and employees volunteering to put in extra hours when crises arise. Any employee behaviors that make the workplace more pleasant are valuable. Yet none of these things is part of anyone's formal job description. Some scholars refer to these kinds of behaviors as organizational citizenship behaviors, whereas others simply refer to them as examples of contextual performance. Regardless of what they are called, they represent part of an employee's potential

contribution to the organization's goals, and they are part of any complete definition of competence. Although there has been disagreement over whether these things should be part of any evaluation of competence, most experts agree that these behaviors are considered when evaluation decisions are being made.

Finally, the operational definition of competence, usually expressed in terms of an evaluation instrument, can be stated in several different ways. The assumption that competence should be based on job analysis would lead to evaluation systems that focus on tasks that are to be carried out by the employees or on behaviors that employees should exhibit to be effective on the job. Others argue that the behaviors themselves are not as important as the outcomes of those behaviors. For example, we may be interested in whether salespeople follow up on sales calls, but what we really care about is whether or not they make the sales. Therefore, some have suggested that we define competency and assess contributions in terms of observable outcomes such as units produced and sales volume.

This approach can work only when the outcomes involved are under the direct control of the employees, and systems based on outcomes tend to work better when they are tied to specific goals that the employees must accomplish. That is, the exact nature of the contribution should be specified and should serve as a goal the employees try to reach during some time period. We could, for example, set a sales goal of 10,000 units or of \$1 million. This would then define what we mean as competence at work; it would mean meeting that goal.

This approach has the benefit of defining expectations in the clearest of terms, and it allows employees to judge how well they are doing. It also makes the entire process somewhat less subjective (although the nature and level of goals are typically negotiable), and this should make it more acceptable to all parties involved. But this approach is not without its problems. It is critical that the organization state goals and objectives in the right terms and not just in terms that can be easily quantified. Otherwise, the organization runs the risk of having all of its employees meet their goals while the organization itself fails to meet its goals.

The final way in which competency has been defined at work is based on the presumed underlying traits and abilities needed to carry out the job. For example, regardless of the exact job duties, we might desire employees to demonstrate initiative on the job. Furthermore, we might believe that initiative will help those employees to carry out their assigned tasks and meet any meaningful goals. Defining competency and

assessing performance in this way allows the organization to use one measurement instrument across a wide variety of jobs, and this is the most commonly found approach to assessing performance. Although this approach leads to the most subjective of evaluation systems with standards that are difficult to define, there is reason to believe that there are certain underlying traits (e.g., dependability) that truly do differentiate outstanding employees from merely competent employees.

Each of these approaches to defining competence at work has its advantages and disadvantages. Although no one approach is clearly the best, the definition used will drive many of the management initiatives undertaken by the organization, so it is a critical decision. Thus, the key is to understand the implications of each approach and then decide on which one is best for the particular organization.

2. MEASUREMENT AND ASSESSMENT OF COMPETENCE

After the best working definition of competence is determined, the next major issue is determining how competence is to be measured. As noted previously, it is often not feasible to assess competence based directly on tasks performed. In addition, although there are instances where we can count units produced or monitor scrap rates, these instances are relatively rare, and as noted previously, the use of more objective measures can have the effect of focusing the employees' attention on the wrong things. As a result, most organizations use some type of rating scale for assessing competence, and many organizations spend a great deal of time experimenting with new forms.

Unfortunately, there is little evidence that any one type of rating instrument provides consistently better outcomes than other types of instruments. Therefore, it makes sense for an organization to use what works best for the organization and not to pay a lot of attention to what others are using. This issue is further complicated by the fact that there is no clear consensus as to what should be the criterion in any evaluation of measurement techniques. Furthermore, it is probably more important to focus on performance management techniques to try to improve competence than to focus on appraisal techniques designed to better assess competence.

Some of the efforts to develop better rating instruments have focused on the nature of the actual rating scales or on the number of points on those scales and

the anchors used. Others have focused on exactly what is being assessed—whether behaviors, traits, or outcomes. But these efforts were hampered, in part, by the fact that there was no consensus as to how one should go about evaluating appraisal systems.

For a long time, the focus of improving appraisals was on the reduction of rating errors. These errors include things such as halo error (i.e., when someone who is rated highly on one aspect of a job is rated highly on all other aspects of the job) and leniency (i.e., when employee evaluations are inflated to be higher than they should be), and it was assumed that if there were less halo error and leniency in a set of evaluations, these would better reflect the true levels of competence of the employees being evaluated. But there is no reason to believe that a set of ratings that are lower, or are less intercorrelated, are necessarily better. It became clear that these “errors” might not be errors at all and that, in any case, they were generally unrelated to the accuracy of the evaluations provided.

Some scholars then began to assess rating accuracy directly. This made sense because it seemed reasonable to say that measures of competence were better if they accurately reflected the “true” levels of competence displayed by the employees. However, this approach requires a “true score” measure against which actual ratings can be compared, and such true scores are available only in laboratory settings.

More recently, it has become apparent that all of these efforts to reduce errors or improve accuracy are somewhat misplaced. In most organizations, the primary purpose of assessing competence is to allow employees to improve their levels of competence. In other words, the main purpose is to help employees improve the contributions they make to their organizations. Employees are more likely to improve if they perceive the assessment system as fair and accurate. To the extent that rating accuracy and the absence of what have been called rating errors can lead to perception of fairness and accuracy, these efforts are important. But they are important only as a means of getting to the ultimate goal—improvement.

Finally, there is the problem of how to deal with contextual performance when assessing competence. As noted previously, contextual performance refers to behaviors that benefit the organization but are not part of any employee's formal job requirements. The challenge here is not in deciding how to measure contextual performance (there are several scales available) but rather in deciding whether or not contextual performance should be assessed. If these behaviors

are included as part of a formal evaluation system, they will no longer be examples of contextual performance and instead will be part of the job duties. Would that be fair? Unfortunately, we do not have an answer yet.

3. BARRIERS TO EFFECTIVE ASSESSMENT

The solution to better assessment probably does not lie with the nature of the rating system used. Instead, the key component is the rater, that is, the person carrying out the evaluation of the employee's competence. Specifically, there are two issues involved. First, the rater must have the ability to provide fair and accurate evaluations. Second, and perhaps more important, the rater must be motivated to provide fair and accurate ratings. In other words, the rater must be able to recognize truly outstanding employees and then to make that recognition part of the public record.

Of course, the entire issue of what constitutes "fair and accurate ratings" is not a simple matter. We can define fair and accurate ratings as those that correctly describe employees' strengths and weaknesses and that assign the highest rating to the best performer, the next highest rating to the next best performer, and so on. There has been a great deal of research and discussion about how to determine rating accuracy, and many complicated formulas have been developed to help assess accuracy. However, the perception that a set of ratings is accurate is probably more important than the actual formula used to assess accuracy. It is this perception that will be critical for employees' belief as to whether a set of ratings is fair.

Attempts to improve rater ability have generally focused on training raters to be better judges. Consistent with the earlier view that reducing rating errors would lead to better evaluations, there was a great deal of interest in developing training programs to help raters reduce these errors. This interest gave way to developing training programs designed to help raters make more accurate ratings, usually referred to as "frame of reference" training. These programs emphasize helping raters to understand what constitutes good and poor performance in each area of competence being assessed. They are generally well received and have been found to improve rating accuracy in carefully controlled settings.

A different approach to improving rater ability deals with keeping performance logs or diaries. Formal appraisals are usually conducted no more than once

or twice a year. Therefore, a rater must be able to recall the behaviors of each employee over a period of at least 6 months to provide accurate and meaningful evaluations. Clearly, if a rater "forgets" an incident, that incident cannot become part of the employee's evaluation. If the rater forgets enough of these critical behaviors, the evaluation will become less accurate. Furthermore, if there were some tendency to forget incidents involving good performance, the employee who received the evaluation would perceive it as unfair even though the rater was providing the fairest evaluation possible. A simple solution to this problem is to have the rater keep a diary or incident log over the evaluation period. The rater writes down (or somehow notes) every incident of good or poor performance and then uses this record to make an evaluation later. Although raters do not always keep these diaries as conscientiously as they should, there is evidence that such diaries are effective when they are used.

But even if the rater has the ability to provide fair and accurate evaluations, he or she might not always choose to act on that ability. Rater motivation is much more complex and less well understood than is rater ability. Why would a rater choose to be inaccurate? There are many reasons. Raters are human and so are prone to human biases. Many will favor people they like over people they dislike. Other forms of potential bias are along the lines of race, gender, and even age. Also, a rater may assign a lower rating than should be assigned just to establish his or her power to do so. Organizational policies and bureaucratic procedures may also make it easier for the rater to assign an inaccurate rating in some cases.

Raters will do what is in their own best interests. Assuming that they have the ability to provide fair and accurate ratings, they will actually do so only when they believe that either they will be rewarded for doing so or, at least, that they will not be punished for doing so. Organizational policies play a large role in this decision. For example, in some organizations, raters are required to provide excessive documentation if they give someone a truly outstanding evaluation. Faced with this requirement, raters may simply decide that it makes more sense to give a slightly lower evaluation.

In conclusion, raters are probably much more critical to the process of evaluating competence than is the instrument used. Raters must be trained, or otherwise helped, so that they have the ability to provide fair and accurate ratings, and policies must be such that raters will also be motivated to provide those ratings. If raters are capable of being fair and accurate as well as

motivated to be fair and accurate, the employees will be more likely to perceive the ratings as fair and accurate. Employees' reactions to these ratings, however, are critical to the effective management of performance at work.

4. REACTION TO ASSESSMENTS

As noted previously, the ultimate purpose of assessing competence at work is to motivate employees to improve their performance on the job and so increase their contributions to the organization. The issues of rater ability and motivation were discussed, and these factors are relevant for the employees as well. However, the question of employees' ability to improve performance relates more to selection and training activities in the organization and is not discussed in this article. The issue of employee motivation to improve, on the other hand, is central to any discussion of assessing and improving competence at work.

Following an evaluation, the desired outcome is for the employee to take the feedback he or she receives and to work to improve. If the feedback is positive (the employee is generally doing fine), this may require maintaining effort coupled with some refinement of where to allocate effort. This is typically not a problem. However, when the feedback is more negative (the employee needs real improvement), there are a number of problems that can occur.

A fairly typical reaction to negative feedback is simply to ignore the feedback. An employee might decide that the feedback is not fair or that the poor performance is somehow not the employee's fault. In any case, no improvement will follow this reaction. For the chances of acceptance to be high, the evaluation on which the feedback is based must be perceived as fair. That is, the evaluation itself must be seen as fair, and the procedures used by the rater to develop that evaluation must be seen as fair. In addition, the feedback must be delivered in a constructive way that does not threaten the self-esteem of the employee. Finally, the feedback should focus on the behaviors at work rather than on the person. Research suggests that feedback is not nearly as effective in changing behavior as is typically assumed, so it is critical that the employee accepts the feedback and works to improve.

During recent years, there has been a great deal of interest in a particular approach to competence assessment that is concerned with the issue of feedback. Multisource assessments, more commonly referred to

as "360 degree appraisals," were designed to provide employees with feedback from peers, subordinates, and superiors and to compare this feedback with their own self-assessments. The assumption underlying this approach is that various individuals who have different relationships with an employee will focus on different behaviors. By providing feedback from all of the various sources, the employee should have a clearer picture of his or her strengths and weaknesses. There is actually little research about the effectiveness of 360 degree appraisals, and the results of the research that does exist are somewhat mixed. Nonetheless, the notion that individuals from various perspectives might have different views of an employee's competence, and that all of these may be useful, is an interesting idea.

5. DEVELOPING AND IMPROVING COMPETENCE

The penultimate goal of assessing competence is to improve competence. In truth, the ultimate goal of the process is to improve the performance of the entire organization. This must begin, however, with helping employees to accept and act on feedback. Once the employee is motivated to improve, the organization can take steps to aid in that improvement. In fact, if the organization does not take some steps in this direction, it is unlikely that real change will occur.

For example, if it is important to build and develop competence, feedback needs to be a regular thing. That is, feedback about performance should not occur just once or twice a year; it should occur constantly. Whenever an employee exhibits desirable or undesirable behavior on the job, someone should note this; in the case of undesirable behavior, the employee should also be told how to improve. Having supervisors set improvement goals with employees and regularly monitor progress toward those goals is also essential for real improvement. It is also important that supervisors and managers be constantly aware of cases where they might actually be punishing employees who perform well. A classic example is asking an employee to perform a "rush job" and then "rewarding" that employee by assigning him or her an additional job to perform.

It is hoped that if all individual employees improve their level of competence on the job, the organization as a whole will somehow be more effective. The truth is that this upward aggregation of improvement is not inevitable and requires close monitoring. Management, at the highest levels, must ensure that the goals and

directions set for individual employees at every level are consistent with, and supportive of, the organization's strategic goals. Therefore, it is critical that organizational goals be set with some recognition of the human resources available to meet them and that tactics for improving competence consider how improvement can help to serve those strategic goals. It is also important for high-level managers to recognize that they must be able to leverage the competence they have. That is, if an organization has extremely creative employees, its managers should pursue strategies that emphasize the importance of creativity. In this way, an organization can ensure that improvements in individual competence can translate to improvements in organizational effectiveness.

6. CONCLUSION

An organization improves its effectiveness by improving the competence of individual employees at work so that these individuals can make greater contributions to the organization's strategic goals. This process begins with the definition of competence at work and what exactly is included in that definition. Once a definition is selected, the organization must develop the means by which to determine the current level of employee competence versus where the employee needs to be. Although this might sound simple, there are a number of barriers to effective assessment. Some of them stem from the characteristics of the persons doing the assessment, whereas others stem from organizational policies that may (unintentionally) make this assessment more difficult.

But it is not enough to develop sound assessment techniques. Those assessments must be fed back to the employee in ways that will encourage him or her to work toward improvement. Organizational policies

related to goal setting and regular feedback can help to ensure that this occurs. In addition, it is important to coordinate goals and incentives at every level in the organization so that improved competence at the individual level can translate to improved organizational effectiveness.

GLOSSARY

burnout A psychological, physiological, and/or emotional withdrawal from sport due to exhaustion, depersonalization, and low accomplishment feelings resulting from chronic stress.

competition According to Martens, a process whereby an individual's performance is compared with some standard of excellence in the presence of at least one other person who is aware of the criterion for comparison.

state anxiety Feelings of apprehension and tension associated with activation of the organism.

stress An athlete's perception of the imbalance between the environmental demands placed on him or her and the athlete's response capacity and resources for meeting those demands.

trait anxiety A personality disposition that predisposes individuals to perceive evaluative contexts as more or less threatening and to respond with varying levels of state anxiety.

Competition is a process that has important positive and negative consequences for athletes. Positive consequences can include increased confidence, motivation,

and satisfaction, whereas negative consequences can include stress and burnout. The degree to which competition has positive or negative consequences depends on the competitive context (e.g., the importance placed on performance and uncertainty) and the personality (e.g., trait anxiety, self-esteem) and perception of the athlete involved. Positive coaching strategies and stress management techniques can be used to reduce or cope with competitive stress.

1. INTRODUCTION

1.1. Competitive Sport: A Worldwide Phenomenon

Competitive sport is a worldwide phenomenon of enormous popularity. Epitomized by the Olympic Games and World Cup soccer championships, millions of individuals watch these events with tremendous enthusiasm. Moreover, countless others participate in various levels of competitive sport every year.

Competitive sport is not without controversy. Some argue that it is an excellent training ground for psychological attributes such as leadership, confidence, and teamwork, whereas others suggest that it leads to excessive anxiety, immoral behavior, and aggression.

Because of the persuasiveness of competitive sport, better understanding competition and the competitive process has been an important task for those in applied psychology. Three decades of sport psychological

research on competition have provided a solid understanding of the area.

1.2. Purposes

This article has three purposes. First, competition is defined and the competitive process is discussed. Second, the issue of whether sport competition has positive or negative effects on participants is examined. Finally, competitive stress, its sources, and its consequences are discussed.

2. COMPETITION AND THE COMPETITION PROCESS

Based on the groundbreaking work of Deutsch in 1949, early definitions of competition focused on situations where rewards were distributed unequally based on the performance of participants. Although this definition did much to guide early research in the area, its shortcomings (e.g., the fact that individuals do not always define rewards in the same way and, hence, that a person might lose an event but define his or her personal improvement as rewarding) led to the development of other definitions.

Today, competition is defined as a social process that encompasses a sequence of stages rather than a single event. Martens did much to advance the scientific study of competition when, in 1975, he defined it as a process where “an individual’s performance is compared with some standard of excellence in the presence of at least one other person who is aware of the criterion for comparison.” This differs from the reward definition in that the person is the focal point of the competition process and can influence the relationship among the various stages of competition. Primary emphasis is also placed on the individual’s perception of the competitive context and on how personality factors influence one’s competitive experience.

Standards of excellence involved in the competition process can be self-referenced (e.g., set a personal best in a 100-meter swim competition) or other-referenced (e.g., beat a particular individual in the competition). Considerable attention in contemporary sport psychology focuses on the utility of making self- versus outcome-oriented comparisons. Self-referenced standards are often emphasized because they are more in an individual’s control, and have been found to be associated with long-term motivation and greater satisfaction, compared with other-referenced comparisons.

3. A MODEL FOR UNDERSTANDING COMPETITION

Guided by the process definition of competition, Martens also developed a four-stage model of competition (Fig. 1). An inspection of this model reveals that the objective competitive situation (Stage 1) begins the competitive process and consists of a situation where an individual’s performance is compared with others in the presence of at least one other individual. For example, for most individuals, entering a gymnasium and seeing a basketball at midcourt and one’s name on the scoreboard would signal a competitive situation. However, not everyone would perceive this situation as competitive, for example, an elderly person who has no interest in or knowledge of basketball. Hence, Stage 2 of the process involves an individual’s subjective perception of the objective competitive situation. Research has shown that an individual’s personality orientations, particularly his or her levels of competitiveness or achievement goals (i.e., orientation to judge ability relative to oneself or a comparison with others), influence the degree to which the person sees situations as competitive.

After an individual appraises a situation as competitive, he or she may approach or avoid it or may become motivated, anxious, or excited. Thus, Stage 3 of the model focuses on an individual’s psychological-physiological response (e.g., anxiety, increased muscle tension, enhanced motivation). Interestingly, research also shows that it is not the absolute level of anxiety

FIGURE 1 Martens’ model of competition. Reprinted from Martens (1975).

that influences an athlete's performance; rather, it is whether the individual views that increased anxiety as facilitative and helpful or as debilitating and a hindrance to performance. The athlete's perception, then, not only influences whether he or she views competition as anxiety provoking but also influences whether that anxiety is seen as helpful or hurtful.

Finally, the positive or negative consequences are the fourth stage in the competition process. An individual wins or loses on the scoreboard or perceives that he or she performed well or not. However, as with the three preceding stages, an athlete's perception of the consequences is more important than the objective outcome.

This model of competition is important because it shows that competition can best be understood as a series of stages. Moreover, it places an athlete at the center of the competitive process, with his or her personality dispositions interacting with environmental considerations.

4. POSITIVE AND NEGATIVE EFFECTS OF COMPETITION

The competitive ethic is a driving force in contemporary sport. It is common to hear coaches, athletes, and sports journalists say positive things such as "competition brings out the best in people" and "she is a fiery competitor." At the same time, an overly competitive, win-at-all-costs mentality is blamed for violence, rules infractions, and unsportsmanlike behavior. Hence, sports competition appears to be a double-edged sword, cutting both ways and having both positive and negative effects on participants.

Most researchers do not view competition as inherently good or bad today. Research shows that it can have both positive and negative effects on participants. For instance, in some studies, competition has been shown to lead to negative effects such as increased aggression and decreased performance. In other investigations, competition has been found to facilitate motivation and lead to improved performance. Whether these effects are positive or negative depend greatly on the competitive context and the emphasis that sport leaders and coaches place on competition and its meaning. For example, the quality of adult leadership has been shown to be a crucial determinant of whether competition has positive or negative outcomes for children. In their classic youth sports coaching research, Smoll and Smith found that children playing for coaches trained in a positive approach (i.e., who focused on encouragement and giving praise) exhibited

higher self-esteem and lower anxiety and were less likely to drop out of sport. When coaches were not trained to be positive and encouraging, children involved in competitive sport did not experience increased motivation, lower anxiety and enhanced self-esteem.

Much of the sport psychological research focusing on competition has been conducted with young athletes in entry-level programs. Less research on competition has been conducted at different levels of competition (local, national, and international). However, recent research with elite athletes shows that these outstanding performers are highly competitive. Their standards of comparison are both self- and other-referenced, they are both intrinsically and extrinsically motivated, and they have high perceptions of ability.

Champion athletes have also been found to approach competition differently across various phases of their careers. For instance, in the classic research by Bloom in 1985, elite athlete development was retrospectively traced across the careers of champion athletes. Bloom's research, as well as more recent research, found that these individuals did not begin their careers with an emphasis on competitive outcome (i.e., winning medals and defeating others). Rather, the focus was on having fun, learning fundamentals, and being active. It was only later that they approached competition in a very serious fashion. In addition, for much of their careers, they focused on long-term development rather than short-term competitive results.

5. COMPETITIVE STRESS IN SPORT

One of the most studied aspects of competitive sport has been its association with competitive stress. Levels of stress experienced by young athletes, sources of stress, and managing stress all have been topics of considerable interest to sport psychology researchers.

5.1. Stress in Sport

Stress has been defined as an athlete's perception of the imbalance between the environmental demands placed on him or her and the athlete's response capacity and resources for meeting those demands. For example, a golfer may face a situation where he or she needs to sink a crucial 15-foot putt to win a tournament. If the golfer perceives the demands as exceeding his or her capabilities, the result is increased competitive state anxiety, that is, feelings of apprehension and tension accompanied by physiological activation. Furthermore,

heightened levels of state anxiety, especially if they are perceived as debilitating, have been associated with poor performance and lower levels of enjoyment and satisfaction.

5.2. Sources of Stress in Athletes

Identifying sources of stress experienced by athletes engaging in competition has been a topic of interest to sport psychologists. This research has generally shown that although there are a variety of specific stress sources that an athlete can experience (e.g., self-doubts about performance capabilities, team selection), these fall into two general situational categories: (a) the importance placed on performance and (b) uncertainty. Specifically, the more importance that an athlete perceives is placed on an event, the more state anxiety is experienced. Similarly, the greater the degree of uncertainty (whether about performance or nonperformance issues) that the athlete perceives, the more competitive state anxiety is experienced.

However, situational factors are not the only class of factors influencing competitive stress responses. Consistent with Martens' model of competition, personality dispositions have been associated with elevated stress responses. Specifically, an athlete's level of trait anxiety (i.e., a personality orientation that predisposes the individual to view social evaluation and competitive contexts as threatening) influences his or her level of state anxiety. Performers with high trait anxiety consistently respond with greater levels of state anxiety in competitive situations. Self-esteem has also been consistently associated with levels of competitive state anxiety experienced in socially evaluative sport contexts. In competitive situations, athletes with low self-esteem experience higher levels of state anxiety than do those with high self-esteem. Finally, more recent studies have found relationships between increased anxiety and high levels of hardiness, perfectionism, and self-presentation concerns as well as low social support, although these findings need to be further verified in additional studies.

5.3. Are Young Athletes Placed under Too Much Stress?

For a number of years, researchers have been concerned with the levels of stress experienced by athletes, especially young athletes engaged in competitive sports. Thus, researchers have compared the amounts of state anxiety experienced during practices with those experienced during competitive sport situations. The thinking

behind these comparisons is that competition is more anxiety provoking than are practices, but it is important to note that at times practices can include considerable social evaluation (e.g., team selections). Although the results of these studies have consistently revealed that most young athletes experience more anxiety during competitions than during practices, the most important finding is that the vast majority of children do not experience excessive levels of state anxiety during competitions. However, certain children in certain situations do experience high levels of competitive stress and anxiety.

For example, in a set of classic studies of competitive youth sport participants, Scanlan and colleagues assessed the state anxiety levels of youth sport participants during practices (i.e., nonevaluative contexts) and compared these levels with those during competitions (i.e., evaluative contexts). A variety of personality and background factors were also assessed. Results of this research led to the general conclusion that most young athletes did not experience excessively high levels of state anxiety during competitions. Certain children in certain situations did experience high levels of state anxiety. These children were characterized by high competitive trait anxiety, low self-esteem, less fun, less satisfaction with performance, low personal performance expectancies, and worries about failure and adult evaluation.

In a related area of research, "burnout" or withdrawal from competitive sport has been studied. In these studies, burnout has been defined as a psychological, physiological, and/or emotional withdrawal from sport due to exhaustion, depersonalization, and low-accomplishment feelings resulting from chronic stress. Results reveal that a small percentage of sport participants experience burnout of sport and that chronic stress plays an important role in the burnout process. Moreover, the chronic stress results from physical overtraining and/or psychological factors such as overbearing parents or coaches, a lack of athlete multidimensional identity development, a perfectionistic personality orientation, high trait anxiety, and low self-esteem.

5.4. Managing Competitive Stress

Because competitive sport can be stressful, and high levels of stress have been associated with inferior performance and decreased enjoyment and satisfaction, researchers have been very interested in helping athletes to manage stress.

One important but often overlooked class of techniques for managing competitive stress is environmental engineering. With environmental engineering

techniques, coaches, adult leaders, and significant others can influence athlete stress levels by increasing the importance placed on competition (e.g., giving a fiery pregame pep talk, repeatedly emphasizing the importance of victory) or by creating uncertainty (e.g., not announcing starting lineups for games, basing liking for a child on performance). Or, they can reduce competitive stress by reducing the importance placed on performance (e.g., not giving a pregame pep talk, not repeatedly emphasizing the importance of victory) or by increasing certainty (e.g., announcing starting lineups early, not basing liking for a child on performance). Training youth sport coaches to adopt a positive and encouraging coaching orientation, rather than a negative or critical one, can reduce the levels of competitive stress experienced.

A number of techniques, mirroring general stress management research in psychology, have been used successfully by athletes to manage their competitive stress. These include cognitive anxiety reduction strategies (e.g., imagery, meditation), somatic anxiety reduction techniques (e.g., progressive muscle relaxation, breath control, biofeedback), and multimodal techniques (e.g., stress inoculation, cognitive-affective stress management training). Competitive athletes have also been found to use a variety of problem-focused (e.g., time management, goal setting) or emotion-focused (e.g., controlled breathing, relaxation training) coping techniques to control the stress of competition.

Relative to the utility of teaching stress management to athletes, sport psychologists emphasize the need for long-term training/practice and the incorporation of these techniques into the actual competitive setting (e.g., learning how to relax while an athlete actually runs vs using relaxation techniques the night before a race). Finally, research has also revealed that there is an optimal recipe of emotions that lead to superior sport performance, so that using stress management techniques to eliminate all stress is counterproductive. Thus, competitive athletes must know their optimal levels of emotional arousal and arousal-related emotions needed for best performance and then use stress reduction and enhancement strategies accordingly.

each individual's) interests are violated, or in danger of being violated, by the other individual.

judgment conflict Conflict between parties where one party's assertion about something is inconsistent with another party's assertion about it.

normative conflict Conflict between parties where one party perceives that the other party has exhibited behavior that is believed to be wrong.

GLOSSARY

conflict episode A single engagement between two parties in conflict over some issue.

conflict process The series of activities from initiating conflict to resolving it.

distributive outcome Zero-sum resolution to a conflict in which the outcome is perceived as fixed and the purpose of the conflict is to distribute the outcome in some proportion between the parties (e.g., 50/50, 60/40, 100/0).

external conflict Conflict existing between an individual or group and another individual or group.

goal conflict Conflict between parties where one party has a goal that is mutually exclusive with a goal of another party.

integrative outcome Resolution to a conflict in which the parties work to create an outcome that is compatible with both parties' goals.

internal conflict Conflict existing within an individual who is experiencing mutually exclusive desires or beliefs.

interpersonal conflict A state that exists between two individuals with valued interests in which one individual's (or

Organizational conflict is a state that exists between two parties within an organization or between organizations, each with valued interests, in which one party's (or each party's) interests are violated, or in danger of being violated, by the other party.

1. INTRODUCTION

Both within and between organizations, individuals interact regularly and almost as regularly experience conflict with one another. Sometimes the conflict between individuals is minor and unnoticed, whereas other times it is heated and drawn out. Whatever the case, the characteristics of conflict between individuals are important to understand for the sake of the individuals and the organizations where they work. This article provides a general understanding of interpersonal conflict in organizations and highlights some of the most recognized ideas that have been presented in research on the subject.

Interpersonal conflict is a state that exists between two individuals with valued interests in which one individual's (or each individual's) interests are violated, or in danger of being violated, by the other individual. It is an external form of conflict, as opposed to internal conflict where two or more of an individual's interests are mutually exclusive (e.g., role conflict, conflict of interest).

Interpersonal conflict occurs between parties with opposing interests and can take three forms: normative, judgment, and goal. Normative conflict exists when one individual is offended by another individual's behavior and believes that the latter should have behaved differently. Judgment conflict occurs when the individuals disagree over a factual issue (e.g., how a particular event transpired). Goal conflict is a situation in which two individuals are seeking mutually exclusive outcomes (e.g., how a slice of cake will be divided between them).

In 1992, Thomas, an extremely influential figure in conflict research, divided conflict into four factors that affect one another directly or indirectly: structural conditions, the conflict process, outcomes, and third-party intervention. Structural conditions make up the context of the situation in which conflict occurs and include the relatively stable factors of the parties and their surroundings. When conflict is triggered, the conflict process ensues with interactions between the parties involved. Both experiences and behaviors of the parties affect the process. Conflict outcomes are the result of the conflict process (specific episodes or series of episodes) and can include task outcomes (relevant to the matter of the conflict) and social system outcomes (relevant to the organization, the relationship between the parties, etc.). During the process, a third party may intervene. Third-party intervention is the involvement of an individual or a group whose primary concern is the resolution of the conflict as opposed to the substantive concerns of the conflicting parties.

Some third parties may, on resolution, change the structural conditions of the context, thereby influencing the resolution of future conflict. An example might be a manager who helps to resolve a dispute between two employees and then creates a policy to handle similar disputes in the future. Aside from these primary effects, feedback effects are likely to occur. For instance, the social system outcomes of a conflict episode are likely to alter structural conditions such that no two conflict episodes occur in identical environments.

2. THE CONFLICT PROCESS

When two individuals are experiencing conflict, the conflict process is the most apparent and explicit aspect of all that goes on between the parties. They are likely unaware of the contextual factors and their individual characteristics that set the conflict in motion. Although they have an idea of what they want out of the conflict, they are probably not considering all of the effects that the conflict will have beyond their individual goals. It is likely that each party is most interested in how to behave, and in how the other party should behave, in dealing with the conflict. The series of activities that run from initiating conflict to resolving it is referred to as the conflict process. The most popular research on the conflict process suggests that the conflict process is best observed at the level of the conflict episode. A conflict episode is a single engagement between two parties in conflict over some issue.

Two researchers developed and presented influential models of the conflict process: Pondy in 1967 and Thomas in 1992. Although both models have similar aspects, Thomas's model gives attention to additional characteristics of the process such as the interaction of emotions, rational reasoning, and normative reasoning. The main aspects of this model are awareness that conflict exists, a series of thoughts and emotions leading to intentions that determine how the conflict will be handled, and interaction between the parties beginning with the first party's behavior and continuing with the other party's reaction. This leads to a continuous exchange cycle between the parties through thoughts/emotions, intentions, and behavior that ends with resolution and outcomes.

Thomas defined conflict as "the process that begins when one party perceives that the other has negatively affected, or is about to negatively affect, something that he or she cares about." At some point before an individual becomes involved in handling conflict with another person, that individual must first recognize that conflict exists. This point of first recognizing conflict is referred to as awareness. There will often be an event that triggers awareness such as an action or a statement made by the opposing party.

On becoming aware of conflict, an individual then begins to make sense of the situation by considering what is at stake and how the process should be handled. One aspect of this sense-making is defining the issue of the conflict. In addition to recognizing the issue at stake, an individual will begin to consider what

outcomes are likely to result in a resolution that is acceptable to both parties.

Having defined the issue and considered possible settlements, an individual will then begin to reason both rationally and normatively in considering ways in which to handle the conflict that (a) are likely to result in efficiently and effectively achieving a beneficial resolution and (b) are perceived as acceptable and fair by the social environment. For example, if two individuals are in conflict over purchasing the last of a particular toy in a store before Christmas, the issue is apparent: Which of the two will get to purchase the toy? Rationally, one party may consider that attacking the other party and stealing the toy would efficiently and effectively result in a beneficial outcome. However, normatively, the social environment would not approve of this behavior. Therefore, the party should consider a more acceptable strategy for acquiring the toy.

The writer Oscar Wilde once said, “Man is a reasonable animal who always loses his temper when he is called upon to act in accordance with the dictates of reason.” Accordingly, individuals engaged in conflict are often affected by their emotions in addition to considering rational and normative reasoning. Both positive and negative emotions can affect how the opposing party’s behavior is interpreted and can amplify or dampen the influence of rational and normative reasoning. All of this will filter down to influence behavior. For instance, anger can result in aggression and negative interpretations of behavior, anxiety can lead to withdrawal, and innocent humor can decrease the negative effects of aggression and anger.

The interaction of an individual’s reasoning and emotions leads to a set of strategic and tactical intentions for handling the conflict episode. Strategic intentions refer to the overall goal one party has for the situation such as cooperating with or competing against the other party. Research on strategic intentions often refers to them as conflict management strategies and is discussed in the next section. Tactical intentions, on the other hand, are more specific goals or plans for achieving a beneficial outcome such as using a calm tone in presenting a case to keep the other party from becoming angry and focusing on the benefits that a proposed solution has for the other party. These intentions serve as guides for an individual’s behavior in managing conflict.

The intentions that an individual forms for dealing with a conflict episode will influence that party’s behavior. After the first party expresses behavior, the other party experiences a similar process of reasoning and experiencing emotions, forming intentions, and

expressing behavior as a response to the interpretation of the first party’s behavior. This is not necessarily a turn-based activity, although it can be in certain negotiation situations. Each party responds to the other party through the stages of thoughts/emotions, intentions, and behavior in a continuous interaction between the parties until some outcome is reached. This might not be the end of the conflict between these parties; however, it is the end of the conflict episode. The outcomes of conflict are discussed in a later section.

3. CONFLICT MANAGEMENT STRATEGIES

Five strategies for managing conflict have been used throughout numerous research studies on conflict: avoiding, accommodating, competing, compromising, and collaborating. These strategies are coordinated on a two-dimensional grid with the axes labeled either “concern for own interests” and “concern for other’s interests” or “assertiveness” and “cooperativeness” (Fig. 1). Thus, avoiding would represent either a low concern for self-interests and for other’s interests or low levels of assertiveness and cooperation, respectively.

The first conflict management strategy is accommodating, also referred to as obliging. Figure 1 shows that this strategy is low in assertiveness and high in cooperativeness—a lose–win strategy. In this case, one party chooses to allow the other party to satisfy its interests

FIGURE 1 Conflict management strategies.

completely. One party may choose accommodation for several reasons. For example, the party may be unwilling to compete, may want to minimize losses, may consider the other party's interests as more valuable, or may seek to prevent damage to the relationship between the parties. Accommodating can be an active strategy in which one party helps to satisfy the other party's interests. It can also be a passive strategy in which inaction results in the satisfaction of the other party's interests.

The second conflict management strategy is competing or dominating. This is the opposing strategy to accommodating and is classified as high in assertiveness and low in cooperativeness—a win-lose strategy. Competing is an active strategy in which one party attempts to satisfy its own interests, usually by preventing the other party from satisfying its interests when both parties' interests are perceived as mutually exclusive. Competing may be more effective when quick and decisive action is vital, unpopular but important decisions must be made, an organization's welfare is at stake and the right course of action is known, and/or the other party takes advantage of noncompetitive behavior.

Compromising or sharing is the third strategy shown in Fig. 1. In this case, one party is moderately assertive and cooperative. In contrast to either party winning or losing, compromising seeks a "middle ground" in which each party wins in part and loses in part. Compromising may be perceived as a weaker form of collaborating, but the use of compromising assumes a fixed amount of resolution that must be distributed, whereas collaborating seeks to determine both the size of the resolution and how it is to be divided. Compromising may be effective when opponents with equal power are committed to mutually exclusive goals, the issue is complex and at least a temporary settlement must be reached, interests cannot be fully sacrificed but there is no time for integration, collaborating and competing fail, and/or goals are important enough to fight for but not so important that concessions cannot be made.

The fourth conflict management strategy is avoiding. This strategy reflects low assertiveness and low cooperation—a lose-lose situation. With this strategy, one party chooses not to engage the other party in resolving the conflict in such a way that neither party is able to satisfy its interests. Avoiding may be a good strategy when an issue is trivial, there is no chance to satisfy a party's own interests, the other party is enraged and irrational, and/or others can resolve the conflict more easily.

The last of the conflict management strategies is collaborating or integrating. As the term implies, this strategy has an integrative focus. Parties using the

collaborating strategy are classified as being both highly assertive and cooperative—a win-win attitude. In this case, the two parties attempt to work with each other to develop a resolution that will completely satisfy the interests of both parties. Although much of the research on conflict has proposed that collaborating is always the ideal conflict management strategy, others have suggested that there may be situations in which other strategies are more effective. Collaborating may be a more effective strategy when each party's interests are too important to be compromised, full commitment to the resolution by both parties is desired, and/or there is sufficient time to resolve the conflict by integrating both parties' interests.

Research on conflict management strategies has comprised a large portion of the total research on interpersonal conflict. The five strategies outlined here have become somewhat canonical in conflict research. Much research has validated the existence of these strategies and shown the advantage of a two-dimensional model over a one-dimensional (two-strategy) model, but there have been no remarkable attempts to improve on or add to this model of conflict management. Although there is much room for more research to be done in this area of interpersonal conflict, it has not suffered from a lack of attention as other areas of conflict have.

4. STRUCTURAL CONDITIONS AFFECTING CONFLICT

The conflict process does not occur in a void; there are structural conditions that affect the process. Both the contextual situation and the parties involved have characteristics that may affect the various factors in the conflict process such as the choice of a conflict management strategy, inclusion of a third party, and norms for behavior. In 1992, Thomas suggested, "Whereas process refers to the temporal sequence of events that occurs in a system, structure refers to the parameters of the system—the more or less stable (or slow-changing) conditions or characteristics of the system that shape the course of those events." Research has revealed several structural factors in both individuals and organizations that may have an effect on the conflict process. For instance, Wall and Callister's review of conflict literature in 1995 discussed several individual and issue-related factors affecting conflict.

4.1. Individual Characteristics

Individuals constitute the primary parties in interpersonal conflict; therefore, it is likely that characteristics of those individuals will influence how the conflict episode is played out. It could be that differences in characteristics between individuals are the very reason for a conflict episode, for example, when two team members get into an argument because one is task oriented and the other is more relationship oriented. This difference can be the root of a series of events that result in conflict. Similarly, these differences may lead to each party handling the episode in a different way. Thus, individuals have stable or slow-changing characteristics that can influence conflict and the conflict process.

One characteristic that affects conflict is an individual's culture (i.e., societal norms). Conflict is seen by some cultures as beneficial but is seen as detrimental by others. Thus, more assertive strategies are likely to be preferred by individuals from cultures seeing conflict as beneficial. Other individual characteristics affecting conflict are goal characteristics, stress, and the need for autonomy. An individual with high aspirations or extremely rigid goals is more likely to engage in conflict due to increased awareness of possible impediments to his or her goals. In addition, an individual whose goals are interdependent with another person's goals is more likely to engage in conflict because the latter person's behavior has an impact on the former person's ability to achieve a goal. Stress may also lead to greater conflict due to the tension that an individual experiences, much like a rubber band pulled tight and ready to snap. Finally, if an individual has a high need for autonomy and another party makes demands that infringe on that autonomy, there is an increased likelihood of conflict.

Another individual characteristic that affects conflict is personality. For example, "Type A" and "Type B" personalities are likely to manage conflict in different ways given that Type B individuals are less competitive, less temperamental, and more patient. Studies by Antonioni in 1998 and Moberg in 2001 examined the effects of the "Big Five" personality factors—Extraversion, Openness, Agreeableness, Conscientiousness, and Neuroticism—on preference of conflict management strategy. For instance, avoiding seems to be preferred by individuals with low Extraversion and low Conscientiousness, collaborating is preferred by those with high Extraversion and high Conscientiousness, and competing is associated with low Agreeableness.

Self-esteem has received considerable attention in conflict research. Research has shown that individuals

with high self-esteem value satisfying both their own concerns and their counterparts' concerns. These individuals are also more confident that collaboration is possible and are less likely to become defensive, a condition that negatively affects collaboration. Thus, individuals with high self-esteem are more likely to use collaboration in managing conflict. Other individual factors affecting conflict include locus of control (internal may provide greater confidence for resolving conflict), dogmatism (high levels may limit the flexibility of resolution possibilities), and stage of moral development (higher stage individuals are more likely to use collaboration). The individual characteristics presented here do not represent a comprehensive list of individuals' structural variables that may affect conflict. However, these are some that have been addressed in research. Primarily, the discussion presented here suggests that it is important to consider more than the issue when trying to understand a conflict episode. The individuals themselves may have characteristics that contribute to both the triggering of the conflict episode and its management.

4.2. Organizational Characteristics

Conflict does not occur in a vacuum; rather, it occurs in some sort of interactive setting such as the workplace. Much of the research presented here (and in general) has concentrated on conflict occurring in an organizational context. Thus, much research has focused on examining the characteristics of organizations that influence conflict and its management.

Task characteristics may affect how a party manages conflict. When performing competitive tasks, an individual may be more likely to either compete or avoid. However, when performing a cooperative task within a group setting, collaborating and compromising are more likely to be used to manage within-group conflict. In addition, if the individual is performing a task that is highly interdependent with the other party's task, he or she is more likely to prefer a collaboration strategy.

In addition to these, organizational culture and norms are likely to affect both parties' behaviors during conflict. For instance, some conflict management strategies may be taboo within an organization. Rules and procedures are likely to affect conflict management as well because these can constrain certain behaviors while requiring other behaviors.

Structural conditions are considered fixed in the short run during the conflict process. However, in the long

run, structural conditions may be manipulated to make the conflict process more effective for the parties and the organization of which they are members. Some structural conditions can be affected by individual or organizational intervention. That is, parties can make adjustments to these conditions to influence how conflict is managed when it occurs. For instance, if increased stress results in undesirable behaviors and outcomes of a conflict episode, an organization may benefit by fostering an environment of low stress for its members. Intervening in this way can improve the way in which conflict is managed throughout the organization. Understanding individual and organizational characteristics that influence conflict can help managers and organizations to deal with conflict more effectively.

5. CONFLICT OUTCOMES

During a conflict episode, the primary parties and any third parties are continually working toward some sort of resolution. The ideal or acceptable outcomes of a conflict episode are likely to be related to the type of conflict management strategy employed by a primary party or to the type of intervention used by a third party. However, a conflict episode may have outcomes that go beyond what is expected by the parties involved. Conflict has several distinct types of outcomes: task, performance, and structural. Task outcomes include the resolution of the issue and the direct repercussions of the specific episode. Conflict can also have an effect on individual or group performance, for better or for worse, in the case where the conflict occurs in an organizational context; thus, performance is related to the direct repercussions portion of task outcomes. Finally, the effects of the episode on structural characteristics are a third distinct outcome. Thus, the three categories of outcomes that are discussed here are issue resolution, performance outcomes, and structural characteristics.

Issue resolution outcomes are related to the types of strategies employed to manage conflict. Much of the negotiation literature suggests that an agreement can result in either a distributive outcome or an integrative outcome. In addition, a third possibility is an impasse, that is, no agreement at all. A distributive outcome is one in which there is a fixed resolution that is either taken wholly by one party or somehow divided between the parties. An integrative outcome, on the other hand, is one in which the parties create an arrangement in which both parties are able to fully or significantly

achieve their goals in resolving the conflict. This seems to be an ideal outcome, but in some situations integrative outcomes are not possible. In such cases, impasses and distributive outcomes are the only possibilities.

Jehn has contributed greatly to the research on performance outcomes of interpersonal conflict in organizations. Increased or decreased performance is a conflict outcome of which the primary parties might be unaware. That is, during conflict or as a result of conflict, each party's performance in an organization may either suffer or benefit. Two types of conflict with differing effects on performance in organizations are task conflict and relational conflict. Task conflict is concerned with the content and goals of the work itself such as a disagreement between managers on which market to enter next. Relational conflict focuses on the interpersonal relationship between the parties such as one party having a personal vendetta against the other party.

Moderate to high levels of task conflict appear to result in better performance in an organization. This is likely due to the fact that when bad or less effective ideas are opposed, countering with good or more effective ideas is likely to have a positive effect on performance. On the other hand, relational conflict has a negative effect on an individual's performance, probably due to the distractive effects of interpersonal feuding. In addition, each type of conflict is unique, with one type of conflict rarely transforming into the other (e.g., task conflict becoming relational conflict). This suggests two important points. First, an individual's work performance is affected by conflict. Second, whether an individual's work performance is affected positively or negatively by conflict depends on whether the conflict faced is task conflict or relational conflict.

When a conflict episode ends, the effects of the episode can affect future conflict episodes by influencing or changing characteristics of the parties or the organization. For instance, in 2000, Frone found that conflict with a supervisor can cause a worker to be less committed to an organization and can lead to lower job satisfaction and increase a worker's intention to quit. Similarly, a particularly influential conflict episode can lead to instituting or changing organizational policies on how conflict is handled such as creating an "open door" policy and requiring managers to oversee conflicts between coworkers. Thus, one unintended outcome of a conflict episode might be changes in individual or organizational characteristics that may linger and have important effects on future conflict episodes involving those parties or within that organization.

This suggests that conflict outcomes can be intended or unintended, direct or indirect, and beneficial or detrimental. It is likely that some of the outcomes of a conflict episode will be unintended such as performance outcomes and structural changes. The intended outcome, usually the issue resolution, may be the primary or only focus of a party engaged in a conflict episode. However, it is important for the two parties to recognize that conflict can lead to unintended detrimental outcomes that can outlast the intended beneficial outcomes they are trying to achieve. It is even more important for an organization to recognize that internal interpersonal conflict can result in detrimental outcomes for the firm, requiring third parties to intervene on behalf of the organization's interests and for the benefit of the two parties.

6. THIRD-PARTY INTERVENTION

In some situations, the two parties involved in conflict need assistance in reaching a resolution. For instance, if each party refuses to make any concession and neither party can exert influence over the other party, the result is an impasse. If a resolution is necessary, a third party may get involved to assist in resolution. In other instances, resolution of the conflict may have an effect on organizational interests and a third party may get involved to look out for those interests. Because third parties are often involved in managing conflict, it is important to understand the ways in which third parties can help (or hinder) the management of conflict. It is also helpful to understand what factors affect how third parties will intervene and the effects of such intervention on the organization and the primary parties.

6.1. Methods of Intervention

Two aspects of a conflict situation are relevant to third-party intervention: the conflict process and the resolution or outcome of the conflict episode. Process intervention is primarily concerned with managing the manner in which the primary parties interact. Outcome intervention is a matter of whether the third party has any control over the final decision regarding resolution. In 1985, Lewicki and Sheppard presented a set of third-party intervention methods, each of which exerts high or low process or outcome control. These intervention methods can be seen in Fig. 2.

Using high outcome and process control is referred to as inquisitorial intervention and has been shown

Outcome control	High	Inquisitorial intervention	Adversarial intervention
	Low	Mediation	Providing impetus
		High	Low
		Process control	

FIGURE 2 Third-party intervention methods. Reprinted from Lewicki, R. J., & Sheppard, B. H. (1985). Choosing how to intervene: Factors affecting the use of process and outcome control in third party dispute resolution. *Journal of Occupational Behavior*, 6, 49–64. Copyright John Wiley & Sons Limited. Reproduced with permission.

empirically to be the most common form of intervention employed by managers in dealing with conflict between subordinates. Using this type of intervention, a third party is likely to direct the interaction between the primary parties, deciding what information should be shared, deciding what is relevant or irrelevant, and possibly instructing parties as to how they should behave during the process. The third party is then likely to decide on a good resolution independently and to enforce this on the primary parties.

High outcome and low process control by a third party is referred to as adversarial intervention and is also a common method of intervention used by managers. This method is compared to the American judicial system in which parties present arguments and evidence with little or no direction from the third party. After each party has made a case, the third party makes the decision of how the conflict will be resolved and may even enforce the decision.

A less popular yet still used method of third-party intervention is the low outcome and low process control technique providing impetus. When using this method, a manager may listen to the primary parties to get a basic understanding of what the conflict is about and then suggest that the parties figure out a resolution themselves quickly or else some sort of punishment will be given or enforced. This is similar to a parent telling two children that they had better work out their differences or else they will be punished. A style with similar control as this method, yet more constructive and less threatening, is a method in

which the third party listens to disputants' views, incorporates their ideas, and asks for resolution proposals from the primary parties.

The low outcome and high process control method, or mediation, has been normatively described as the ideal means of third-party intervention but is rarely, if ever, used by managers in handling conflict between subordinates. It is suspected that this type of intervention is not used due to the large time investment required to direct the conflict process yet allow the primary parties to decide on a mutually beneficial resolution. Managers may prefer the other three methods of intervention so as to bring the conflict to a swift conclusion.

A third party is more likely to exert greater outcome control when time pressure is high, when the two parties are not expected to interact frequently in the future, and when the conflict outcome will have an impact on other parties and/or the organization. Greater process control is more likely to be used when the parties are less likely to interact in the future. Thus, it is suggested that managers are likely to use inquisitorial intervention when there are disputes between subordinates who do not interact very often. In addition, managers as third parties are more likely to use more autocratic (high-control) methods than are peers as third parties.

6.2. Outcomes of Intervention

How does one determine to what degree third-party intervention has succeeded? The effectiveness of a third party's involvement can be interpreted according to the achievement and quality of a resolution or according to the primary parties' perceived fairness of the process and outcome. Much of the research on the effects of third-party intervention focuses on the latter. Because third parties can vary in the amount of control exerted over the conflict process and outcome, the primary parties can have different perceptions about the fairness of the process and the outcome.

Procedural justice refers to the degree to which a party perceives that the conflict process was handled fairly by a third party. A party is more likely to perceive the process as fair if a compromise is reached or if the outcome is otherwise favorable to that party. In addition, a party is likely to perceive greater procedural justice when a third party uses mediation, which is a more facilitating role. Providing impetus and inquisitorial intervention may lead to negative perceptions of fairness in the conflict process because these roles are more autocratic.

Distributive justice refers to the degree to which a party perceives the outcome of an episode as fair. In a similar reflection of procedural justice, a party is more likely to perceive the outcome as fair if a compromise is reached or if the outcome is favorable to that party. Therefore, it is no surprise that a party is more likely to perceive an outcome as unfair when the outcome favors the other party. Unlike procedural justice, however, the method of intervention does not appear to have an impact on perceived fairness of the outcome. Research has shown that a party is more likely to perceive the outcome as fair if the process is perceived as fair.

Another possible outcome of a conflict episode is the lack of reaching a resolution, that is, an impasse. The use of autocratic intervention by third parties often increases the chances of impasses or one-sided resolutions, whereas facilitating methods of intervention often increase the chances of compromise resolutions. In addition, an impasse is more likely if a peer, rather than a manager, takes on an autocratic third-party role.

7. CONCLUSION

Interpersonal conflict is an unavoidable aspect of organizational life and can have a substantial impact on individuals and organizations. As noted in this article, conflict can affect task outcomes, performance, and organizational structure. Thus, learning to manage conflict is a worthwhile investment for both individuals and organizations.

This article summarized information that may help to develop a general understanding of interpersonal conflict in organizations. The conflict process was first described in an effort to elucidate the sequence of a conflict episode. Five conflict management strategies were discussed along with suggestions as to when each might be more appropriate. Individual and organizational characteristics that may influence both the development and management of a conflict episode were presented. The effects or outcomes of conflict were noted, as were the possibilities for third-party intervention. Because interpersonal conflict is inevitable, the challenge for individuals in organizations is to use this information to manage conflict more effectively such that positive outcomes are obtained.

GLOSSARY

collectivist cultures Cultures in which the emphasis is on interdependence and the self is defined in relation to group membership.

cultural group A group sharing a common culture.

developed society A society with developed systems of political authority and use of technology in economic production.

individualist cultures Cultures in which individuals are independent of one another and social behavior is largely determined by personal goals rather than collective goals.

pastoral society A society in which grazing sheep and/or raising livestock form the primary mode of subsistence.

subsistence economy An economy that meets little more than the basic necessities and is typically characterized by low levels of production used for consumption rather than exchange.

Theories of conformity have long stressed the importance of cultural values in shaping people's responses to group pressure. Asch, for example, believed that his classic demonstrations of conformity—of people's willingness

to "call White Black"—raised questions about the values fostered by American society and about its educational practices. Others have argued that the early demonstrations of conformity in the United States, especially those of Asch, reflect the particular climate of the McCarthy era and would not be found in the more tolerant culture of post-cold war society. In line with these arguments, evidence for the cultural roots of conformity has come from two types of comparisons: those across cultures and those within a culture at different periods in its history.

1. COMPARISONS ACROSS CULTURES

Studies that have compared conformity across cultural groups can be divided into three broad types: comparisons of subsistence economies, comparisons of developed societies, and comparisons of different cultural groups within a society.

1.1. Comparisons of Subsistence Economies

Berry has argued that different modes of subsistence require different human qualities that are reflected in cultural values and socialization practices and that give rise to differences in conformity. It has been found that pastoral and agricultural peoples emphasize obedience and responsibility in their socialization practices because these economies need people who are

conscientious and compliant, whereas hunting and fishing economies emphasize independence, self-reliance, and individual achievement because these economies need people who are individualist and assertive. Berry argued that if this is the case, pastoral and agricultural peoples should also be more likely to conform than are hunting and fishing peoples. Consistent with this reasoning, he found greater conformity on a line judgment task among the Temne of Sierra Leone, an agricultural society with strict disciplinarian socialization practices, than among the Eskimo of Baffin Island, a hunting and fishing society whose socialization practices are lenient and encourage individualism. However, his later research in Australia and New Guinea, as well as among North American Indians, obtained weaker support for this theory. He also found that where a subsistence economy had been exposed to Western values, there was less cross-cultural variation in conformity.

1.2. Comparisons of Developed Societies

Comparisons of developed societies have yielded a mixed set of findings. Several studies have reported cross-cultural differences in conformity that are explained by the relative values attached to conformity in the societies concerned. One of the earliest comparisons by Milgram found greater conformity on a perceptual task among Norwegian students than among French students, and this was taken as reflecting the fact that Norway is less tolerant of deviance than is France. Some investigators have replicated the Asch experiment, in which participants judge which of three lines is the same length as another line after hearing the unanimous, but manifestly erroneous, judgment of a group of other participants who are in fact confederates of the experimenter. Replications in Brazil, Zimbabwe, Ghana, and Fiji, as well as among the Chinese, found high levels of conformity when compared with the original results, and these findings were interpreted as reflecting the higher value attached to conformity in these societies.

Anticipated differences have not always emerged, however, and further studies of conformity from countries as diverse as Brazil, Lebanon, Zaire, France, Kuwait, Portugal, and Hong Kong all have reported comparable results, leading some authors to remark on the cross-cultural stability of the classic demonstrations of conformity. Studies in Japan, a country that at

first sight might be expected to have higher levels of conformity, have also been inconclusive and point to the importance of taking into account the relationship between the individual and the group. When the majority are strangers to the individual, there is some evidence for a lower level of conformity (relative to the United States) among Japanese students, but other evidence suggests a higher level of conformity when the majority are friends of the individual.

1.3. Comparisons of Cultural Groups within a Society

Some investigators have compared cultural groups within a society as a way in which to study the cultural roots of conformity, although this has not proved to be a fruitful line of inquiry. There is some indication that conformity is higher among minority groups than among majority groups. For example, some studies have found higher conformity among Blacks than among Whites in the United States, and another study found higher conformity among Puerto Ricans than among Whites. A study in Britain found higher conformity among West Indians than among Whites. A study in Fiji found greater conformity among Fijian Indians than among native Fijians. However, there is no consistent pattern of results, nor is it clear why such differences have been found.

1.4. Conformity and Individualism–Collectivism

Cross-cultural comparisons have yielded a mixed set of findings. This may be due, in part, to the methodological limitations of many of the studies in that frequently poor control is exercised over differences in sample and method between the cultures that are compared. Also, comparisons typically are made with single samples from each culture, and evidence from other studies carried out in a culture is disregarded. The explanation for cross-cultural differences, when they are found, is usually post hoc, and there has been little attempt to directly assess the values presumed to mediate responses to group influence. To address these concerns, Bond and Smith in 1996 conducted a meta-analysis of 133 Asch-type conformity studies from 17 countries that was able to provide tighter control over extraneous factors and combine all available evidence from various cultures. Moreover, they proposed that cross-cultural differences in conformity would depend on the extent to which a culture subscribed to

collectivist values as opposed to individualist values. Individualism–collectivism has emerged as the most important dimension on which cross-cultural differences in values have been described, albeit one that continues to be a central topic of debate. In individualist cultures such as European Americans, individuals are independent of one another and social behavior is largely determined by personal goals rather than collective goals. Where personal goals conflict with collective goals, it is personal goals that tend to be prioritized. In contrast, in collectivist cultures such as East Asian societies, the emphasis is on interdependence and the self is defined in relation to group membership. Social behavior is largely determined by collective rather than personal goals, and collective goals are given priority whenever they are in conflict with personal goals. Conformity to the majority would be more likely in collectivist cultures than in individualist cultures given the higher value placed on maintaining harmony in group relations. This was what Bond and Smith found. Using measures of collectivist values derived from three independent cross-national value surveys, they found that studies conducted in collectivist countries tended to report larger conformity effects than did those conducted in individualist countries.

2. COMPARISONS WITHIN A CULTURE AT DIFFERENT PERIODS IN ITS HISTORY

A second line of evidence for the cultural roots of conformity comes from the observation that replications of conformity experiments within a society produce different results at different points in time. Larsen conducted three replications of the Asch experiment and interpreted the different levels of conformity as reflecting sociopolitical changes in American society. The more questioning attitude of students of the Vietnam War era explained the lower level of conformity found in 1974, whereas the decline of student activism explained the rise of conformity levels by 1979. In 1988, conformity had declined again somewhat, and this was seen as reflecting the increase in protest activities. Similarly, Perrin and Spencer were unable to replicate the Asch experiment with British students in 1980, and they attributed this to their more questioning attitude compared with Asch's respondents during the 1950s. They concluded that the Asch experiment was not an enduring social

psychological phenomenon but rather one rooted in its historical context. A few years later, another study found some conformity among British students that was attributed to the greater cohesiveness brought about by the Falklands war.

Not all investigators have found it difficult to replicate the Asch experiment, however, and several other recent studies of university students conducted in Britain, Belgium, Holland, and Portugal all have found reasonably high levels of conformity comparable to those found in Asch's research. Another line of argument, proposed by Lamb and Alsifaki, is that levels of conformity have been steadily on the increase, drawing on the hypothesis that modern industrial societies are characterized by increasing numbers of "other-directed" types who are more easily influenced by peer pressure.

This line of inquiry is highly speculative given that there are many potential reasons, apart from changes in the sociopolitical context, why two studies conducted at different points in time would give different results. Nevertheless, Bond and Smith's meta-analysis of Asch-type conformity studies enabled a synthesis of a number of studies and controlled for differences in study design and method. Using only those studies carried out in the United States, of which there were 97 in total, Bond and Smith found that the level of conformity was related to the time when the study was carried out. Studies carried out more recently have tended to report lower levels of conformity than did earlier studies, perhaps suggesting that there has been a greater value placed on independence in U.S. society during the post-World War II era.

3. CONFORMITY OR HARMONY?

The social psychological literature, by and large, portrays conformity in negative terms. The individual is pitted against the group, and to yield to group pressure is an act of submission and a sign of weakness. Individuals are expected to express their own opinions, and those who continue to do so in spite of pressures to do otherwise are admired. Such a view of conformity is rooted in Western individualist values in which self-expression and independence from the group are highly valued. Viewed from the standpoint of collectivist values, however, such behavior may seem selfish and immature. In such societies, individuals should seek to maintain harmony with the group, and open disagreement can be a source of embarrassment. Thus, the same behavior might be viewed as conformity in an

individualist culture (and be judged negatively) but be viewed as maintaining harmony in a collectivist culture (and be judged positively).

In 1999, Kim and Markus demonstrated the different values placed on conformity and uniqueness in collectivist and individualist cultures. For example, they found that magazine advertisements in Korea were more likely to have conformity themes, emphasizing respect for collective values and beliefs as well as harmony with group norms, than were those in the United States. In contrast, advertisements in the United States were more likely to have uniqueness themes consisting of freedom, choice, individual uniqueness, and rebelling against collective values and beliefs. These authors also studied preferences for unique or common elements of abstract geometrical figures and found that European Americans preferred unique elements, whereas East Asians preferred common elements. Thus, conformity takes on different meanings depending on the network of values and beliefs that comprise the cultural context within which the behavior occurs, and these differences in meaning in turn will entail that conformity or independence will carry different affective consequences.

4. CONCLUSION

The literature on cross-cultural differences in conformity has provided a mixed set of results. This is due, in part, to the difficulty in ensuring comparable methods and samples when conducting cross-cultural research, and conformity studies are in any case difficult to carry out because it is so easy to arouse suspicion among participants. Most studies have used the classic conformity paradigms of Asch or Crutchfield and have used mostly perceptual judgment tasks. The major limitation has been the lack of attention to underlying process or theoretical elaboration of relevant features of the situation. Recent work relating individualism–collectivism to conformity goes some way in redressing

this issue and suggests that people in collectivist cultures will conform more. There is also some evidence that conformity in U.S. society has declined since World War II. However, no studies have yet directly assessed how collectivist values relate to conformity. Moreover, the nature of collectivism suggests that the relation of the individual to the group is crucial and that it is not generally true that people in collectivist societies will conform more. In collectivist cultures, individuals will seek to maintain harmony with in-group members but may be less concerned about maintaining harmony with out-group members. Finally, care must be taken in interpreting behavior within its cultural context. Conformity may reflect a different capacity to resist group pressure or a different determination to avoid embarrassment. Similar behavior may take on different meanings and reflect different processes in different cultural contexts.

GLOSSARY

delta rule (backpropagation rule) A well-known algorithm used in a connectionist network for adjusting the strength of links among artificial neurons as a function of the amount of errors generated when the network predicts outputs based on its inputs.

distributed approach to meaning An approach where a meaningful concept is represented in a connectionist network by a pattern of activation over a number of nodes or artificial neurons.

“exclusive or” operation A logical operation where either one or the other alternative is selected and where both alternatives may not be selected.

feedforward network A type of connectionist network architecture in which input signals are transmitted forward, but not backward, to output nodes.

generalized delta rule An algorithm for adjusting the strength of links among artificial neurons so that a connectionist network can learn input–output relations.

Hebbian learning rule An algorithm for adjusting the strength of connections among artificial neurons where the amount of change in connection strength is a function of the amount of activation of the connected neurons; it is named after Donald Hebb, who first proposed the idea for the learning involving real neurons.

localist approach to meaning An approach where a meaningful concept is represented in a connectionist network by a corresponding node or artificial neuron.

multilayer feedforward network A type of connectionist network architecture in which several clusters (or layers) of artificial neurons are connected with each other and input signals are transmitted only forward through multiple layers of artificial neurons to an output layer.

recurrent network A type of connectionist network architecture in which input signals are transmitted forward from input nodes to output nodes but also backward from output nodes to input nodes.

sigmoid function A mathematical function that links input amount to output amount (typically of an artificial neuron) where output increases slowly when the amount of input is small or large but increases rapidly when the input amount is medium.

supervised learning A type of learning that occurs in connectionist networks where outputs that are to be associated with inputs are provided as standards or “teachers” from which to learn.

synaptic link A link between neurons in a nervous system through which neural signals are transmitted.

tensor network A type of connectionist network architecture in which several clusters of artificial neurons are connected with each other.

threshold function A mathematical function that links input amount to output amount (typically of an artificial neuron)

where an output occurs when an input reaches a certain level or a threshold.

unsupervised learning A type of learning that occurs in connectionist networks where outputs that are to be associated with inputs do not act as standards or “teachers.”

Connectionism is a way of conceptualizing psychological processes that gets its inspiration from the way in which the biological brain processes information. In this approach, psychological phenomena are explained in terms of activations of interconnected neuron-like units whose operations are governed by simple rules.

1. INTRODUCTION

Although ideas akin to connectionism may be attributed to past thinkers such as Aristotle and William James, modern connectionism began its tenure during the mid-20th century. Alongside the theoretical and actuarial development of digital computing based on von Neumann’s concept of serial computing (most current computers are of this type), there emerged a research tradition that took seriously the biological brain as a metaphor for information processing. In this view, just as the brain does its work through neurons and synaptic links, the mind too may be conceptualized as functioning through neuron-like simple units and connections among them. Connectionism, also known as neural networks, is so called due to the network of connections among the neuron-like units that are postulated to explain psychological phenomena.

McCulloch and Pitts, Hebb, and Rosenblatt conducted their pioneering work during the 1940s and 1950s. Nevertheless, Minsky and Papert pointed out in 1969 that some of the simple logical operations such as “exclusive or” cannot be performed by the then available mechanisms. These limitations, together with the development of serial computers as a main technological tool of computation, resulted in a decline in the research on brain-inspired information processing mechanisms. While Anderson, Fukushima, Grossberg, Kohonen, and others continued to work during the 1960s and 1970s, it was the 1980s that witnessed the renaissance of connectionism. A mechanism called the generalized delta rule, which rectified connectionism’s problem identified by Minsky and Papert, was developed. A network of simple neuron-like units was shown to be able to model psychological processes such as perception, memory, and learning. Rumelhart and colleagues’

Parallel Distributed Processing, published in 1986, popularized the connectionist approach.

By this time, however, the approach that used the von Neumann serial computer as a metaphor of mind (a psychological process is considered to be a series of discrete steps of mental operations on some mental representations) had established itself as the dominant research program in psychology and cognitive science. Controversies ensued as to how connectionism differs from the serial processing approach, which approach explains psychological processes better, and whether connectionism provides a realistic model of brain processes.

2. GENERAL FEATURES OF THE CONNECTIONIST COGNITIVE ARCHITECTURE

Although connectionist architectures vary considerably, they can be characterized in general terms. First, a connectionist network typically consists of a large number of units (sometimes called nodes) that are connected to each other with varying strengths (Fig. 1). The operation of each unit is governed by a simple rule (discussed later) that determines its activation state (“firing” or “resting”) as a function of the inputs it receives from the connected units. The connection strength (often called weight) of a given unit to another unit indicates the amount of influence the first unit has over the second unit. Second, the pattern of activation of the units changes over time. The rules used in connectionist networks specify how the activation of a unit at one point in time (t) affects other units at a later time ($t + \Delta t$). Interunit effects occur in parallel, so that during a given time interval (Δt), the effects of all units on other units (a unit may have an effect on itself) take place. As

FIGURE 1 A hypothetical connectionist network. The shaded unit is activated.

a result, the state of a connectionist network can continue to change, potentially forever. However, under some circumstances, the state of a connectionist network shows a discernible temporal pattern. For instance, it may come to a stable pattern, oscillate between two or more patterns, or exhibit a chaotic pattern. Third, a connectionist network performs its function collectively. If one unit is activated, its activation spreads via its connections to other units in accordance with a rule. As these activations reverberate through the network, the network as a whole may then perform various functions such as the encoding and retrieval of information.

Connectionism differs from models of cognition based on the serial computer metaphor in several respects. A serial computer typically has a central processing unit (CPU), data, and procedures (i.e., software) that operate on the data, and the CPU executes the procedures to handle the data. One fundamental assumption of the serial computer metaphor of cognitive processes is that both data and procedures are written in terms of physical symbols. Physical symbols (e.g., the word “cat”) refer to or stand for some objects and events in the world (e.g., the cat on the mat) and are themselves physically coded on a physical medium such as an ink mark on paper, an electronic circuit, or a synaptic circuit in the brain. In contrast, connectionism does not assume the existence of a single CPU; rather, it assumes the existence of a multitude of simple processing units. What the CPU does in a serial computer is governed by a simple or complex set of procedures that can be programmed (e.g., a simple calculator, complex word processing software), but processing units in connectionist networks have a simple and fixed rule. In other words, connectionist networks are not programmable in the same way in which a serial computer can be programmed—although they can be trained or taught (discussed later). Finally, connectionism does not assume the explicit coding of information in physical symbols. Despite these differences, both metaphors have been fruitfully used to advance psychological science. One metaphor appears to be more suited to model some psychological processes than to model others, but both metaphors often do a similarly good job of explaining a set of phenomena. At this point in history, they may be best considered to be different research programs with different theoretical assumptions and conventions rather than two competing paradigms.

Although neurally inspired, connectionist networks are not models of brain functions. Put differently, the relationship between the connectionist network and the

brain is metaphorical rather than literal. To be sure, connectionist modelers often make use of design principles that are observable in the brain. For instance, just as the firing of a neuron is not a simple linear function of the excitation it receives, the activation of a unit in a neural network is often governed by a nonlinear function of the inputs it receives. Just as synaptic connections may be excitatory or inhibitory, connections among connectionist units may be excitatory or inhibitory. However, a learning rule such as the generalized delta rule, which plays an important role in neural network research, has no known corresponding mechanism in the brain. More generally, the brain anatomy is highly structured, but most neural networks do not have differentiated architectures that resemble the brain structure. In the long run, neural network research may become more informed by neuroscience (and, in fact, there is research that tries to model brain functions). Currently, however, connectionist networks are at best highly abstracted and stylized models of how the brain works. For this reason, connectionist networks are often called artificial neural networks.

3. LOCALIST AND DISTRIBUTED REPRESENTATIONAL SYSTEMS AND THEIR PROPERTIES

How do we understand objects and events in the world, and how do we experience our world as meaningful? Meaning is one of the most important questions for models of cognition. In cognitive models based on the serial computer metaphor, symbols gain their referential meanings by designation; a symbol is designated to refer to a certain object or event in the world. In this sense, meaning is built into the system of cognition. In neural networks, meaning is handled in two different ways. The localist approach is akin to the serial models of cognition. Here, a unit in a connectionist network is designated to have its referent. When this unit is activated, the person is considered to be in some sense “thinking about” the referent that the unit represents. In contrast, in the distributed approach, any given unit might not have a clear referent, and its activation cannot be interpreted as corresponding to any meaningful thought in and of itself. Rather, it is a pattern of activations of many units that imply a meaning. In other words, meaning is not localized to a unit but rather distributed across units. A unit in a distributed system then represents some microfeature of a meaningful

concept that may or may not be interpretable using symbols such as words and phrases. In this sense, a distributed approach models subsymbolic processes.

An advantage of the localist approach is its ease of interpretation. The activation of a unit means that the concept represented by the unit is being thought about; changes in activation of a network can be easily interpreted as changes in the content of thought. Although the localist approach may be sufficient to model many psychological processes, the distributed approach might be necessary when some of the following features are important. First, the distributed representational system has a built-in capacity to model similarity. Because a concept is represented by a pattern of unit activation in the distributed system, the similarity between one pattern and another pattern of activation can be naturally interpretable as a similarity in meaning. Second, the capacity to represent similarity enables the distributed system to have the capacity for psychological generalization as an inherent aspect of the system. If a system responds to a pattern in a certain way, it responds to a similar pattern in a similar way; that is, the system generalizes as a natural consequence of its distributed format. Third, these capacities often result in a graceful degradation if the system is damaged. For instance, if one unit in a localist network is damaged or removed, it loses the capacity to represent the corresponding concept. However, even if one unit in a distributed network is lost, it still retains most of the capacity to represent concepts even though the clarity of representation might be compromised to some extent.

4. DYNAMICS OF AN INFORMATION PROCESSING UNIT

In a time interval (Δt), an information processing unit in a neural network receives inputs from other units, computes its net inputs, gets activated according to an activation function, and sends out its output to other units according to an output function. Figure 2 shows a schematic picture in which Unit i receives inputs from its neighbors, Unit j and other connected units, and sends out its output. When a neighboring Unit j sends out its output, o_j , it spreads via the connection with its connection strength or weight, w_{ij} , to Unit i . The input from j to i then is the product of the output and weight, that is, $w_{ij}o_j$. The inputs from other units are also computed in a similar fashion. The Unit i then sums

FIGURE 2 Information processing unit and activation functions.

all inputs to compute its net input, that is, $net_i = \sum w_{ij}o_j$, where the summation is over j , which indexes units that send out their outputs to Unit i .

Whether, or how much, Unit i is activated depends on the net input and the activation function of the unit. Typically, the resting state of a unit is indicated by the activation level of zero and the firing state is 1; however, depending on the architecture, a unit may take a value between -1 and $+1$ or between negative and positive infinity. The activation function determines activation level of the unit as a function of net inputs. Although activation function may be a simple linear function, it often takes a nonlinear form. One example is a threshold function (lower left panel of Fig. 2), where the activation level remains zero if the net inputs remain lower than a threshold value but its level becomes 1 when the net inputs exceeds the threshold.

Another example is a sigmoid function, where activation changes smoothly as a function of net inputs in the shape depicted (lower right panel of Fig. 2). These nonlinear activation functions are critical in some applications. The output of Unit *i* is determined by the activation level of the unit and its output function. Although output is often identical to activation (i.e., $o_i = a_i$), it may vary for some applications.

When activation spreads in only one direction (i.e., from Unit *j* to Unit *i*), activation feeds forward from one set of units to another set in one time interval, whose activation then spreads to a third set in the next interval, and so on. This type of network, called a feedforward network, basically transforms one set of activations in the first set of units into another set of activations in the last set of units. Its main function is to convert one set of signals to another set of signals. In psychological terms, it may be useful, for instance, for modeling how a given situation or stimulus may induce a set of responses. However, activation may spread bidirectionally (from Unit *j* to Unit *i* as well as from Unit *i* to Unit *j*), and the connection strength in one direction may or may not be the same as that in the opposite direction. In these cases, more complex dynamics emerge where activation may spread back and forth and reverberate through the network. This type of network, sometimes called a recurrent network, may tend toward a stable pattern of activation in which activation levels of the units change little or oscillate among several stable patterns. These networks may be used to model memory retrieval processes. Recurrent networks may sometimes exhibit an even more complex pattern known as chaos.

5. DYNAMICS OF INTERUNIT CONNECTIONS

Interunit connections in a connectionist network may be fixed or modifiable. In the latter case, connections are modified in accordance with a learning rule, so that the network may learn contingencies among events in its environment. For illustrative purposes, let us consider a simple example of a distributed feedforward network with two layers. In this network, each layer has three units and there is no connection among the units within each layer, but all of the units in one layer are fully connected to the units in the other layer (Fig. 3). Let us suppose that the network is to learn that when Event A happens, Event B follows. Further

FIGURE 3 A two-layer distributed feedforward network. Shaded units are activated at +1. The bottom layer represents Event A, and the top layer represents Event B.

assume that Event A is encoded by the units in the first layer; when the first unit is activated (+1) but the other units are not activated (0), this means that Event A is represented in the network. Event B is encoded by the units in the second layer; when the first unit in this layer is not activated (0) but the second and third units are activated (+1), this means that Event B is represented in the network.

For the network to learn the association between Event A and Event B, the network needs to modify its connections so that when Event A is represented in the first layer, its activation would spread to the second layer and Event B should then be represented in the second layer. There are two basic types of learning rules that can accomplish this. One is called unsupervised learning, and the typical learning rule is called the Hebbian learning rule, named after the psychologist Donald Hebb. The rule is to strengthen the connection between the units that are activated at the same time. In this example, the connections between the first unit in the first layer and the second and third units in the second layer should be strengthened (e.g., from 0 to 1), whereas the other connections should remain unchanged (e.g., 0). In this case, assuming that input, activation, and output all are the same for a given unit, it is easy to see that the pattern of activation {1 0 0} in the first layer would spread to the second layer and activate the second and third units but would not activate the first unit in the second layer. More formally, this rule is more generally expressed by the following equation: $\Delta w_{ij} = \epsilon a_i o_j$, where Δw_{ij} is the amount of change in connection strength from Unit *j*

to Unit i , a_i is the activation level of Unit j , o_j is the output of Unit j , and ε specifies a learning rate, that is, the parameter that governs the speed of learning.

The other type of learning is called supervised learning, for which the typical rule is the delta (or back-propagation) rule. Here, the connections are changed so that if Event A is represented in the first layer, it predicts Event B in the second layer. Event B acts as a “teacher” that is to be emulated by the network. Here is how the rule works. Assuming that all of the connection strengths are initially zero, all of the inputs to the units in the second layer would be zero. For the first unit in the second layer, then, the teacher is zero and the activation is also zero, that is, no error. When there is no error, the connection strengths remain the same. So, the connections coming into the first unit in the second layer remain zero. However, the teacher for the second and third units says that they should be activated (i.e., +1) even though they are not activated (i.e., 0). The difference between the teacher and the predicted activation is an error, which is then used to modify the connection strength. The rule is to change the connection strength to reduce the error so that the connection with the activated unit gets stronger but that with the resting unit remains the same. Therefore, the connection from the first unit in the first layer to the second and third units in the second layer is strengthened (e.g., from 0 to +1), but the other connections remain unchanged (e.g., 0). Again, this rule can modify the connection strengths appropriately so that the network predicts Event B when Event A is encoded. More generally, this rule is expressed by the following equation: $\Delta w_{ij} = \varepsilon(t_i - a_i)o_j$, where Δw_{ij} is the amount of change in connection strength from Unit j to Unit i , t_i is the teacher’s activation level, a_i is the predicted activation level of Unit j , o_j is the output of Unit j , and ε is the learning rate.

At one level, supervised learning differs from unsupervised learning in the presence of a teacher or supervisor in the learning process. Supervised learning is sometimes said to be less realistic because people learn without being told what they have expected is wrong by how much. However, even with supervised learning rules, there is no need to postulate the explicit presence of a human teacher. The only necessary assumption is that one of the events to be associated is regarded as a teacher. In other words, the “teacher” may be a human, a machine, or nature. More significantly, supervised and unsupervised learning rules differ in terms of their conceptualization of learning. On the one hand, unsupervised learning conceptualizes learning as the observation and learning of the co-occurrence of events in the world.

On the other hand, supervised learning presupposes a learning agent that implicitly predicts what follows what (e.g., Event B follows Event A) and learns from mistakes. In this sense, supervised learning may be able to model adaptation. However, networks with supervised learning may actually be too adaptive in that they might forget previously learned associations—sometimes even catastrophically—when new associations are learned. Unsupervised learning does not have this problem most of the time. Both the Hebbian and delta rules can be generalized to more complex forms.

6. EXAMPLES OF CONNECTIONIST ARCHITECTURES

A tensor network is an example of the connectionist architecture that embodies a generalized form of the Hebbian learning rule (Fig. 4). In the example in the previous section, the network learned the association between two events, but a tensor network is designed to learn to associate three or more events (Fig. 4 depicts a network that associates three events). One cluster of units represents one type of event, the units in one cluster are connected to the units in other clusters, and the connection among units (the connection among three units in Fig. 4) changes as a function of the activation levels of those units. This type of network is called a tensor network because the learning rule can be mathematically described by a mathematical representation called tensor. When one of the clusters of units is activated, its activation spreads to other units, which are then activated to retrieve stored information. A tensor network is suitable for integrating multiple pieces of information into a structured representation. It can bind together different types of information such as color, time of blooming, and

FIGURE 4 A tensor network that associates three events.

habitat; for instance, it can represent the name of a red flower that blooms during the early spring in wetlands. More generally, a tensor network can approximate the intersection of different sets.

A multilayer feedforward network is an example of the architecture that uses a generalized form of the delta rule (Fig. 5). In the previous example, there were two layers of units, but a multilayer network has three or more layers of units. The first and last layers are called input and output layers because they interface with the environment, encoding the incoming information (input layer) and decoding the outgoing response (output layer). The middle layers are called hidden layers because they are hidden from the environment. When the input layer units are activated, their activation spreads to the hidden layer units, which are then activated. The activation feeds forward so that the output layer units are activated. The output layer activation is compared to the relevant teacher, and the discrepancy (error) is then used to modify the connection strengths among the units. First, the connections between the output layer units and the units in the next last layer are modified, then the connections between the next last layer and the units before this layer (input layer in Fig. 5) are modified, and so on. Thus, the error information propagates backward, so to speak, to modify the connections. This is why the generalized delta rule is also called the backpropagation rule. Although a two-layer feedforward network cannot perform a simple logical operation of “exclusive or” (i.e., either/or), a three-layer network with a hidden layer can do so. More generally,

a hidden layer is useful for transforming an input representation to re-represent it.

Some architectures use the Hebbian or delta rule with further modifications to the basic network structure. In recurrent networks (sometimes called auto-associative networks), units may have connections that spread activation not only in one direction but also in the opposite direction. This type of architecture tends to amplify strong activation and dampen weak activation, sharpening the pattern of activation. It can be used for pattern completion; that is, when only a part of the original information is presented, this network can often fill in the missing part to complete the original pattern. Its practical uses include noise reduction and error correction.

Although these types of connectionist networks are based on somewhat different conceptions of learning and have different advantages and disadvantages, they may be combined to model more complex processes. A complex network that combines different types of network architectures is sometimes called a modular architecture. Each module is designed to perform a specified function, whose output is then used by another module for further processing. For example, a recurrent network may be used to clean noisy inputs so as to provide a clearer input to a tensor network, whose output may then be transferred to a multilayer feedforward network for modeling adaptive learning. Several modules may then function in tandem to provide a more complete model of human and animal psychological processes.

FIGURE 5 A three-layer feedforward network.

7. APPLICATIONS OF CONNECTIONISM

Connectionist networks provide versatile research tools for developing a model of human psychological processes. For example, they have been used to model some basic perceptual and cognitive processes such as pattern recognition, learning, memory, categorization, judgment and decision making, and natural language processing as well as more social psychological processes such as person impression formation, stereotyping, causal attribution, and stereotype formation and change. Some models have been used to discuss issues pertaining to developmental psychology. Some networks have been used to model neuropsychological issues; when parts of the interunit connections of a network are removed, the network exhibits behaviors that are similar to those of people with brain lesions. Other variants can model

animal behaviors as well. Although more applied areas of psychological research have been relatively slow to embrace connectionism, there are some signs of its use. Finally, the technology used in connectionist networks has been adopted not only to model psychological processes but also for engineering or other purposes. For instance, optic pattern recognition is useful for machine pattern recognition, and feedforward networks may be used for forecasting.

GLOSSARY

cross-observer agreement Agreement between two or more observers on characteristics of a target person.

exvia In Cattell's system, a broad factor resembling introversion–extraversion.

heritable Determined in part by genes inherited from one's parents.

intercorrelate To vary together such that people who are high on one of the variables are likely to be high on the others as well.

orthogonal In factor analysis, referring to factors that are unrelated to each other.

psychopathology Mental and emotional disorders.

Conscientiousness is one of five major dimensions of individual differences in personality. It contrasts people who are methodical, purposeful, and deliberate with those who are disorganized, lazy, and hasty. Conscientiousness shows strong genetic influences. It is relatively low among adolescents and increases up to 30 years of age. Thereafter, mean levels and individual differences are generally stable throughout adulthood. Low levels of the Conscientiousness factor are associated

with several forms of psychopathology, whereas high levels are associated with academic achievement and superior job performance.

1. CONSCIENTIOUSNESS AS A DIMENSION OF PERSONALITY

Personality traits are tendencies to think, feel, and act in consistent ways. People in every culture learn to describe themselves and others in trait terms, with words such as *nervous*, *energetic*, *original*, *altruistic*, and *careful* referring to personality traits. The English language has several thousand such words. In addition, personality psychologists working in a variety of theoretical perspectives have identified traits such as ego strength, *exvia*, tolerance of ambiguity, dependency, and socialization.

All of these traits are similar in some respects. All are normally distributed; that is, a few people score low, most score in the average range, and a few score high. All traits are relatively stable across time. All of them affect behavior, but their impact is often weak and observable only when averaged across a wide sample of occasions.

It has become clear during the past 20 years or so that nearly all personality traits are related to one or more of five basic personality dimensions or factors, most commonly labeled Neuroticism, Extraversion, Openness to Experience, Agreeableness, and Conscientiousness. Together, these factors and their constituent traits are known as the Five-Factor Model (FFM). Each of the five factors is a broad disposition defined by many narrower

traits. Furthermore, the factors are orthogonal in that people who are very high in Conscientiousness may be introverted or extraverted and may be agreeable or antagonistic.

Many personality theorists have described traits akin to Conscientiousness. These include Tupes and Christal's dependability, Tellegen's constraint, Gough's norm adhering, Cloninger's persistence, Digman's will to achieve, and Cattell's control. These various names reflect somewhat different conceptions of the Conscientiousness factor, with some suggesting a proactive purposefulness and others suggesting an inhibitive self-control. In an attempt to represent the full range of relevant traits, Costa and McCrae in 1991 assessed six facets of Conscientiousness in their Revised NEO Personality Inventory (NEO-PI-R): competence, order, dutifulness, achievement striving, self-discipline, and deliberation. Factor analyses have shown that these six facets intercorrelate and define a clear factor in both men and women, as well as in both adults and children, in many different languages and cultures.

2. ORIGIN AND DEVELOPMENT OF CONSCIENTIOUSNESS

Terms such as *hard-working*, *reliable*, and *persevering* describe desirable aspects of character. Indeed, Conscientiousness was omitted from some personality systems because it was once believed to be a moral evaluation rather than a real psychological attribute. The reality of individual differences in Conscientiousness has now been clearly established by studies of cross-observer agreement. Peer and expert ratings confirm the self-reports that people make about their degrees of Conscientiousness. Furthermore, both self-reports and observer ratings of Conscientiousness predict real-life outcomes such as academic success.

During most of the 20th century, psychologists believed that personality traits could be divided into two categories: temperament and character. Temperament traits were thought to be biologically based, whereas character traits were thought to be learned either during childhood or throughout life. With the advent of the FFM, behavior geneticists began systematic studies of the full range of personality traits, and it soon became clear that all five factors are substantially heritable. Identical twins showed very similar personality traits even when they had been separated at birth and raised apart, and this was equally

true for both character traits and temperament traits. Parents and communities influence the ways in which Conscientiousness is expressed, but they apparently do not influence its level.

Currently, little is known about Conscientiousness in young children because the self-report inventories typically used to assess it are not appropriate for that age group. It is obvious, however, that there are individual differences on this factor at an early age. We know, for example, that some children have attention deficit/hyperactivity disorder, which is characterized in part by problems with concentration, organization, and persistence—traits related to Conscientiousness. Longitudinal and cross-sectional studies suggest that Conscientiousness is relatively low among adolescents but increases between 18 and 30 years of age. Through most of the rest of adult life, there is relatively little change in the average level of Conscientiousness, although it is less clear what happens during extreme old age. Individual differences are strongly preserved, meaning that a careful, neat, and scrupulous 30-year-old is likely to become a careful, neat, and scrupulous 80-year-old.

3. APPLICATIONS

It matters greatly whether one is purposeful, diligent, and persistent or aimless, undisciplined, and impulsive. Consequently, Conscientiousness is associated with a variety of important life outcomes.

3.1. Mental Health and Psychotherapy

Individuals who are low in Conscientiousness are at risk for a number of psychiatric disorders. Because they act without due consideration of the long-term consequences of their actions, and because they lack self-control, they are prone to alcohol and substance abuse. Because they are chronically low in motivation to pursue goals, they are more susceptible to demoralization and depression. Because they do not have a strong sense of social obligations, they are more likely to be psychopaths or to have antisocial personality disorder. In 1998, Ransen and colleagues showed strong associations between Conscientiousness and adult attention deficit disorder.

In principle, very high levels of Conscientiousness might also lead to problems in living. Some theorists link high Conscientiousness to obsessive-compulsive

personality disorder and perfectionism. Highly conscientious people might also be workaholics whose task orientation interferes with family and social life.

The importance of Conscientiousness for clinical psychology and psychiatry was long underrated, in part because one of the chief measures of psychopathology, the Minnesota Multiphasic Personality Inventory (MMPI), does not include clear measures of this factor. It would appear that the assessment of Conscientiousness should be of considerable value in the diagnosis of psychopathology.

Conscientiousness has implications for psychotherapy as well. Individuals who are lax and careless might not show up for therapy sessions, and they are less likely to complete homework assignments. Clinicians whose patients are low in Conscientiousness might need to make special efforts or enlist the assistance of family members to compensate for these patients' low motivation and persistence.

3.2. Physical Health

For several reasons, Conscientiousness is an important determinant of physical health. Conscientious people have the self-discipline to develop and maintain good health habits. They exercise, stick to diets, and drink in moderation. Because they are thoughtful and deliberate, they avoid unnecessary risks in driving, and they are less likely to engage in unsafe sex. Conscientious individuals are likely to be better patients who are more willing and able to comply with prescribed medical regimens. Research has generally shown higher levels of adherence among highly conscientious patients, although many other variables are also involved. For at least some of these reasons, some studies have reported an association of Conscientiousness with longevity.

Conscientiousness may sometimes be affected by physical health, particularly brain injuries or diseases. In both Alzheimer's and traumatic brain injury patients, one of the most notable features is a precipitous decline in level of Conscientiousness. Observed declines in organized and purposeful behavior may prove to be early indicators of brain disease.

3.3. Academic Performance

Research on personality and academic performance can be traced as far back as Webb's 1915 study of character and intelligence. Webb identified a factor called persistence of motives or will that clearly anticipated the construct of Conscientiousness. Many

subsequent studies confirmed that the organization, diligence, neatness, and punctuality of highly conscientious students contribute to academic success.

Academic performance is also affected by Openness to Experience, and combinations of Conscientiousness and Openness define different learning styles. Students high on both factors are prototypical good students, pursuing a wide range of interests with careful and thorough study. Students who are conscientious but closed are more likely to excel in fields such as accounting and pharmacy that emphasize accuracy over imagination.

3.4. Job Performance

Conscientiousness is best known to applied psychologists as the dimension of personality most consistently associated with job performance. A series of meta-analyses have confirmed that highly conscientious people are rated as superior performers in nearly every occupation. Other personality factors are also related to job success, but usually only in specific job categories; for example, Openness is likely to be more useful to a novelist than to a banker. But organization, persistence, meticulousness, and achievement orientation are assets in any job.

Typically, Conscientiousness scores correlate roughly .20 to .30 with performance ratings. This correlation is small, in part because performance ratings are themselves imperfect measures and in part because vocational success also depends on a host of other factors, including intelligence, training and experience, and compatibility with coworkers. Nevertheless, other things being equal, employers would be better off hiring more conscientious candidates.

If test respondents are instructed to "fake good" on a personality inventory, they typically score high in Conscientiousness. Furthermore, job applicant samples typically score higher on desirable traits than do volunteers with no incentive to manage the impressions they are making. These facts have led some industrial and organizational (I/O) psychologists to question whether self-reports on personality inventories can be trusted. However, research to date has shown that Conscientiousness scores are valid predictors even when they are administered as part of a job selection battery.

4. CONCLUSION

Conscientiousness is the dimension of personality most directly relevant to the accomplishment of tasks. Individuals who score high on this factor have clear

goals and the ability to persevere in their efforts to attain them. It is possible, of course, that one's goals are inimical to society, and highly conscientious individuals can sometimes become dangerous criminals or entrenched dictators. For the most part, however, Conscientiousness is useful to both the individual and society, and anyone interested in success in life must take it into account.

GLOSSARY

conservation behavior Actions such as recycling, energy and water conservation, and the use of public transportation that contribute toward environmental preservation and/or conservation.

ecological footprint A measure of the totality of the environmental resources used and waste produced by a single actor (i.e., a person, a company, a nation).

face value action Behavior defined from an observer's viewpoint by its apparent consequences.

factor analysis/extraction A set of mathematical models designed to search for one or more underlying latent (i.e., unobservable) variables, the so-called factors; factors account for the intercorrelations among a set of (observed) variables.

goal-directed action Behavior defined from an actor's viewpoint as a means to achieve a subjective goal.

item A task that provokes a response that is the basis for designing variables.

item response theory (IRT) A set of measurement models in which the observed variable is understood as a function of one or more latent (i.e., unobservable) traits and one or more item features (e.g., difficulty, discrimination, guessing chance).

Rasch model The most basic model within item response theory; in the dichotomous Rasch model, the probability of an approving or correct response in an observed

variable is expected to depend on two parameters only: the difficulty of the item and a latent (i.e., unobservable) trait of the respondent.

true score model The measurement model fundamental to classical test theory (CTT), the prevailing measurement model in psychology; in this model, the scores in the observed variable are a composite of the persons' (unknown) true scores and a random error.

varimax rotation A rotation method that generates orthogonal (i.e., noncorrelated) factor structures; rotation methods are designed to transform the solution from factor extraction into a solution that is easier to interpret.

Conservation behavior can be approached from either an observer's or an actor's viewpoint. When behavior is defined from the outside by its face value, even seemingly similar behaviors such as glass, paper, and battery recycling fall into distinct categories. When behavior is defined from the inside as a goal-directed performance, even diverse acts such as recycling and ownership of solar panels appear to belong to one class of actions. Correspondingly, there are two distinct research traditions that differ substantially.

1. CONCEPTIONS OF CONSERVATION BEHAVIOR

The impact of individuals' actions on the natural environment has led to ecological transformations of yet unknown gravity. Psychological analyses of

environmental problems have focused on effectively promoting more ecologically sustainable patterns and courses of action such as recycling, choice of transportation, and energy conservation. According to a recent *Journal of Social Issues* article by Stern, behaviors such as these, like other human performances, can be approached from two different angles: from an observer's viewpoint, when behavior is defined by its face value (which is evident in its consequences), and from an actor's subjective viewpoint, when behavior is defined as a motivated or goal-directed performance, namely, as the behavioral means by which people try to achieve a particular goal. Based on these two conceptions of behavior, there are two distinct research traditions that differ substantially in their behavior typology and measurement approach, in the ways in which they link behavior to its environmental consequences, and in the ways in which they tackle behavior change.

1.1. Face Value Action: A Multitude of Behavior Types

As a person drives to the grocery store, to the kindergarten, or to work, he or she is using a car that consumes fossil fuel and pollutes the air. In general, the environmental consequences—air pollution and resource consumption—are the basis for classifying a behavior as conservational or, in this case, nonconservational or environmentally harmful. An example of this view is Axelrod and Lehman's definition that categorizes "actions which contribute towards environmental preservation and/or conservation" as being conservational. Strictly speaking, however, all behaviors have environmental consequences given that every behavior uses the physical environment in which it takes place. Taking a leisurely walk down the sidewalk, for instance, involves breathing air and rubbing off microscopic pieces of concrete and rubber. Because behavior is generally consumptive, it is the relative extent and the particular quality of the environmental consumption that matter in this face value conception of conservation behavior.

When behavior is defined by its face value as it normally is, measurement is traditionally based on factor analysis, varimax rotation, and the true score (measurement) model. In this tradition, even seemingly similar behaviors such as glass, paper, and battery recycling are commonly found to fall into distinct and independent categories of conservation behavior. In turn, psychological research has focused on rather

specific behaviors, such as environmental activism, consumerism, and energy conservation, with a dominant preference for recycling behavior, as was pointed out by Vining and Ebreo. Studying behavior rather particularly, however, ultimately means that modification programs have to be specifically tailored to each type of conservation behavior.

1.2. Goal-Directed Action: One Class of Behavioral Means

Even when a behavior has environmentally harmful consequences, the individual might not necessarily intend to cause damage. At most, the individual accepts harm as a side effect of a particular performance. Thus, from a motivational viewpoint, air pollution and resource consumption often are irrelevant. For example, by taking the car to the grocery store, to the kindergarten, or to work, a person tries to increase his or her comfort level or to decrease transit time. The environmental consequences of the action are by and large ignored. However, if the person's intent is not to pollute the air or use fuel but rather to easily transport groceries home or give his or her child a safe ride, we cannot expect environmental values and attitudes to be the essential internal drives that determine car use. Instead, child-rearing and convenience-related considerations are presumably more crucial. Obviously, it is not a behavior's apparent face value that matters from a motivational viewpoint; rather, it is the personal reason, that is, the subjective goal or purpose that accompanies the act. By this logic, behavior cannot be meaningfully defined by its face value (i.e., by its obvious consequences); instead, it must be defined by its underlying motive (i.e., the goal for which a behavior is a means to an end).

When behavior is defined from a motivational viewpoint as a goal-directed performance (i.e., as the behavioral means necessary to achieve the conservation goal), research has unanimously found even seemingly diverse acts such as glass recycling and ownership of private solar panels to belong to one class of actions (based on the Rasch model within item response theory).

According to Kaiser and Wilson's model, a person's dedication to a conservation goal is most obvious in the face of increasingly demanding hurdles and progressively intolerable sacrifices. Similarly, the more obstacles a person overcomes and the more effort he or she expends along the way to the goal, the more evident

that person's commitment is to the particular cause. Likewise, if the tiniest difficulty is enough to stop a person from taking the goal-implied behavioral steps, devotion to this goal likely is rather low. In other words, the more demanding the behavioral tasks, the greater the commitment to achieving the goal implied by the performances (and vice versa).

In this second research tradition, measurement of conservation behavior essentially takes on the format of a performance test. Thus, motivationally relevant goal-directed behavior cannot be identified by the inspection of single acts. It can be measured only when several performances—all of which are necessary to achieve a particular goal—are considered and when each behavior can be characterized by the personal effort (i.e., the behavioral costs) involved in its realization. These costs are determined by the sociocultural boundary conditions (e.g., terrain, climate, customs, legal regulations, economy, societal infrastructure) in which an act takes place.

2. PERFORMANCE AND CONSEQUENCES

Regardless of whether one favors a consequences- or a goal-based conception of behavior in the conservation domain, it is the environmental impact that matters rather than conduct per se. Thus, psychology's ultimate aspiration must be to reduce people's ecological footprints in terms of pollution and energy and other resources consumed.

2.1. A Primary Focus on Consequences

In a recent *American Psychologist* article, Stern advised psychologists to justify their choice of behavior to study by its relative contribution to environmental preservation. In contrast, others decide to skip behavior entirely and to aim directly at predicting environmental consequences such as the amount of energy or water people consume. The former strategy generally diminishes psychology's significance by encouraging comparison of the impact of individual behavior with that of commercial sectors or industry. Individual households account for only approximately one-third of energy use and for only approximately 5% of solid waste. Such a focus necessarily points to the relative irrelevance of people's motives, values, and beliefs and ultimately to the relative insignificance of psychology.

Research that directly addresses the consequences rather than individual performances typically finds the boundary conditions of an act—the technology that is used, product price, and household size—to be by far the most significant determinants in affecting a person's ecological footprint. For example, regardless of any motivational differences, people consume relatively more energy for heating during the winter than during the summer. Thus, despite the fact that the absolute quantity might be decreased with an extremely conservational attitude compared with a more mundane position, the outside temperature will generally dominate the absolute amount of energy that is consumed. This relative supremacy of the external conditions is especially striking for the most environmentally crucial actions, that is, the expensive and/or high-effort performances such as retrofitting homes and purchasing energy-efficient cars.

2.2. A Deficient Relationship

Focusing on the environmental impact of people's actions obviously takes the face value definition of behavior to its extreme. However, with shared variances of 5 to 15%, the link between conservation behavior and its environmental impact is far from perfect. This finding also explains the diverse results of research based on the two discrepant criteria: behavior and its consequences. Concomitantly, if acting does not have the desired outcome, we can also conclude that people lack knowledge about the actual environmental consequences of what they themselves call conservation behavior. In other words, people may know about the general class of actions that contribute to environmental conservation and/or preservation, but at the same time they might remain ignorant of the relative environmental effectiveness of different behaviors. Logically, consequences are an unreasonable substitute for behavior.

2.3. No Goal, No Drive

Focusing too closely on the consequences ignores the actor's perspective in two essential ways. First, there are myriad environmental consequences that people should or could take into account—energy savings, biodiversity-relevant effects, greenhouse gases, and various air, soil, or water pollutants—all of which are worthwhile to consider but are far too numerous to reflect on altogether concurrently and constantly. Second, if a certain amount of energy to be saved is the ultimate goal, an actor needs to know about the

quantitative conservation effects of the various behavioral alternatives. For instance, what saves how much or relatively more energy: purchasing a fuel-efficient car or driving less? Without such knowledge, we cannot expect people to form a corresponding quantitative performance goal, and without an individual goal, there is no motive for a person to strive for it either. In other words, we cannot expect subjective reasons to be significant for a goal that does not exist. In summary, a focus on the environmental consequences makes it unlikely to find psychological determinants to be notable, and if we wish to assess psychology's factual significance in contributing to environmental conservation, psychologists must pay attention to behavior.

3. SHAPING PERFORMANCE

Despite environmentalists' and environmental scientists' arguments to the contrary, various conservation behaviors seem to fall into one mental category for a majority of people. This implies that various people who wish to act in a conservational way do not necessarily take on the same behavioral tasks to achieve their conservation goals. Whereas one person rides a bike to work, another person uses a car for daily commuting but compensates by avoiding the use of batteries. Whereas one person perceives his or her contribution to environmental preservation by switching to a vegetarian diet, another person sees some irregular recycling of bottles as his or her part. This explains why people excuse their unecological behavior by pointing to their conservational engagement. For example, an intercontinental holiday flight can subjectively be compensated by regularly buying seasonal produce, recycling, and so forth. According to Thøgersen, this interchangeability of various conservation behaviors, from a subjective viewpoint, has not received much attention yet.

3.1. Multiple Behaviors, Determinants, and Complex Interventions

When behavior is defined by its face value as it normally is, conservation behaviors are found to fall into distinct mental categories. However, if avoiding household chemicals and energy conservation are unrelated, substituting one with the other is unreasonable. Not surprisingly, various behaviors have different determinants. And predictably, an integrated theory of the

antecedents of conservation behavior has become a remote goal as well. What psychologists normally find is a multitude of influences differentially significant with various behaviors. And as it turns out, with many specific behaviors, the sociocultural boundary conditions result in the most striking effects. In terms of effect size, sociocultural boundary conditions are clearly more prominent than environmental motives, attitudes, and values, and sociocultural boundary conditions often are even more pronounced than the numerous psychological factors combined. Axiomatically, the more powerful the external conditions are, the less influential the internal ones will be.

In line with Stern in his *American Psychologist* article, conservation psychologists infer that the presence of the appropriate psychological condition, such as the right attitude, explains behavior only when there are relatively insignificant external barriers present—and even then, to a modest degree at best. Predictably, increasing sociocultural opportunities or removing such barriers to performing conservation behaviors often achieves the most powerful effects, especially when the conditions are demanding.

The psychological measures and strategies that are thought to be effective in this line of research are complex because they need to incorporate the fact that people are diverse, live under a variety of different circumstances, and respond to various interventions differentially. In contrast, intervention strategies that consist of single measures, such as a particular persuasion technique that aims at changing people's environmental attitude, often fail to have the desired behavioral consequences. However, the more sophisticated interventions become, the less efficient they are and the more time, effort, and money that are needed to develop and employ them—and, consequently, the less appealing they are for policymakers to widely promote behavior change.

3.2. Differentially Striving for a Single Goal

Because people can do different things to strive for a conservation goal, they can normally choose among various behavioral alternatives. Correspondingly, we cannot deterministically predict future behaviors; that is, we cannot foresee whether people will limit their leisure time mobility, recycle glass, or retrofit their houses. All we can safely expect is a prudent selection of the behavioral means to achieve the goal. Because any behavior being performed requires personal

resources such as time, money, and effort, we can anticipate that if two behaviors seem equally suited to achieve an objective, people will favor the relatively less demanding action over the more challenging one. Hence, if a conservation goal can be accomplished with a variety of different acts, people will most likely go with the less strenuous or less costly one.

Moreover, we can also predict that a person will engage in an act only if his or her motivation to achieve the conservation goal exceeds, or at least matches, the behavioral costs involved in its realization. In other words, the more central the conservation goal is to the person's life, the more demanding the behavioral tasks the person takes on. Predictably, Kaiser and colleagues repeatedly found that people's motivation (i.e., their intention to achieve a conservation goal) almost perfectly reflected in their goal-directed performances.

Behavior interventions, such as improving environmental motivation, generally leave people with a choice. Because the conservation goal can be accomplished with a variety of different acts, people can engage in several activities. They can buy energy-efficient light bulbs, recycle paper, refrain from using a dryer for their laundry, purchase solar panels for their own energy supply, boycott companies with poor conservation reputations, contribute to environmental organizations, and so on. Logically, because psychological measures always aim at the entire range of behavioral means, researchers cannot confirm successful behavior changes when they opt for specific and narrow performance criteria. In other words, the neglect of alternative behavioral means by which people can strive for the conservation goal makes it likely that researchers underestimate the effectiveness of psychological interventions.

Focusing on the entire range of the behavioral means implies that researchers' attention ultimately shifts away from single environmental consequences, such as the amount of heating energy or certain carbon dioxide emissions, and moves toward a person's overall environmental effect. Necessarily, with a goal-directed behavior perspective, psychology addresses the person's entire ecological footprint as well.

GLOSSARY

consultant A professional who provides consultative assistance.

consultee A person who seeks assistance from a helping professional for someone for whom they bear responsibility (e.g., a student).

ecobehavioral Theoretical orientation that combines ecological (broad viewpoint that recognizes environmental, contextual, and individual factors as influencing behavior) and behavioral (focusing on elucidating and changing inappropriate or maladaptive behavior) perspectives to help understand people's actions.

empower Acquire the means or skills to obtain resources necessary for success.

indirect service Assistance provided through a third party rather than directly as in teaching or counseling.

Consultation is the process of establishing a partnership with a parent or professional to provide problem-solving assistance regarding a child or student for whom the parent or professional is responsible. The goal is to promote students' academic and/or social-emotional well-being and performance.

1. INTRODUCTION

Most educators find that they are better able to provide the highest quality education services for their students when they work as partners with other staff and families to address student-related problems and promote competence. School consultation is a systematic process for implementing this partnership and engaging in problem solving. This article describes the knowledge, beliefs, and procedures required for successful practice.

Interest in school consultation became prominent during the late 1960s and 1970s, and there continues to be a high demand for training and practice in this area today. The impetus was that many school practitioners found that demands on their time for direct one-on-one service exceeded their capacity to provide assistance, and they also observed that many problems could be solved or prevented from becoming more serious if teachers and parents were given relatively immediate support in addressing problems that arose. Consultation addressed both of these needs, and it continues to be an important job activity for many school professionals who provide support services, including school psychologists, special educators, guidance counselors, school social workers, speech and language pathologists, and school nurses. As a result, many universities that offer professional training in education and applied psychology now offer formal coursework and practicums in this area. Further

support for such services results from the mounting body of empirical evidence demonstrating the effectiveness of consultative services.

2. DEFINITION

School consultation refers to the process of providing preventively oriented, systematic, reciprocal problem-solving assistance to empower consultees, thereby promoting students' academic and/or social-emotional well-being and performance. Participants form cooperative partnerships using an ecobehavioral perspective, with the consultees retaining responsibility for the students. The process is distinguished from "collaboration" and other services in that students are helped indirectly through the consultative problem-solving process.

3. KEY COMPONENTS AND APPLICATIONS

3.1. Participants

Consultation can involve two or more individuals. The person who provides help (e.g., school psychologist, special educator) is the consultant, and those seeking assistance are consultees (e.g., teachers, parents). The majority of school consultation takes place on a one-on-one basis, but group consultation frequently occurs as well, as with intervention assistance teams and in individualized education program (IEP) meetings or when major school reform initiatives are introduced by an external consultant. A critical distinction between consultation and other services is that the student who is the focus of the problem solving generally is not directly involved in the consultation sessions. In other words, the student is helped indirectly rather than directly as in teaching or counseling.

3.2. Ecobehavioral Perspective

Students and problems must be examined from a broad perspective because many times the issues being discussed have their origins in factors outside of the students and students live in systems outside of the school (e.g., family, community). Frequent causes of problems include the manner in which instruction is delivered, limited opportunities provided for student engagement in class, methods used for behavior management, social relationships, district policies, and

family issues. However, sometimes problems are related to factors internal to students (e.g., those resulting from medical conditions such as attention deficit/hyperactivity disorder, autism, and traumatic brain injury) and to environmental factors (e.g., poverty, emotional neglect or abuse). A behavioral approach is commonly used to identify and define problems, understand the contingencies maintaining them, alter consequences to change the problem behavior, and assess the outcomes of the intervention.

3.3. Preventive Orientation

Consultation makes assistance more readily available rather than requiring a formal referral for an evaluation and then waiting for extended periods of time for it to take place as is traditionally done in many schools. Through consultation, problems can be solved in a timely manner and consultees are likely to seek assistance early before problems become more entrenched and habitual. Likewise, through the process, consultees improve their own skills and learn techniques for solving problem situations that they can apply to similar issues in the future.

3.4. Problem Solving

The essence and purpose of consultation is to solve problems. The starting point is problem identification. If problems are correctly identified, it is highly likely that they will be solved successfully. A structured systematic approach to problem solving is followed, as outlined in [Table I](#).

3.5. Relationship and Interpersonal Aspects

Consultants exhibit warmth, genuineness, and empathy, and the consultant-consultee relationship is characterized by mutual respect, trust, and cooperation. Establishing a partnership with colleagues and parents is critical for effective consultative problem solving. What this means is that the consultant not only must view consultees as partners who possess expertise but also must actively involve and engage them as the problem-solving process unfolds. As a result, consultees are more likely to support and carry out interventions that are developed.

TABLE I
Consultative Problem-Solving Process

Establishment of cooperative partnership

- Promote understanding of each other’s roles and responsibilities
- Avoid the “egalitarian virus” (failure to challenge erroneous opinions)

Problem identification and analysis

- Define problem in behavioral terms and obtain agreement with consultee
- Collect baseline data regarding problem frequency, duration, and/or intensity and conduct task analysis as needed
- Identify antecedent determinants of the problem behavior
- Identify consequences that may maintain the behavior
- Assess other relevant environmental factors
- Identify all available resources

Intervention development and selection

- Brainstorm range of possible interventions
- Evaluate the positive and negative aspects of the interventions
- Select intervention(s) from the alternatives generated

Intervention implementation, sustainability, evaluation, and follow-up

- Clarify implementation procedures and responsibilities
- Implement the chosen strategy
- Evaluate intended outcomes and any side effects
- Program generalization, plan maintenance, and develop appropriate fading procedures
- Recycle and follow up as necessary

3.6. External Consultants

In addition to having special services and other staff providing consultation services, some schools hire outside experts to assist with specific projects, for example, introducing a new program such as Positive Behavioral Intervention and Support Systems and evaluating district efforts to achieve No Child Left Behind Act goal attainment. The services these individuals offer can be highly specialized, but these individuals generally work with districts on a time-limited basis.

3.7. Other Approaches to Consultation

There are many approaches to consultation in schools. Although a behavioral approach, as described in this article, is used most often in schools, mental health and organizational consultation often can be found. The essential commonalities among these approaches far exceed the differences. The term “consultation” should not, however, be confused with the “expert advice-giving” approach typically found in medical settings. The latter approach is very different from the egalitarian process described in this article.

GLOSSARY

archetypes Universally shared ideas and behavior patterns, involving themes such as birth, death, and the devil, that frequently appear in myths, stories, and dreams.

brand loyalty A form of repeat purchasing behavior reflecting a conscious decision to continue buying the same brand.

consumer addiction A physiological and/or psychological dependence on products or services.

consumer psychology The study of the processes involved when individuals or groups select, purchase, use, or dispose of products, services, ideas, or experiences to satisfy needs and desires.

consumer satisfaction/dissatisfaction (CS/D) The attitude a person has about a product after it has been purchased.

consumption situation Factors beyond characteristics of the product that influence a purchase decision.

diffusion of innovations The process whereby a new product, service, or idea spreads through a population.

evaluative criteria Dimensions used to judge the merits of competing options.

evoked set The options identified by a consumer that may satisfy a need.

expectancy disconfirmation model Model whereby consumers form beliefs about product performance based on

prior experience with the product and/or communications about the product that imply a certain level of quality.

heuristics Mental rules-of-thumb that simplify decision making.

information search A scan of the environment to identify the options available to satisfy a need.

lifestyle A pattern of consumption reflecting a person's choices of how he or she spends time and money.

market segmentation The process of identifying groups of consumers who are similar to one another in one or more ways and devising marketing strategies that appeal to the needs of one or more of these groups.

need recognition The stage in decision making when the consumer experiences a significant difference between his or her current state of affairs and some desired state.

opinion leader A person who is frequently able to influence others' attitudes or behaviors.

perceived risk The belief that a poor product choice will produce potentially negative consequences.

psychographics Data about a person's attitudes, interests, and opinions (AIOs) that allow marketers to cluster consumers into similar groups based on lifestyles and shared personality traits.

reference group An actual or imaginary individual or group that influences an individual's evaluations, aspirations, or behavior.

self-concept The beliefs a person holds about his or her own qualities and how he or she evaluates these qualities.

self-image congruence models Models that examine the process of cognitive matching between product attributes and the consumer's self-image.

subculture A group whose members' shared beliefs and common experiences set them apart from others in the larger culture to which they belong.

symbolic self-completion theory Theory that argues that people who have an incomplete self-definition tend to bolster this identity by acquiring and displaying symbols associated with it.

values Culturally determined general ideas about good and bad goals.

Consumer psychology is the study of the processes involved when individuals or groups select, purchase, use, or dispose of products, services, ideas, or experiences to satisfy needs and desires. The decision to consume typically is the culmination of a series of stages that include need recognition, information search, evaluation of alternatives, purchase, and postpurchase evaluation. However, in some cases (especially when involvement with the product or service to be chosen is low), this rational sequence is short-circuited as consumers make decisions based on “shortcuts” called heuristics (e.g., “Choose a well-known brand name”). In other cases (especially when involvement with the product or service to be chosen is especially high, as is the case with extremely risky decisions or when the object carries extreme emotional significance to the individual), subjective criteria also may cause the person’s choice to diverge from the outcome predicted by a strictly rational perspective on behavior. Indeed, many consumer behaviors, including addictions to gambling, shoplifting, and even shopping itself, are quite irrational and may literally harm the decision maker. The study of consumer psychology underscores the importance of individual and group variables that help to shape preferences for products and services. In addition to demographic differences such as age, stage in the life cycle, gender, and social class, psychographic factors such as personality traits often play a major role. A person’s identification with others who constitute significant reference groups or who share the bonds of subcultural memberships also exerts a powerful impact on his or her consumption decisions. These macro influences on behavior make it more or less likely that an individual will choose to adopt new products, ideas, or services as these innovations diffuse through a market or culture.

1. I BUY, THEREFORE I AM

Consumer psychology is the study of the processes involved when individuals or groups select, purchase, use, or dispose of products, services, ideas, or experiences to satisfy needs and desires. The field embraces many kinds

of consumption experiences, ranging from canned peas, a massage, or democracy to hip-hop music or a celebrity such as Madonna. Needs and desires to be satisfied range from physiological conditions such as hunger and thirst to love, status, or even spiritual fulfillment.

Consumers take many forms, ranging from an 8-year-old girl begging her mother for Pokémon cards to an executive in a large corporation deciding on a multi-million-dollar computer system. This article focuses on individual consumers, but with the caveat that many important issues relate to the psychology of group decision making involving dyads, families, and organizations. One must also recognize that the study of consumer behavior is extremely interdisciplinary. Although psychology is one of the core disciplines that have shaped the field, many other important perspectives from economics, sociology, and other social sciences also play a dominant role.

During its early stages of development, the field was often referred to as buyer behavior, reflecting an emphasis on the exchange, a transaction in which two or more organizations or people give and receive something of value. Most marketers now recognize that consumer behavior is in fact an ongoing process and not merely what happens at the moment a consumer hands over money or a credit card and, in turn, receives some good or service. This expanded view emphasizes the entire consumption process, which includes the issues that influence the consumer before, during, and after a purchase.

One of the fundamental premises of the modern field of consumer psychology is that people often buy products not for what they do but for what they mean. This principle does not imply that a product’s basic function is unimportant; rather, it implies that the roles that products play in our lives extend well beyond the tasks that they perform. The deeper meanings of a product may help it to stand out from other similar goods and services. All things being equal, a person will choose the brand that has an image (or even a personality) consistent with the purchaser’s underlying needs.

People’s allegiances to certain sneakers, musicians, or even soft drinks help them to define their place in modern society, and these choices also enable people to form bonds with others who share similar preferences. Following are some of the types of relationships a person might have with a product:

- *Self-concept attachment.* The product helps to establish the user’s identity.
- *Nostalgic attachment.* The product serves as a link with a past self.

- *Interdependence.* The product is a part of the user's daily routine.
- *Love.* The product elicits emotional bonds of warmth, passion, or other strong emotion.

Self-concept refers to the beliefs that a person holds about his or her own qualities and how he or she evaluates these qualities. People with low self-esteem may choose products that will enable them to avoid embarrassment, failure, or rejection. For example, in developing a new line of snack cakes, Sara Lee found that consumers low in self-esteem preferred portion-controlled snack items because they believed that they lacked the self-control to regulate their own eating.

A consumer exhibits attachment to an object to the extent that it is used to maintain his or her self-concept. Objects can act as a "security blanket" by reinforcing people's identities, especially in unfamiliar situations. For example, students who decorate their dorm rooms with personal items are less likely to drop out of college. This coping process may protect the self from being diluted in a strange environment. Products, especially those that serve as status symbols, also can play a pivotal role in impression management strategies as consumers attempt to influence how others think of them. Despite the adage, "You can't judge a book by its cover," in reality people often do.

The use of consumption information to define the self is especially important when an identity is yet to be adequately formed, as occurs when a person plays a new or unfamiliar role. Symbolic self-completion theory suggests that people who have an incomplete self-definition tend to bolster this identity by acquiring and displaying symbols associated with it. For example, adolescent boys may use "macho" products, such as cars and cigarettes, to augment their developing masculinity; these items act as a "social crutch" during periods of self-uncertainty.

Self-image congruence models assume a process of cognitive matching between product attributes and the consumer's self-image. Research tends to support the idea of congruence between product use and self-image. One of the earliest studies to examine this process found that car owners' ratings of themselves tended to match their perceptions of their cars; for example, Pontiac drivers saw themselves as more active and flashy than Volkswagen drivers saw themselves. Some specific attributes useful in describing matches between consumers and products include rugged/delicate, excitable/calm, rational/emotional, and formal/informal.

2. CONSUMERS AS DECISION MAKERS

Traditionally, consumer researchers have approached decision making from a rational perspective. In this view, consumers calmly and carefully integrate as much information as possible with what they already know about a product, weigh the pluses and minuses of each alternative painstakingly, and arrive at satisfactory decisions.

2.1. Stages in the Decision-Making Process

This process implies that marketing managers should carefully study the stages in decision making shown in Fig. 1 to understand how product information is obtained, how beliefs are formed, and what product choice criteria are specified by consumers. This knowledge will enable them to develop products that emphasize appropriate attributes and to tailor promotional strategies to deliver the types of information most likely to be desired in the most effective formats.

2.1.1. Need Recognition

The decision-making process begins with the stage of need recognition, when the consumer experiences a significant difference between his or her current state

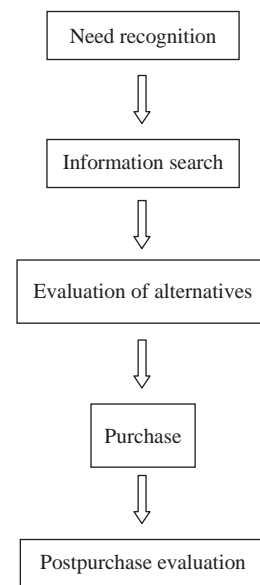

FIGURE 1 Stages in consumer decision making.

of affairs and some desired state. A person who unexpectedly runs out of gas on the highway recognizes a need, as does the person who becomes dissatisfied with the image of his or her car even though there is nothing mechanically wrong with it.

Once a need has been activated, there is a state of tension that drives the consumer to attempt to reduce or eliminate the need. This need may be utilitarian (i.e., a desire to achieve some functional or practical benefit, e.g., when a person loads up on green vegetables for nutritional reasons), or it may be hedonic (i.e., an experiential need involving emotional responses or fantasies, e.g., when a consumer thinks longingly about a juicy steak). Marketers strive to create products and services that will provide the desired benefits and permit the consumer to reduce this tension. This reduction is reinforcing, making it more likely that the consumer will seek the same path the next time the need is recognized.

Maslow's hierarchy of biogenic and psychogenic needs specifies certain levels of motives. This hierarchical approach, shown in Fig. 2, implies that one level must be attained before the next higher one is

FIGURE 2 Maslow's hierarchy of needs. Adapted from Maslow, A. H. (1970). *Motivation and personality* (2nd ed.). New York: Harper & Row.

activated. Marketers have embraced this perspective because it (indirectly) specifies certain types of product benefits that people might be looking for, depending on the various stages in their development and/or their environmental conditions.

2.1.2. Information Search

Need recognition prompts information search, that is, a scan of the environment to identify the options available to satisfy the need. As a rule, purchase decisions that involve extensive search also entail perceived risk, that is, the belief that a poor choice will produce potentially negative consequences. As shown in Table I, perceived risk may be a factor if the product is expensive, complex, and hard to understand or if the consumer believes that the product will not work as promised and/or could pose a safety risk. Alternatively, perceived risk can be present when a product choice is visible to others and the consumer runs the risk of social embarrassment if the wrong choice is made.

2.1.3. Evaluation of Alternatives

Information search yields a set of alternative solutions to satisfy the need. Those identified constitute the consumer's evoked set. How does a consumer decide which criteria are important, and how does he or she narrow down product alternatives to an acceptable number and eventually choose one instead of others? The answer varies depending on the decision-making process used. A consumer engaged in extended problem solving may carefully evaluate several brands, whereas someone making a habitual decision might not consider any

TABLE I
Types of Perceived Risk

Monetary risk	Expensive products
Functional risk	Products requiring time or effort to understand
Physical risk	Mechanical products, medical products, food
Social risk	Socially visible products or those that can influence the impressions made on others (e.g., deodorant)
Psychological risk	Expensive luxuries that may involve guilt or addiction

Source: Solomon, M. R. (2004). *Consumer behavior: Buying, having, and being* (6th ed.). Upper Saddle River, NJ: Prentice Hall.

alternatives to his or her normal brand. Variety seeking, or the desire to choose new alternatives over more familiar ones, can also play a role; consumers at times are willing to trade enjoyment for variety because the unpredictability itself is rewarding.

Evaluative criteria are the dimensions used to judge the merits of competing options. If all brands being considered rate equally well on one attribute (e.g., if all televisions come with remote control), consumers will have to find other reasons to choose one over the others. Determinant attributes are the characteristics actually used to differentiate among choices. For example, consumer research by Church & Dwight Company indicated that many consumers view the use of natural ingredients as a determinant attribute when selecting personal care products. This prompted the firm to develop toothpaste made from baking soda, an ingredient that the company already manufactured for its Arm & Hammer brand.

2.1.4. Purchase

Once a need has been recognized, a set of feasible options (often competing brands) that will satisfy the need have been identified, and each of these options has been evaluated, the “moment of truth” arrives: The consumer must make a choice and actually procure the product or service. However, other factors at the time of purchase may influence this decision. A consumption situation is defined by factors beyond characteristics of the product that influence a purchase decision. These factors can be behavioral (e.g., entertaining friends) or perceptual (e.g., being depressed, feeling pressed for time).

A consumer’s mood can have a big impact on purchase decisions. For example, stress can impair information-processing and problem-solving abilities. The two dimensions of pleasure and arousal determine whether a shopper will react positively or negatively to a consumption situation. In addition, the act of shopping itself often produces psychological outcomes ranging from frustration to gratification or even exhilaration.

Despite all of their efforts to “pre-sell” consumers through advertising, marketers increasingly recognize that many purchases are strongly influenced by the purchasing environment. Indeed, researchers estimate that shoppers decide on approximately two of every three products while wheeling their carts through supermarket aisles. Dimensions of the physical environment, such as decor, ambient sounds or music, and even

temperature, can influence consumption significantly. One study even found that pumping in certain odors in a Las Vegas casino actually increased the amount of money that patrons fed into slot machines. Time is another important situational variable. Common sense dictates that more careful information search and deliberation occurs when consumers have the luxury of taking their time.

2.1.5. Postpurchase Evaluation and Satisfaction

Consumer satisfaction/dissatisfaction (CS/D) refers to the attitude that a person has about a product after it has been purchased. This attitude, in turn, is an important determinant of whether the item will be bought again in the future. Despite evidence that customer satisfaction is steadily declining in many industries, marketers are constantly on the lookout for sources of dissatisfaction. For example, United Airlines’ advertising agency set out to identify specific aspects of air travel that contributed to discontent during the travel experience. The agency gave frequent fliers crayons and a map showing different stages in a long-distance trip and asked passengers to fill in colors using hot hues to symbolize areas causing stress and anger and using cool colors for parts of the trip associated with satisfaction and calm feelings. Although jet cabins tended to be filled in with a serene aqua color, ticket counters were colored orange and terminal waiting areas were colored fire red. This research led the airline to focus more on overall operations instead of just on in-flight experiences, and the “United Rising” advertising campaign was born.

Satisfaction is not determined solely by the actual performance quality of a product or service. It is also influenced by prior expectations regarding the level of quality. According to the expectancy disconfirmation model, consumers form beliefs about product performance based on prior experience with the product and/or communications about the product that imply a certain level of quality. When something performs the way in which consumers thought it would, they might not think much about it. If, on the other hand, the product fails to live up to expectations (even if those expectations are unrealistic), negative affect may result. If performance happens to exceed their expectations, consumers are satisfied and pleased. This explains why companies sometimes try to “under-promise” what they can actually deliver.

2.2. Biases in the Decision-Making Process

Although the rational model of decision making is compelling, many researchers now recognize that decision makers actually possess a repertoire of strategies—and not all of these strategies are necessarily rational. The constructive processing perspective argues that a consumer evaluates the effort required to make a particular choice and then chooses a strategy best suited to the level of effort required.

As shown in Table II, some purchases are made under conditions of low involvement, where the consumer is not willing to invest a lot of cognitive effort. Instead, the consumer's decision is a learned response to environmental cues, for example, when he or she impulsively decides to buy something that is promoted as a "surprise special" in a store. In other cases, the consumer is highly involved in a decision, and again the stages of rational information processing might not capture the process. For example, the traditional approach is hard-pressed to explain a person's choice of art, music, or even a spouse. In these cases, no single quality may be the determining factor. Instead, an experiential perspective stresses the Gestalt, or totality, of the product or service.

Consumption at the low end of involvement typically is characterized by inertia, where decisions are made out of habit because the consumer lacks the motivation to consider alternatives. Many people tend to buy the same brand nearly every time they go to the store. A competitor who is trying to change a buying pattern based on inertia often can do so rather easily because little resistance to brand switching will be encountered if the right incentive is offered.

At the high end of involvement, one can expect to find the type of passionate intensity that is reserved for people and objects that carry great meaning for the individual. When consumers are truly involved with a product, an ad, or a Web site, they enter a flow state. Flow is an optimal experience characterized by a sense of playfulness, a feeling of being in control, highly focused attention, and a distorted sense of time.

Especially when limited problem solving occurs prior to making a choice, consumers often fall back on heuristics, that is, mental rules-of-thumb that lead to a speedy decision. These rules range from the very general (e.g., "Higher priced products are higher quality products," "Buy the same brand I bought last time") to the very specific (e.g., "Buy Domino, the brand of sugar my mother always bought").

One frequently used shortcut is the tendency to infer hidden dimensions of products from observable attributes. These are known as product signals. Country of origin is an example of a commonly used product signal. In some cases, people may assume that a product made overseas is of better quality (e.g., cameras, cars), whereas in other cases, the knowledge that a product has been imported tends to lower perceptions of product quality (e.g., apparel). Price is also a heuristic; all things equal, people often assume that "Brand A" is of higher quality simply because it costs more than "Brand B."

A well-known brand also frequently functions as a heuristic. People form preferences for a favorite brand and then literally might never change their minds in the course of a lifetime. In contrast to inertia, brand loyalty is a form of repeat purchasing behavior reflecting a conscious decision to continue buying the same brand. Purchase decisions based on brand loyalty also become habitual over time, although in these cases the underlying commitment to the product is much more firm. Because of the emotional bonds that can come about between brand-loyal consumers and products, "true blue" users react more vehemently when these products are altered, redesigned, or eliminated. For example, when Coca-Cola replaced its tried-and-true

TABLE II
Limited Versus Extended Problem Solving

Motivation	Low risk	High risk
Information search	Low search	High search
Evaluation of alternatives	Weak beliefs Few differences perceived among alternatives	Strong beliefs Significant differences perceived among alternatives
	Most prominent criteria or heuristics used	Many criteria used
Purchase	Limited time spent	Extensive time spent
	Few stores shopped	Many stores shopped
	Store displays influential	Advertising and store personnel influential

formula with New Coke during the 1980s, the company encountered a firestorm of national call-in campaigns, boycotts, and other protests.

Finally, many of people's reactions to products are based on aesthetic responses to colors, shapes, and objects. Many of these preferences are deep-seated or culturally determined. Package designs often incorporate extensive research regarding consumers' interpretations of the meanings accorded to symbols on the box or can. These meanings may be subtle or blatant, but they can exert a powerful effect on expectations about the product within the box or can. In one study, respondents rated the taste of a beer as heavier and more robust when it was served in a brown glass bottle than when the same product was dispensed in a clear bottle.

2.3. "Irrational" Decision Making

Psychologists have identified many cognitive mechanisms that interfere with "objective" information processing and decision making. Other researchers have gone a step further in their focus on domains of consumer behavior that cannot be readily explained by a cognitive perspective or where an individual's actions are actually irrational and perhaps even dysfunctional. Indeed, some of consumers' buying behaviors do not seem rational at all because they do not serve a logical purpose (e.g., collectors who pay large sums of money for paraphernalia formerly owned by rock stars). Other actions occur with virtually no advance planning at all (e.g., impulsively grabbing a tempting candy bar from the rack while waiting to pay for groceries).

Still other consumer behaviors, such as excessive eating, excessive drinking, and cigarette smoking, are actually harmful to the individual. These actions may be facilitated by many psychological factors, including the desire to conform to the expectations of others, learned responses to environmental cues, and observational learning prompted by exposure to media. The cultural emphasis on wealth as an indicator of self-worth may encourage activities such as shoplifting and insurance fraud. Exposure to unattainable ideals of beauty and success in advertising can create dissatisfaction with the self, sometimes resulting in eating disorders or self-mutilation.

Consumer addiction is a physiological and/or psychological dependence on products or services. Although most people equate addiction with drugs, virtually any product or service can be the focus of psychological dependence; for example, there is even a support group for Chap Stick addicts. Some psychologists are

now voicing strong concerns about "Internet addiction," a condition whereby Web surfers become obsessed by online chat rooms to the point where their "virtual" lives take priority over their real ones. Compulsive consumption refers to repetitive excessive shopping that serves as an antidote to tension, anxiety, depression, or boredom.

3. PSYCHOLOGICAL INFLUENCES ON CONSUMPTION

The business process of market segmentation identifies groups of consumers who are similar to one another in one or more ways and then devises marketing strategies that appeal to the needs of one or more of these groups. One very common way in which to segment consumers is along demographic dimensions such as the following:

- *Age.* People who belong to the same age group tend to share a set of values and common cultural experiences that they carry throughout life.
- *Gender.* Many products are sex typed, and consumers often associate them with one gender or the other. Marketers typically develop a product to appeal to one gender or the other. For example, Crest's Rejuvenating Effects toothpaste, made specifically for women, is packaged in a teal tube nestled inside a glimmering "pearlescent" box.
- *Social class and income.* Working-class consumers tend to evaluate products in more utilitarian terms such as sturdiness and comfort. They are less likely to experiment with new products or styles such as modern furniture and colored appliances. Higher classes tend to focus on more long-term goals such as saving for college tuition and retirement.
- *Family structure.* People's family and marital status influences their spending priorities. For example, young bachelors and newlyweds are the most likely to exercise, consume alcohol, and go to bars, concerts, and movies.
- *Race and ethnicity.* Ethnic minorities in the United States spend more than \$600 billion per year on products and services, so firms must devise products and communications strategies tailored to the needs of these subcultures. Sometimes these differences are subtle yet important. When Coffee-Mate discovered that African Americans tend to drink their coffee with sugar and cream more so than do Caucasians, the company mounted a promotional blitz in black-oriented media that resulted in double-digit increases in sales volume.

- *Geography.* Place of residence influences preferences within many product categories, from entertainment to favorite cars, decorating styles, or leisure activities. For example, BMW found that drivers in France prized its cars for their road-handling abilities and the self-confidence this gave them, whereas drivers in Austria were more interested in the status aspect of the BMW brand.

3.1. Psychographics and Lifestyles

Although these segmentation variables are very important, consumers can share the same demographic characteristics and still be very different people. Psychographics are data about people's attitudes, interests, and opinions (AIOs) that allow marketers to cluster consumers into similar groups based on lifestyles and shared personality traits.

Lifestyle refers to a pattern of consumption reflecting a person's choices of how he or she spends time and money. In an economic sense, a person's lifestyle represents the way in which he or she has elected to allocate income in terms of relative allocations to various products and services and to specific alternatives within these categories. Lifestyle, however, is more than the allocation of discretionary income; it is a statement about who a person is in society and who the person is not. Group identities, whether of hobbyists, athletes, or drug users, gel around forms of expressive symbolism.

3.2. Personality Theory Applications to Consumer Behavior

A consumer's personality, or unique psychological makeup, may influence the products and marketing messages that he or she prefers. Consumer psychologists have adapted insights from major personality theorists to explain people's consumption choices.

3.2.1. Freudian Theory

Freudian psychology exerted a significant influence on applied consumer research, especially during the early days of the discipline. Freud's writings highlight the potential importance of unconscious motives underlying purchases. This perspective also hints at the possibility that the ego relies on the symbolism in products to compromise between the demands of the id and the prohibitions of the superego. During the 1950s, motivational researchers attempted to apply Freudian ideas

to understand the deeper meanings of products and advertisements. For example, for many years, Esso (now Exxon) reminded consumers to "Put a Tiger in Your Tank" after researchers found that people responded well to this powerful animal symbolism containing vaguely sexual undertones.

3.2.2. Jungian Theory

Freud's disciple, Jung, introduced the concept of the collective unconscious, that is, a storehouse of memories inherited from a person's ancestral past. These shared memories create archetypes, that is, universally shared ideas and behavior patterns involving themes such as birth, death, and the devil, that frequently appear in myths, stories, and dreams. For example, some of the archetypes identified by Jung and his followers include the "old wise man" and the "earth mother," and these images appear frequently in marketing messages that use characters such as wizards, revered teachers, and even Mother Nature.

3.2.3. Trait Theory

Trait theory focuses on the quantitative measurement of personality traits, that is, identifiable characteristics that define a person. Some specific traits relevant to consumer behavior include innovativeness (i.e., the degree to which a person likes to try new things), materialism (i.e., the amount of emphasis placed on acquiring and owning products), self-consciousness (i.e., the degree to which a person deliberately monitors and controls the image of the self that is projected to others), need for cognition (i.e., the degree to which a person likes to think about things and, by extension, expend the necessary effort to process brand information), and self-monitoring (i.e., the degree to which a person is concerned with the impression that his or her behaviors make on others).

4. CULTURAL AND INTERPERSONAL INFLUENCES ON CONSUMPTION

Values are very general ideas about good and bad goals, and these priorities typically are culturally determined. From these flow norms, that is, rules dictating what is right or wrong and what is acceptable or unacceptable. Consumers purchase many products and services because they believe that these products will help them

to attain value-related goals. For example, an emphasis on personal hygiene in Japan has created a demand for products such as automated teller machines (ATMs) that literally “launder” money by sanitizing yen before dispensing them to bank customers.

4.1. Subcultures and Reference Groups

Members of a subculture share beliefs and common experiences that set them apart from others in the larger culture. Whether “Dead Heads” or “Skinheads,” each group exhibits its own unique set of norms, vocabulary, and product insignias (e.g., the skull and roses that signifies the Grateful Dead subculture).

A reference group is an actual or imaginary individual or group that influences an individual’s evaluations, aspirations, or behavior. As a rule, reference group effects are more robust for purchases that are (a) luxuries (e.g., sailboats) rather than necessities and (b) socially conspicuous or visible to others (e.g., living room furniture, clothing).

4.2. Opinion Leaders

An opinion leader is a person who is frequently able to influence others’ attitudes or behaviors. Opinion leaders are extremely valuable information sources because (a) they are technically competent and, thus, more credible; (b) they have prescreened, evaluated, and synthesized product information in an unbiased way; and (c) they tend to be socially active and highly interconnected in their communities.

4.3. Diffusion of Innovations

Diffusion of innovations refers to the process whereby a new product, service, or idea spreads through a population. If an innovation is successful (most are not), it typically is initially bought or used by only a few people. Then, more and more consumers decide to adopt it until it might seem (sometimes) that nearly everyone has bought or tried the innovation.

A consumer’s adoption of an innovation resembles the standard decision-making sequence whereby he or she moves through the stages of awareness, information search, evaluation, trial, and adoption. The relative importance of each stage may differ depending on how much is already known about the innovation as well as on cultural factors that may affect people’s willingness

to try new things. However, even within the same culture, not all people adopt an innovation at the same rate. Some do so quite rapidly, whereas others never do at all.

Consumers can be placed into approximate categories based on their likelihood of adopting an innovation. Roughly one-sixth of the people are very quick to adopt new products (i.e., innovators and early adopters), and one-sixth of the people are very slow (i.e., laggards). The other two-thirds are somewhere in the middle (i.e., late adopters). These latter consumers are the mainstream public; they are interested in new things, but they do not want them to be too new.

Even though innovators represent only approximately 2.5% of the population, marketers are always interested in identifying them. Innovators are the brave souls who are always on the lookout for novel developments and who will be the first to try new offerings. They tend to have more favorable attitudes toward taking risks, have higher educational and income levels, and be socially active. In addition, many innovators also are opinion leaders, so their acceptance of an innovation may be a crucial factor in persuading others to try it as well.

As a rule, consumers are less likely to adapt innovations that demand radical behavior changes—unless they are convinced that the effort will be worthwhile. As a result, evolutionary changes (e.g., a cinnamon version of Quaker oatmeal) are more likely to be rapidly adapted than are revolutionary changes (e.g., ready-to-eat microwaveable Quaker oatmeal). The following factors make it more likely that consumers will accept an innovation:

- Compatibility with current lifestyle
- Ability to try the product before buying
- Simplicity of use
- Ease of observing others using the innovation
- Relative advantage over benefits offered by other alternatives

GLOSSARY

obligation A commitment to some future action.

relational relationship Focusing on open-ended relationships involving considerable investments of all parties.

transactional relationship Focusing on short-term and monetizable exchanges.

violation A failure to comply with the terms of the contract.

zone of negotiability Room at the level of the individual party for negotiation about contract terms.

A contract is an exchange agreement between parties. In employment, psychological contracts are drivers of employee behavior with a strong influence on organizational outcomes.

1. INTRODUCTION

Contracts are the cornerstones of our society. Contracts about exchanges are a common feature of

societies all over the world. We seem not to be able to do without contracts. In our private lives, we have marriage contracts and other forms of contractual arrangements that people make when they decide to live together. In our social lives, we have contracts in the form of sports club memberships, political party memberships, and the like. We make contractual exchanges when buying houses, booking holidays, paying for insurance, and so on. At work, we have labor contracts. Contracts play a very prominent role in our daily lives. One could say that, in a way, we are nearly permanently occupied with fulfilling contract terms. Therefore, it is inevitable that we will sometimes be confronted with unfulfilled or broken contracts by ourselves or by other parties.

2. WHAT IS A CONTRACT?

The belief of obligations existing between two or more parties is the basis for a contract. A contract is an exchange agreement between two (or more) parties. The contract may include written terms, orally communicated terms, or other expressions of commitment and future intent. As generally defined, a contract is based on a mutually agreed on, voluntarily made exchange of promises between two (or more) parties, where each party gains if the exchange agreement is fulfilled and each party loses if it is not.

3. DIFFERENT TYPES OF CONTRACTS

Contracts can be viewed from various angles. The economic focus is on transaction or relationship costs of the contractual exchange relationships. The legal focus is on the formalized terms and procedures and on issues related to contract fulfillment. The term “social contract” refers to a pact or an agreement made by all of the individuals who are to compose it.

The term “psychological contract” refers to ideas about mutual obligations in the exchange agreement. One view on the psychological contract is that it includes the perceptions of both parties. Another view limits the psychological contract to individual beliefs about the exchange agreement. It includes and adds to the economic and legal perspectives. The social contract is based on generalized psychological contracts.

Psychological contracts address the important issue of incompleteness of contracts. It is virtually impossible to create complete formal contracts. Unforeseen events may arise over time. Foreseen events cannot always be described unambiguously, and the costs of negotiating all possible events and consequences might be too high. Psychological contracts are generally understood agreements that fill in the gaps of the formal agreement.

A general distinction can be made between transactional contracts, which have the characteristics of an “arm’s length” market transaction (e.g., between buyer and seller), and relational contracts such as complex long-term relationships between employer and employee.

4. CONTRACTS IN EMPLOYMENT

A basic feature of employee–employer interaction is the nature of the exchange in the employment relationship. An employment relationship is a contract based on a mutually agreed on, voluntarily made exchange of promises between two (or more) parties, where each party gains if the exchange agreement is fulfilled and each party loses if it is not. Each component can vary in response to the social context in which employment is embedded.

A meeting of the minds of employer and employee is implied in the term “mutuality.” Whether there is actually a moment when parties share a crystal clear understanding regarding the terms of their exchange is open to question. Nevertheless, at the start of the employment relationship, there is at least a perception of agreement if not necessarily agreement in fact.

Both employer and employee have free choice in entering into and accepting the terms of an employment arrangement. However, this is always a matter of degree. Voluntariness in employment is historically rooted in the evolution of institutions such as individual rights, ownership of private property, and collective bargaining. Voluntariness in employment is possible when individuals have the right to control their own time, services, and use of their skills. Employer beliefs regarding worker freedom of choice (e.g., job opportunities elsewhere) influence the inducements that employers offer in exchange for worker contributions.

5. CONSEQUENCES OF VIOLATIONS OF CONTRACTS

Fulfilling contract terms by the organization leads to greater employee commitment to the organization and to the relationship. Consequently, readiness to accept work roles and tasks, willingness to engage in extra-role behaviors, and willingness to avoid negative behaviors (e.g., coming to work late, not performing well) will be greater. This will result in more committed, motivated, and trusting organizational citizens.

More favorable psychological contracts are related to a higher degree of organizational commitment and a lower degree of intention to leave the organization. On the other hand, when employees believe that the organization has not fulfilled its side of the bargain, they are less likely to engage in extra-role behaviors (e.g., organizational citizenship). Employees who believe that the organization has violated certain terms of the psychological contract will be more likely to have high rates of tardiness and absenteeism and a higher intention to leave the organization. Anger, disappointment, and strong emotions may also be consequences of not fulfilling contract terms.

6. CROSS-NATIONAL DIFFERENCES

Who the parties to the employment agreement are varies considerably across countries, as does the actual level at which the exchange agreement is created. Societies ascribe varying importance to the parties of an employment contract. The status and esteem of government and the state per se differ considerably. Because parties to employment agreements entail a wide range of societal actors, employment agreements can arise at several

levels: between the individual worker and the firm, between groups of workers and the firm, between groups of workers and groups of firms, and in central agreements involving groups of workers, employers, and the state. An industrial relations system involves three sets of actors: employers, workers (typically in groups either within or between firms), and the government (including direct negotiation involving governmental officials, governmental mediation of employee–employer agreements, or creation of laws and statutes specifying conditions of employment).

Three general types of employment and industrial relations systems are direct exchanges between firm and employee; central agreements between employer organizations and unions (or comparable parties), with possible segregation at various levels (e.g., nationwide, type of industry); and employment relationships anchored in society (i.e., the state and institutions), where regulations and statutes predominate in the construction of the employee–employer exchange.

Direct firm–employee exchanges are more prevalent in countries such as Israel, New Zealand, Singapore, and the United States (except in the case of unionized firms). Central agreements play an important role in countries such as Australia, Belgium, India, Mexico, The Netherlands, and Sweden. Regulations play a significant role in countries such as France and Japan.

One striking difference across societies is in the zone of negotiability of the individual employment relationship. Factors shaping it include the individual's personal power in constructing an idiosyncratic arrangement with the employer, the employer's willingness to demand or offer unique or varied employment conditions to individual workers, and the society's regulation of employment and tolerance for unequal outcomes. State intervention or central agreements have the most salient effect on the range and boundaries for what is negotiable between employers and workers. State-level interventions have several effects. Regulations constrain what conditions are negotiable and mandate others. Central agreements, negotiated collectively, limit individual-level variability in contract terms. Both appear to be more prevalent in societies that are relatively intolerant of outcome inequality or where there are institutional concerns regarding disparities in power between labor, on the one hand, and management and owners, on the other. Laws stipulate which conditions are non-negotiable, for example, requiring payment of retirement or unemployment taxes and providing extended family leave benefits following childbirth. Laws also serve to enforce negotiated terms of employment.

Nonlegal factors can also constrain the zone of negotiability. Cultural norms, in particular, can effectively remove certain employment terms from the bargaining table. In societies with strong state influence or central agreements, the focus of negotiation and flexibility shifts to what is possible within or around the rules. There tends to be a relatively clear demarcation of which issues are on the negotiation table and which ones are not. Yet even when the wage system has been standardized with strict rules for salary ranges for certain jobs, there is often room at the level of the individual worker for negotiation about salary within the given range or about the title of a particular job.

7. IMPLICATIONS

Contractual agreements play a very prominent role in our society and in the world of work. Contractual exchange agreements at work determine employee behavior and organizational outcomes.

In the contracting process clear communication and careful assessment of the contract terms is necessary; constant monitoring and renegotiating, adjusting to changing needs of the organization and the individual employee.

In the future, we can expect considerable innovation and experimentation in contracting. Critical questions will center on how to balance differentiation and fairness, especially in situations where employees are interdependent, and how to integrate groups and promote cooperation while keeping clear boundaries for individual psychological contracts. A greater variety of contract types, including more “individualized” results of contract negotiations, will exist. Contracts made today are a way in which to both know and shape the future. The management of psychological contracts is a core task for firms that attempt to develop “people-building” rather than “people-using” organizations in an organizational climate characterized by trust. Increasingly, managing the psychological contract is a core task for workers themselves, who seek to meet their own needs in active individual- and group-level negotiations with their employers.

GLOSSARY

adaptability The ability to gather information from the task environment and use it to adjust the team's strategy through the use of compensatory behavior and the reallocation of interteam resources.

cooperation Includes offering help to only those team members who need it, pacing activities to fit the needs of the team, and behaving in an unambiguous manner so that actions are not misinterpreted.

cross-training A training strategy in which teammates develop an understanding for the tasks, mission, objectives, and responsibilities of the team; this strategy targets team members' interpositional knowledge and shared mental models for development with resulting gains in team coordination.

mutual performance monitoring Monitoring fellow team members' performance while maintaining individual responsibilities to improve overall group performance.

shared mental models (SMMs) Shared understandings or representations of the goals of the team, individual team member tasks, and how team members will coordinate to achieve their common goals; individual team members can

have a varying degree of overlap or "sharedness" among their mental model of the team.

team Collective of interdependent individuals who have shared habits of thinking, mental models, and paradigms that guide their perceptions and behaviors toward a common goal.

team building Targets role clarification, goal setting, problem solving, and/or interpersonal relations for improvement.

team coordination training Focuses on teaching team members about basic processes underlying teamwork; this strategy targets mutual performance monitoring and backup behavior as well as other critical teamwork competencies and skills for improvement.

team orientation The preference for working collectively and the tendency to enhance individual performance by using task inputs from other group members during group tasks.

team self-correction training Team members are taught techniques for monitoring and then categorizing their own behaviors; this process generates instructive feedback so that team members can review performance episodes and correct deficiencies.

team structure Refers to the power structure (e.g., hierarchical), the number of team members, and the diversity among them.

Teamwork is a set of flexible behaviors, cognitions, and attitudes that interact to achieve desired mutual goals and adaptation to changing internal and external environments. It consists of the knowledge, skills, and attitudes (KSAs) that are displayed in support of one's teammates and the team's objectives. Essentially, teamwork is a set of interrelated thoughts, actions, and feelings that combine to facilitate coordinated adaptive

performance and the completion of taskwork objectives. When teamwork KSAs are mastered and displayed, teams can achieve a level of performance and effectiveness that is greater than the total efforts of all individual team members.

1. IMPORTANCE OF TEAMWORK

The nature of work is changing. Recent technological advances, a shift from manufacturing to service-based organizations, increased global competition, and the importance of knowledge workers all have contributed to a dynamic and complex work environment. To survive, organizations must embrace flexibility and adaptability. They must have a systems view that helps them to integrate the meaning of common everyday occurrences into overall interrelationships, interdependencies, and patterns of change to allow them to achieve this needed adaptability. Very often, organizations accomplish these goals through the implementation of teams. It is in direct response to increasingly severe time pressures, technological advancements, and other elements of highly complex environments that teamwork has become an established stronghold and a source of competitive advantage for today's organizations. Teams are also called on when the task demands are such that the capabilities of one individual are exceeded or the consequences of error are high. Therefore, the utility of teams and teamwork has spanned industry to include aviation, nuclear power, and the military.

A team is a collective of interdependent individuals who together have shared objectives, mental models, and procedures that guide their perceptions, thinking, and behaviors toward a common goal. The process in which teams achieve this commonality is called collaboration. Similarly, cooperation has been discussed as a team skill competency that includes offering help to those team members who need it, pacing activities to fit the needs of the team, and behaving so that actions are not misinterpreted. Collective organizations immerse themselves in the virtues of collaboration and cooperation by reducing the hierarchy of social stratification on which traditional bureaucratic organizations rely. Furthermore, they encourage decisions to be made by the collective group to foster a sense of community and shared purpose. Cooperation and teamwork facilitate coordination, communication, adaptability, enhanced employee participation, and empowerment, thereby allowing individuals to achieve collective outputs that are greater than the sum of their parts.

Organizations continue to depend on teams and the synergy they engender to assist in streamlining work processes that promote efficiency, increased innovation, and quality products and services.

This article outlines the nature of cooperation and teamwork as it is manifested in organizations. It examines what derails teamwork and what facilitates it as well as how to promote it through training. The article concludes with a discussion of the need to measure training effectiveness and offers a brief discussion on how this is done. Because teams and teamwork will likely continue to play a vital role in organizations into the future, it is a worthy endeavor to examine their nature.

2. TEAMWORK EXAMINED

Despite extensive writing on the topic, a clear definition and description of teamwork continues to be elusive. In general, teamwork is more than just the summated task or task-related accomplishments of the individuals who make up a group. It is the interaction of team-related knowledge, skills, and attitudes (KSAs) of all team members—and the ability to capitalize on this pool of resources—that maximizes the potential effectiveness of the group to outperform even the most competent individual member of the team. The definition of teamwork provided here is a synthesis of previous definitions that have been advanced by established team researchers. Therefore, teamwork is defined as a set of flexible behaviors, cognitions, and attitudes that interact to facilitate taskwork and achieve mutually desired goals and adaptation to the changing internal and external environments. Although many behaviors, cognitions, and attitudes have been presented in the teamwork literature, this article presents and briefly describes only a subset of those “components of teamwork” previously identified as critically important.

Team members may exhibit several behaviors that comprise teamwork: mutual performance monitoring, backup behavior, adaptability, closed-loop communication, and leadership. Mutual performance monitoring involves monitoring fellow team members' performance while still maintaining individual responsibilities. The intent is to improve overall group performance by detecting errors, deficiencies, and overloads that inhibit the team's actions. As team members monitor their teammates' performance and are able to detect deficiencies or overloads, they are able to shift work responsibilities to other team members or provide feedback about errors if and when it becomes necessary. This is referred to as

backup behavior. Taken together, mutual performance monitoring and backup behavior result in a team that is adaptable and flexible. Adaptability has been described as the capacity to recognize deviations from expected action and to readjust those actions accordingly.

Closed-loop communication also facilitates teamwork by ensuring that accurate information is given and understood by team members. It involves the sender initiating a message, the receiver accepting and acknowledging the message, and the sender ensuring that the intended message was received. When communication fails, implicit coordination and the shared understanding of the team's task may deteriorate. Finally, effective team leaders facilitate teamwork by consistently encouraging mutual performance monitoring, backup behavior, adaptability, and communication. The team leader's failure to guide the team in these behaviors may inhibit coordinated and adaptive action and can be a key factor in deficient team performance. However, the behaviors described previously are only a part of the overall picture of teamwork. There are also cognitive and attitudinal components of teamwork that facilitate these behaviors, and a few of them are briefly described in what follows.

Shared mental models have been a frequently discussed cognitive component of teamwork. In 1995, Cannon-Bowers and colleagues suggested that shared mental models are shared understandings or representations of the goals of the team, individual team member tasks, and how the team members will coordinate to achieve their common goals. Similarly, familiarity of task-specific teammate characteristics is also an important component of teamwork. Familiarity includes knowledge of the task-related competencies, preferences, tendencies, and strengths and weaknesses of teammates. Knowledge of teammates and their weaknesses can have a profound influence on team communication and interaction patterns. In fact, research has demonstrated a moderate relationship between high levels of familiarity in teams and both productivity and decision-making effectiveness.

The primary attitudinal component of teamwork is team orientation. Team orientation is frequently described as a preference for working with others. More specifically, however, it is a tendency to enhance individual performance by placing value on group input and using input from other group members while performing a group task. When discrepancies occur among team members' levels of understanding, those with a team orientation have been found to spend more time comparing their comprehension of the situation with that of their teammates to resolve the discrepancy. This provides greater opportunity to reevaluate their shared

understanding of a task and to assist in error detection. Team members who do not have a team orientation are more likely to reject the validity of input from other team members, and this can potentially lead to a decline in team performance. Not all employees see value in working with others, and those who do not are less likely to succeed on teams or to be as cooperative as others. Research has shown that better decisions and higher performance result from teams that contain team-oriented individuals.

Now that the primary cognitive, behavioral, and attitudinal components of teamwork have been examined, the next section presents some concrete explanations for why teams might go off-track or "derail." Although other factors can lead to deficient teamwork (e.g., individual differences, organizational climate, stress), the section focuses specifically on factors that can be influenced through team training and team building.

3. TEAMWORK DERAILERS

Teamwork does not "just happen." Often, an organization will place a group of well-qualified individuals together to work on a project and is surprised when the team does not achieve greatness. Despite the many benefits of teamwork and cooperation at work, teamwork does not occur automatically. But why do teams derail, and how does teamwork erode? Team derailment is defined as the process whereby an effective team experiences a significant decline in performance. This section, from the vantage point of a team competency framework, identifies three primary culprits: high levels of stress; lack of knowledge of the team's mission, objectives, norms, and resources; and dissolution of trust. Any of these may lead to a decrement in team performance and cooperation.

Stress can have a significant effect on an individual's or a team's ability to perform a job. For example, teams operating in the military often face a high-stress environment in which multiple tasks must be performed under time pressure and in ambiguous situations. However, stress can result from situations in which resources are stretched or exceeded, there is danger of physical or personal harm, or the capacity to perform is diminished. Outcomes of stress for individuals in teams can be physiological (e.g., increased heartbeat, sweating), emotional (e.g., fear or anxiety), social (e.g., difficulty in coordinating actions), cognitive (e.g., a narrowing of attention), or have a direct influence on performance (e.g., trade-offs in the speed and accuracy of task performance, impaired decision making). None of these

outcomes is particularly pleasant, and all can potentially impair team performance. One solution for teams operating in high-stress environments may be to provide stress exposure training (SET), which is designed to reduce stress through the provision of information, skills training, and practice to trainees.

To avoid team derailment, team members also need to know their team's strategic and tactical goals, what resources are available to help achieve those goals, and under what conditions the team members will be expected to perform. When this knowledge is lacking, coordination of team member actions and provision of backup behavior and support are also deficient. It has been suggested that when a team initially forms, team members should be given the opportunity to gauge each other's abilities and skills and to cooperatively determine the purpose of their team. This is often referred to as creating a shared mental model of the team, the task, and the processes by which the team will complete the task. Having completed this, the team can then determine how it will accomplish its goals and establish norms of behavior and performance. When a team lacks a clear mental model, it fails to recognize and integrate task contingencies as they arise. Similarly, failure to maintain a shared perception of the situation, strategic and tactical goals, and the resources available to accomplish those goals can lead to decreased cooperation and teamwork.

Finally, trust has become a common construct in the teamwork literature due to its positive relationship to organizational citizenship behaviors, successful negotiation, and conflict management. Understandably, all of these behaviors are essential to cooperation as well. In 1998, Rousseau and colleagues defined trust as a willingness to accept vulnerability due to positive expectations of the intentions or behaviors of others. Mutual trust in a team is a deeply held confidence toward the team's climate, internal environment, and members. It is an attitude held by team members regarding the climate or mood of the team's internal environment. When team members work interdependently to achieve group goals, they must be willing to accept a certain amount of risk so as to rely on each other and openly share information. Lack of trust in this situation may result in a reduction of information sharing as well as extensive time spent in monitoring team members, not for the purpose of improving performance but rather for ensuring their trustworthiness. When organizations fail to create policies that foster trust among team members or do not allow sufficient team interaction, cooperation will deteriorate. Now that some ways in which teams and teamwork may erode have been presented, the next

section describes ways in which teamwork may be enhanced in work organizations.

4. FACILITATORS OF TEAMWORK

A successful team is infused with an energizing spirit that draws the participants together into a cohesive unit and has everyone pulling together to reach a common goal. In general, teamwork can be facilitated, promoted, or encouraged at either the organizational or team level. Important organizational variables include the amount of organizational support offered and the design of the team (e.g., size, diversity, skill composition). At the team level, effective leadership, closed-loop communication, interdependence, and cohesion all contribute to team effectiveness. Although this is clearly not an exhaustive list of all elements that contribute to team functioning, these variables are instrumental in facilitating effective team performance. Each is briefly discussed in turn.

Organizational support is a primary facilitator of teamwork. It is the organization and managers that must instill cultures that encourage common objectives, shared values, mutual trust, frequent and honest communication, and the ability to act in a unitary manner. Sometimes, organizations maintain cultures that do not promote interaction. Instead, these organizations maintain a culture in which blame is constantly placed and responsibility is shifted elsewhere. When this happens, teamwork cannot be facilitated. Furthermore, it is the responsibility of the team leaders to structure team tasks. This includes delegating and assigning the tasks, managing resources, and establishing priorities. Broadly speaking, team leaders set the direction and provide the resources, whereas team members enact organizational objectives and engage in teamwork in service of their organizations.

The design of the team is another organizational level factor that can act as a facilitator of teamwork. Factors such as the size of the team, the diversity within it, and team member skill composition are important. As such, proper selection of team members is important to facilitating team performance. Research suggests that effective teams are composed of between 6 and 10 members. Larger teams provide individual members with the opportunity to "social loaf" as individual inputs may become uninterpretable and indistinguishable from the group's product or service.

Team diversity is another design issue. Research has demonstrated that the amount of cooperation that occurs in teams can be dependent on the degree of heterogeneity of individuals within it, and this heterogeneity can be

related to any differences such as those in skill, qualifications, gender, and/or ethnicity. For example, accomplishing innovation and creativity goals in product teams is more likely when members are very diverse (i.e., heterogeneous). Conversely, teams whose goals include quick production and decision making exhibit increased levels of teamwork when members are very similar (i.e., homogenous). Typically, however, teams composed of heterogeneous members will take longer to begin working together effectively. Over time, and as team members become more familiar with each other, team performance generally increases for teams composed of diverse members.

Team members must display critical knowledge, skill, and attitude competencies while performing in dynamic environments. Team researchers have suggested that general team skills should be used when selecting team members to ensure team effectiveness. Ideally, individuals possessing both task-specific skills (i.e., those relating directly to the tasks to be performed) and team-contingent skills (e.g., those with a team or collective orientation) would be selected to participate in teams. Unfortunately, this luxury is not always available. So, how do the team-level variables of leadership, closed-loop communication, and shared awareness influence team performance and effectiveness?

Team leadership may be the most important element in creating a cooperative work environment. Leadership affects team effectiveness through many processes (e.g., cognitive, motivational, affective). Team leaders set the tone by articulating a clear and motivating vision and creating a supportive climate that promotes effective team processes and behaviors, which may include specific advanced planning, communication of critical process information, and promotion of functional coordination among team members. Information from all team members must be pooled to develop plans and evaluate the consequences of team decisions. However, team leaders must remain flexible and must adapt plans and team strategies to meet task demands so as to avoid a deterioration of teamwork in dynamic and stressful situations. Team leaders' failure to guide and structure team experiences that would otherwise facilitate the development and maintenance of cooperative interactions can be a key factor in ineffective performance. An important point not frequently discussed in teamwork literature is that team members cooperate and commit to teams for different reasons. Some may be motivated to cooperate due to a desire for results, others may be motivated by the satisfaction of working with others, and still others may have less admirable aims.

Therefore, leaders should not assume that motivations are the same for all team members. However, if handled appropriately, even individualistic team member motivations can contribute to common overall team goals.

Communication is also essential for teamwork. Communication creates a shared understanding of the task at hand and ensures that all members possess the required and precise information needed. This is especially important for teams operating in very complex and dynamic environments (e.g., flight deck crews, surgical teams) because it facilitates teamwork behaviors (e.g., backup behaviors) and shared mental models that allow teams to adapt quickly and implicitly. As mentioned previously, closed-loop communication is a particularly important enabler of effective teamwork. Communiqués presented in the prescribed form, tempo, and cadence are examples of proceduralized closed-loop communication used in the military today.

Finally, teamwork behaviors are facilitated by a sense of cohesion and interdependence among team members. Teamwork involves group members' collectively viewing themselves as a group whose success depends on their interaction. Cohesion can be understood as a shared value, whereby the group interests, responsibilities, and success all are taken into account, even at the expense of individual goals. Similarly, interdependence is also typically seen as an essential characteristic of team performance. Effective teams not only have an awareness of the importance of their role in team functioning but also put this into action by fostering within-team interdependence. Effective teams contain individuals who know one another's jobs, offer to help fellow members when it is appropriate to help, and depend on one another for this help.

Discussions of both the possible derailers and potential facilitators of teamwork have now been provided. However, very little has been said about how to promote these behaviors, cognitions, and attitudes. The next section describes ways in which cooperation can be promoted at work through training.

5. PROMOTING COOPERATION AND TEAMWORK AT WORK THROUGH TRAINING

The primary purpose of team training is to provide skills that enhance teamwork. For instance, team training often emphasizes interpersonal and feedback skills in addition to clarifying the need for mutual performance

monitoring, backup behavior, and goal setting. Without this training, efficient and effective taskwork might be handicapped or hindered altogether. Team training is not a program, a place, a simulator, or a collection of individuals being trained together; rather, it is a set of instructional strategies designed to enhance teamwork competencies. Nor is team training the same as team building. Team building primarily targets role clarification and has a greater influence on team member attitudes than on performance.

Although many types of instructional strategies have been developed to assist individuals in teams to cooperate at work, only four of the most prominent and relevant ones are briefly discussed in this section: cross-training, team coordination training, team self-correction training, and team leader training. A discussion of team building is also provided, with a specific focus on the distinction between team building and team training.

The first strategy, cross-training, generally involves training each individual member on the tasks of all other team members. The goal is to create shared task models and knowledge of task-specific role responsibilities to facilitate enhanced performance monitoring and backup behavior. Knowledge of the team's mission and objectives is also targeted in cross-training. This strategy is primarily information based but may also involve simulation exercises.

Team coordination training is similar to cross-training in that it creates a general understanding of teamwork skills, but it does so with a more specific focus on promoting mutual performance monitoring and backup behavior. Coordination training uses practice and behavioral modeling to teach members about teamwork skills and help them understand the underlying processes of teamwork. Team members may be given opportunities to practice and demonstrate the skills taught in low- to moderate-fidelity simulations. These are similar to the ideas that are presented in discussions of crew resource management (CRM) and are frequently used in aviation and military settings.

Another type of training that improves mutual performance monitoring, as well as initiative, leadership, and communication, is team self-guided correction training. The team directly drives this instructional strategy in that team members are taught techniques for monitoring their own behavior and assessing the degree of training effectiveness. The team members then use feedback regarding their performance and effectiveness to correct problems that may have surfaced. The primary focus of this strategy is improved communication and increased levels of performance

feedback to facilitate future performance. Feedback enables team members to perform their subtasks competently and demonstrates the contribution of that performance to the performance of others and of the team as a whole.

Finally, team leader training aims to create leaders who are better able to motivate others, structure tasks, and facilitate shared task models of teamwork behaviors within the team. The emphasis is often on teaching team leaders to effectively debrief their members using input from their whole teams regarding specific behaviors rather than general results or proxies of effectiveness. Lecture, behavioral modeling, and practice are the typical mechanisms used to deliver this type of training.

Another technique that is often used to improve team functioning and effectiveness is team building. Team building should not, however, be confused with team training. Although team training and team building are seemingly similar, they approach teamwork from different perspectives. For instance, team training is generally intended to facilitate a shared understanding of job-related KSAs, whereas team building focuses on the process of teamwork and is intended to assist individuals and groups in examining their own behavior and relationships. It is important to note, however, that team building has been found to have a greater impact on the attitudes of individual team members than on overall team performance. Researchers have suggested that this is due to the fact that team building typically focuses on interpersonal relations, communication, problem solving, goal setting, and/or decision making rather than focusing directly on affecting performance. Because team building is generally one-dimensional in its aim (e.g., problem solving, interpersonal skills), its impact on overall team performance is limited. Finally, it should also be noted that team building is not a one-shot deal; observable improvements in cooperation may take time to appear and often require ongoing attention to attain long-term effectiveness.

Taken together, the importance of team training (and, to a lesser extent, team building) is that it focuses on deficiencies in teamwork KSAs to bolster and coordinate team member actions. Both team and organizational performance are likely to improve as a result of team training interventions. Studies conducted in military and aviation settings have found that enhanced training has resulted in significant team performance improvements. For example, researchers have seen as much as a 45% improvement in mission performance following team training. This includes a 33% improvement in tactical decision-making performance and a 10 to 34%

improvement in team coordination. Regardless of the training strategy used, it is important to measure the impact of training on team performance to determine its utility to the organization. The next section discusses issues related to measuring team effectiveness.

6. MEASURING TEAM PERFORMANCE AND EFFECTIVENESS

The underlying assumption of team training is that teams can be led to perform more effectively. However, to determine whether the enhanced instruction produced its desired effect, the effectiveness of training must be assessed. The effectiveness of training refers to the degree to which desired training outcomes are achieved, that is, the degree to which a team accomplishes its assigned tasks and mission objectives. The most important of these outcomes is the degree to which trainees transfer learned material to the job. When training transfers, the organization can be certain that learned material is used by trainees when they return to their normal work roles. Team performance measures can focus on any section of the team effectiveness input, process, or outcome system and can indicate how the team carried out assigned tasks and objectives.

Extant literature on teams and team effectiveness has identified a number of issues that should be addressed during measurement. Specifically, Salas and colleagues identified five ingredients for any team performance measurement system. First, it must be theoretically based. Second, it must consider multiple levels of measurement. Third, it must be able to describe, evaluate, and diagnose performance. Fourth, it must provide a basis for remediation. Fifth, it must support ease of use. These requirements are described in turn.

The measurement of team performance must be theoretically based, preferably on previously identified models of teamwork. After all, theory building requires that established models be empirically tested to advance the current state of knowledge. Capturing, defining, and measuring the interactions that characterize teamwork are basic to our ability to understand its meaning. Furthermore, understanding the KSAs that define teamwork is critical to establishing a nomological net of the interrelationships of these variables that should be used as the basis for structuring measurement tools. Without grounding the measurement of team performance in theoretical models of

teamwork, team theory cannot move beyond the conceptual stage.

The level of measurement must also be considered. Multiple levels of measurement should be used in the measurement system because teamwork occurs at multiple levels (e.g., individual vs team, process vs outcome). To begin, team performance needs to be evaluated at the individual level, as well as at the team level, to get a complete picture. Effective team performance can be enabled by the actions of team members operating both individually and as a collective.

Often it is impossible to determine what part of performance is due to an individual's abilities and what part is due to the actions of the team as a whole. For teams with a large number of members, individual input to the overall task may be obscured, causing individuals to lose sight of team goals. When this happens, team members will often put their needs in front of helping other team members to achieve the collective goal. Similarly, research has suggested that many individuals prefer individual assessment and find that method to be fairer. This is especially the case when individuals perceive that their individual performance is higher than what is observed at the team level. The consensus seems to indicate that individual performance should be evaluated throughout, whereas team-level outcomes should be assessed following completion of the training task or objective.

Another issue concerning the level of measurement relates to whether a greater emphasis should be placed on evaluating teamwork processes (e.g., compensatory behavior, communication, information exchange, shared task models) or team outcomes (e.g., accuracy, timeliness, product quality, goal accomplishment). Although the outcome of performance is nearly always significant, the measurement instrument should clearly differentiate between the outcome and how the outcome was achieved. In team performance measurement, the decision to evaluate team effectiveness as a team process or a team outcome is particularly important when the purpose of performance evaluation is to provide feedback for performance improvement.

Although many managers focus on team outcomes (e.g., factors that directly affect the bottom line), this evaluation provides no information to the team as to how to make performance improvements. For instance, telling sales team members they did not make the goal of selling 300 widgets provides less information to guide performance improvement than does telling the same team that there had been a noticeable decrease in information exchange among the team members during the past month that resulted in

decreased sales. Measurement must provide information that indicates why processes occurred and how those processes are linked to performance outcomes.

To be of any value, the measurement mechanism must be able to describe, evaluate, and diagnose performance. Measures must be sensitive enough to document the moment-to-moment interactions and changes in performance. Measures must also distinguish between effective and ineffective processes, strategies, and teamwork behaviors. The level of evaluation, type of performance to be evaluated (i.e., process or outcome), and environmental constraints within the organization collectively determine the measurement tools needed to measure team effectiveness. However, if the performance evaluation is conducted for developmental or remediation purposes, it is especially important that the tool be able to describe, evaluate, diagnose, and provide feedback regarding performance. Cannon-Bowers and colleagues provided a concise framework of team performance measurement tools. A few of the more flexible tools (i.e., those that can be used in most situations) are observational scales and expert ratings. More situation-specific tools include decision analysis, policy capturing, and archival records. In a broad sense, performance is typically evaluated through direct observation (e.g., employee behavior) or indirect observation (e.g., employee records, customer communication). The decision to use direct or indirect observation generally depends on what information is available to the evaluator. Both forms have their pros and cons. Similarly, the choice of measurement tool may be guided by the particular organizational and situational constraints imposed on the researcher.

Next, team performance measurement systems must outline a path to improvement. From the performance diagnosis generated, a logical basis for remediation that includes feedback, knowledge of results, and direction for subsequent instruction must be provided. Practitioners must be able to provide teams with feedback necessary to improve future performance. Measurement tools must provide information that indicates why processes occurred as they did and how particular processes are linked to certain outcomes.

A final ingredient of team performance measurement systems is that they must be easy to use. The focus of a particular measure should always be operationalized from a construct that is relatively free of contamination and deficiency, and it should not be tedious or cost-prohibitive to use. One challenge of team research has been to develop powerful, reliable, and valid measurement techniques for measuring team performance.
