In addition to affecting the control of oncogene expression, translocations can alter the form of the oncogene product. In chronic myelogenous leukemia the c-*abl* oncogene on chromosome 9 is moved into the *bcr* gene on chromosome 22 by t(9;22), the classic Philadelphia translocation.[134] Each translocation accomplishes the same result, truncating the N-terminus of c-*abl.* The coding sequences responsible for the N-terminus of the c-*abl* protein are replaced with coding sequences from *bcr.* Thus, an entirely new fusion protein is derived from two genes on two different chromosomes. Functionally, the translocation results in one certain and another possible outcome. The normal c-*abl* product, as discussed above, is an intracellular tyrosine kinase. The activity of the enzyme is tightly regulated in vivo, however. Following translocation, the fusion product, which retains the tyrosine kinase domain of the original c-*abl* oncogene, has constitutively high kinase activity.[135] The second likely outcome of the translocation, although not yet proved, must be to alter some aspect of c-*abl* effector specificity or domain of action. This is inferred from the regularity of the translocation: only *bcr* is involved, and the same region of the c-*abl* protein is affected.

TUMOR SUPPRESSOR GENES

We have shown that proto-oncogenes comprise a set of cellular genes that are involved at all levels of control of cell division and differentiation. In each of the genes discussed thus far, a somatic activating event results in a dominant change. A mutant *ras* gene has a dominant phenotype in the presence of the wild-type allele. A translocated c-*myc* gene is dominant over its unrearranged counterpart. In principle, however, genes that regulate growth and differentiation could demonstrate the opposite pattern: regulatory function preserving a normal pattern of growth would only be observed in the wild-type form. Any mutation or rearrangement would tend to inactivate such genes, leading to loss of growth control. Since the wild-type allele could suppress these mutations, they would be recessive at the cellular level.

Genes that display this property have now been discovered. Originally called recessive oncogenes or anti-oncogenes, they have come to be known as tumor suppressor genes because of several additional properties described below. Although tumor suppressor gene products may participate in many different regulatory pathways, it is generally true that inhibition of cell division, often combined with control of repair of DNA damage, is the principal action of this class of regulators. Thus, cell cycle control at checkpoints that determine passage of the cell from G_1 to S or from G_2 to M is a common means by which tumor suppressor genes influence cell division. As discussed later, the proteins encoded by the *RB1* and *TP53* genes are prominent examples of such regulation. More recently, a host of small proteins that function as cyclin-dependent kinase inhibitors have also been characterized as growth inhibitors. At least one has been implicated in familial melanoma. Others have been placed in the pathways influenced by such genes as *TP53* (see following sections).

Retinoblastoma Model

The childhood tumor retinoblastoma is currently the best-characterized model for action of a recessive oncogene. In this cancer, which occurs in both inherited and sporadic forms, a retinoblastoma gene was proposed as the recessive oncogene, which normally suppresses the malignant transformation of retinoblasts. Individuals at risk for the familial form of the disease, according to a two-hit hypothesis advanced by Knudson, [136] inherit a damaged, nonfunctional gene. The second hit in such individuals would then be a somatic mutation that inactivated the remaining normal allele (Fig. 49-6). Individuals with sporadic retinoblastoma would suffer two independent somatic mutations damaging both alleles. More recent investigations have advanced this set of conjectures a considerable distance, culminating in the molecular cloning and characterization of the retinoblastoma gene, *RB1.*

Cytogenetic abnormalities in the form of interstitial deletions and a fortuitously observed linkage to the enzyme esterase D established the long arm of chromosome 13 as the probable site of a retinoblastoma gene. [137] Shortly thereafter investigators were able to exploit the newly developed technique of restriction fragment length polymorphism (RFLP) to confirm an important prediction of the above-described model, namely, that loss of genetic material in the region of the putative *RB1* gene routinely occurred in tumors. [138] DNA probes identifying several polymorphic regions on chromosome 13 were used to compare patients tumor DNA with their normal, or constitutional, DNA. In this approach the polymorphic probes identify both maternal and paternal chromosomes on Southern blots; loss of genetic material is evident as a loss of heterozygosity. The results indicated a specific loss of heterozygosity at 13q. Furthermore, the chromosome (*RB1* allele) retained in each tumor of a patient with familial retinoblastoma was from the affected parent. This was additional evidence for the supposition that somatic mutation (in this instance, gene loss) was required to advance the pathogenetic process in an individual inheriting one bad copy of the retinoblastoma gene. Subsequent work with DNA probes specific to 13q has demonstrated that chromosome loss and duplication, as well as mitotic recombination, are the somatic mechanisms by which loss of genetic material occurs.

Several groups have now reported molecular cloning of the human *RB1* gene. [139] [140] The locus is quite large, extending over 200 kb of DNA and consisting of 27 exons. mRNA transcribed from this gene encodes a 110-kd phosphoprotein, described in more detail later. All cell types examined thus far express the *RB1* gene, and knowledge of its structure has enabled workers in the field to complete the molecular characterization of pathogenetic lesions in familial and sporadic retinoblastoma. First, *RB1* mRNA is either absent or of aberrant size in almost all tumors examined. In those tumors with grossly undetectable changes in mRNA, small deletions or mutations are observed that either alter the reading frame of the mRNA or lead to abnormal splicing. Interestingly, similar lesions of the *RB1* locus occur in the osteosarcomas that arise frequently during adolescence in those patients surviving childhood retinoblastoma. The ability of the *RB1* gene to suppress tumorigenesis has been demonstrated directly by transferring a copy of the wild-type gene into cells of a retinoblastoma cell line. [141] Those cells incorporating the normal *RB1* gene assume a slower growth rate in vitro and are no longer tumorigenic when injected into nude mice. Thus, the anti-oncogene or tumor suppressor gene phenotype of *RB1* is evident.

The *RB1* product, $pp110^{RB}$, is a zinc finger protein that displays interesting behavior during the course of the cell cycle. In G_1 , most molecules of $pp110^{RB}$ are relatively underphosphorylated. [142] [143] During S and G_2 , all become hyperphosphorylated at multiple sites. Several DNA tumor viruses encode protein products that bind only the underphosphorylated form of $pp110^{RB}$.[144] [145] It is probably through this binding of the cellular *RB1* gene product that transformation by these viruses is mediated. Thus far, this set of observations suggests that the underphosphorylated form of the *RB1* protein is the active one and that $pp110^{RB}$ probably functions as part of the barrier to entry into S phase. The mechanism by which this occurs involves the binding of underphosphorylated *RB1* protein through its

Figure 49-6 (Left) Tumor progression in familial retinoblastoma. One damaged allele is inherited from an affected parent. (The allele could also represent a new mutation in the parents germ cells.) Cells with one functioning (wild-type) copy of the *RB1* gene remain normal. As a result of somatic genetic damage (mutation, loss, mitotic recombination), the second allele may be inactivated, with malignant conversion resulting. This scenario is depicted for retinoblastoma but holds for most dominantly inherited familial cancer syndromes. In sporadic retinoblastoma, damage to the first allele occurs as a somatic event. **(Right)** Tumor loss of heterozygosity. If informative (heterozygous) polymorphic markers are used to analyze patients normal and tumor DNA, a common accompaniment of damage to recessively acting oncogenes is loss of heterozygosity. Generally, one band (allele) on a Southern blot will disappear if the marker employed is close enough to the recessive oncogene locus, in this case, *RB1.*

pocket to the E2F family of transcription factors. [146] [147] Phosphorylation of $pp110^{RB}$ by cyclin-dependent kinases releases E2F to activate transcription at a host of critical gene promoters (see Chap. 6). *RB1* protein also interacts with histone deacetylase, [148] [149] an enzyme thought to have a major role in remodeling chromatin structure. Presumably, the *RB1* protein may act through this enzyme to rearrange inhibitory nucleosome arrays at critical gene promoters. Several other pocket proteins related to $pp110^{RB}$ have subsequently been discovered, although how each functions in relation to cell cycle control is not yet known.

TP53, Guardian of the Genome

Although *RB1* was the first well-characterized example of a human tumor suppressor gene, *TP53* has proved more important as a gene central to human tumorigenesis. First discovered as a 53-kd nuclear protein associated with the SV40 large T antigen,

TP53 has subsequently been shown to be mutated in the overwhelming majority of nearly all human tumor types.[150] Inactivation of the gene takes one of two forms: missense mutations resulting in dominant-negative forms of the protein that are capable of binding to and inactivating wild-type protein produced by the other, normal allele, and nonsense and deletion mutations that completely inactivate the gene.

The p53 protein operates at the intersection of three important cell processes: DNA damage recognition, control of cell cycle progression, and programmed cell death (apoptosis). It connects these processes in such a way that DNA damage produces cell cycle arrest at the G_1/S boundary.[151] This checkpoint is active until DNA repair occurs and the cell re-enters the cell cycle. If repair does not occur within a certain period of time, programmed cell death is initiated. Several cyclin-dependent kinase inhibitors, most prominently CDKN1A ($p21^{cip/waf}$), are the downstream targets of p53 that are responsible for this blockade.[152]

Thus, from the point of view of tumorigenesis, cells lacking a functional p53 protein tolerate genetic damage and genetic instability that would produce arrest and repair or death in normal cells. From the point of view of anticancer therapy, cells lacking a functional p53 are often incapable of initiating certain forms of programmed cell death. Since most cytotoxic therapies, including irradiation, kill cells through apoptotic pathways, cells without p53 are relatively resistant to such agents.

Tumor Suppressor Genes in Other Familial Tumors

A pattern of similarity has emerged between familial retinoblastoma and nearly all the dominantly inherited cancer syndromes. In the past several years many of the disease loci for these familial syndromes have been mapped and cloned, including loci for Wilms tumor,[153] several forms of multiple endocrine neoplasia,[154] [155] polyposis coli,[156] and neurofibromatosis types I[157] and II.[158] In each instance examined, tumor DNAs from such patients show loss of heterozygosity, with markers near the appropriate family cancer gene. Each disease locus maps to a unique chromosome position, which strongly suggests the existence of multiple genes with the properties of *RB1.* Finally, mutations of the *TP53* gene itself have been shown to be responsible for the Li-Fraumeni syndrome.[159]

In recent years, genes responsible for several familial forms of more common tumors have been isolated and characterized. The *BRCA1* and *BRCA2* genes are now known to account for approximately 50% of cases of familial breast cancer.[160] [161] The proteins encoded by these genes are large, with no previously known domains or functions. Recently, both products have been detected in nuclear macromolecular complexes with the Rad51 protein, a component of DNA repair and recombination.[162] [163] Finally, mutations in at least a half-dozen genes responsible for DNA mismatch repair, including *MLH1, MSH2, PMS1,* and *PMS2,* have been implicated in hereditary nonpolyposis colon cancer.[164] [165] [166] The implication of these results, coupled with previous findings concerning *TP53,* is that compromise of genomic stability from defects in any one of several possible pathways results in cancer.

Tumor Suppressor Genes in Sporadic Cancer

Although patients with dominantly inherited cancer syndromes do not form a large fraction of all cancer patients, the molecular genetics of these syndromes is highly relevant to sporadic cancer. First, specific patterns of loss of heterozygosity are observed in cancers of the breast, lung, colon, stomach, and kidney.[167] [168] [169] [170] [171] As we have shown, this molecular lesion is the hallmark of a recessive oncogene. Since each of these tumors displays different chromosomal sites for loss of heterozygosity, the existence of a large set of anti-oncogenes is likely. Furthermore, in tumors such as colon cancer, sporadic cases sometimes show loss of heterozygosity of the same chromosome region (in this instance 5q) as the familial form of the same cancer.[172] This implies that, like retinoblastoma, sporadic cancer can involve molecular lesions of the same genes that cause the familial form of the disease. *BRCA1* and *BRCA2* are, thus far, interesting exceptions to this pattern.

STAGES OF CARCINOGENESIS

One of the seminal achievements of research in molecular oncology has been the development of a paradigm for stages of carcinogenesis. [173] Early studies established that cell lines that are nontumorigenic and that display relatively normal growth and morphology in vitro often require only one activated *ras* gene to become tumorigenic. This probably reflects genetic damage already undergone simply to obtain the immortalized state that cell lines by definition possess. Cells that have not been established permanently in culture and that have normal karyotypes are not significantly altered by the introduction of one activated oncogene. In this case, two activated oncogenes are required, one with a product located in the cytoplasm and one with a nuclear product. [174] [175] [176] Thus, the introduction of a mutant *ras* gene and a constitutively expressed *myc* gene (but not either alone) will transform a normal diploid fibroblast. Interestingly, cells transformed in this fashion will produce tumors when injected into recipient animals, but the tumors are generally small and often regress. Therefore, at least one other event must occur for the appearance of the fully malignant phenotype.

If tumorigenic cells bearing activated oncogenes are fused to normal cells, the tumorigenic phenotype is usually suppressed. [177] Such hybrid cells, injected into an animal host, will differentiate normally and remain quiescent. With prolonged passage in culture, however, tumorigenic segregants do arise rarely. This subset of the original population of hybrids maintains the activated oncogenes but now demonstrates specific chromosome loss and/or loss of heterozygosity. The loss of heterozygosity is often specific to the cell types employed in the original fusions. Thus, somatic cell genetic experiments with activated oncogenes provide additional evidence for the class of tumor suppressor genes or anti-oncogenes discussed above and suggest that loss of such genes is required for progression of tumorigenesis. Furthermore, wild-type tumor suppressor genes appear dominant over mutant (activated) proto-oncogenes of the *ras* and *myc* variety.

The model system that has subsequently advanced this earlier work is colon cancer. This is because histopathologic progression from benign adenoma to frankly invasive carcinoma may be observed microscopically and characterized at the molecular level. A series of studies have revealed that adenoma formation is frequently coincident with *ras* gene mutation, followed sequentially by loss of genetic material at several locations on chromosomes 5, 17, and 18. [118] Eventually, genes at each of these locations were identified: *APC* on chromosome 5,[156] *TP53* on chromosome 17, and *DCC* on chromosome 18.[178]

Another finding from these studies, representing a new and potentially fruitful area of investigation, is the change in DNA methylation that occurs in colorectal tumor progression. Relatively early in tumor development, DNA becomes hypomethylated. Because DNA methylation is inversely correlated with gene expression, this strongly implicates such epigenetic changes in carcinogenesis. Although a comprehensive discussion of epigenetic changes is beyond the scope of this chapter, we now know that specific sites of methylation, rather than global changes, are more important to the expression patterns

of specific genes. Tumor suppressor genes may potentially be inactivated by inappropriate methylation of their expression control regions. [179]

Finally, although malignant transformation apparently requires the complex interplay of oncogenes and tumor suppressor genes, the evolution of cancer cells with metastatic potential may require the participation of further classes of genes not ordinarily included in the oncogene category. These classes include adhesion molecules and homing receptors expressed on the tumor cell surface, as well as specific proteases secreted by these same cells. Such products presumably enable a cell in which genetic changes are altering the mitogenic signal apparatus and program for cell division to invade local blood vessels and lymphatics, travel to distant tissue targets, and begin anew the expansion of a malignant cell population.

GENETIC INSTABILITY IN THE EVOLUTION OF CANCER AND LEUKEMIA

It is evident from recent work that the preservation of genomic integrity is a central feature of the protection of cells from malignant transformation. Abrogation of checkpoints and/or repair and recombination pathways, as indicated by studies of *TP53, BRCA1*, and *BRCA2,* mismatch repair, radiation sensitivity, and gene amplification, is now recognized as a major, and perhaps the most significant, contribution to carcinogenesis. This work complements an extensive series of earlier observations coupling chromosome instability and UV- and x-irradiation sensitivity to risk of cancer and leukemia. Recently, genes responsible for several of these syndromes, including xeroderma pigmentosa group G (XP-G) and ataxia-telangiectasia (AT), have been cloned. The AT gene, *ATM,* is now placed in the pathway linking DNA strand break detection to p53 activation.[180] It is related to another protein involved in double strand break repair, the DNA-dependent protein kinase. The XP-G product is implicated not only in DNA excision repair but also in transcriptional repair, by participating as a component of the basal transcription apparatus.[181]

These cumulative results bring us closer to elucidating two long-standing speculations about the nature of cancer. First, tumor cell heterogeneity and the plasticity of tumor cell response to therapy had previously led to the predominant view that cancer cells are intrinsically genetically unstable and that this instability is directly related to the progression of the neoplastic state. We now know that this view is largely correct, and we know further that inherited states of genetic instability can be responsible for the initiation as well as the progression of cancer and leukemia.

The second area of speculation that is yielding to current research is the relationship during tumorigenesis between extrinsic and intrinsic insults to the genome. Although many somatic mutations (e.g., *TP53* and *ras* family members) are clearly important, it has not been possible to specify the meansenvironmental damage versus intrinsic mutation mechanismsby which these changes arise. Now, as the result of a better understanding of mechanisms, as well as the development of sensitive technology to detect DNA damage, we are positioned to characterize comprehensively the source and nature of DNA damage in tumors. Several examples serve to illustrate the range of possibilities. When mismatch repair is malfunctioning, genes possessing short tracts of repetitive nucleotides should be at risk of mutation. This is because replication slippage at such sites is not repaired. At least one important confirmation of this prediction has been published. The transforming growth factor- type II receptor, which contains just such a nucleotide tract, is frequently mutated in gastrointestinal tumors with mismatch repair defects.[182] Also, inherited gene variants can be intrinsically more mutable. A relatively frequent variant of the familial polyposis gene *APC* in Ashkenazim bears a mutation that converts a portion of the coding sequence to a short repetitive tract. The inherited mutation does not itself cause any change in the function of the gene. However, the region becomes a hotspot of somatic mutation because of increased replication slippage, leading to pathogenetic damage to the gene.[183] Finally, recent work has directly connected environmental mutagens to specific DNA targets within cancer-related genes. Adducts of benzo(a)pyrene, one of the principal mutagens of cigarette smoke, have been detected at precisely the nucleotides of *TP53* that are frequently mutated in lung tumors of smokers.[184] We may expect future studies to elucidate further the interplay between host and environmental determinants of carcinogenesis.

Chapter 50 - Pharmacology and Molecular Mechanism of Action or Resistance of Antineoplastic Agents: Current Status and Future Potential

Kapil N. Bhalla
Stanton L. Gerson
Steven Grant
Daniel M. Sullivan

INTRODUCTION

The past few decades represent the modern era of chemotherapy against cancer. During these decades, the activities of diverse anticancer agents, alone or in combination, have been explored through clinical trials. The development of antimetabolites (e.g., cytosine arabinoside, methotrexate, and hydroxyurea), alkylating agents (e.g., cyclophosphamide, melphalan, and busulfan), anthracyclines (e.g., doxorubicin, daunomycin, and idarubicin), topoisomerase I or II inhibitors (e.g., etoposide, mitoxantrone, and topotecan), the platinum compounds (e.g., cisplatin and carboplatin), as well as the antimicrotubule drugs (e.g., vincristine, vinblastine, and taxol), has gradually expanded our armamentarium of chemotherapeutic agents. Impressive gains have been made in our understanding of the pharmacology, toxicity profile, and antitumor activity of these and other classes of drugs. Combination chemotherapy incorporating drugs with different mechanisms of action and toxicity profiles has produced a long-term disease-free state in some patients with leukemia, lymphoma, and epithelial cancers. However, in the majority of patients, these attempts have resulted in considerable morbidity and eventual tumor progression. Collectively, this clinical trial experience in cancer has highlighted the importance of understanding the unique features of tumor biology that may either confer drug resistance or explain the antitumor selectivity of the chemotherapeutic drugs. A rapidly expanding knowledge of the functions of proteins encoded by oncogenes, tumor suppressor genes, and the DNA mismatch repair genes has greatly contributed toward a better understanding of tumor cell genomic instability and biology. The role of some of these proteins in growth factor receptor signaling, cell-cycle progression, and programmed cell death (apoptosis) has elucidated potential determinants of drug sensitivity and mechanisms of resistance in tumor cells.

This chapter reviews the mechanism of action and pharmacology of antineoplastic drugs, with special emphasis on drugs used in the treatment of hematologic malignancies. In addition, it provides an overview of the recent advances in our understanding of tumor biology as it relates to anticancer drug sensitivity and strategies to overcome drug resistance.

CELL KINETICS, THE CELL CYCLE, AND TUMOR GROWTH

The cell cycle consists of a series of stages through which normal and neoplastic cells proceed during the course of cellular

replication (Fig. 50-1). It is divided into G_1 (pre-DNA synthetic phase), S (in which DNA replication takes place), G_2 (post-DNA synthetic phase), and mitosis (M), during which chromosomal division and segregation occur.[1] In addition, nonproliferating, resting cells are said to reside in G_o, a phase that may theoretically last for an indefinite period. Such cells remain in G_o until they are induced to enter the cell cycle (at G_1) by specific triggers, such as hematopoietic growth factors. The *growth fraction* of a tumor represents the percentage of cycling cells relative to the total cell population and is given by the formula $(G_1 + S + G_2 + M)/(G_o + G_1 + S + G_2 + M)$. The *noncycling fraction* is given by the formula $(G_o)/(G_1 + S + G_2 + M)$. Growth fractions of various neoplasms range from <10% in the case of certain slowly growing solid tumors to >90% in the case of certain hematologic malignancies (e.g., Burkitts lymphoma). The *generation time* represents the time required for a cell to proceed through a single cell cycle (generally 2436 hours for hematopoietic tissues). Surprisingly, in the case of acute myeloid leukemia (AML), the generation time of leukemic blasts is not

Figure 50-1 Progression through the cell cycle is controlled through complex interactions between cyclins, cyclin-dependent kinases (CDKs), and cyclin-dependent kinase inhibitors (CDKIs). Progression across the G_1 -S interface and through S phase involves the E2F transcription factor, which activates numerous enzymes (e.g., thymidylate synthase, dihydrofolate reductase) required for DNA replication. The retinoblastoma protein (pRb) in its dephosphorylated state binds to and inactivates E2F in conjunction with DP proteins, thereby inhibiting S-phase progression. Conversely, phosphorylation of pRb antagonizes binding to E2F, allowing S-phase events to proceed. Phosphorylation of pRb results from activation of (a) cyclin-dependent kinase-2 (CDK2):cyclin A/E and (b) CDK4/6:cyclin D complexes. The former complexes are inhibited by the CDKIs p21, p27, and p57, whereas the latter are inhibited by the low-molecular-weight CDKIs (p1418), but also by p21 and p27. The complex formed by CDK1 ($p34^{cdc2}$) and cyclins A and B regulates G_2 M progression and is inhibited by the universal CDKI, p21. Moreover, its phosphorylation status, which plays a major role in determining activity, is regulated by the phosphatase, cdc25. Proteins such as pRb, E2F, p21, and p27 can influence the response of cells to chemotherapeutic agents by controlling cell-cycle progression, and possibly via cell cycle-unrelated actions.

significantly shorter than that of normal hematopoietic progenitors, and may in fact be longer. The proliferative advantage of malignant hematopoietic cells (and of many nonhematopoietic tumors) stems, at least in part, from the fact that a higher percentage is in cycle at any one point in time (i.e., the growth fraction is higher). The *doubling time* represents the period required for a tumor to double in mass, and is in general inversely related to the tumors growth fraction. Thus, tumor doubling times range from >120 days in the case of some solid tumors (e.g., lung and colon) to <2 weeks (in the case of some leukemias and lymphomas). Tumor doubling times are influenced by multiple other factors, including the rate of spontaneous cell death (or apoptosis) and the availability of appropriate nutrients. The importance of these considerations stems from the fact that tumors with high growth fractions and short doubling times tend to be more sensitive to chemotherapy than slowly growing neoplasms with low growth fractions and long doubling times. It is unlikely to be a coincidence that many advanced neoplasms that are potentially curable by chemotherapy (e.g., hematologic malignancies such as leukemia, lymphoma; testicular cancer) fall into the former group; conversely, most incurable advanced malignancies (e.g., non-small cell lung cancer, colon cancer) fall into the latter.

The traverse of neoplastic cells through the cell cycle, as in the case of their normal counterparts, is governed by a complex network of proteins consisting of *cyclins*, *cyclin-dependent kinases* (CDKs), and *CDK inhibitors* (CDKIs).[2] S-phase traverse is regulated primarily by CDK2 in association with cyclins A and E; G_2 M traverse is regulated by CDK1 ($p34^{cdc2}$) and cyclin B; and progression through G_1 involves CDKs 4/6 in conjunction with cyclin D. CDKIs fall into two major categories: the low-molecular-weight inhibitors (pINK14, 15, 16, 17, and 18), which primarily inhibit cyclin D (and to some extent CDK2) complexes, and the higher-molecular-weight inhibitors (p21, p27, and p57), which are more universal in their actions and inhibit most or all CDKs.[3] Signals for progression of cells through G_1 -S are clearly essential to maintenance of the neoplastic phenotype. In the commonly accepted model of G_1 -S progression, inactivation of the retinoblastoma protein (pRB) is required. In quiescent cells, pRB is in an active dephosphorylated state and bound to the transcription factor E2F. Phosphorylation of pRB by CDK4/6 and CDK2 leads to release of E2F, which is then free to activate diverse genes essential for S-phase progression, such as c-Myc, thymidylate synthetase, and dihydrofolate reductase (DHFR). Conversely, induction of CDKIs (e.g., by TGF or differentiation-inducing agents) results in inactivation of CDK 4/6 and CDK2, dephosphorylation of pRB, inactivation of E2F, and inhibition of S-phase traverse. Aberrant expression prediction induction of cyclins and CDKIs is commonly encountered in human malignancies, including those of hematopoietic origin, and it has been postulated that the resultant cell-cycle dysregulation contributes to the neoplastic phenotype.

In addition to cellular growth control, cell-cycle proteins are intimately involved in the regulation of programmed cell death (apoptosis) and checkpoint control mechanisms.[4] Consequently, cell-cycle regulatory proteins can exert a major influence on the response of neoplastic cells to various cytotoxic agents. For example, when cells undergo DNA damage, they may arrest in G_2 M or G_1, during which repair occurs; if the damage is too severe, the cells undergo apoptosis. In particular, the tumor suppressor gene, *p53*, and its downstream inducible target, p21, have been implicated in the G_1 arrest process following genotoxic insult.[5]

During the past several years, it has been shown that dysregulation of various cell-cycle regulatory proteins can have a major impact on the sensitivity of neoplastic cells to various chemotherapeutic agents. Thus, loss of the *p53* gene renders cells resistant to diverse chemotherapeutic agents, presumably by preventing cells from undergoing repair in G_1. Conversely,

transfection of *p53*-negative cells with wild-type *p53* restores responsiveness to most drugs.[6] More recently, it has been reported that dysregulation of the CDKIs p21 (a downstream target of *p53*) and p27 increases the sensitivity of neoplastic cells to various cytotoxic agents, possibly by uncoupling S-phase progression and mitosis.[7] [8] In this model, loss of the CDKI p21 or p27 prevents cells that have sustained DNA damage from arresting in G_1 and allows them to progress inappropriately through S and ultimately G_2 M, eventually leading to cell death. Mutations in the E2F protein have been shown to lengthen the S phase and to increase the sensitivity of malignant cells to S-phase-specific agents.[9] Further, cells lacking functional pRB have been shown to be significantly less sensitive to the actions of antimetabolites, including methotrexate.[10] Thus, aside from regulating cell-cycle status and the susceptibility of neoplastic cells to cell-cycle-specific agents, cell-cycle regulatory proteins can actively contribute to the cell death response.

The growth of tumors is best described by *Gompertzian*, rather than classic exponential kinetics. For neoplasms that grow exponentially, the tumor growth rate remains constant as the number of cells increases. However, in the in vivo setting, the growth of tumors is limited by various factors such as vascular supply, nutritional requirements, and possibly physical restraints. Consequently, the rate of tumor growth declines as the number of cells increases (i.e., *Gompertzian* growth

kinetics). To the extent that tumor doubling times are inversely correlated with drug responsiveness, large, late-stage tumors would be predicted to be less susceptible to cytotoxic drugs than their earlier, higher-growth-fraction counterparts. Most chemotherapeutic drugs kill by *first-order kinetics:* this indicates that a given drug dose kills a constant fraction, rather than number, of tumor cells. The implication of this phenomenon is that it requires the same drug dose to reduce the number of tumor cells from 10^4 to 10^1 cells as it does to reduce the tumor burden from 10^{10} to 10^7 cells.

Cytotoxic agents may be divided into several categories with respect to their effects on the cell cycle and/or the cell-cycle specificity of their actions:

1. Non-cycle-active drugs kill both cycling and noncycling cells in all phases of the cell cycle. Examples include steroids and antitumor antibiotics (except bleomycin).
2. Cycle-active, non-phase-specific drugs are more active against cycling cells and can kill cells in each phase of the cell cycle. However, such drugs may preferentially kill cells in a particular phase of the cell cycle. Examples include alkylating agents, cisplatinum, and 5-fluorouracil.
3. Cycle-active, phase-specific drugs kill cells primarily in a specific phase of the cell cycle. Examples include most antimetabolites, which are active against cells engaged in DNA synthesis (S-phase cells), and microtubule-active drugs (e.g., vinca alkaloids, taxanes), which kill cells in G_2 M.

An example of a cytokinetically rational approach to chemotherapy involves the combination of a non-cycle-active agent (e.g., daunorubicin) with a cycle- and phase-specific agent (e.g., Ara-C). From a theoretical standpoint, administration of a non-cycle-active agent may reduce tumor mass, leading in turn to an increase in the growth fraction via recruitment of cells into cycle. Such cells would then be more susceptible to a cycle- and phase-specific agent, particularly one administered over a prolonged interval. In the case of hematopoietic malignancies, attempts have been made to recruit neoplastic cells into the more susceptible S phase of the cell cycle through the use of *hematopoietic growth factors*. The success of such a strategy may be limited by several factors, including the inability of growth factors to increase the S-phase fraction significantly, the lack of selectivity of this strategy, and the theoretical possibility that growth factors may protect neoplastic cells from apoptosis.

Unfortunately, cytokinetic differences between normal and neoplastic tissues have been difficult to identify and exploit. Consequently, rapidly dividing normal tissues such as gastrointestinal epithelium and normal hematopoietic progenitors tend to be very sensitive to most chemotherapeutic agents. As a result, mucositis and myelosuppression represent frequent dose-limiting toxicities for many cytotoxic drugs.

TUMOR CELL HETEROGENEITY

Although there is considerable evidence that most if not all hematopoietic malignancies are of *clonal* origin (i.e., they are derived from a single transformed cell), individual neoplastic cells may exhibit a great deal of phenotypic diversity with respect to their behavior. Such differences may involve growth rates and cytokinetic features, growth factor responsiveness and dependence, and chemosensitivity, among many other features. The diversity in neoplastic cell behavior is referred to as *tumor cell heterogeneity.* There is general agreement that tumor cell heterogeneity arises as a consequence of spontaneous mutational events that provide a survival advantage for the affected cells and their progeny. [11] For example, a mutation that renders a hematopoietic cell clone autonomous or growth-factor-independent would be expected to render such cells less susceptible to adverse environmental conditions (e.g., growth factor withdrawal). Similarly, one would also predict that a genetic change facilitating cell-cycle entry or disruption of cellular maturation would ultimately lead to overgrowth of affected clones. For obvious reasons, mutations that interfere with drug metabolism or the cell death pathway itself would provide a net survival advantage, particularly under the selection pressure of cytotoxic drug treatment. In view of the multiple mechanisms by which cellular growth or survival may be enhanced, it is not surprising that tumor cells exhibit considerable phenotypic diversity despite their putative derivation from a common ancestor.

Common mechanisms may be involved in events associated with malignant transformation and the development of mutations that result in tumor heterogeneity. For example, the cell-cycle checkpoint and tumor suppressor gene, *p53*, is induced during DNA damage, leading to G_1 arrest and, if the damage is too severe to repair, cell death by apoptosis. The presumed goal of this process is to eliminate cells that develop deleterious mutations as a result of damage to the genome. Thus, loss of *p53* may not only increase cellular survival by inhibiting the cell death process, but may also promote the transmission of mutations in cells that would otherwise be deleted. In this manner, a defect of the cell death pathway can have multiple consequences: (1) selection of cells exhibiting a growth advantage over their normal counterparts; (2) development of drug resistance; and (3) promotion of mutations that result in either (1) or (2) as well as neoplastic cell heterogeneity.

A model for understanding the relation among tumor growth rate, the occurrence of spontaneous mutations, and the development of drug resistance was first described by Goldie and Coldman, and is referred to as the *Goldie and Coldman hypothesis*.[12] In this model, the size of a tumor depends on a complex interaction between tumor growth rate and cell loss, the latter stemming from the status of the cell death process, exhaustion of available nutrients, and outstripping of the blood supply. As tumors increase in size, the cell death rate tends to increase. Thus, for larger tumors, further increases in tumor mass require a progressively greater number of cell doublings. If one assumes a constant mutational rate, the cells of which a large tumor is composed (and which have undergone a considerably greater number of cell divisions than smaller tumors) would have had a much greater opportunity to acquire mutations conferring a survival advantage. The heterogeneous nature of such mutations makes it likely that multiple mechanisms of resistance will develop as well. Such a model may explain

the common observation that advanced, late-stage tumors are frequently resistant to all available classes of antineoplastic agents.

From an operational standpoint, this model has clear implications for the rational design of therapeutic strategies and provides a basis for early and intensive therapy, as proposed by Hyrniuk and Bush.[13] Thus, treatment of tumors with high-dose, multiagent therapy early in their history (i.e., when their growth fraction is high and the number of cell divisions has been relatively low) is less likely to fail due to the prior development of tumor resistance. Conversely, delay of therapy until the tumor mass is high (and under circumstances in which many cell divisions have occurred) or treatment with suboptimal drug doses is more likely to fail due to the greater opportunity that cells have had to undergo mutations conferring drug resistance.

The successful implementation of this strategy is exemplified by the administration of dose-intensive multidrug regimens (i.e., MOPP in Hodgkins disease, PROMACE-CYTOBOM in non-Hodgkins lymphoma), which are potentially curative when given early in the course of the disease. However, as predicted by the model, administration of these or other intensive regimens in patients with relapsed or late-stage disease generally fails due to a generalized resistance of tumor cells to all classes of chemotherapeutic agents.

APOPTOSIS AND DRUG SENSITIVITY

All normal and cancer cells possess the requisite molecular machinery to execute apoptosis. This includes a family of cysteine proteases recently designated as caspases because they cleave or degrade a growing list of protein substrates after an aspartic acid residue (Fig. 50-2).[14] This degradation of several protein substrates collectively results in the morphologic and biochemical features of apoptosis. [15] Stimuli that activate the intracellular

Figure 50-2 Overview of the molecular signaling leading to apoptosis.

caspases and trigger apoptosis include anticancer drugs, radiation, and growth factor withdrawal. [15] It is now well established that following interaction with their specific intracellular targets, cytotoxic agents ultimately produce DNA damage and/or cell-cycle perturbation. With most agents, this is somehow translated into a signal that triggers specific preapoptotic mitochondrial events that culminate in the cleavage and activity of the key caspases involved in apoptosis. [16] The preapoptotic mitochondrial perturbations include the release of the electron transfer protein, cytochrome c (cyt c), into the cytosol and the mitochondrial permeability transition (m) associated with a fall in the inner membrane potential (MMP) and an increase in the generation of reactive oxygen species (ROS). The cytosolic cyt c binds to an adaptor protein, APAF-1 (apoptotic protease activation factor-1), which in the presence of dATP binds, cleaves, and activates caspase-9. This in turn cleaves and activates the key executioner caspase, caspase-3. Caspase-3 and other executioner caspases (caspases 6 and 7) cleave the various protein substrates that result in apoptosis.

Among a growing list of genes that regulate apoptosis is the *bcl-2* family of genes.[17] The prototype *bcl-2* gene encodes for p26Bcl-2 protein, which inhibits apoptosis. *bcl-x*$_L$, a homolog of *bcl-2*, encodes for p29Bcl-x$_L$, which is also an antiapoptotic protein. Both Bcl-2 and Bcl-x $_L$ are located in the outer mitochondrial membrane, endoplasmic reticulum, and nuclear envelope. Bcl-2 and Bcl-x $_L$ exert their antiapoptotic effect by inhibiting the mitochondrial m and blocking the release of cyt c into the cytosol.[16] Bax, Bak, and Bad are the key proapoptotic members of the Bcl-2 family of proteins. Bax, Bak, or Bad can form heterodimers with Bcl-2 or Bcl-x$_L$. A low ratio of Bcl-2 to Bax by increasing free Bax may promote cell death due to anticancer drugs. [19] [20] The loss or low levels of Bax have been correlated with poor response to chemotherapy.[21] The phosphorylation of Bad by Akt kinase, which is activated by growth factor receptor tyrosine kinase signaling, forces disassociation of Bad from Bcl-x$_L$ and Bcl-2.[22] The latter can then exert their antiapoptotic effect.

The three-dimensional structure of Bcl-2 or Bcl-x$_L$ is strikingly similar to the pore-forming domains of certain bacterial toxins. [17] This indicates that Bcl-2 and Bcl-x $_L$ may be channel proteins regulating the traffic of ions or small peptides such as cyt c across mitochondrial membranes, thereby regulating m and apoptosis. The channel function of these proteins may be affected by their levels, oligomerization status, or post-translational modification such as phosphorylation. [17] For example, studies have demonstrated that antimicrotubule drugs such as taxol or vinca alkaloids induce mitotic arrest and the phosphorylation of Bcl-2, which is associated with an increase in free Bax levels and apoptosis of human leukemia cells. [19]

Recently, various cytotoxic drugs, irrespective of their intracellular targets, have also been shown to trigger apoptosis through the death receptor/death ligand-mediated signaling for apoptosis. [23] Cytotoxic drugs may induce Fas death receptor (FasR, CD95)/Fas ligand (FasL) expression. [24] CD95 is a transmembrane cell surface receptor belonging to the TNF receptor family. Following oligomerization, FasR triggers apoptosis through interaction with adaptor molecules (FADD/MORT-1) and caspase-8 (FLICE/Mach-1). This results in the autocleavage and activity of the upstream (e.g., caspase-8 and caspase-10) followed by downstream (e.g., caspase-3 and caspase-6) caspases. Recruitment of this apoptotic pathway by cytotoxic drugs has been shown to be blocked by the inhibitors of CD95-mediated signaling for apoptosis, although this mechanism may not be induced by all cytotoxic agents or operative in all cell types. FasR-mediated caspase activation can also result in the mitochondrial release of cyt c. [16] In addition, the induction of FasR-mediated signaling has been shown to generate intracellular ceramide through the activation of neutral sphingomyelinase

(SMase) and hydrolysis of sphingomyelin (SM) in the cell membrane. [25] Increase in the intracellular ceramide levels triggers the mitochondrial release of cyt c and the molecular cascade of apoptosis. This has been shown to be inhibited by sphingosine phosphate (SPP) or the activation of protein kinase C (PKC). [26] [27]

The normal (wild-type) gene product of the tumor suppressor gene *p53*^{wt} is a sequence-specific transcription factor that exists as a mutated protein in almost 50% of cancers.[5] In response to DNA damage induced by cytotoxic drugs, p53^{wt} induces the expression of p21 protein, which inhibits cell-cycle progression in the G $_1$ /S phase. As noted above, this cell-cycle checkpoint provides an opportunity for DNA repair and genomic integrity. In addition to mediating G $_1$ arrest, p53^{wt} can also induce apoptosis. p53^{wt} has been shown to transcriptionally upregulate Bax and decrease Bcl-2 levels, which may promote apoptosis. [28] These observations have spurred gene therapy trials of adenoviral vectors containing p53 ^{wt} to target malignancies with mutant p53.

Various steps in this sequence of molecular events culminating in the activity of cytosolic caspases can potentially be blocked by any of several mechanisms. These mechanisms would inhibit drug-induced apoptosis and confer drug resistance on cancer cells. Therefore, resistance to drug-induced apoptosis may result from a proximal or upstream mechanism based on the reduced intracellular uptake of drugs, drug target interaction, or drug-induced DNA damage or cell-cycle effect. Alternatively, a mechanism that blocks the preapoptotic mitochondrial events or inhibits cytosolic caspase activity would represent a more distal or downstream mechanism of resistance to drug-induced apoptosis.

DEVELOPMENT OF CHEMOTHERAPEUTIC AGENTS

Following the initial description of sulfur mustard gas as a biologic warfare agent in World War I, the nitrogen mustard compounds were developed as chemotherapeutic agents in the 1940s. Since that time, the National Cancer Institute (NCI) and the pharmaceutical industry have developed complex techniques for drug development, screening, and evaluation. [29] Initial screening consisted of toxicity assessment against murine tumor cell lines. [30] Current screening is directed toward numerous cell targets known to influence cell death pathways, interrupt cell cycle, induce apoptosis, block mitosis, cause DNA damage, and interrupt DNA repair. Killing cells remains the backbone of chemotherapeutic approaches to human malignancies, although a number of differentiating agents have now entered the chemotherapy armamentarium. With cytotoxic alkylating agents, the most common dose-limiting toxicity is toward hematopoietic progenitor cells, leading to neutropenia, thrombocytopenia, and anemia. [31] Thus, these agents are often used to treat hematologic malignancies. Certain chemotherapeutic agents induce cumulative myelosuppression by killing early hematopoietic progenitor cells, whereas others attack only late progenitors. Secondary leukemias have arisen in patients receiving alkylating agents, [32] topoisomerase inhibitors, [33] [34] and combination chemotherapy and radiation. [35] Thus, chemotherapeutic agents have an important role in both the treatment and etiology of hematologic malignancies.

Screening for Antitumor Activity Among Chemotherapeutic Agents

In the 1950s, the NCI initiated a drug-screening program centered on antitumor activity of the murine leukemia cell lines L1210 and P388, as well as murine tumor panels, which included the Lewis lung carcinoma and the B16 melanoma. [30] [36] Since 1985, a new program for drug screening has been developed within the NCI Division of Cancer Treatment that has resulted in the ability to evaluate >60,000 compounds for cytotoxic and growth inhibitory activity. The NCI in vitro human tumor cell line screen consists of 60 cell lines. [37] [38] These lines include major adult solid tumors such as lung, colon, renal, ovary, melanoma, and brain tumors, as well as rhabdomyosarcomas, medulloblastomas, and neuroblastomas affecting children. Among the leukemia cell lines, K562, MOLT-4, and HL-60 are used, but there are few B-cell lymphomas. [39] Initial screening is performed using the stain sulforhodamine-b, which binds to basic immuno acids and is stable after cell fixation. The screen was validated against known anticancer drugs and standard cytotoxicity assays before formal implementation. [40] Incubation of the various tumor cells at routine drug dilutions (10^{-4} 10^{-8} molar) of the various test compounds is performed followed by an assessment of the compounds effects on the growth of the tumor cell lines. [38]

Following an initial in vitro assay screen, human tumor cell activity is evaluated with a series of athymic mouse xenograft studies targeting tumors from tissues that show promise in in vitro assays. [41] The NCI Decision Network Panel meets regularly to evaluate the progress of drugs through the development pathway. Drugs with promising efficacy and novel mechanisms of action then go on to formulation and toxicology testing and ultimately are developed for phase I clinical testing [38] [42] through the NCI Cancer Therapy Evaluation Program. A number of novel observations have been made regarding these chemotherapeutic agents from the comprehensive database of toxicity assessment. As recently reported by Weinstein, [38] the database has been used to identify clustered cytotoxic activity among agents based on similar cytotoxicity profiles against the 60-cell line panel. Among many observed clustered responses, agents with clustered activity against p53 wild-type or mutant cells, multiple drug resistance, gene-expressing cells, and agents that cause G_1 checkpoint arrest have been identified. With this information, a better understanding of the mechanisms of drug effect and disease-specific responses can be proposed. This has profound implications for future drug development and for use of the NCI database for further assessment of existing compounds.

Human tumor xenografts have been used as a requisite screen in preclinical testing of new chemotherapeutic agents. All tumors are grown either subcutaneously or as ascites in athymic nude mice. In the subcutaneous models, tumor volume is assessed three times weekly and anticancer efficacy is documented by *tumor growth delay*, a measure of the time required to reach a certain volume based on a multiple of the tumor volume at the time of treatment, expressed as (T C)/C × 100, where T is the treatment time and C is the untreated time in days. [41] Other critical parameters and assessments of drug efficacy include drug-related deaths and maximum percent relative mean body weight loss. Other investigators measure net log cell kill, an indication of the number of cells killed at the end of treatment, defined by the formula [(T C) duration of treatment × 0.3 ÷ median doubling time], where the doubling time is the time required for the tumor to enlarge from 200 to 400 mm^3 regardless of tumor regression. [43] [44] [45] [46] Finally, tumor regressions are noted as partial if the tumor increases volume by 50% and as complete if the residual tumor size is below measurable limits of approximately 15 mm. [31]

For leukemia and lymphomas, increase in life span is used as an endpoint for ascites tumors or after intravenous injection. This is measured as the percent increased life span (T C)/c × 100, where T is the life span after drug treatment and C is untreated. [43] Recently, severe combined immunodeficiency (SCID) mice, which carry a nonsense mutation in the DNA-dependent protein kinase disabling the production of normal T and B cells, have been used as hosts for leukemia, lymphoma, and myeloma cell lines. [47] Zhang et al. [48] established a human acute promyelocytic leukemia ascites model in the SCID mouse and found responses to all-transretinoic acid. A number of other

investigators have used the SCID/leukemia model to test antisense oligonucleotide strategies [49] for such tumor-specific genes as bcr-abl [50] for chronic myelogenous leukemia. In both instances, infusion of antisense constructs increased the life span significantly and led to clinical studies with these agents. Others have used the SCID model for B-cell lymphomas to study either chemotherapy or lymphotoxins. [51] While these models have not entered the NCI drug screen, they represent potentially useful systems with which to test new agents, in particular novel gene therapy and immunotoxin approaches.

Phase I Clinical Trial Design

New anticancer agents are assessed through a series of clinical trials termed phase I, phase II, and phase III (Table 50-1). The purpose of phase I clinical trials is to establish the safe and optimal biochemically active dose of the compound in question with acceptable toxicity that can be used in disease-targeted phase II testing. During phase I development, pharmacokinetics and pharmacodynamic measures are studied in detail so that appreciable information can be forthcoming from the very first set of patients targeted for treatment and so that these observations can be confirmed in larger phase II disease-focused trials. Dose, schedule and route of administration are key considerations in early phase I development for some agents, such as those with cell-cycle-dependent toxicity (e.g., cytosine arabinoside), radiolabeled antibodies, photodynamic therapy, and agents with particularly long half-lives. When these issues are resolved early in development, phase II trials proceed more quickly.

A number of considerations have guided dose-escalation strategies that accompany phase I trial development. The starting dose is typically approximately 10% of the lethal dose (LD_{10}) in animals. In classic phase I development, a modified Fibonacci dose schedule is used. [52] Groups of 3 patients are treated at each of the following doses until the maximum tolerated dose (MTD) is observed: 1N (the starting dose), 2N, 5N, 7N, 9N, 12N, and 16N. Typically, the MTD is defined as the maximum tolerated dose not causing irreversible toxicity of any type and causing less than grade 4 toxicity in any organ. For some myeloablative strategies used in high-dose therapy, grade 4 myelosuppression, mucositis, and diarrhea are allowed, but only with careful consideration of supportive care, including the use of hematopoietic

growth factors, antidiarrheal agents, narcotics, and intravenous alimentation to manage patients through severe mucositis. Typically, if 1 dose-limiting toxicity is observed, the patient cohort is expanded to 6 patients; if 2 patients develop dose-limiting toxicity, typically defined as grade 4 toxicity except as noted above, then further entry at this dose is not pursued and the next lower dose level is used to establish the MTD with a total of 6 patients accrued at that dose level.

Alternative strategies of drug escalation have included the use of toxicity grades to enhance dose escalation in early drug development; in other words, if no toxicity is observed, fewer

TABLE 50-1 -- Clinical Trial Design

Phase 1
Evaluate safety by dose escalation, multiple dose schedules.
Establish maximum tolerated dose and dose-limiting toxicity.
Consider use of hematopoietic support if myelosuppression is dose-limiting.
Phase 2
Establish response (complete, partial, objective) in specific diseases.
Phase 3
Compare new treatment with established regimen for the disease in randomized trials.

patients may be accrued to each dose.[53] Recently, the NCI has finished an evaluation of phase I trials conducted under the auspices of the Cancer Therapy Evaluation Program.[54] [55] A modified dose-escalation strategy has been proposed. Using the modified Fibonacci scheme, 1 patient is entered at each dose level until grade 2 toxicity is observed, at which point cohorts of 3 patients are entered at each level. Early in drug development, level-skipping may take place if no toxicity is observed. The overall impact of this is to reduce the number of patients treated at suboptimal doses of therapy and to enhance the ultimate number of patients evaluated at biologically active doses.

With the rapid development of new anticancer agents in preclinical and early clinical testing, emphasis has shifted toward mechanism-based therapeutics. Recent targets of interest include receptor tyrosine kinases, [56] [57] DNA repair enzymes,[58] drug resistance proteins,[59] drug detoxifying enzymes,[60] protein kinase C,[61] topoisomerase,[62] chromosomal translocationally activated protein products such as Bcr-abl and Bcl-2, [49] [50] and cell-cycle-regulating proteins. Many agents are now being evaluated in the phase I setting for evidence of biochemical efficacy using either tumor tissue or surrogate cells to define the drug effect. These will clearly have increased emphasis in the near future as new agents are developed that target specific malignant cell phenotypes; examples include the multidrug resistance in MDR-1,[59] O^6 -alkylguanine-DNA alkyltransferase, [63] glutathione synthesis,[64] and topoisomerase I and II. Analysis of inhibition of these enzyme systems in tumor cells is currently the focus of a number of phase I clinical trials and has led to a new concept in drug development: using a biochemical rather than a toxic endpoint in drug development.

Phase II and III Drug Development

Phase II drug development uses the established phase I dose to define therapeutic efficacy, typically in a two-stage design. An expectant response rate >20% is deemed clinically significant; 15 patients are accrued, and if 2 or more responses are seen, accrual is continued to a total of 26 patients to establish the definite response rate.[65] At this point, combination therapies are instituted in an effort to optimize therapeutic efficacy. For instance, topotecan was found in phase I testing to have efficacy against refractory leukemias, leading to combinations of topotecan with cytosine arabinoside and other agents. [66] [67] [68] Likewise, fludarabine was initially evaluated as a single agent for activity against low-grade lymphomas and both acute and chronic leukemias, and is now used in combination with Ara-C for the treatment of acute lymphocytic leukemia and with chlorambucil for the treatment of chronic lymphocytic leukemias. [69] [70] [71] In the past, strategies for combination chemotherapeutic agents included the use of non-cross-resistant agents with nonoverlapping toxicities. More recently, however, mechanism-based therapeutics have become the focus of drug development. For instance, with the combination of fludarabine and cisplatin, the proposal has been made that fludarabine will inhibit nucleotide excision repair and enhance persistence of cisplatin-induced DNA adducts, resulting in increased antitumor efficacy in chronic lymphocytic leukemia (CLL).[72]

Most phase III trials randomize between an established standard therapy and a new therapy that appeared promising in the phase II setting. These studies are usually multi-institutional, and many involve large national and international cooperative groups. The endpoint of these studies is disease response, survival, and patient tolerance. Linking multiple centers removes the vagaries of reports from single centers, which remain the focus of phase II trials. Phase III trials are important for both positive and negative results. Statistically significant differences between outcomes may cause early cessation of the trial, such as the Eastern Cooperative Oncology Group trial comparing the hybrid of MOPP/ABV with sequential MOPP-ABVD, which found superiority of the MOPP/ABV hybrid with better patient tolerance, a higher complete response rate, and a lower incidence of secondary leukemias. [73] Likewise, a trial in intermediate-grade non-Hodgkins lymphomas comparing PROMACE-CYTOBOM and CHOP therapy found no difference in survival and better tolerance with CHOP. [74]

PHARMACOLOGY OF CHEMOTHERAPEUTIC AGENTS

As noted above, although cytotoxic anticancer agents may be divided into several categories based on the cell-cycle specificity of their action, in keeping with traditional classification they are more appropriately divided into alkylating agents, antimicrotubule agents, antimetabolites, inhibitors of topoisomerases, platinum analogs, and miscellaneous agents. The pharmacology and cellular mechanisms of action of these agents are shown in Figure 50-3 .

Alkylating Agents

Drug treatment for cancer began with the use of the mustard class of alkylating agentsinitially mechlorethamine (nitrogen mustard), which entered into clinical use in the mid-1940s.[75] Alkylating agents remain a mainstay of treatment for numerous hematologic malignancies and are the backbone of high-dose chemotherapeutic agents used to eradicate cancer in the setting of bone marrow or peripheral blood progenitor cell reinfusion (Table 50-2). The use of mechlorethamine in combination with vincristine, procarbazine, and prednisone in the MOPP regimen for the treatment of advanced stage IIIIV Hodgkins disease represented the first example of an empiric combination chemotherapy approach, which led to a dramatic improvement in cure rates for this disease. [76] This model has been replicated in numerous other settings for the systematic treatment of numerous hematologic and solid tumor malignancies.

Nitrogen Mustard

The nitrogen mustard class includes mechlorethamine, cyclophosphamide, 4-hydroperoxy cyclophosphamide (Fig. 50-4), ifosfamide, chlorambucil, and melphalan. These all share a common bis-chloroethyl group attached to nitrogen and a substituted R group, which provides drug specificity (Fig. 50-5). All nitrogen mustards react with DNA in an SN2 reaction, a bimolecular nucleophilic displacement reaction, also called a second-order reaction. [77] While numerous sites are targeted for alkylation, including protein, membranes, RNA, and DNA, the latter appears to be most critical for cytotoxic effects. Nucleophiles in DNA, including nitrogen (N), oxygen (O), and phosphate (P), attract the chloroethyl moiety attached to the R-N backbone, and the chlorine is displaced by the nucleophilic atom to form an aziridinium moiety.[78] The remaining

Temozolomide

chloroethyl group is then attracted to a second nucleophilic atom, forming a second aziridinium intermediate leading to a second alkylation, forming a cross-link. Both intrastrand and interstrand cross-links are formed. [79] The cytotoxic cross-link formed by the mustard class of alkylating agents appears to be a displaced one or two bases on the opposite strand yielding diguanin-7-ethylene, [80] which appears to provide the needed structural apposition based on base stacking and the helical structure of DNA.[81] [82] This displaced cross-link has been isolated from reaction mixtures between mechlorethamine and DNA. While the nitrogen mustards also attack DNA at other nitrogens, including N1 and N3 of the adenosine and N3 of thymidine, it appears that the N7 guanine position is critical for cytotoxic cross-link formation.[80]

Clinical use of mechlorethamine is now limited to MOPP chemotherapy in Hodgkins disease [73] [83] and local use in a dermatologic suspension for the treatment of

cutaneous T-cell lymphomas.[84] Mechlorethamine is a highly reactive compound, with a half-life <15 minutes, and is a highly reactive vesicant.

Cyclophosphamide and ifosfamide are similar agents with ringed structures off the end-chloroethyl backbone that stabilize the compounds and make them much less reactive. Enzymatic activation is required through multifunction P450 enzymes in the liver, which is why a number of agents, including phenobarbital and prednisone, may alter activation. Cyclophosphamide is an effective oral as well as intravenous agent used in numerous protocols for solid tumors, as well as in regimens for non-Hodgkins lymphomas and high-dose therapy regimens designed to eradicate tumor and bone marrow in patients with solid tumors, lymphomas, and leukemias and those undergoing bone marrow transplantation. Cyclophosphamide is a potent immunosuppressive as well as immunomodulating agent that is toxic to lymphocytes.[85] It has also been identified as an immunomodulatory agent capable of inducing tolerance. [86] While the immunosuppression is useful for patients undergoing allogeneic bone marrow transplantation and for patients with immune thrombocytopenic purpura, as well as other nonmalignant autoimmune diseases such as rheumatoid arthritis[87] and nephritis,[88] it also has been used in settings in which tolerance to allogeneic infused cells may be preferred, such as for tumor vaccine therapy.[89]

Cyclophosphamide is metabolically activated by cytochrome P450 mixed-function oxidases in the liver to 4-hydroxycyclophosphamide (Fig. 50-4).[90] 4-hydroxycyclophosphamide is further converted to aldophosphamide and then to phosphoramide mustard, the alkylated species, and acrolein. Acrolein is a highly reactive aldehyde and the cause of hemorrhagic cystitis. Initially, N-acetylcistein [91] and, more recently, mercaptoethane sulfanate (mesna)[92] have been used to prevent hemorrhagic cystitis secondary to the use of cyclophosphamide and ifosfamide. Use of mesna as a protective agent is now standard for doses of cyclophosphamide and ifosfamide >1,000 mg/m^2 . Mesna is given in divided doses every 4 hours or as a continuous infusion for 1824 hours in a dose equivalent to either cyclophosphamide or ifosfamide.[92]

Figure 50-4 Metabolism of cyclophosphamide.

Figure 50-5 Structure of common alkylating agents.

Bioavailability of cyclophosphamide is quite similar whether given orally or intravenously, although the drug is generally given by bolus intravenous injection. Cyclophosphamide is detoxified through oxidation to 4-keto-cyclophosphamide and carboxyphosphamide by aldehyde dehydrogenase. [77] Cyclophosphamide is used in doses as little as 50100 mg/day orally and in bolus doses of 400750 mg/m ^{2} for solid tumors and 700 mg/m^2 in combination with doxorubicin and vincristine and prednisone as part of the CHOP regimen for non-Hodgkins lymphomas.[74] It is also used at doses of up to 60 mg/kg daily for 4 days in autologous and allogeneic bone marrow transplantation protocols.[93] [94] [95] Other than hemorrhagic cystitis, bone marrow suppression is dose-limiting. Patients receiving such high doses of cyclophosphamide can be rescued by reinfusion of autologous or allogeneic hematopoietic progenitor cells. [96] [97] Other toxicities observed include alopecia and cardiac toxicity,[98] which are unusual and most often seen after high-dose therapy.

4-Hydroperoxycyclophosphamide is a chemically stable form of the reactive intermediate of cyclophosphamide, 4-hydroxycyclophosphamide. It has been used to purge leukemic cells from the bone marrow of patients with minimal residual disease [99] and is currently under evaluation as an effective method to remove leukemic cells from peripheral blood progenitor cell collections in patients with both acute myelogenous and lymphoid malignancies undergoing progenitor cell infusions after high-dose therapy.[100] [101] Remarkably, both cyclophosphamide and 4-hydroperoxycyclophosphamide are much more toxic to committed hematopoietic progenitors such as CFU-GM, BFU-E, and CFU-E, but spare early progenitors, presumably on the basis of their expression of the detoxifying enzyme, aldehyde dehydrogenase.[102] [103] The difficulty in proving efficacy in previous leukemia-purging studies has been the toxicity associated with delayed engraftment following depletion of these committed progenitor cells in the ex vivo graft. [101]

Ifosfamide also undergoes hepatic activation and yields a similar alkylating species. [104] However, hydroxylation appears to occur at a slower rate, yielding a longer terminal half-life of the parent compound in the alkylating species. Chloroacetate acetaldehyde, a metabolite of ifosfamide, reacts with proteins and may be responsible for its urinary toxicity.[105] Biphosphamide is used mainly in the treatment of solid tumors such as renal cell carcinoma, sarcomas, and non-small cell lung cancer.[106] Recently, high-dose ifosfamide regimens have been described in combination with carboplatin and etoposide. [107] High-dose therapy protocols with peripheral blood progenitor cell and/or bone marrow reinfusion have been used to treat patients with testicular and ovarian carcinomas.

Melphalan, or phenylalanine mustard, has an amino acid side chain that stabilizes its structure, allowing oral administration. It is available in both oral and intravenous dosing and has a similar intracellular pathway to DNA cross-linking as cyclophosphamide and the other nitrogen mustards. Melphalan uptake into cells is by means of a neutral amino acid transporter.[108] [109] Its rate of cross-link formation is much slower than that of mechlorethamine, presumably due to delayed metabolism. Melphalan is used orally predominantly in the treatment of multiple myeloma and intravenously in high-dose regimens for multiple myeloma. [108] Its unpredictable oral high availability has led investigators to suggest dose adjustment in the treatment of myeloma based on evidence of myelosuppression rather than simply using a standard oral dose of 0.2 mg/kg.

Chlorambucil is used in the treatment of chronic lymphocytic leukemia [110] and in some instances for low-grade non-Hodgkins lymphomas. Chlorambucil is the phenylbutyric acid derivative of nitrogen mustard and is very stable, entering the cell by diffusion rather than by a specific uptake mechanism. It is typically administered orally on a daily basis or intermittently for 47 days per month. [109] It appears to have greater bioavailability than melphalan and to have a more consistent half-life of approximately 2 hours.

Busulfan

Busulfan is an alkylsulfonate, unique among alkylating agents because of its two sulfur groups and the lack of a chloroethyl moiety (Fig. 50-5). Busulfan, like the nitrogen mustards, reacts predominantly at the N7 position of guanine and produces an N7-N7 biguanyl DNA cross-link, although the precise nature of this cross-link appears different than that of the nitrogen mustards.[81] This may explain the different clinical utility of busulfan in comparison with the nitrogen mustards. The pharmacokinetics of busulfan are important for its use in high-dose therapy for ablation of the bone marrow in patients undergoing autologous transplantation for acute leukemia or allogeneic transplantation. Busulfan clearance does not appear to be predicted accurately by creatinine clearance; thus, children are typically dosed at much higher levels per kilogram than adults to achieve the same peak concentrations and area under the curve values. [111] [112] [113] Recently, it has been shown that the incidence of

veno-occlusive disease is lower in patients receiving high-dose busulfan based on predosing pharmacokinetics. [114] Busulfan is a potent stem cell toxin, killing both early and late hematopoietic progenitor cells and damaging the bone marrow stroma.[115] [116] In this regard, busulfan is quite different from cyclophosphamide but similar to the nitrosoureas in their ability to cause cumulative and severe myelosuppression. Other toxicities of busulfan include nausea and vomiting and pulmonary interstitial and intra-alveolar edema, leading to fibrosis. [117] [118] The pulmonary fibrosis is distinct from the interstitial pneumonitis that accompanies allogeneic bone marrow transplantation and is not related to cytomegaloviral or other viral infections.

In the past, busulfan was recommended for the management of chronic myelogenous leukemia.[119] However, it has been supplanted by the use of hydroxyurea and interferon-.[120] [121] It has excellent bioavailability and is given orally, even in high-dose regimens, where it has an uptake within 12 hours. [111] [112] [113] [114] In high-dose regimens, a standard dose of 1 mg/kg every 6 hours for 4 days is used to target an area under the curve of 6,0007,000 ng/ml. [113]

Nitrosoureas

There are four chloroethyl-nitrosoureas and one methyl-nitrosourea in clinical use. The chloroethyl nitrosoureas were derived from methylnitrosourea by

Montgomery.[122] These agents are different from the nitrogen mustards in that they alkylate through an SN1 reaction, forming a highly reactive intermediate in the presence of N, O, and P nucleophiles in DNA, leading to decomposition of the parent compound and chloroethylation. The commonly used clinical agent is (2-chloroethyl)-N-nitro-sourea (BCNU, carmustine) (Fig. 50-5).[123] [124] [125] N-[(4-amino-2-methyl-5-pyrimidinyl) methyl]-N-(2-chloroethyl)-N-nitrosourea (ACNU) is commonly used in Japan.[126] A third agent, N-(2-chloroethyl)-N-cyclohexyl-N-nitrosourea (CCNU, lomustine), is used predominantly as an oral nitrosourea in children with brain tumors.[126] All of these compounds have a high hydrophobicity, actively penetrate the bloodbrain barrier, and are useful for the treatment of gliomas and other central nervous system malignancies.[126]

The key chemical activation process is decomposition of the parent nitrosourea in the presence of a nucleophile, forming a chloroethyl-diazonium hydroxide that becomes the chloroethyl donor group. The DNA alkylation sites [124] [126] include N7 and O^6 of guanine. Chloroethylation at the O^6 position of guanine appears critical to cytotoxicity. In addition, Ludlum and Tong[124] identified hydroxyethyl derivatives at N7 and O^6 guanine that appear to have arisen either from hydrolysis of the chloroethyl group or an ill-defined decomposition product. DNA cross-linking by chloroethyl nitrosoureas was identified by Erickson et al., [127] and two types of cross-links were found, at 1-(3-cytosinyl), 2-(1-guanyl) ethane and 1-2-bis(7-guanyl) ethane (Fig. 50-6). [124] [126] The former appears to be responsible for much of the cytotoxicity observed with the chloroethyl nitrosoureas. It is formed after alkylation at the O^6 position of guanine. This adduct undergoes intramolecular rearrangement to a circular intermediate, N1; O^6 ethanoguanine is formed, which can then rearrange by attack at the opposite hydrogen-bonded base N3 of cystine, forming the interstrand cross-link.[128] This is a unique DNA cross-link and is poorly recognized by DNA repair processes, leading to the marked cytotoxic potency of this cross-link.

The pharmacokinetics of the chloroethyl-nitrosoureas has been evaluated in both conventional and high-dose schedules. A very short half-life has been detected, which is quite variable, but an association between the area under the curve of BCNU and pulmonary toxicity has been observed by Jones et al. [129] [130] BCNU is predominantly used for the treatment of gliomas and malignant melanoma.[131] [132] [133] [134] At high doses it is part of the STAMP 1 and 5 regimen for the treatment of advanced breast cancer[129] [135] and the BEP and related regimens for the treatment of recurrent lymphomas.[136] [137] In both settings, it is an effective form of therapy

Figure 50-6 Cross-links formed by nitrogen mustards **(top)** and chloroethyl nitrosoureas such as carmustine (BCNU) **(bottom)**.

with sustained complete remission rates of approximately 40%. Doses of 6001,000 mg/m^2 have been safely administered.

The chloroethyl-nitrosoureas cause profound and cumulative bone marrow suppression at conventional doses of 120150 mg/m^2, limiting treatment to 35 cycles at 6-week intervals.[129] [135] The 6-week administration interval is needed because the nitrosoureas are most toxic to hematopoietic progenitor cells and myelosuppression nadirs are typically observed 35 weeks after treatment, becoming intensified with additional cycles of treatment. [136] [137] [138] [139] [140]

Complications of high-dose BCNU therapy include pulmonary toxicity and renal toxicity at doses >6001,200 mg/m^2. Pulmonary toxicity, as evidenced by a decrease in the DLCO, occurs in up to 40% of patients and is symptomatic in 1015%.[129] [130] [136] It can be managed with steroids during the inflammatory but not the fibrotic phase and is lethal in some cases.[141] Chronic pulmonary damage leading to fibrosis is particularly common at cumulative doses >1,000 mg/m^2 or following single doses of 9001500 mg/m^2. However, symptoms of pulmonary dysfunction are found in only 1015% of patients receiving 450600 mg/m^2.[136] Fibrosis is associated with an early interstitial infiltrate followed by evidence of hyaline membrane formation and replacement of the chronic inflammatory cells by fibrosis over a 4- to 6-week period. [142] Renal dysfunction associated with nitrosourea therapy occurs less frequently than severe cumulative myelosuppression and pulmonary fibrosis and is typically seen at doses >1,000 mg/m^2. Interstitial nephritis with glomerulosclerosis, interstitial fibrosis, and dropout of tubules has been reported [143] [144] with BCNU or CCNU. This can progress to renal failure but is reversible in many instances. Finally, a new nitrosourea derivative, 2-chloroethyl-3-sarcosinamide-1-nitrosourea, [145] will soon enter clinical trials and in preclinical models has improved activity against gliomas and colon cancers. [146]

Methylating Agents

Four methylating chemotherapeutic agents are available for clinical use: procarbazine, dacarbazine, streptozotocin, and temozolomide. Procarbazine and dacarbazine are triazines.[147] Streptozotocin is a monofunctional methylnitrosourea derivative with an attached sugar moiety. [31] [148] Temozolomide is an imidazotetrazinone synthesized in England in the 1960s, reaching clinical trials in the late 1980s. [149] All react with DNA by undergoing SN1 reactions forming a methyldiazonium ion, resulting in methylation of N^7 guanine, O^6 guanine, O^4 and O^2 thymine,

and N^3 adenine.[150] [151] [152] None form DNA cross-links, but all induce high levels of DNA methylation. N^7 methylguanine is unstable, leading to ring opening and both spontaneous and enzymatically mediated depurination. Repair proceeds through the base excision repair system. [153] [154] Recognition by the N-methylpurine glycosylase results in removal of the adducted base with formation of an abasic site recognized by the apurinic endonuclease, which then cleaves the backbone at the apurinic site.[115] Subsequently, the free 5 sugar is released by DNA lyase, with repair initiated by polymerase and DNA ligase. [153] Base excision repair effectively removes N7 methylguanine and N3 methyladenine and restores DNA to normal. These lesions appear to contribute little to cytotoxicity and appear to be up to 500-fold less potent as cytotoxic adducts than O^6 methylguanine.[152]

O^6 methylguanine mispairs with thymine during DNA synthesis, resulting in a lesion recognized by the mismatch repair system. [152] [156] This system consists of two sets of enzyme homologs of mismatch repair in prokaryotes, mutS and mutL.[156] Mispair recognition proteins are GT binding protein or MSH6 and MSH2, homologs of the mutS system in bacteria. MSH2 and MSH6 form a stable heterodimer.[156] Recognition of the mispair recruits additional proteins to the complex, including MLH1 and PMS1/PMS2, which are homologs of mutL- in bacteria. These proteins initiate exonuclease cleavage of a long patch in the newly synthesized strand of DNA. This is then repaired by polymerases and . Unfortunately, if the O^6 methylguanine adduct is not removed before repair synthesis, a thymine is again inserted opposite the O^6 methylguanine and the repair process begins again, resulting in an aberrant episode of repair and multiple single-strand breaks. [152] [156] [157] [158] [159] Cell protection from methylating agents arises either by removal of O^6 methylguanine or inactivation of the mismatch repair system.[152] Cells expressing high levels of the DNA repair protein for O^6 methylguanine, O^6 alkylguanine DNA alkyltransferase are approximately 10-fold more resistant to methylating agents than alkyltransferase-negative cells.[152] [160] Mismatch repair-mediated, single-strand patches promote chromosomal aberrations, homologous and nonhomologous recombination, and induction of apoptosis in a p53-dependent and -independent manner.[161] Absence of one or more protein components of mismatch repair, leading to the phenotype of replication error repair, is commonly observed in hereditary colon cancer as well as endometrial cancer, gastric cancer, [156] [162] [163] [164] and about 15% of lymphomas.[165] Cells lacking mismatch repair are up to 100-fold more resistant to methylating agents than are cells with mismatch repair, regardless of alkyltransferase activity. [152] Acquisition of mismatch repair defects is associated with acquired resistance to methylating agents and cisplatin, which is also recognized by this protein complex. [152] [156] [157] [158] [159]

Procarbazine was originally synthesized as a monoamine oxidase inhibitor but has been used since the 1950s for the treatment of both Hodgkins and non-Hodgkins lymphomas, as well as in combination therapies for gliomas.[166] [167] [168] [169] It is used with mechlorethamine, prednisone, and vincristine in the MOPP regimen; with BCNU, vinblastine, cyclophosphamide, and prednisone (BVCPP) for Hodgkins disease; [170] and in combination with vincristine and BCNU for the treatment of high-grade gliomas.[132] Procarbazine is metabolically activated in the liver by P450 multifunction oxidase. [171] A methyldiazonium derivative formed by each of the methylating agents is the penultimate compound leading to DNA methylation by an SN1 reaction.[172] Recent evidence has shown that patients receiving procarbazine form O^6 methylguanine DNA adducts with depletion of the alkyltransferase enzyme, a suicide protein that removes the methyl group in an irreversible stoichiometric reaction.[46] Chromosomal breaks, single-strand breaks, and chromosomal aberrations and sister chromosome exchanges observed following procarbazine treatment support its association with treatment-related myelodysplasia and leukemia. [173] [174] All methylating agents are more cytotoxic to cells in the second round of DNA synthesis following DNA methylation with a G_2 blocked cell cycle. This is due to processing of the methyl adducts by both base excision repair and mismatched repair, leading to apoptosis and cell death. [58] [175] Inhibition of DNA synthesis, RNA synthesis, and protein synthesis is delayed until the second round of DNA synthesis, again suggesting that disruption of replication by processing of the methyl adducts leads to the cytotoxic effect rather than the direct effect of the adducts themselves. Procarbazine is administered orally with moderate nausea and vomiting. During the 14-day course, induction of microsomal cytochrome P450 oxidoreductase alters the enzymatic conversion and may increase formation of the methyldiazonium ion, leading to increased methylation. [145]

Dacarbazine (DTIC) is metabolically activated by cytochrome P450 microsomal oxidoreductases, ultimately leading to formation of the methyldiazonium ion and DNA methylation.[150] Dacarbazine is used in combination with doxorubicin, vinblastine, and bleomycin for the treatment of Hodgkins disease [75] and is also used for the treatment of metastatic malignant melanoma in combination with BCNU, cisplatin, and tamoxifen.[176] Activation of dacarbazine requires hydroxylation of one terminal

methyl group caused by demethylation, forming 5(3-methyltriazeno) imidazole-4-carboxamide (MTIC), with spontaneous decomposition to the methyldiazonium ion, which alkylates the DNA as noted previously.[61] [177] [178] Like procarbazine, dacarbazine has been shown to form N^7 methylguanine and O^6 methylguanine DNA adducts in human peripheral blood lymphocytes and to deplete alkyltransferase through repair of O^6 methylguanine DNA adducts. A correlation has been found between tumor response and formation of O^6 methylguanine DNA adducts,[179] indicating the importance of this lesion in clinical antitumor effects. Maximum tolerated doses of dacarbazine are approximately 1,000 mg/m^2 , with myelosuppression and gastrointestinal toxicity (including severe watery diarrhea) as the most common side effects.[180] [181] As with all methylating agents, cumulative myelosuppression has not been observed, unlike with the chloroethyl-nitrosoureas, suggesting preservation of primitive quiescent hematopoietic progenitor cells, which may take longer to recognize and repair O^6 methylguanine DNA adducts, such that they contribute less to cytotoxicity than do DNA cross-links.

Temozolomide represents a new class of imidazotetrazinones synthesized at the Medical Research Council of Great Britain in the 1960s. [149] [182] [183] It differs from DTIC in that it is chemically degraded to the monomethyl triazine, MTIC, at neutral pH and does not require P450 enzymatic demethylation. [184] Thus, in phase I and II trials, it has much more consistent pharmacokinetic parameters, including peak serum concentrations, volume of distribution, and clearance, as well as conversion to MTIC, compared to dacarbazine.[149] [182] [183] It continues to undergo phase II and III clinical testing in Europe and the United States and has shown particular effectiveness against high-grade gliomas, anaplastic astrocytomas, [149] [183] and malignant melanomas.[185] Dose-limiting toxicity is thrombocytopenia and, less frequently, neutropenia, with maximum tolerated doses of 1,000 mg/m^2 given over 5 days on a daily or twice-daily regimen. [149] [182] [183] Nausea and vomiting, the other common side effects, are easily controlled with antiemetics. Formation of O^6 methylguanine has been documented in clinical trials with temozolomide with much more rapid depletion of the alkyltransferase, suggesting that temozolomide may be a more effective methylating agent because of its ability to form higher levels of toxic O^6 methylguanine DNA adducts. It may eventually replace the other methylating agents in combination regimens.

Alkylating Agent-Induced Leukemias

Alkylating agents induce dose-limiting myelosuppression, and thus it is not surprising that these agents also cause sublethal

DNA damage to hematopoietic progenitors, causing mutational events leading to both myelodysplastic syndromes and malignant transformation to preleukemic and leukemic states. A concern has been the use of hematopoietic growth factors after exposure to alkylating agents. There is evidence of increased cytotoxicity to hematopoietic progenitors during simultaneous exposure to these agents and growth factors.[186] Treatment-related acute nonlymphocytic leukemia (T-ANLL) accounts for approximately 15% of all cases of adult ANLL. About 50% of T-ANLL patients have a preleukemic phase, compared to only 10% of patients with de novo ANLL. [35] Complete remission rates are 1530% in patients with T-ANLL.[187] In addition, remission duration is a mean of only 2 months. Chromosomal abnormalities are common in T-ANLL, with >90% of cases expressing a chromosomal rearrangement, loss, or addition.[35]

Historically, patients with Hodgkins disease treated with mechlorethamine and procarbazine in the MOPP regimen or with CCNU were at highest risk if exposed to radiation as well as an alkylating agent combination.[188] Patients with polycythemia vera treated with chlorambucil were at a much higher risk than patients treated with phlebotomy alone, which contributed to the shift in treatment strategy.[189] Patients with myeloma and ovarian cancer also developed T-ANLL, especially following prolonged exposure to alkylating agents.[190] Patients treated with alkylating agents for benign diseases also have an increased risk of T-ANLL, such as patients with nephritis, lupus, psoriasis, rheumatoid arthritis, [191] and Wegeners granulomatosis. [192] The mean latency between exposure and T-ANLL from alkylating agents is 45 years,[32] [35] [189] [190] [193] in contrast to T-ANLL from etoposide, which has a latency as short as 1 year.[194] The cumulative risk for developing T-ANLL is 1017% at 46 years for myeloma treated with nitrogen mustards and 210% at 710 years for Hodgkins disease.[188] More recently, alkylating agent-associated T-ANLL has been recognized in patients with breast [195] [196] or colon[197] cancer. A series of nonrandom chromosomal aberrations associated with T-ANLL have been identified.[193] Loss or deletion of all or part of the long arm [q] of chromosomes 5 or 7 [190] is common, as are trisomy chromosome 8, deletions of the short arm of chromosomes 12 and 17, and 21.[35]

The etiology of alkylating agent-induced leukemias has been established in murine models of nitrosourea-induced T-cell lymphoblastic lymphoma/leukemia and ANLL.[198] [199] The mouse lymphoma/leukemia is often associated with nitrosourea-mediated activating mutations of K-*ras*.[200] In addition, transgenic mice carrying mutant p53 or pim-1 are much more susceptible to nitrosourea induction of lymphoblastic lymphoma than their nontransgenic counterparts. [200] [201] A reasonable hypothesis is that hematopoietic cells are susceptible to nitrosourea-induced carcinogenesis due to the low capacity for DNA repair. Because mouse thymus and human bone marrow contain very low levels of O^6 -alkylguanine-DNA alkyltransferase,[202] they accumulate mutagenic O^6 -alkylguanine-DNA adducts. Proof of the association between lack of DNA repair and nitrosourea susceptibility was established by Dumenco et al., [203] who generated transgenic mice expressing high levels of the human alkyltransferase DNA repair protein in the thymus. These mice had significant protection from nitrosourea-induced lymphomas.

Antimicrotubule Agents

The antimicrotubule drugs include vinca alkaloids (e.g., vincristine, vinblastine, and vinorelbine), taxanes (e.g., paclitaxel and docetaxel), and a unique synthetic compound, estramustine (Table 50-3).

The vinca alkaloids are naturally occurring (vincristine and vinblastine) or semisynthetic (vinorelbine) nitrogenous bases derived from the pink periwinkle plant, *Catharanthus roseus*.[204] Paclitaxel was originally isolated from the bark of the Pacific yew, *Taxus brevifolia*.[205] Paclitaxel can also be isolated from other

members of the *Taxus* gene and from a fungal endophyte that grows on the Pacific yew.[206] Docetaxel is derived semisynthetically from 10-deacetyl-baccatin III, which is obtained from the needles of the European yew, *Taxus baccata*. [207]

Both vincristine and vinblastine bind to the protein tubulin at a site distinct from the taxanes and, at low concentrations, inhibit microtubule dynamics. At higher concentrations these vinca alkaloids disrupt microtubules and the mitotic spindle, resulting in cell-cycle mitotic arrest and apoptosis of cells (Fig. 50-2). In contrast, after binding to -tubulin, taxanes kinetically stabilize microtubule dynamics at their plus ends, as well as shift the equilibrium toward tubulin polymerization into microtubule bundles. This also causes mitotic arrest and apoptosis of cells.[19] The mitotic arrest caused by antimicrotubule drugs is associated with phosphorylation of Bcl-2 protein and increased intracellular levels of the free Bax protein, which promote apoptosis. [19]

Antimetabolites

The antimetabolites consist of low-molecular-weight compounds that interfere with micromolecular synthesis. As a group, they may be contrasted with agents such as the anthracycline antibiotics, which interfere with macromolecular synthesis. The nucleoside analogs exhibit structural similarities to naturally occurring nucleosides and are incorporated into either DNA or RNA with lethal consequences. Alternatively, they block key enzymes in de novo purine or pyrimidine biosynthesis. The antimetabolites in use in hematologic disorders can be divided into the following broad categories:

1. Inhibitors of de novo purine or pyrimidine synthesis (e.g., hydroxyurea)
2. Folic acid analogs (e.g., methotrexate)
3. Pyrimidine analogs (e.g., Ara-C, 5-azacytidine, gemcitabine)
4. Purine analogs (e.g., 6-thioguanine, 6-mercaptopurine, fludarabine, chlorodeoxyadenosine, deoxycoformycin)

These categories are not mutually exclusive; for example, some nucleoside analogs (e.g., Ara-C and 6-thioguanine) also inhibit enzymes involved in DNA or deoxyribonucleotide biosynthesis. As noted previously, the antimetabolites are always cycle-active agents and in most cases are phase-specific, being primarily active against cells in S phase. Because the growth fraction of hematologic malignancies tends to be higher than that of nonhematologic malignancies, antimetabolites are particularly useful in the former disorders. In contrast to alkylating agents, antimetabolites have limited carcinogenic and leukemogenic potential. The fluorinated pyrimidines (e.g., 5-fluorouracil) are generally not employed in hematologic disorders and are not discussed here.

Inhibitors of DNA Topoisomerase I and II

The inhibitors of DNA topoisomerase I and II, some of the most commonly used antineoplastic agents in the treatment of hematologic malignancies, include such drugs as doxorubicin, daunorubicin, m-AMSA, mitoxantrone, VP-16, and topotecan. Before

TABLE 50-4 -- Characteristics of Mammalian DNA Topoisomerases

	Topo I	Topo II	Topo II
Size of monomer	100 kDa	170 kDa	180 kDa
mRNA	4.2 kb	6.2 kb	6.5 kb
Chromosome	20q1213.2	17q2122	3p24
DNA cleavage	Single-strand breaks	Double-strand breaks	Double-strand breaks
Covalent intermediate	$3PO_4$ -Tyr^{723}	$5PO_4$ -Tyr^{804}	$5PO_4$ -Tyr^{821}

Inhibitors	Camptothecins		

describing the specific inhibitors, a brief review of the drug targets (topoisomerase enzymes) will be presented (Table 50-4).

DNA Topoisomerase I

Several excellent recent reviews describe the structure, enzymology, and biologic function of mammalian topoisomerase I. [208] [209] [210] [211] [212] Topoisomerase I is a ubiquitous enzyme whose function in vivo is to relieve the torsional strain in DNA, specifically to remove positive supercoils generated in front of the replication fork and to relieve negative supercoils occurring downstream of RNA polymerase during transcription. Topoisomerase I is catalytically active as a 100 kDa monomer and is concentrated in nucleoli, although lower amounts are found in a diffuse nuclear distribution. The gene for this enzyme is located on human chromosome 20q1213.2. Topoisomerase I, in contrast to the type II enzymes, does not require ATP for catalytic activity. Its mechanism of action involves binding double-strand DNA over 1525 bp (with a preference for supercoiled or bent DNA), followed by cleavage of one DNA strand and the formation of a transient covalent phosphotyrosyl bond at the 3-end of DNA. DNA torsional strain is then relieved by a controlled rotation mechanism (Plate 50-1), subsequent to which the cleaved DNA is religated. The three-dimensional crystal structure of human topoisomerase I, both in covalent and noncovalent complexes with DNA, has defined the structural elements of the enzyme that contact DNA.[213] [214] The association between topoisomerase I and the 3-end of cleaved DNA has been termed the cleavable complex, and it is this complex that is stabilized by topoisomerase I inhibitors.

DNA Topoisomerase II

The biochemistry and enzymology of type II enzymes have been recently reviewed by several authors. [208] [210] [212] [215] Two isoforms of human topoisomerase II exist, and . The and isoforms are similar in that they are active as homodimers, their activity results in cleavage of double-strand DNA with a transient covalent phosphotyrosyl bond at the 5-end of DNA, they both require ATP for full activity, their role in vivo is to relieve torsional strain in DNA, and their cellular distribution is determined by nuclear localization signals contained in the C-terminal domain. [216] [217] These isoforms are distinct in that they have different-size monomers (Table 50-1), their genes are on separate chromosomes, their nuclear distribution is different, and only the isoform shows cell-cycle variations in amount and activity (with maximal activity in G_2 /M). The mechanism of action of topoisomerase II involves several steps (Fig. 50-7 (Figure Not Available)): DNA recognition and binding (curved and supercoiled DNA,

Figure 50-7 (Figure Not Available) DNA topoisomerase II catalytic cycle. (1) Noncovalent binding of DNA by the topoisomerase II homodimer. (2) DNA recognition and preferential binding to crossovers by topoisomerase II. (3) Binding of ATP promotes the formation of a topologic complex. (4) DNA cleavage with covalent linkage of each topoisomerase II monomer to the 5-DNA terminus of the break. (5) Poststrand passage cleavable complex. (6) Religation of the cleaved DNA is followed by ATP hydrolysis and enzyme turnover. DNA topoisomerase II inhibitors generally increase cleavable complexes by inhibiting the religation activity. *(Reproduced with permission from Pommier et al.[234])*

Figure 50-8 Structure of camptothecin analogs.

as well as DNA crossovers, are preferred); the sequential cleavage of the two strands of DNA with covalent attachment of a monomer to each 5-end of the cleaved DNA; passage of another DNA duplex through the break site (e.g., to relieve DNA torsional strain or decatenate daughter chromosomes at the end of replication); religation of the cleaved DNA; and ATP hydrolysis-dependent enzyme turnover. The binding of ATP by topoisomerase II is required for the strand passage reaction. Again, the association between topoisomerase II monomers and the 5-end of the cleaved DNA has been termed the cleavable complex, the stabilization of which generally correlates with the cytotoxic activity of specific topoisomerase II inhibitors.

Because topoisomerase I and II inhibitors convert their respective enzymes into DNA-damaging agents, it is usually true that the more enzyme target a cell contains

(provided it is in the nucleus), the more cytotoxic the specific inhibitor. An exception to this generalization is found in CLL cells, which have abundant topoisomerase I but are not very sensitive to topoisomerase I inhibitors. This is because topoisomerase I inhibitors are S phase-specific and CLL cells have very few cells in S phase.

Finally, in addition to topoisomerase I and II, a mammalian DNA topoisomerase III has recently been described and found to be essential for early embryogenesis in the mouse.[218] Thus, in addition to the presumed lethality of a homozygous deletion of the topoisomerase II gene, topoisomerase I and III appear to be essential for cell growth and division in mammals.[218] [219] The specific role of topoisomerase III in humans is not known at present.

DNA Topoisomerase I Inhibitors

Camptothecin is a plant alkaloid first identified in 1966 from the tree *Camptotheca acuminata.* Early clinical studies with camptothecin were stopped primarily because of hemorrhagic cystitis, resulting from conversion of the sodium salt form given to the active lactone form by the acidic pH in the bladder. Renewed interest in camptothecin occurred in 1985 when topoisomerase I was identified as the target of this drug, [220] and as new, more water-soluble analogs became available. At present, there are two topoisomerase I inhibitors approved by the FDA as second-line agents for the treatment of ovarian carcinoma and colorectal cancer; these are topotecan and CPT-11 (irinotecan), respectively. Other analogs, including 9-aminocamptothecin, are in clinical trials (Fig. 50-8). With respect to hematologic malignancies, topotecan has been shown to be active in the treatment of myelodysplastic syndromes [221] and inactive in the treatment of CLL.[222] Responses to topotecan have also been seen in refractory multiple myeloma [223] and refractory acute leukemia.[224] [225]

There are several recent reviews of topoisomerase I inhibitors and the clinical trials using them. [226] [227] [228] [229] The lactone forms of topotecan and SN-38 (the active form of CPT-11 generated in vivo by the action of a carboxylesterase) are as much as 1,000-fold

Figure 50-9 (Figure Not Available) Action of camptothecin to stabilize the DNAtopoisomerase I cleavable complex. Cytotoxicity is believed to result from the collision of the DNA replication fork with the cleavable complex, which results in a lethal double-strand DNA break. *(Reproduced with permission from Takimoto and Arbuck.[225])*

TABLE 50-5 -- Mechanism(s) of Action of Antineoplastic Agents That Are Primarily Topoisomerase II Inhibitors

more active inhibitors of DNA topoisomerase I than their carboxylate forms. The lactone form predominates at an acidic pH. Topoisomerase I inhibitors stabilize the DNAenzyme cleavable complex and thus inhibit DNA religation, but it is the production of DNA double-strand breaks that results from a collision of the DNA replication fork with the ternary drugenzymeDNA complex that is the lethal event (Fig. 50-9 (Figure Not Available)). [230] [231] [232] Topoisomerase I inhibitors are considered S phase-specific agents because they require ongoing DNA synthesis to exert their cytotoxic effect.

DNA Topoisomerase II Inhibitors

Inhibitors of DNA topoisomerase II are some of the most commonly used agents in the treatment of hematopoietic malignancies, and their biochemical and pharmacologic properties have recently been reviewed by several investigators. [233] [234] [235] [236] There are three general types of topoisomerase II inhibitors (Table 50-5). The first group are the topoisomerase II *poisons*, typified by VP-16 and m-AMSA, whose activity results in the stabilization of cleavable complexes. The second group are the *catalytic inhibitors*, represented by aclarubicin, merbarone, and the bis-2,6-dioxopiperazine derivatives (ICRF-193, ICRF-159, ICRF-187). These drugs, except for aclarubicin, do not bind DNA and do not stabilize cleavable complexes; rather, they interfere with some aspect of topoisomerase II catalytic activity (e.g., ICRF-187 inhibits topoisomerase II ATPase activity). The final class includes drugs that can inhibit both DNA topoisomerase I and II, and is represented by intoplicine[237] and saintopin.[238] These dual inhibitors are in clinical trials and will not be discussed further. These first two classes of inhibitors are not mutually exclusive; that is, anthracyclines at low doses behave more like topoisomerase II poisons, but at higher concentrations they suppress the formation of cleavable complexes. Some of these antineoplastic agents, especially the anthracyclines and mitoxantrone, exert their cytotoxic effects (at least in part) by also intercalating in DNA and by forming free radicals.

DNA topoisomerase II poisons, the most frequently used drugs in the clinical setting (Fig. 50-10), are most likely cytotoxic because they trap DNAtopoisomerase II complexes on nascent DNA in the nuclear matrix.[239] [240] Recent evidence suggests that the topoisomerase II poison-stabilized enzymeDNA complex acts as a replication fork barrier and leads to the generation of irreversible DNA damage and cell death in proliferating cells, [241] while other experiments in yeast show that although DNA synthesis is a major determinant for cell killing by topoisomerase I inhibitors, topoisomerase II poisons may be cytotoxic during other phases of the cell cycle as well.[242] [243]

Platinum Analogs

During a study of the effects of electric current on growing bacteria, the antibacterial and, later, the antitumor activities of the platinum compounds were fortuitously discovered. The antitumor agent, cisplatin, and its cis-carboxylester analog, carboplatin, are heavy-metal platinum complexes. Both are activated by displacement of their ligands (cisplatin: chloride; carboplatin: carboxylester) by water to form positively charged aquated platinum complexes. This allows platinum to stably bind DNA, RNA, proteins, or other critical biomacromolecules. With DNA, platinum complexes form covalent links to the N7 position of guanine and adenine. The N7 adducts at d(GpG) or d(ApG) result in intra- or interstrand DNA cross-links, which bend the DNA helix and inhibit DNA synthesis. The cytotoxicity of platinum analogs correlates with the total platinum binding to DNA, as well as with the intra- or interstrand cross-links. This results in DNA damage, which triggers apoptosis of sensitive cells.

Miscellaneous Agents

Among the agents in this category, only plicamycin, bleomycin, procarbazine, L-asparaginase, gallium nitrate, and glucocorticoids are of current interest to the

hematologist; these are discussed in Appendix 50-6 .

DRUG RESISTANCE TO ALKYLATING AGENTS

Tumors and some normal tissues express high levels of some detoxification enzymes and DNA repair enzymes that reduce the cytotoxic effect of alkylating agents (Table 50-6). For the most part, however, normal hematopoietic progenitors have lower levels of these enzymes, and are thus more sensitive to these agents, than do malignant cells.[186] The exception to this is the high level of aldehyde dehydrogenase found in early CD34+ and even earlier CD34 hematopoietic progenitors, [102] which converts cyclophosphamide to 4 keto-cyclophosphamide

Figure 50-10 Structure of DNA topoisomerase II inhibitors. For epirubicin and idarubicin, arrows point to the sites where these new drugs differ, respectively, from doxorubicin and daunomycin.

and carboxyphosphamide and prevents formation of phosphoramide mustard, the cytotoxic alkylating species. For this reason, early progenitors are resistant to cyclophosphamide, cumulative hematopoietic toxicity is usually not observed with this class of agents, [244] and purging of leukemic cells from bone marrow preparations with 4-hydroperoxycyclophosphamide [100] preserves sufficient normal progenitors to allow engraftment after autologous transplantation. Since multidrug resistance-1 (MDR-1) protein is not involved in the resistance to alkylating agents, expression of MDR-1 is not a factor either in progenitor cell sensitivity to alkylating agents or in tumor responses to these agents. However, the high level of this aldehyde dehydrogenase, as well as the MDR-1 protein, in early progenitors protects [245] them from combination chemotherapy involving alkylating agents and other agents such as paclitaxel and etoposide, [59] and may explain the efficacy of combination therapy against tumors expressing MDR-1.

Glutathione and Glutathione S-Transferase

The enzymes involved in glutathione conjugation of drugs are important in resistance to the nitrogen mustard class of alkylating

agents, including melphalan, and to a lesser extent the nitrosoureas, where direct reaction with glutathione S-transferase (GST) has been noted, associated with a reduction in DNA cross-links.[246] Many of the 12 enzymes in the GST superfamily have been shown to detoxify alkylating agents, but their activity varies considerably. The members of the GST family bind directly to alkylating agents and conjugate them to glutathione (GSH), and they also bind and reduce organic peroxides formed during the initial uptake of drugs into cells even before decomposition to DNA-damaging agents. [247] For instance, human GST enzyme catalyzes the reaction of the aziridinium ion of the phosphoramide mustard derivative of cyclophosphamide with glutathione [248] and also reacts with melphalan. [249] High expression of these enzymes in the NCI tumor bank is associated with resistance to alkylating agents. When the patterns for the GST enzymes and mRNA levels were correlated with drug sensitivity patterns using the COMPARE program, alkylating agents had the greatest correlation between GST expression and drug resistance. [250] In contrast, none of the other enzymes or GSH had patterns of expression that resulted in an obvious correlation with the pattern of alkylating agent resistance. [250] In this study, -glutamylcysteine synthase, the synthetic enzyme for glutathione, also showed a high degree of correlation with alkylating agent resistance in the COMPARE program, suggesting that the ability to generate glutathione, the substrate for GST conjugation, contributed to drug resistance.

Overexpression of multiple enzymes in the GST family confers resistance to alkylating agents to variable degrees, [251] [252] although little effect is seen in cell lines that express the enzymes constitutively. Increased expression of GSTs is associated with alkylating agent resistance in tumor cell lines and in human tumors treated with alkylating agents.[44] [60] [253] [254] Whether this represents selection of pre-existing, high-expressing cells or selection of cells mutant in GST expression remains unclear and the focus of current study. However, GST expression has been used as a predictor of clinical responses to alkylating agents. [255]

Among hematologic malignancies, non-Hodgkins lymphomas were found to display high levels of GST , whereas the expression of and GST varied from undetectable to levels as high as those observed in drug-resistant cell lines. [256] In a group of nine of the patients treated with bifunctional alkylating agents, a significant correlation was observed between complete response to chemotherapy and low expression of GST but not GST .[256] In CLL, Marie et al.[257] found similar levels of GST , , and in normal and CLL cells, and suggested that low GST levels may explain the sensitivity of CLL cells to nitrogen mustards such as chlorambucil observed clinically.

A number of studies have found that depletion of glutathione by buthionine sulfoximine (L-BSO) sensitizes cells and xenografts to melphalan, other nitrogen mustards, and cisplatin.[44] [258] [259] This led to clinical trials with L-BSO designed to achieve the biochemical endpoint of >90% depletion of blood mononuclear cell GSH levels; however, very large doses of L-BSO were required because it was found that glutamylcysteine synthase was induced in vivo during exposure to L-BSO. [260] [261] A number of dosing strategies have been used, and early phase II studies are underway. Despite the suggestion that GST binds BCNU and decreases cross-links, [246] the effect of L-BSO on nitrosourea resistance in breast cancer cells expressing GST was modest, much less than the effect of inhibition of alkyltransferase, suggesting that L-BSO and the GST conjugation pathway play a modest role in nitrosourea resistance. [262] For this reason, there are no current plans to pursue the

use of the L-BSO and nitrosourea combination.

DNA Repair Pathway Mechanisms of Drug Resistance

O^6 -Alkylguanine-DNA Alkyltransferase

As noted above, the nitrosoureas and methylating agents are cytotoxic in large part due to formation of DNA adducts at the O^6 position of guanine. [263] The most efficient means of protection from the cytotoxicity of adducts at O^6 position of guanine is rapid repair by the O^6 -alkylguanine-DNA alkyltransferase (AGT). [263] This protein serves as the stoichiometric acceptor protein for O^6 -alkylguanine DNA monoadducts, transferring the alkyl group from DNA to the active site of the protein, inactivating the protein, and restoring DNA to normal. [263] [264] However, the N^1 G-N^3 C DNA cross-link that follows chloroethylation is not a substrate for AGT. There is a striking correlation between drug resistance and alkyltransferase activity. [45] [46] High levels of AGT are found in many leukemias, [265] whereas low levels are observed in normal human CD34+ cells, [186] perhaps explaining why nitrosoureas are not used in leukemia management and why nitrosoureas are effective myeloablative agents used in high-dose chemotherapy regimens. Recently, a novel inhibitor of AGT, O^6 -benzylguanine (BG), has been used to sensitize human tumors to BCNU. [45] [266] [267] On the basis of these studies, BG passed the NCI decision network review and entered clinical trials as a biochemical modulator of AGT. The endpoint of these trials is to establish the dose of BG that inhibits AGT in tumor tissues, thereby sensitizing these tumors to BCNU and, in future studies, to methylating agents such as procarbazine or temozolomide. Results indicate that biochemical modulation can be achieved at nontoxic doses of BG. [268]

Mismatch Repair

The spectrum of drug resistance and sensitivity to methylating agents does not end with AGT. Recent evidence suggests that methylating agent-induced cell death involves an aborted effort at mismatch repair. Karran et al. [157] and others, in mammalian systems, have shown that the replicative DNA polymerase and the repair polymerase pauses at O^6 -mG and preferentially inserts a thymine (T) at the site. [157] [269] The O^6 -mG:T base pair is recognized by the mismatch repair (MMR) system that initiates base excision repair. In human cells, the MMR complex consists of at least six proteins involved in the recognition and repair of mismatch lesions: hMLH1, hMSH2, hMSH3, hPMS1, hPMS2, and GTBP (GT binding protein, also called MSH6), all of which appear to be homologs of MMR proteins found in *E. coli* and in yeast. [156] [270] [271] Following binding recognition, an endonuclease removes a patch of 1001000 bp containing the T mismatch, DNA polymerase or fills in the patch, with reinsertion of a T opposite the O^6 -mG, and a DNA ligase closes the strand break. [156] Since the O^6 -mG:T is reformed, cytotoxicity ensues due to repetitive efforts at DNA repair and induction of chromosomal breakage, rearrangements, energy depletion, and apoptosis. [272] The mutator phenotype was originally described in cells with acquired resistance to methylnitrosourea (MNU), methylmethanesulfonate, or N-methyl-N-nitroso-N-nitrosogua-nidine, which were tolerant to G A point mutations based on the inability to repair O^6 -mG. [273] Parallel studies identifying mutations in the MMR pathway suggested that these cell lines carry an MMR mutation, rendering them unable to recognize or initiate repair at the O^6 -mG:T mismatch. [274] Cells resistant to the abortive MMR process had a survival advantage in the face of persistent mutations. In addition, Karran et al. [157] noted that MNU-resistant Chinese hamster ovary (CHO) cells replicated DNA past O^6 -mG or 6-thioguanine lesions without cell-cycle arrest. These MNU- and methylmethanesulfonate-resistant cells were cross-resistant to 6-thioguanine, which forms the 6-thioguanine:T mismatch, but were sensitive to chloroethylating agents. [158]

MMR Mutations and Methylating Agent Resistance

Mismatch repair defects in humans were initially described in hereditary nonpolyposis colon cancer, which represents 15% of all colon cancer cases, [156] [164] [271] and more recently in some lymphomas. [165] The genetic defect results in a high rate of spontaneous mutations within microsatellite DNA, resulting in the replication error phenotype arising as the expansion or contraction of mono-, di-, or tri-nucleotide repeats within the microsatellites. [156] In affected individuals, a heterozygous mutation is inherited and a homozygous defect occurs in the tumor. Tumor cell lines defective in MMR are remarkably resistant to temozolomide, regardless of AGT activity or its inhibition by BG, confirming the importance of MMR in regulating sensitivity to methylating agents. [152] Of interest, MMR mutant cell lines are also two- to three-fold more resistant to cisplatin, [275] perhaps because the cisplatin DNA adduct is bound by the MMR complex, slowing its recognition and repair by the nucleotide repair pathway and increasing its cytotoxicity. [276]

Base Excision Repair

Methylating agents such as procarbazine and temozolomide form large numbers of N^3 -A and N^7 -G adducts in addition to O^6 -mG (with temozolomide, the relative amounts are 72 N^7 mG, 8 O^6 mG, 5 N^3 mA). Thus, under normal circumstances, cells process many more N^7 mG and N^3 mA lesions than O^6 mG lesions, even though the latter appear much more cytotoxic, except in MMR-defective cells. Repair of N^3 -A and N^7 -G adducts through base excision repair is efficient and normally leads to cell survival rather than cell death. Adducts are recognized by the methylpurine glycosylase with removal of the base, generating an abasic (or AP) site. The AP site is then cleaved by the class II hydrolytic endonuclease (or apurinic endonuclease), generating a single-strand break with a 5PO_4 that becomes the substrate for DNA polymerase and to a lesser extent polymerases and , followed by DNA ligase (reviewed by Sancar [153]). In addition, MAG mediates the repair of CNU lesions, either by repair of the pre-crosslink N^7 G adduct or by initiating repair of

the cross-link. [277] [278] Thus, the base excision repair pathway appears to have a role in both repair of temozolomide- and BCNU-induced lesions and reduction in cytotoxicity. Recently, it has been proposed that defects in base excision repair may lead to drug sensitivity. The clearest experiments come from studies in homozygous knockout ES cell lines. Knockout of methylpurine glycosylase increased sensitivity to methylmethanesulfonate and BCNU. [277] [278] Knockout of polymerase - [154] produced sensitivity to methylating agents.

Another component of alkylating agent resistance is poly (ADP)ribose polymerase (PARP), which binds single-strand breaks formed during repair of alkylating agents and cisplatin-induced DNA adducts, resulting in autoribosylation of PARP. The negative charge induced by this process unfolds the DNA, exposing the site to repair enzymes. Ultimately, PARP disassociates from the break, allowing repair to proceed. [279] [280] Alternatively, through p53-dependent and -independent means, PARP is cleaved by the caspases activated during apoptosis, preventing DNA repair and inducing DNA strand breaks and cell death. [62] [281] Inhibitors of PARP result in increased sensitivity to alkylating agents [279] [280] and are a potential therapeutic intervention for drug resistance.

Transfer of Drug Resistance Genes into Hematopoietic Progenitors to Confer Protection from Chemotherapy-Induced Myelosuppression

Any discussion of chemotherapy-induced myelosuppression would be incomplete without mention of the progress being made in the delivery of drug resistance genes to hematopoietic progenitor cells to increase the resistance of these cells during chemotherapy exposure.

Transfer of a number of drug resistance genes, including dihydrofolate reductase (DHFR), [282] [283] MDR-1, [284] [285] and ALDH-1, [286] into hematopoietic progenitors has been proposed as a method to protect the bone marrow from the toxic effects of chemotherapeutic agents, improving tolerance to anticancer agents and perhaps providing a means for dominant selection of a second therapeutic gene. [287] Studies using mutant forms of the murine or human DHFR have shown the ability to select for drug-resistant cells after methotrexate treatment in transplanted mice. [288] Clearly, MDR-1 provides the broadest spectrum of drug resistance and may be very useful in the clinical setting. Two clinical trials have been reported showing evidence of gene transfer, but no therapeutic benefit has yet been observed. [289] [290] Nonetheless, the observation that expression of endogenous MDR is relatively high in CD34+ cells suggests that early hematopoietic progenitors may be more resistant than later committed cells. [291] [292]

The methyl guanine methyl transferase (MGMT) or AGT gene has also been retrovirally transduced into mouse and human hematopoietic progenitor cells, resulting in resistance to BCNU in vitro and in mice [291] [292] for at least 37 weeks after bone marrow transplantation. In addition, recent studies have shown that this vector can be used as a dominant selectable marker because treatment of mice with BCNU increases the proportion of hematopoietic progenitors carrying the provirus and increases expression of MGMT as well. [293] Animals receiving mock-transduced cells suffered severe pancytopenia, whereas animals receiving MGMT-transduced bone marrow progenitors had significantly higher hematocrits and leukocyte and platelet counts. [294] Recently, a series of AGT point mutations that retain the functional activity of DNA repair but are remarkably resistant to inactivation by BG have been described. [295] One of these, the glycine to alanine mutation at position 156 in the human protein, results in a 240-fold resistance to BG in cell-free systems. Based on these data, a retrovirus containing this mutant MGMT was introduced into human CD34 cells and mouse bone marrow cells, both of which became resistant to the combination of BG and BCNU. [296] [297] Further, the degree of resistance was much greater for marrow progenitors transduced with the mutant MGMT and treated with the BCNUBG combination than in cells transduced with the wild-type

gene and treated with BCNU alone. Cumulatively, these studies suggest that gene transfer strategies may protect the marrow progenitor pool from the myelosuppression of a wide range of chemotherapeutic agents. Whether this improves tolerance to these agents or has application for selection of cells carrying other genes remains to be experimentally determined.

DRUG RESISTANCE TO PLATINUM ANALOGS

Several mechanisms of resistance to platinum analogs have been described, including altered transport across the cell membrane, which results in decreased intracellular drug accumulation. Increased intracellular levels of glutathione (GSH) or sulfhydryl conjugating enzymes (e.g., GST) may also confer in vitro resistance to platinum analogs. As noted previously, MMR mutations also confer resistance to cisplatin. Finally, platinum resistance may also be due to an enhanced ability to repair DNAplatinum adducts. Decreased intracellular accumulation of platinum analogs is a consistent finding in platinum-resistant cells. Platinum analogs may form complexes with two GSH molecules in a nonenzymatic reaction, and this complex may be exported out of the cell by an organic ion pump referred to as the GS-X pump. However, the nature of this pump has not been established conclusively.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

DRUG RESISTANCE TO ANTIMICROTUBULE AGENTS

Two main mechanisms of in vitro resistance to antimicrotubule drugs have been elucidated. Cells resistant to antimicrotubule agents often display an MDR phenotype. This results in decreased drug accumulation and retention and confers varying degrees of cross-resistance to other natural products, including anthracyclines, epipodophyllotoxins, and actinomycin D. As discussed previously, the MDR phenotype is due to the overexpression of a membrane transporter, P-glycoprotein, encoded by the *mdr-1* gene. This is discussed below in the section on MDR. The second mechanism of acquired drug resistance to antimicrotubule agents results from alterations in - and/or -tubulin proteins. These alterations may cause either decreased drug binding or increased resistance to microtubule assembly or disassembly. This would impair the cell-cycle mitotic arrest due to antimicrotubule drugs.

DRUG RESISTANCE TO ANTIMETABOLITES

Although overlap exists, antimetabolites can be classified into nucleoside analogs that are incorporated into RNA and/or DNA, and agents that inhibit de novo purine and pyrimidine biosynthetic pathways. Mechanisms of resistance to these agents fall into several broad categories. For example, many antimetabolites are prodrugs in that they must be converted intracellularly into active nucleotide forms to exert their cytotoxic actions. Consequently, events that interfere with cellular accumulation of drug and/or nucleotide formation will reduce activity. Examples include decreased transport of methotrexate, or decreased nucleotide formation of Ara-C and 6-thioguanine by reductions in activity of deoxycytidine kinase or hypoxanthine guanine phosphoribosyl transferase (HGPRT), respectively. Alternatively, enhanced drug catabolism reduces cytotoxicity. Examples include the deamination of Ara-C (to inactive Ara-U) by cytidine deaminase or catabolism of 6-thioguanine by thiopurine methyltransferase. A third mechanism of resistance stems from the presence of increased intracellular levels of a competing metabolite (e.g., dCTP in the case of Ara-C, or

hypoxanthine or guanine in the case of 6-thioguanine). Fourth, alterations in the level of activity of a target enzyme or the presence of a mutant form that is less inhibitable will also confer resistance. Examples include increased activity or a mutant form of DHFR (in the case of methotrexate), an altered DNA polymerase (in the case of Ara-C), or increased activity of ribonucleotide reductase (through overexpression of either subunit). Finally, cytokinetic factors represent a common theme in the case of most (but not all) antimetabolites in that a reduction in the S-phase fraction generally leads to reduced drug sensitivity. These resistance mechanisms are agent-specific and are distinct from the more general modes of resistance (e.g., increased expression of Bcl-2) associated with defects in the distal cell death pathway.

DRUG RESISTANCE RESULTING FROM ALTERATIONS IN DNA TOPOISOMERASE I OR DNA TOPOISOMERASE II

Resistance to several antineoplastic agents may result from a perturbation in either DNA topoisomerase I or II; for example, decreased expression of topoisomerase II may result in MDR to VP-16, doxorubicin, mitoxantrone, actinomycin D, and m-AMSA (Fig. 50-11). The mechanisms of drug resistance to either topoisomerase I or II inhibitors have been defined at a molecular level by detailed in vitro studies with cell lines; only recently have studies attempted to define the role of these putative resistance mechanisms in clinical samples. Since more is known about the mechanisms of resistance to topoisomerase II inhibitors, these will be discussed first, followed by a brief review of the ways cells become resistant to topoisomerase I inhibitors. The basic biochemistry and pharmacology of the topoisomerase enzymes and their inhibitors were described previously.

Drug Resistance to Topoisomerase II Inhibitors

In vitro studies have demonstrated that cells can become resistant to topoisomerase II inhibitors by four general mechanisms. [298] [299] [300] [301] First, altered transport of the antitumor agent, either decreased uptake or increased efflux, can certainly result in drug resistance. Essentially all of the topoisomerase II poisons (Table 50-7) are substrates for the drug efflux pump Pgp, and many are substrates for MDR-associated protein (MRP) and lung resistance-related protein (LRP). Second, several point mutations and gene deletions have been defined in the gene for topoisomerase II resulting in the production of an enzyme with altered catalytic and/or cleavage activity.[301] [302] The third mechanism of drug resistance to topoisomerase II poisons, and probably the most common, is a decrease in expression of the enzyme such that there is less target for the inhibitor to convert to a DNA-damaging agent. This can result from a proliferation-dependent or cell cycle-dependent decrease in topoisomerase II,[303] from a specific attenuation of either topoisomerase II [304] or topoisomerase II,[305] or from an intrinsic absence of topoisomerase II (e.g., CLL cells have virtually no topoisomerase II protein). The fourth and final mechanism of resistance to

Figure 50-11 Mitoxantrone.

topoisomerase II inhibitors involves alterations in the subcellular distribution of the enzyme. Truncation of the COOH-end of topoisomerase II has resulted in the cytoplasmic distribution of enzyme due to a loss of nuclear localization signals; thus, the enzyme cannot interact with DNA in the presence of an inhibitor, and the cell is thus resistant.[306] [307] [308] An altered subcellular distribution of topoisomerase II, such that the quantity of enzyme associated with the nuclear matrix is reduced (thought to be a critical location for interacting with nascent DNA transcripts), has also been found to result in drug resistance to topoisomerase II inhibitors. [309]

The possible roles of these four general mechanisms in clinical drug resistance and clinical outcomes for patients with hematologic malignancies are under investigation. Mutations in the gene for topoisomerase II do not appear to be a common clinical event, as only a single patient with AML has been found to have a point mutation. The available data indicate that the content of topoisomerase II in blast does not correlate with clinical outcome in AML, [310] and this may also be true for acute lymphocytic leukemia (ALL). CLL cells are resistant to topoisomerase II inhibitors because they express very low levels of the protein. Further studies using sequential biopsy samples and assays that focus on topoisomerase II activity should establish the role that changes in topoisomerase II play in the development of drug resistance in hematologic malignancies.

Drug Resistance to Topoisomerase I Inhibitors

Defining the molecular mechanisms of resistance to topoisomerase I inhibitors has lagged behind topoisomerase II inhibitors, but in general the four mechanisms described above have been found with the camptothecins. Although alterations in drug transport of topoisomerase I inhibitors may result in drug resistance, it is unlikely that either Pgp or MRP will have a major role in clinical drug resistance. [311] [312] Similar to the previous discussion, drug resistance to topoisomerase I inhibitors has been found in vitro to result from point mutations in the gene for topoisomerase I, [298] [313] [314] [315] an attenuation of nuclear topoisomerase I content, [315] [316] and a subcellular redistribution of topoisomerase I in cells treated with topotecan. [316] The role of these mechanisms of resistance to topoisomerase I inhibitors in the development of drug resistance in clinical hematologic malignancies is unknown.

MULTIDRUG RESISTANCE

One of the major reasons for the failure of antineoplastic agents in the treatment of both solid tumors and hematologic malignancies is the presence of drug resistance mechanisms that efficiently neutralize the cytotoxic effects of the antitumor drugs. Drug resistance may be either an intrinsic (de novo) property of the tumor or an acquired characteristic. Examples of malignancies that are intrinsically drug-resistant include malignant melanoma and primary refractory non-Hodgkins lymphoma, while relapsed small cell lung cancer, AML, and multiple myeloma commonly have acquired drug-resistance mechanisms. With very few exceptions, it is not possible to attribute a specific mechanism(s) of drug resistance (discussed later) to a particular tumor type to account for either de novo or acquired drug resistance. This is for several reasons. First, and most importantly, large-scale prospective studies of clinical tumor biopsies obtained before and after drug exposure and at the time of disease relapse, which assess the relevant gene product function, simply have not been done. In addition, by virtue of having been exposed to multiagent chemotherapy, and because the same drug can evoke different resistance mechanisms, it is very likely that the majority of human tumors have multiple concurrent mechanisms, either those already defined or one not yet described, for circumventing the cytotoxic effects of antineoplastic drugs. Finally, the discrete biochemical mechanisms defined in

TABLE 50-7 -- Characteristics of Three Mechanisms of Multidrug Resistance That Result from Overexpression of P-Glycoprotein (PGP), Multidrug Resistance-Associated Protein (MRP), or Lung Resistance-Related Protein (LRP)

	PGP	MRP	LRP

vitro are only one potential contributor to the overall resistance of the tumor in vivo; consideration must also be given to pharmacologic sanctuaries (testes, central nervous system), the activation (phosphorylation) and metabolism of certain drugs, the pH and blood supply of the tumor, and possible kinetic resistance of noncycling cells residing in G_0 .

The Goldie-Coldman hypothesis predicts that drug-resistant tumor cell clones survive because of a favorable spontaneous mutation that occurs in about one in a million cells. Since 1 g of tumor contains 1×10^9 cells, it becomes obvious that states of high tumor burden have a tremendous number of mutations that can contribute to drug resistance. This is the rationale for using combination chemotherapy at specific dose intervals to maximize dose intensity.

Drug-resistance mechanisms have been discovered and subsequently defined at the molecular level by investigators working in vitro with tumor cell lines selected in the presence of specific antitumor agents. These studies have shown that cellular drug resistance may be to a specific drug (e.g., methotrexate resistance resulting from amplification of the *DHFR* gene), to a class of antineoplastic agents (e.g., resistance to all topoisomerase I inhibitors resulting from a downregulation of nuclear topoisomerase I), or to several different classes of structurally dissimilar drugs (e.g., cross-resistance to taxanes, vinca alkaloids, and anthracyclines resulting from Pgp overexpression). Again, the role of the majority of these in vitro mechanisms in clinical drug resistance will await the completion of translational studies now underway. The cross-resistance to several different classes of antitumor agents that results from exposure to a single drug is termed multidrug resistance and classically refers to the MDR associated with P-glycoprotein overexpression. Here, however, we will use MDR to refer to drug resistance that results from Pgp overexpression, MRP overexpression, lung resistance-related protein overexpression, or alterations in DNA topoisomerase I or II. The reader is referred to two comprehensive reviews of drug resistance in hematologic malignancies recently published. [317] [318]

P-Glycoprotein

Structure and Function

P-glycoprotein has been the subject of intense biochemical and clinical studies since it was discovered in drug-resistant cell lines >20 years ago. [319] The biochemistry of Pgp has been reviewed in detail by several investigators. [320] [321] [322] This phosphorylated glycoprotein has a molecular mass of about 170 kDa and is localized to the plasma membrane, where it functions as a

drug efflux pump (Table 50-3). The ATP-dependent extrusion of antineoplastic agents confers a relative level of resistance to the cell that overexpresses Pgp. The observation of double minute chromosomes and homogeneously staining regions in several MDR cell lines suggested that gene amplification is involved in Pgp-mediated MDR. This has been shown to be true for several mammalian cell lines, [323] [324] but is not a requirement for the involvement of Pgp in MDR. The human *MDR1* gene that codes for Pgp and is involved in antitumor drug resistance, [325] [326] and the human *MDR2* gene, the product of which is expressed by hepatocytes, are located very near each other on human chromosome 7q21.1. The human *MDR1* gene has 28 exons and codes for a protein of 1280 amino acids. The Pgp molecule has homologous halves, each with a hydrophobic region containing six transmembrane domains and a hydrophilic region containing an ATP binding site. The N-linked glycosylation occurs on the extracellular side. Pgp is a member of the ATP-binding cassette superfamily, which includes among more than 100 others MRP; the pf*mdr* pump in *Plasmodium falciparum* that results in chloroquine resistance; STE6, the transporter of the a peptide mating factor in yeast; the cystic fibrosis transmembrane conductance regulator; and the TAP-1 and TAP-2 proteins, which transport antigenic peptides for association with class I molecules and surface antigen presentation. [321] [322] MRP has been demonstrated in several MDR mammalian cell lines and in human tumors (see below), while a recent study [327] in human tumor cell lines has shown TAP overexpression associated with MRP, as well as drug resistance resulting from transfection of the *TAP* genes.

P-glycoprotein has a broad specificity for hydrophobic compounds and can both reduce the influx of drugs into the cytosol and increase efflux from the cytosol. To accomplish the former, this hydrophobic vacuum cleaner must detect drugs and expel them while they are still in the plasma membrane. Drugs are thought to be effluxed from the cytosol through a single barrel of the Pgp transporter, although an exact mechanism has been lacking. A recent study used electron microscopy to generate an initial structure of Pgp to 2.5-nm resolution. [328] The structure was further refined by three-dimensional reconstructions from single particle image analysis of detergent-solubilized Pgp and by Fourier projection maps of small crystalline arrays of Pgp. This is the first structural data for any ATP-binding cassette transporter and demonstrates that Pgp is monomeric with the shape of a cylinder 10 nm in diameter with a maximum height (in the plane of the membrane) of 8 nm (Fig. 50-12). This suggests that about half of the Pgp molecule is within the membrane, as the lipid bilayer is about 4 nm in depth. When viewed from the extracellular surface of the membrane, Pgp is toroidal, with a large central pore 5 nm in diameter. This large aqueous chamber in the membrane, which is open to the extracellular space, is closed on the cytoplasmic side, presumably by the two 3-nm intracellular lobes (putative nucleotide binding domains) and the hydrophilic cytoplasmic loops between the transmembrane domains. Thus, this large pore has a gate on the cytoplasmic side of the membrane that can regulate the transport of different-sized substrates. Finally, this study demonstrated that the transmembrane aqueous chamber is open to the lipid phase within the plane of the membrane, consistent with the role of Pgp as a hydrophobic vacuum cleaner whereby substrates can gain access to the pore from the membrane lipid phase.

Substrates

Cross-resistance phenotypes have been determined after in vitro selection to a primary agent for several mammalian drug-resistant tumor cell lines that overexpress Pgp. These studies have shown that the antineoplastic agents that are substrates

Figure 50-12 Structure of P-glycoprotein determined by electron microscopy; a computer graphic representation of the three-dimensional reconstruction is shown as a shaded surface representation of the structure. The straight arrow shows the putative ATP binding domains. P represents the aqueous pore open at the extracellular face of the membrane. TMD, two thumbs, each of which probably corresponds to one of the two transmembrane domains. NBD, 3-nm lobes projecting from the structure at the cytoplasmic face of the membrane, probably corresponding to the two nucleotide binding domains. **(A)** Shows a view perpendicular to the extracellular surface of the lipid bilayer, and **(B)** shows a side view of P-glycoprotein in which the approximate position of the lipid bilayer is indicated by the two horizontal dashed lines. for Pgp and are actively effluxed in an ATP-dependent manner (Table 50-7) include anthracyclines (doxorubicin, daunorubicin, epirubicin, and idarubicin), anthracenediones (mitoxantrone), aminoacridines (*m*-AMSA), taxanes (taxol and taxotere), epipodophyllotoxins (VP-16 and VM-26), vinca alkaloids (vincristine, vinblastine, and vinorelbine), and actinomycin D (Fig. 50-13). Mitomycin C and one of the topoisomerase I inhibitors (topotecan) are both weak substrates for Pgp. [321] [327] Definitive proof that Pgp is responsible for MDR has come from transfection experiments where, for example, a full-length cDNA for the human *MDR1* gene was transfected into both NIH 3T3 and human KB carcinoma cells and found to result in resistance to doxorubicin, vinblastine, and colchicine. [329] [330]

Several drugs have been found to reverse the resistance mediated by Pgp overexpression and sensitize cells to the cytotoxic effects of antineoplastic agents. These drugs compete with antitumor agents for efflux from the cell, effectively increasing the intracellular concentration of the cytotoxic drug. They include immunosuppressants (cyclosporin A, FK 506, rapamycin, PSC 833), calcium channel blockers (verapamil, nifedipine), antiarrhythmics (quinidine), and other miscellaneous agents. [321] [322] [329] [331] Several of these MDR-modulating agents have been used in clinical trials in an effort to sensitize resistant tumor cells.

Methods of Detection

When defining the role of any particular molecular mechanism (e.g., Pgp, MRP, LRP) in the drug resistance of a tumor, several considerations should be kept in mind. First, one should assess the functional moiety of the putative mechanism in the tumor; for example, it is more germane to measure Pgp itself or rhodamine efflux rather than the mRNA for Pgp. The amount and activity of DNA topoisomerase II determine cellular sensitivity to topoisomerase II inhibitors, not the mRNA level. Second, the heterogeneity of the tumor sample may give misleading results due to the contribution of nontumor cells to gross measurements of specific RNA and protein. This is not as significant a concern with the relatively homogeneous hematologic tumors (compared to solid tumors) and can be overcome by evaluating individual cells by immunocytochemistry. Third, the investigator needs to know whether the monoclonal or polyclonal antibody being used detects an external or internal epitope (for ATP-binding cassette proteins), and if the antibody cross-reacts with nonfunctional isoforms or analogs. For example, the C219 monoclonal antibody detects both the *MDR1* and *MDR2* gene products; however, the *MDR1* gene product (Pgp) alone is involved in antineoplastic drug resistance, although the *MDR2* gene product is detected in human liver. [332] Finally, the most informative studies will sample the same patient tumor before and after chemotherapy and at relapse for the presence and amount of resistance protein. Only then is it possible to correlate, for example, the attenuation of topoisomerase II amount with drug resistance at relapse following treatment with VP-16.

Several monoclonal antibodies that recognize Pgp and are commercially available for routine analyses have been described. [321] [322] [333] Monoclonal antibodies C219[334] and JSB-1[335] recognize internal epitopes of Pgp, while antibodies MRK16 [336] and UIC2[337] detect external antigens and are more suited for flow-cytometric analysis.

Pgp Expression in Normal Human Tissue

High levels of expression of *MDR1*/Pgp have been found in the epithelia of several human tissues with excretory function, suggesting that Pgp is normally involved in transporting both exogenous toxic compounds and endogenous metabolites. [321] These tissues include the adrenal cortex, renal proximal tubule epithelium, biliary hepatocytes, small and large intestinal mucosa, pancreas, and endothelial cells of the brain and testis. High levels of Pgp expression have also been found in the placenta and pregnant endometrium. Normal human hematopoietic tissues

Figure 50-13 Chemical structure of epipodophyllotoxins, *m*-AMSA, CI921, and elliptinium.

with high levels of *MDR1*/Pgp include $CD34^+$ progenitor cells, $CD56^+$ (natural killer) cells, and $CD8^+$ (T-suppressor) cells.[332] [336] Lower levels of expression have also been observed in $CD4^+$ (T-helper) cells, $CD19^+$ B cells, and $CD14^+$ cells (monocytes). In these specific lineages, the expression of Pgp measured with the MRK16 monoclonal antibody correlated with the *MDR1* mRNA analysis. $CD15^+$ cells (granulocytes) have no functional Pgp, are negative by MRK16 analysis, but do have a level of *MDR1* mRNA expression similar to T-helper cells and do express Pgp by analysis with the monoclonal antibodies C219 and JSB1. Perhaps the Pgp in granulocytes is not in the membrane.

Pgp Expression in Human Malignancies

Increased expression of Pgp has been observed in several human tumors, especially those malignancies that arise in tissues that normally have high levels of Pgp expression. Thus, the presence of Pgp in a tumor at diagnosis may contribute to de novo drug resistance, while its overexpression at relapse following chemotherapy may result in acquired drug resistance. The drug resistance of a particular tumor is unlikely to depend on a single mechanism (e.g., overexpression of Pgp or MRP, attenuation of topoisomerase II levels). It is more likely to result from the involvement of more than one mechanism. A recent analysis of 61 human tumor cell lines (from leukemia, central nervous system tumors, melanoma, breast cancer, ovarian cancer, colon cancer, lung cancer, and kidney cancer), which were not selected for resistance to antitumor agents, demonstrated coexpression of 2 or 3 of the MDR proteins (Pgp, LRP, or MRP) in 64% of the cell lines. [339] Pgp and LRP were overexpressed in 3% of the tumors, MRP and LRP in 43%, and Pgp, LRP, and MRP in 18%. The cell lines with the highest levels of drug resistance were found to overexpress all three proteins. Whether this is true in primary human tumors awaits further investigations.

Solid Tumors

MDR1/Pgp expression has been determined in several solid human tumors[321] [322] [333] [340] [341] and has been found to be elevated in untreated tumors whose tissues of origin normally have increased expression of Pgp, including renal cell cancer, colon cancer, hepatomas, adrenocortical tumors, islet cell tumors of the pancreas, carcinoid tumors, and pheochromocytomas. Untreated tumors with increased Pgp expression arising in tissues that normally have low levels of expression include neuroblastomas, sarcomas, astrocytomas, and non-small cell lung cancer with neuroendocrine features. Human malignancies that often demonstrate increased levels of Pgp after exposure to antitumor agents include breast cancer, ovarian cancer, neuroblastoma, pheochromocytoma, and rhabdomyosarcoma. An association between Pgp level and poor clinical outcome has been found in neuroblastoma in children [342] and in high-grade osteosarcoma. [343]

MDR1/Pgp has been found to have increased expression (with significant variation between studies for a specific tumor type) in essentially all hematologic malignancies.[319] [322] [332] [344] [345] The wide variation in the number of positive tumor samples for a particular malignancy results from the different assays used to detect Pgp or *MDR1* mRNA (which involved different monoclonal antibodies and nucleic acid probes), as well as from the different criteria used to define positivity. At present, the hematologic malignancies in which Pgp has significant prognostic value are AML and multiple myeloma, and perhaps non-Hodgkins lymphoma.

Acute Myeloid Leukemia

A meta-analysis of the first 12 studies that examined, by various techniques, the expression of *MDR1*/Pgp in blasts of patients with AML, at different stages of disease with different chemotherapy regimens, was reported in 1994.[346] When 2 studies (360 patients total) were excluded due to lack of detail in the abstract form reported, the MDR remission relative risk was found to be 0.50. Forty percent (105/261) of the patients who were Pgp-positive achieved a complete response, while 81% (192/238) of the Pgp-negative patients obtained a complete response. When the other 360 patients were included in the analysis, the relative risk was 0.68. This meta-analysis suggests that there are significant differences in remission rates between patients whose AML blasts do or do not overexpress Pgp. Thus, as suggested by early investigators,[347] [348] Pgp is a contributor to drug resistance in AML, and this should be considered when treatment regimens are designed.

Subsequent studies have expanded on these findings. An analysis of 96 untreated patients with AML showed that Pgp expression predicted induction failure ($p = 0.0001$) and decreased overall survival ($p = 0.001$), as did unfavorable cytogenetics. [349] Pgp expression was not detected in patients with favorable cytogenetic abnormalities [t(15;17), inv(16), t(8;21)], was found in 29% of those samples with a normal karyotype, and was present in 62% of patients with an unfavorable cytogenetic abnormality. Pgp was also detected in 63% of those with secondary AML, compared to 25% of those with de novo disease. Another recent study of 110 newly diagnosed untreated patients with AML detected *MDR1* mRNA in 40% at diagnosis and confirmed that this is associated with both a higher rate of resistance to first induction ($p = 0.001$) and decreased overall survival ($p = 0.001$).[350] Pgp analysis with the MRK16 antibody in 211 elderly patients (>55 years old) with untreated AML once again showed that Pgp expression is significantly associated with a decreased complete response rate and resistant disease. [351] Patients in this report with de novo Pgp-negative AML with favorable cytogenetics had a complete response rate of 81%, compared with 12% for those with secondary AML who were Pgp-positive and had unfavorable cytogenetics.

In summary, Pgp expression is increased in secondary AML, in patients with unfavorable cytogenetics, and at the time of relapse; it is associated with chemotherapy induction failure and a decrease in overall survival. The presence of the Pgp drug efflux pump in AML blasts certainly contributes to drug resistance in this disease.

Acute Lymphocytic Leukemia

The role of Pgp in the drug resistance of ALL is not nearly as well established as in AML. This is due to the wide variation in techniques used to detect *MDR1*/Pgp, the variation in criteria used to define positivity, the contamination of samples with nonleukemic cells, and the fact that few large studies have been performed. Finally, and most importantly, the data to date do not support a significant role for Pgp in the drug resistance in ALL, as they have in AML. Of the smaller studies (2435 patients), only one has suggested a relation between Pgp drug transport and clinical outcome. [352] [353] [354] [355] An early study[352] showed Pgp mRNA and protein overexpression in only 14% of 28 patients, while Pgp function (efflux of rhodamine 123) was found in 8% of 24 patients in a more recent study (compared with increased rhodamine 123 efflux in 54% of patients with AML).[353] A study of 35 newly diagnosed patients reported Pgp positivity (defined as >1% positive cells with the JSB1 antibody) in 37% of patients; however, no statistical difference in the Pgp-dependent complete response rate was found ($p = 0.095$), nor did Pgp expression influence the relapse rate.[355] In contrast, a study of 33 children with ALL (19 untreated and 14 relapsed) in which Pgp function (rhodamine 123 efflux) and protein were measured demonstrated a significant increase in rhodamine efflux and Pgp expression in relapsed ALL, as well as a decrease in efflux in those achieving a complete response ($p < 0.001$).[354]

A higher incidence of Pgp positivity has been observed in adult T-cell leukemia, where 40% of 20 patients at diagnosis overexpressed Pgp and all 6 patients who were initially negative at presentation were Pgp-positive at relapse. [356]

Larger studies (50104 patients) in ALL have shown conflicting results. The first large study of 59 cases of de novo ALL (36 children and 23 adults) demonstrated Pgp overexpression in 38%, but only in adults did Pgp expression significantly affect the complete response rate ($p = 0.05$).[357] Relapses were seen in 81% and 37% of those Pgp-positive and -negative, respectively ($p = 0.008$), and survival was significantly increased in Pgp-negative patients. No other study has demonstrated as strong a correlation between Pgp expression and clinical outcome. A retrospective analysis of 104 newly diagnosed children with ALL showed Pgp positivity in 35%, with no significant association between Pgp expression and relapse ($p = 0.099$), but a decreased probability of remaining in first continuous complete remission if Pgp-positive ($p = 0.025$). [358] [359] A recent report of 83 adult ALL patients, which used a higher cutoff of >10% Pgp positive blasts to assess 39 patients at diagnosis and 44 at relapse, demonstrated 10% and 27% positivity, respectively ($p < 0.05$).[360] Pgp expression was found to be significantly less than that in AML at diagnosis (22%), and did not predict the clinical outcome of those newly diagnosed versus relapsed patients. *MDR1* mRNA alone was assayed by polymerase chain reaction in 60 patients and was found to be increased 3- to 4-fold in only the 10 recurrent relapses (not first relapses); however, an association with survival was not examined.[361] Finally, 64% of 50 newly diagnosed adult cases of ALL were found to be Pgp-positive; however, no correlation was found between Pgp expression and pretreatment characteristics, complete response rate, actuarial disease-free survival, or overall survival. [362] In summary, the studies reported to date do not support a major role for Pgp overexpression in the drug resistance of ALL.

Multiple Myeloma

The role of Pgp in the drug resistance of multiple myeloma has been reviewed by several investigators. [322] [344] [363] These studies have demonstrated overexpression of Pgp in human myeloma cell lines selected for resistance to doxorubicin as well as in clinical samples. *MDR1* mRNA was measured in myeloma cells obtained from the bone marrow of 34 patients who were subsequently treated with chemotherapy (7 had prior chemotherapy and 27 were newly diagnosed). [364] The newly diagnosed patients who failed to respond to chemotherapy had a significantly increased level of *MDR1* mRNA ($p = 0.011$), as did those who failed chemotherapy and had received prior treatment ($p = 0.025$). This study showed a correlation between the *MDR1* mRNA level and response to chemotherapy, but no correlation between the mRNA level and survival. [365] [366] Other studies have shown that before chemotherapy exposure, myeloma patients have a low level of Pgp overexpression in their plasma cells (about 5%), which increases to 75% when they become VAD-resistant (VAD: vincristine, doxorubicin, dexamethasone), or to 100% if they have received both a total vincristine dose of >20 mg and a total doxorubicin dose of >340 mg. However, a correlation between Pgp overexpression and survival has not been seen. [366] [367]

The overexpression of Pgp in human myeloma cells certainly contributes to the drug resistance of these cells (see chemosensitization section below as well); however, this is unlikely to be the only mechanism of drug resistance in myeloma. A recent paradigm proposes that the Pgp expressed in plasma cells in the bone marrow of myeloma patients is not functional and the cells are thus chemosensitive; the drug-resistant reservoir may be a CD34- and CD38-positive monoclonal B lineage in the peripheral blood mononuclear cell fraction that upregulates functional Pgp after drug exposure. [368]

Non-Hodgkins Lymphoma

The role of Pgp in the drug resistance of non-Hodgkins lymphoma (NHL) has recently been reviewed [369] and shown to be less well defined than the hematologic malignancies already discussed. The expression of Pgp in NHL depends on the prior exposure to chemotherapeutic agents known to induce Pgp overexpression, as well as on the method used to detect *MDR1*/Pgp and the cut-off to define positivity. The expression of Pgp in untreated intermediate- and high-grade lymphoma is about 10%, which increases to about 40% after treatment. A retrospective study of 60 NHL specimens demonstrated that 25 (42%) overexpressed Pgp; 19 of these patients had drug-resistant disease, while the remaining 6 achieved a complete response. [370] Thus, resistance to chemotherapy was found to be a function of Pgp expression ($p < 0.001$). A later study of 57 untreated large cell and immunoblastic lymphomas showed high (>50% staining) de novo Pgp expression in 23% of the patients, intermediate staining (1150%) in 26% of the patients, and equivocal or negative Pgp expression in the remaining 51%. [371] These investigators found no correlation between the level of Pgp expression and either response to chemotherapy or median survival. No correlation between *MDR1* mRNA expression and either previous exposure to drugs or survival was found in studies of 41 patients [372] and 32 patients [373] with NHL. Clearly, further studies of Pgp expression (and function) need to be performed prospectively in fresh biopsies obtained from all types of NHL at the time of diagnosis and at the time of relapse.

Chronic Myeloid and Lymphocytic Leukemias

The expression of *MDR1*/Pgp in CML and CLL has been examined by several investigators. A low level of Pgp expression has been demonstrated in chronic-phase CML, [374] [375] which appears to increase in accelerated-phase and blast crisis CML. [375] [376] However, a role for Pgp in the drug resistance of CML has not yet been demonstrated. In the treatment of CLL, few Pgp-related antineoplastic agents are used. The expression of *MDR1*/Pgp in B-CLL is highly variable and depends on the assay used and the criteria for positivity. Several studies have shown high levels of *MDR1* mRNA and Pgp expression in CLL cells from both treated and untreated patients, [377] [378] [379] [380] while other studies have shown very limited Pgp expression [381] and function. [382] A single study has shown a correlation between *MDR1* expression and survival, in which the 10 B-CLL patients who were *MDR1*-positive had a median survival of 19 months compared with 46 months for the 17 *MDR1*-negative patients ($p < 0.01$). [380] Normal B lymphocytes from peripheral blood (CD5+/CD19+) [378] and from human tonsils (CD5+/CD19+/CD10) [383] have been shown to have a low level of Pgp expression, to contain *MDR1* mRNA transcripts, and to efflux rhodamine 123. Perhaps these normal Pgp-expressing B lymphocytes give rise to B-CLL cells that overexpress Pgp, thus accounting for the de novo drug resistance of CLL cells. It is unlikely that the overexpression of Pgp plays a major role in the drug resistance of chemotherapy-naive or -exposed CML or CLL cells.

Clinical Studies with Modulators of Pgp

The clinical trials that have used various modulators of Pgp have been reviewed by several investigators. [329] [331] [384] An early study in VAD-refractory multiple myeloma resulted in short-lived partial responses to VAD plus racemic verapamil in 5/22 patients. [385] [386] Four of the five responders overexpressed Pgp, but cardiac side effects precluded further dose escalation of intravenous R,S-verapamil. Continuous intravenous infusion of cyclosporin A with VAD in VAD-resistant myeloma patients resulted in 7/15 responses, which were more common in patients who overexpressed Pgp. [365] A more recent randomized

Southwest Oncology Group (SWOG) phase III study of VAD with or without oral Verapamil in 120 patients with refractory myeloma demonstrated a 41% and 36% response in the VAD and VAD/verapamil arms, respectively, with median survivals of 10 and 13 months. [387] The lack of a beneficial effect of oral verapamil in this study is likely due to suboptimal serum levels of verapamil. A final dose-escalation study of the cyclosporin A (CSA) analog PSC 833 (which is 5- to 10-fold more potent an inhibitor of Pgp than CSA), in VAD-refractory myeloma, resulted in responses in 8/22 patients. [388] This study demonstrated that the dose of doxorubicin had to be decreased in the presence of PSC 833 as the plasma area under the curve of this drug increased twofold.

Modulators of Pgp have also been used in phase I and II studies of poor-risk AML. Continuous-infusion CSA has been dose-escalated in combination with daunorubicin and cytosine arabinoside. [389] A transient hyperbilirubinemia was seen in 62% of the patients; these same patients had increased serum daunorubicin levels and a higher response rate. A complete response was seen in 26/42 patients; however, the MDR phenotype was not found to influence the response. A recent phase I study of continuous-infusion PSC 833 with mitoxantrone and VP-16 in patients with AML demonstrated that the doses of both antineoplastic agents had to be attenuated 66% in the presence of PSC 833 due to severe mucositis. [390] No complete responses were seen with this regimen, and again a transient increase in bilirubin was common. Dexverapamil, the less cardiotoxic enantiomer, has been dose-escalated in oral form in patients with either Hodgkins disease or NHL who are refractory to EPOCH chemotherapy (etoposide, prednisone, vincristine, cytoxan, doxorubicin). [391] Responses were few: 2 partial responses in 10 patients with Hodgkins disease, and 3 complete responses and 2 partial responses in 41 patients with NHL.

The studies discussed above, as well as several others, suggest that modulators of Pgp have a role in reversing MDR in leukemia and lymphoma. However, MDR mediated by Pgp is seldom the only mechanism of resistance in tumors previously exposed to antineoplastic agents; thus, the modulation of Pgp will likely have a minor role in sensitizing cells in this setting. Treating patients upfront at the time of diagnosis with antitumor agents plus a Pgp modulator that achieves optimal serum levels may preclude the emergence of Pgp-mediated drug resistance, an observation reported for myeloma cells selected in vitro to doxorubicin and verapamil. [392]

Multidrug Resistance-Associated Protein

Structure and Function

The multidrug resistance-associated protein was first described in 1992 in the doxorubicin-selected small cell lung cancer cell line, [393] and its biochemical characteristics and biologic properties have recently been reviewed. [394] This N-glycosylated plasma membrane phosphoprotein has a molecular mass of 190 kDa (1531 amino acids) and is a member of the ATP-binding cassette transporter superfamily (Table 50-7 and Fig. 50-14). This transporter has 18 transmembrane domains (12 in the amino end and 6 in the carboxyl end), and its gene is on human chromosome 16p13.1. Several isoforms of the MRP glycoprotein exist, including the GSH S-conjugate export carrier (GS-X pump), the multispecific organic anion transporter, and the leukotriene C_4 (LTC_4) transporter. [395] [396] [397] [398] To confirm that the overexpression of MRP results in an MDR phenotype, HeLa cells have been transfected with vectors containing MRP cDNA and found to have 5- to 15-fold levels of resistance to doxorubicin, daunomycin, epirubicin, vincristine, and VP-16. [399] [400] Low levels of resistance were also found to taxol, vinblastine, and colchicine, as well as to the heavy metals arsenite, arsenate, and antimonials; no cross-resistance to mitoxantrone, CDDP, or cadmium was observed.

Figure 50-14 Models of multidrug resistance protein (MRP) membrane topology. MRP possesses features common to all members of the ATP-binding cassette transporter superfamily, in that each half of the protein is predicted to consist of several transmembrane domains followed by a cytosolic nucleotide binding domain (NBD). The first model **(A)** is based on computer-assisted hydropathy

analyses of the human MRP amino acid sequence and predicts that MRP is composed of 12 transmembrane domains (solid bars), eight of which are within the NH-2 proximal half of the protein. The second model **(B)**, based on a comparison of human and murine MRP with other ATP-binding cassette transporters, suggests that there are up to four additional transmembrane domains in the NH2-proximal half of the protein. *(Reproduced from Loe et al.,[394] with permission from Elsevier Science.)*

Chemosensitization by either verapamil or cyclosporin A was no different in MRP-transfected cells than in cells transfected with vector alone. Human non-small cell lung cancer SW-1573 cells have also been stably transfected with MRP cDNA and been found to be 2.7- to 5.3-fold resistant to doxorubicin, daunomycin, vincristine, VP-16, colchicine, and rhodamine, but not resistant to m-AMSA or taxol.[401] A study of drug sensitivity in single and double knockouts of the MRP gene in W9.5 murine embryonic stem cells, in which no MRP mRNA or MRP protein expression was seen in the double knockout, demonstrates three- to fourfold hypersensitivity to VP-16, VM-26, and Na arsenite, with twofold levels of collateral sensitivity to vincristine, doxorubicin, and daunomycin.[402] Thus, MRP is an ATP-dependent plasma membrane drug transporter that when overexpressed can result in an MDR phenotype that has several substrates in common with Pgp.

Substrates and Modulators of MRP

The overexpression of MRP has been shown in vitro to result in different levels of drug resistance to several classes of antineoplastic agents,[394] [395] [397] [398] [400] [402] [403] represented by actinomycin D, chlorambucil, melphalan, CDDP, daunomycin, doxorubicin, epirubicin, VM-26, VP-16, and vincristine. Low levels of resistance have also been reported to taxol, vinblastine, and colchicine. In addition to antitumor agents, MRP and its isoforms are capable of transporting heavy metals (arsenicals, cadmium, and antimonials), as well as glutathione conjugates and cysteinyl leukotriene.

Compounds reported to modulate MRP-mediated drug resistance in vitro include the calcium channel blocker verapamil, nicardipine, the protein kinase C inhibitor GF109203X, the cyclosporin analog PSC 833, the tyrosine kinase inhibitor genistein, the gyrase-inhibiting antibiotic difloxacin, and amiodarone.[394] More recently, VX-710, a nonmacrocyclic ligand of the

FK506-binding protein FKBP12 and a potent modulator of Pgp-mediated MDR, has been found to restore sensitivity of MRP-expressing HL60/ADR cells to the cytotoxic action of doxorubicin, VP-16, and vincristine.[165] The nonsteroidal anti-inflammatory agent indomethacin has also been shown to increase significantly the sensitivity of HL60/ADR cells to doxorubicin and vincristine, and it may be a specific inhibitor of MRP.[404] Finally, the organic anion transport inhibitor probenecid has been found to reverse the MRP-mediated resistance of HL60/AR cells to daunomycin and vincristine by increasing the accumulation of these drugs.[405] The in vitro work to date suggests that there may be specific inhibitors of MRP-mediated drug resistance, and that these modulators may not overlap with Pgp-reversing agents. Clinical studies using these agents have not yet been reported.

MRP Expression in Normal Human Tissues

Expression of MRP mRNA has been measured in several normal human tissues by reverse transcriptionpolymerase chain reaction (RT-PCR),[406] an RNase protection assay,[407] and by filter hybridization of polyA$^+$ RNA.[408] These studies have demonstrated that most normal peripheral blood cells and bone marrow cells express a basal level of MRP mRNA, which is moderately increased in granulocytes and T cells. High levels of expression were found in skeletal muscle, lung, kidney, pancreas, testis, ovary, prostate, thymus, and pancreas, with low levels of expression in brain, liver, intestine, heart, and spleen. Protein levels of MRP (a more relevant measure of this transporter) have also been determined in normal tissues by both Western blotting and immunohistochemistry with three monoclonal antibodies.[409] Western blotting showed high levels of MRP in the adrenal gland, lung, heart, and skeletal muscle, with lower levels in liver, spleen, kidney, and red blood cell membranes. Immunohistochemistry confirmed the high expression of MRP in epithelial, endocrine, and muscle tissues (i.e., in skin, epithelium of the esophagus and intestine, bronchioles and alveolar macrophages of the lung, testis, stromal cells of the ovary, heart, adrenal cortex, and pancreas).

MRP Expression in Human Malignancies

Solid Tumors

Expression of MRP has been determined in human solid tumors and in cell lines derived from human tumors by measuring either MRP mRNA or the protein expression itself.[408] [409] [410] Cell lines derived from cancers of the lung (non-small cell and small cell), colon, stomach, breast, and ovary, as well as human sarcomas, astrocytomas, and melanomas, were found to have a basal level of MRP expression in 54/55 tumors.[408] When 3 monoclonal anti-MRP antibodies were used to determine MRP expression in 119 solid tumor frozen biopsies, it became apparent that staining was dependent on the specific antibody used.[409] Nonetheless, strong MRP staining was seen in 20% of untreated solid human tumors and was especially prominent in non-small cell lung cancer and esophageal cancer biopsies.

Hematologic Malignancies

The expression of MRP mRNA (measured by a RNase protection assay) and/or the level of MRP protein (by immunohistochemistry) has been assessed in 148 patients with hematopoietic malignancies.[407] [411] [412] MRP mRNA expression was found to be significantly increased in 84% of patients with CLL and in 30% of those with AML. The vast majority of patients with ALL, CML, multiple myeloma, hairy cell leukemia, and NHL were found to have low levels of MRP mRNA expression in the malignant cells. MRP protein was assayed using monoclonal antibody MRPr1, and the results generally followed those of the message, with increased expression in most patients with CLL. Southern analyses of a cohort of these patients showed that the increased expression of MRP was not due to gene amplification, and that the lack of coexpression of Pgp suggested that these two genes are independently expressed. Other investigators, using RT-PCR, have confirmed low levels of expression of MRP mRNA in AML blasts and in bone marrow samples of multiple myeloma.[406] A recent study of 40 patients with refractory lymphoma and 16 with newly diagnosed lymphoma suggests a limited role for MRP mRNA expression in drug resistance in NHL: 15 paired samples in the refractory group showed no difference in MRP expression before and after EPOCH treatment.[413] In addition, the untreated patients MRP mRNA levels were no different than those of the treated patients, before or after EPOCH.

Other studies using RT-PCR to determine MRP mRNA expression have found increased levels in acute leukemic blasts. A study of 49 patients with AML and 29 with ALL demonstrated significantly higher expression of MRP in ALL ($p = 0.007$) and in secondary AML ($p = 0.016$), but not in de novo AML.[414] MRP mRNA expression was found to be significantly ($p < 0.05$) elevated at second and later relapses (but not before treatment or at first relapse) in a group of 60 patients (52 children and 8 adults) with ALL.[415] Finally, 14 patients with relapsed AML were found to have a 2-fold increase in blast MRP mRNA relative to 29 patients with newly diagnosed AML ($p< 0.01$).[416] Paired blast samples (obtained at diagnosis and at relapse) from 13 AML and 4 ALL patients showed a 2-fold increase in 80% of the patients at relapse, suggesting that the expression of the MRP transporter at relapse may be involved in drug resistance.

An interesting association between MRP expression and clinical outcome has been found in patients with inversion 16 AML.[417] [418] Inv(16)(p13q22) is most often associated with acute myelomonocytic leukemia with abnormal eosinophils (M4Eo) and has a favorable prognosis. In a series of 22 patients with inversion 16, 7 were found to have deleted the MRP gene at the short arm breakpoint, 14 had retained the gene, and 1 was indeterminate. The deletion of the MRP gene was associated with an increase in time from diagnosis to relapse or death ($p = 0.007$), possibly due to a loss of this particular mechanism of drug resistance.

The role of the overexpression of the MRP transporter in the drug resistance of hematologic malignancies is not yet defined. Most of the studies to date have not assayed for the level of the effector molecule (protein) or its transport activity, but rather have focused on MRP mRNA expression. Highly concentrated populations of blasts (nearer 100%) need to be assayed both at diagnosis and at relapse, using activity assays and antibodies that are well controlled and validated, to define the role of MRP in drug resistance. The data collected thus far suggest that MRP may be significantly overexpressed in CLL and may be increased in relapsed ALL and AML. The deletion of the MRP gene in inversion 16 AML appears to be a favorable prognostic indicator, and may have a biologic role in the drug resistance of this disease.

Lung Resistance-Related Protein

Structure and Function

The lung resistance-related protein (LRP) or major vault protein (MVP) was first described using murine monoclonal antibody LRP-56 in the doxorubicin-resistant non-small cell lung cancer cell line SW1573/2R120 in 1993.[419] The biochemical and physical characteristics of this putative transporter have subsequently been

described (Table 50-7). [420] [421] [422] LRP has a molecular mass of 110 kDa. Unlike Pgp and MRP, it is not a member of the ATP-binding cassette family, and its gene is located on chromosome 16p11.2 (MRP is at 16p13.1). While the majority of LRP is located

in the cytoplasm of the cell, 5% is associated with the nuclear membranepore complex, where it is thought to be involved in nucleocytoplasmic transport. The human-deduced LRP amino acid sequence has 88% identity with the 104 kDa rat MVP. [420] Vaults are hollow, barrel-like structures approximately 57 × 32 nm with a total mass of 13 MDa. In the cytoplasm they are associated with vesicular structures (Fig. 50-15). The rat vault is a ribonucleoprotein particle containing 4 proteins of molecular mass 210 kDa, 192 kDa, 104 kDa, and 54 kDa and a species of small RNA of approximately 140 bases, in a relative molar ratio of 3:1:55:7:9. Thus, the MVP (or LRP homolog) is the most abundant component of this organelle.

While co-overexpression of LRP and MRP is common in non-Pgp cell lines, LRP and Pgp are rarely overexpressed together. [422] LRP and MRP are rarely coamplified, and gene amplification is unlikely to account for the overexpression of LRP. [421] An increased expression of LRP has been reported in several Pgp-negative human drug-resistant cell lines, including a small cell lung cancer cell line (GLC4/ADR), a fibrosarcoma cell line (HT1080/DR4), breast cancer cell lines (MCF 7/Mitox and MCF 7/MR), and a myeloma cell line (8226/MR40). [419] The expression of LRP mRNA has recently been examined in 8 of the NCI panel of 60 human cancer cell lines used for in vitro anticancer drug screening. [423] These non-drug-selected cell lines were from lung, leukemia, central nervous system, colon, ovarian, and renal cancers. The expression of LRP mRNA, determined by an RNase protection assay, varied widely among the 8 cell lines but correlated closely with in vitro drug resistance to melphalan, CDDP, doxorubicin, and m-AMSA (p = 0.010.0001); the most resistant cell line had the highest LRP mRNA level. Similar to mRNA levels, LRP protein expression in these cell lines was also found to be a better indicator of drug sensitivity than either MRP or Pgp protein expression. The human myeloma 8226/DOXint5 cell line was selected to doxorubicin on a schedule designed to mimic the administration of VAD chemotherapy, and was found to have three- to fourfold levels of resistance to doxorubicin, VP-16, and m-AMSA. [424] DOXint5 cells do not overexpress Pgp, have a minimal increase in MRP levels and a fourfold attenuation of topoisomerase II, and overexpress LRP (detected with the LRP-56 antibody) in 70% of the cells. These findings suggest that LRP overexpression may have a role in drug resistance in multiple myeloma.

The in vitro studies to date suggest that overexpression of LRP may result in an MDR phenotype with cross-resistance to various combinations of doxorubicin, VP-16, m-AMSA, carboplatin, CDDP, melphalan, and vincristine. Transfecting the LRP gene into LRP-negative cells to define the drug resistance phenotype and to help define the role of LRP in cellular drug resistance will be difficult because vaults are composed of four distinct proteins and RNA.

LRP Expression in Normal Human Tissues and Human Malignancies

The expression of LRP in acetone-fixed, frozen normal human tissue has been comprehensively examined by immunohistochemistry using the monoclonal antibody LRP-56. [425] High levels of expression were found in keratinocytes, bronchial cells and alveolar macrophages of the lung, the epithelium of the digestive tract, adrenal cortex, and macrophages, with moderately high levels of LRP in melanocytes, ductal cells of the pancreas, the urothelium, germinal cells of the testes, and proximal tubules of the kidneys. LRP expression was detected in immunoprecipitates of normal peripheral blood and bone marrow

In this same study, the expression of LRP in 174 tumor samples of 28 types of human cancer (mostly untreated tumors) was determined by using the LRP-56 antibody. A low frequency of LRP expression was seen in germ cell tumors, Wilms tumor,

Figure 50-15 Hypothetical role of LRP in drug resistance. LRP, or vaults, may mediate nucleocytoplasmic and vesicular transport of drugs. Through exocytotic vesicles, the drugs would be transported out of the cell. *(Reproduced from Izquierdo et al.,[422] with permission from Elsevier Science.)*

rhabdomyosarcoma, neuroblastoma, Ewings sarcoma, squamous cell carcinoma of the lung, and AML. The majority of the other solid tumors were LRP-positive; colorectal, pancreatic, renal, adrenal, pheochromocytoma, gastric, and endometrial cancers expressed LRP in all cases examined.

An attempt to address the relevance of LRP expression in the drug resistance of human tumors has been made for ovarian cancer [426] and acute leukemias. [427] [428] [429] Fifty-seven frozen ovarian carcinoma samples from patients with stage III and IV disease were assessed for Pgp, MRP, and LRP expression using monoclonal antibodies MRK16/JSB-1, MRPr1, and LRP-56, respectively. [426] Sixteen percent of the tumors were found to stain positively for Pgp, 68% positive for MRP, and 77% positive for LRP. Patients whose tumors stained positive for LRP had a poorer response to chemotherapy (p = 0.004), a shorter progression-free survival (p= 0.003), and a decreased overall survival (p = 0.007) relative to LRP-negative patients. The median overall survival was 5 months for LRP-positive and 42 months for LRP-negative patients. LRP expression appears to have prognostic significance in ovarian cancer, although this needs to be confirmed in a prospective study.

Immunohistochemical analyses of 87 consecutive bone marrow samples for LRP expression from 21 patients with de novo AML, 27 patients with secondary AML, 29 patients with relapsed AML, and 10 patients with blast-phase CML demonstrated significant LRP expression in 33%, 48%, 38%, and 10% of these patient groups. [427] LRP overexpression was found to be associated with an inferior response to induction chemotherapy (p = 0.0017), as complete plus partial responses were seen in 68% of those who were LRP-negative and in only 35% of those who were LRP-positive. LRP expression was found to have independent prognostic significance, to develop after exposure to the Pgp modulator cyclosporin A, and to be associated with prior mitoxantrone exposure. An evaluation of Pgp, MRP, and LRP expression by flow cytometry in 65 patients (38 AML, 8 ALL, 19 blast CML) has shown Pgp expression alone in 24.5%, LRP alone in 11%, MRP alone in 1.5%, Pgp and LRP concurrent expression in 24.5%, and Pgp and MRP concurrent expression in 4.5%. [428] These results suggest that LRP (and not MRP) is frequently overexpressed, and often with Pgp, in acute leukemia. A study of blasts from 67 patients with AML by RT-PCR for MDR1, MRP, and LRP mRNA expression demonstrated significantly higher (p = 0.033) LRP mRNA levels in the 8 patients who did not achieve a complete response compared to the 25 who did. [429] While a significant difference in MDR1 mRNA levels was found between presentation and relapse samples (p = 0.031), no difference in LRP mRNA levels was seen in these groups or in eight paired samples studied sequentially.

In conclusion, the studies presented to date suggest that the overexpression of LRP may indeed be involved in the MDR of ovarian carcinoma and AML, and that its expression may be a significant prognostic indicator for these two diseases. The role of LRP in the drug resistance of other hematopoietic malignancies and the possible circumvention of this mechanism by modulating drugs await further investigation.

FUTURE THERAPEUTIC IMPLICATIONS OF CANCER BIOLOGY

Future treatment strategies against cancer are likely to be directed against the cellular targets responsible for the altered biology and transformed phenotype of cancer versus normal cells. This altered biology results from the accumulation of genetic mutations and alterations secondary to the unique genomic instability of cancer cells. As noted above, defects in the DNA repair pathway and in cell-cycle checkpoints that cause inappropriate progression through the cell cycle facilitate the genomic instability of cancer cells. Promising novel small molecular drugs and other treatments are being developed and investigated that target the altered macromolecular gene products in the cancer cells. Table 50-8 lists some of the potential targets and evolving therapeutic strategies for cancer.

Since dysregulated cell-cycle progression is a common feature of neoplastic cells, several strategies are being developed and tested to exploit this as a therapeutic target. These strategies include the use of drugs that inhibit the function of the mitotic kinase $p34^{cdc-2}$ (CDK1), such as flavopiridol, or inhibitors of the dual specific phosphatase cdc25, which dephosphorylates and activates $p34^{cdc-2}$. Flavopiridol also inhibits CDK2 and CDK4 by binding to the hydrophobic, adenine-binding pocket of the ATP site of these G_1 -S kinases, thereby inducing G_1 arrest. An additional strategy is to inhibit mitogenic signaling mediated by oncogene products such as activated Ras, Raf, and Bcr-Abl. Antisense oligonucleotides to C-Raf, bcr-Abl, C-myb, Ras, or bcl-2 are being tested for their antitumor effects alone or in combination with other cytotoxic drugs. Inhibitors of Ras farnesylation exert their antitumor effects by as yet unclear mechanisms.

Adenoviral vector-mediated transfer of $p53^{wl}$ into cancers that harbor mutant p53 is being investigated in clinical trials against a variety of tumor types. An additional promising approach to eradicate tumor cells expressing a mutant p53 may be to treat with a mutant adenovirus that can selectively replicate and lyse $p53^{wt}$ -deficient tumor cells. Preclinical or clinical trials are also underway to use antibodies or drugs to inhibit HER-2-neu or EGFR-mediated mitogenic signaling in breast or other epithelial cancers.

The relentless growth of tumors and leukemia requires the delivery of nutrients and growth factors through new blood microvessels (angiogenesis). Inhibitors of angiogenesis have exciting potential in cancer and leukemia therapy. These agents target the vascular endothelial growth factors (e.g., VEGF, bFGF, and PDGF) or their receptor-mediated signaling (e.g., SU 5416). Novel angiogenesis inhibitors are also being investigated (e.g., TNP-470, angiostatin, and endostatin) in preclinical or phase I studies. Relative genomic stability of the tumor vascular endothelial cells suggests that these would be far less prone to develop drug-resistance mechanisms than tumor cells. Preclinical in vivo studies have demonstrated that intermittent administration of endostatin for a few courses completely inhibits the regrowth

TABLE 50-8 -- Potential New Targets to Aim for Future Cancer Therapy

Target	Potential Inhibitor(s)
Cell-cycle regulatory genes/protein	$cdc25/p34^{cdc2}$: flavopiridol
Oncogenes	Anti-Raf, -Bcr-Abl, -myb, -Bcl-2 antisense oligonucleotides; Ras: farnesylation inhibitors
Tumor suppressor genes	Adenoviral vector with $p53^{wl}$, adenovirus targeted to $p53^{mut}$
Growth factor receptors	Suramin,[a] pentosanpolysulfate, monoclonal antibodies: anti-HER2-neu, anti-EGFR; PDGFR: SU-101
Signal transduction proteins	Suramin,[a] anti-Raf and anti-Ras monoclonal antibody, SH2 peptide inhibitors, bryostatin-1, anti-PKC: 7- OH-staurosporine
DNA topoisomerases	Camptothecin analogs[a]
Microtubules	Taxotere,[a] dolostatin 10[a]
Mitochondria	Dianylsulfonylureas
Microvessels	TNP-470,[a] angiostatin, endostatin, SU-5416
Immune system	Vaccines,[a] adoptive immunotherapy[a]
Immunotoxins	Rituximab[a]

[a]Currently in clinical trials.

of human tumor xenograft in mice. Clinical studies with the furnigillin (antiangiogenesis fungal product) analog TNP-470 are being conducted in AIDS-related Kaposis sarcoma and hormone-refractory prostate cancer.

The promise of cancer vaccines in the treatment of epithelial cancers and hematologic malignancies resides in the generation of active tumor-specific immune response in the host that would reject metastatic foci and induce long-term immunologic memory against relapse. Autologous tumor cells ex vivo engineered to express immune modulatory cytokines (IL-2, IL-4, IL-7, IL-12, GM-CSF, -interferon) or costimulatory molecules (B7-1 and B7-2) have been used as a source of antigen in preclinical animal studies. However, it is not essential for the autologous tumor to be the source of the cytokine, as long as there is paracrine production of cytokines. Impaired immunoresponsiveness to tumor vaccines has also been linked to high tumor burden, which may induce tumor antigen-specific tolerance and global immunosuppression. To overcome this, tumor vaccines may have to be used in the minimal residual disease setting and in drugvaccine combinations. In hematologic malignancies, the administration of a tumor vaccine during the immunoreconstitution period after bone marrow transplantation is also an attractive strategy. This may force the developing T-cell repertoire toward the recognition of tumor antigens. The adoptive transfer of antitumor immunity by primed T cells from the donor to the recipient may allow transfer of systemic tumor-specific immunity. Because of the large component of lymphocytes in the graft used in peripheral blood stem cell autologous transplantation, this may facilitate adoptive transfer of donor antitumor immunity. The promise of adoptive immunotherapy remains to be investigated in hematologic malignancies.

APPENDIX: Clinical Pharmacology of Alkylating Agents

Mechlorethamine (Mustargen)

Chemistry: Mechlorethamine, also called nitrogen mustard, is a water- and alcohol-soluble analog of sulfur mustard gas. It is a bifunctional chloroethylating agent that alkylates DNA, RNA, and protein.

Absorption, Fate, and Excretion: The parent compound is highly reactive and has a biologic half-life of approximately 15 minutes. The principal route of degradation is spontaneous hydrolysis, but some enzymatic demethylation also occurs.

Preparation and Administration: Mechlorethamine is supplied in vials of 10 mg with 100 mg of sodium chloride, and is reconstituted with 10 ml sterile water to yield a 1-mg/ml solution, ideally prepared immediately before use. However, the manufacturer considers the drug expired 1 hour after reconstitution. The drug is injected over a few minutes through a tubing as a freely running intravenous infusion. For topical application (e.g., in mycosis fungoides), 10 mg of drug is dissolved in 60 ml of tap water. Alternatively, a 10% ointment has been used by dissolving the drug in 95% ethyl alcohol and petrolatum (Aquaphor). Mechlorethamine is a powerful vesicant. In the event of extravasation, vigorous irrigation followed by 0.25% sodium thiosulfate injection at the site of extravasation should be attempted. Ice packs may be placed for 612 hours to minimize the local reaction.

Toxic Effects: Myelosuppression is the dose-limiting systemic side effect. This worsens with each additive cycle. Severe nausea and vomiting, infertility, alopecia, and pain at the site of injection, which can sometimes spread to involve the venous system (tracking), are also common. Occasionally, a macular papular rash is observed, but this does not appear to be allergic in nature and does not contraindicate continuation of therapy. Infertility is common, but may be reversible. Infrequent adverse effects include alopecia, anorexia, weakness, and diarrhea. The drug has also been shown to induce chromosomal abnormalities and may contribute to the development of secondary leukemias, as seen in patients treated with this agent as part of the MOPP regimen.

Potential Drug Interactions: None reported.

Therapeutic Indications in Hematology: Mechlorethamine is incorporated in many chemotherapy combinations used in the treatment of Hodgkin disease (MOPP [mechlorethamine, vincristine, procarbazine, prednisone] and MOPP/ABV [doxorubicin [Adriamycin], bleomycin, and vinblastine] hybrid) and in some non-Hodgkin lymphomas (prednisone, etoposide, methotrexate, doxorubicin, cyclophosphamide, leucovorin [PROMACE]/MOPP). However, its use has largely been supplanted by other agents.

Cyclophosphamide (Cytoxan)

Chemistry: Cyclophosphamide is a cyclic phosphamide ester of mechlorethamine. Once metabolically activated, it alkylates DNA, forming cross-links.

Absorption, Fate, and Excretion: The drug is relatively well absorbed orally, with approximately 75% oral bioavailability. The parent compound is not active. The drug is metabolized by the hepatic cytochrome P-450 system, which ultimately generates at least two active compounds: phosphoramide mustard and acrolein. The latter appears to be responsible for cyclophosphamides bladder toxicities. The plasma half-life of cyclophosphamide varies from 4 to 6.5 hours. Approximately 15% of the drug is excreted unchanged in the urine. Dose reduction should be considered in patients with severe renal failure.

Preparation and Administration: Cyclophosphamide is supplied as 25- and 50-mg tablets and as a powder for parenteral administration in 100-, 200-, and 500-mg and 1- and 2-g vials. It is dissolved by adding 5 ml of preservative-free sterile water for every 100 mg of drug. Cyclophosphamide is chemically stable for 24 hours at room temperature and for 6 days if refrigerated.

Toxic Effects: Marrow suppression is the major side effect. The myeloid series is primarily affected, although thrombocytopenia also occurs at high doses and alopecia is common. Nausea and vomiting can be severe and are usually delayed, occurring 68 hours after administration. Hemorrhagic cystitis occurs in 10% of patients receiving nontransplant doses and is apparently due to the formation of the urotoxin acrolein. Because of this potential side effect, patients should be well hydrated. Mesna disulfide (sodium 2-mercaptoethanesulfonate disulfide) has also been used on a weight equivalent basis to ameliorate cyclophosphamide-induced

bladder toxicity. Other potential toxic effects include stomatitis, skin and nail hyperpigmentation, interstitial pulmonary fibrosis, and the syndrome of inappropriate secretion of antidiuretic hormone. Rare episodes of acute congestive heart failure have been reported. After bone marrow transplant doses, hemorrhagic cystitis is common and cardiac toxicity (cardiomyopathy) may be seen. Late sequelae include bladder fibrosis (more common with daily [oral] therapy), bladder cancer, leukemogenesis, and infertility.

Potential Drug Interactions: Corticosteroids may increase P-450 enzyme-induced metabolism and is often avoided in high-dose therapy. When combined with doxorubicin, it may increase cardiac toxicity. This may be prevented by amifostine. In animal studies, conflicting results were reported when the P-450 enzyme inducer phenobarbital was given with cyclophosphamide. Most investigators, however, have observed a reduction in the amounts of active metabolites. Conversely, when cimetidine (but not ranitidine) was administered in leukemia-bearing mice before treatment with cyclophosphamide, a significant prolongation of their survival and higher plasma concentrations of alkylating metabolites were observed. Although one should remain alert for these potential drug interactions, none has been demonstrated in humans. Cyclophosphamide reduces serum pseudocholinesterase levels, which may prolong the neuromuscular blocking effects if given simultaneously. Caution must be exercised when administering high doses of these two drugs to critically ill patients. Life-threatening hyponatremia may develop when used in conjunction with indomethacin, although the precise incidence is unknown.

Therapeutic Indications in Hematology: Cyclophosphamide is a key drug in the treatment of lymphomas and myeloma. It is incorporated in many chemotherapy regimens, including CHOP, MACOP-B, PROMACE/CYTABOM, CVP, and VMCP (see chapter for details). In addition, cyclophosphamide is the drug most commonly used in preparatory regimens for bone marrow transplantation. It is also used in solid tumors and as an immunosuppressant in nonmalignant conditions such as glomerulonephritis and systemic lupus erythematosus.

Ifosfamide (Ifex)

Chemistry: Ifosfamide is an oxazaphosphine nitrogen mustard that differs from cyclophosphamide by the placement of chloroethyl groups.

Absorption, Fate, and Excretion: As in the case of cyclophosphamide, the parent compound is inactive and is metabolized by the cytochrome P-450 system in the liver. The metabolism of ifosfamide is influenced by the dose and schedule of administration. When administered as a single bolus, 60% is eliminated into the urine, 53% as unchanged inactive drug. When administered daily for 5 consecutive days, 56% is excreted into the urine, 15% as the inactive parent compound. The half-life is 7 hours when administered daily for 5 consecutive days and 15 hours when given as a single bolus dose. There is poor penetration across the bloodbrain barrier. Its longer half-life and slower metabolic activation allows higher doses to be given.

Preparation and Administration: The drug is provided in 1-g vials and should be reconstituted in sterile water or bacteriostatic water to a final concentration of 50 mg/ml. Ifosfamide can be diluted further in 5% dextrose, normal saline, or Ringers solution for injection to achieve concentrations of 0.620 mg/ml. The solution should be infused over 30 min. To prevent hemorrhagic cystitis, patients must receive mesna disulfide for protection against urotoxicity and must be kept well hydrated (2 L/day). Mesna is a thiol compound that is rapidly oxidized to dimesna in vivo. Both mesna and dimesna are filtered by the glomeruli, reabsorbed in the proximal tubule, and finally secreted back into the tubular lumen of the kidney. In the tubules, approximately one third of the filtered dimesna is readily converted back to mesna. The free sulfhydryl group of this compound reacts with the urotoxic metabolite, acrolein, produced by both ifosfamide and cyclophosphamide (Fig. 50-6). This reaction creates a nontoxic acrolein/mesna thioether that is safely eliminated in the urine. Mesna has also been shown to inhibit the degradation of ifosfamide or cyclophosphamide to acrolein.

Mesna has been given in combination with ifosfamide in different doses and schedules. One recommended schedule employs intravenous bolus injection in a dosage equal to 20% of the ifosfamide dose (on a milligram-to-milligram basis) at the time of ifosfamide administration and 4 and 8 hours after each dose of ifosfamide. Mesna has also been given by continuous infusion with excellent results. The two agents may be mixed together in the same intravenous solution; however, mesna is not compatible with cisplatin.

Toxic Effects: With the use of mesna to protect against urotoxicity, myelosuppressionespecially leukopenia and, to a lesser extent, thrombocytopeniais the dose-limiting side effect. Renal tubular acidosis can occur. Central nervous system effects, observed in approximately 10% of patients treated, include somnolence, confusion, depressive psychosis, and hallucinations. Less commonly, dizziness, disorientation, and cranial nerve dysfunction occur. Nausea and vomiting are common. Low serum albumin and elevated serum creatinine may enhance central nervous system toxicity. As with cyclophosphamide, such side effects as alopecia, leukemogenesis, and infertility also occur. Cardiac toxicity is rare.

Potential Drug Interactions: Since ifosfamide is also metabolized by the P-450 system, one should remain alert for the same type of potential drug interactions that have been reported with cyclophosphamide. A recent report advises close monitoring of warfarin anticoagulant control in patients receiving ifosfamide/mesna.

Therapeutic Indications in Hematology: Ifosfamide was recently approved for treatment of patients with refractory testicular cancer. In hematologic malignancies its major indication is in the treatment of refractory lymphomas.

Melphalan (Melphalan)

Chemistry: Melphalan is synthesized from nitrogen mustard and phenylalanine. It is a bifunctional chloroethylating agent that forms DNA cross-links.

Absorption, Fate, and Excretion: The oral bioavailability of melphalan is quite variable, 2050% of the drug being excreted in the stool. Some patients show virtually no oral absorption. This fact is particularly pertinent in the treatment of myeloma patients, in whom a lack of response to melphal may be due simply to poor oral absorption. Melphalan has a half-life of approximately 90 minutes. It is extensively metabolized, with only about 1015% of an administered dose excreted unchanged in the urine.

Preparation and Administration: Melphalan is available in 2-mg tablets and in intravenous formulation for high-dose therapy.

Toxic Effects: The dose-limiting toxicity is myelosuppression, manifested by leukopenia and thrombocytopenia and generally occurring 23 weeks after therapy. Recovery may take 6 weeks, however, in patients who have been heavily pretreated

with chemotherapy drugs or radiotherapy, or both. Nausea, vomiting, and alopecia are uncommon side effects and are usually mild. Occasionally, amenorrhea and azoospermia, pulmonary fibrosis, dermatitis, and secondary malignancies (e.g., leukemia) occur, especially in patients receiving the drug over the long term. At cumulative doses of <600 mg, the incidence of second hematologic malignancy is probably <2%, but may be 15% at higher doses. Higher doses used in transplant patients result in gastrointestinal toxicity that is dose-limiting. At these doses, the syndrome of inappropriate secretion of antidiuretic hormone, pneumonitis, and hepatic veno-occlusive disease have been observed.

Potential Drug Interactions: Administration of high-dose intravenous melphalan with cyclosporine increases the risk of cyclosporine nephrotoxicity.

Therapeutic Indications: The major use of melphalan is for the treatment of multiple myeloma, either as a single agent or in combination with other alkylating agents and prednisone (e.g., the MP and VMCP regimens [CP, cyclophosphamide]). The intravenous formulation has been approved for isolated limb perfusion in melanoma. It is used in high-dose protocols for myeloma and solid tumors at doses of 140200 mg/m^2 .

Chlorambucil (Chlorambucil)

Chemistry: Chlorambucil is an aromatic derivative of mechlorethamine.

Absorption, Fate, and Excretion: Chlorambucil is well absorbed after oral administration. It is extensively metabolized in the liver to its major metabolite, phenylacetic acid mustard (PAAM), which also has bifunctional alkylating activity. The half-lives of chlorambucil and PAAM are 1.5 and 2.5 hours, respectively; <1% of either chlorambucil or PAAM is excreted in the urine.

Preparation and Administration: Chlorambucil is available as 2-mg tablets.

Toxic Effects: Treatment is usually well tolerated, with myelosuppression the dose-limiting toxic effect. Patients on a daily oral schedule should have biweekly CBCs. Nausea and vomiting are uncommon, but mild alopecia and skin rashes occasionally occur. As with the other alkylating agents, azoospermia (especially above cumulative dose of 400 mg), amenorrhea, and secondary leukemia are potential risks of prolonged therapy. Rare cases of pulmonary fibrosis have also been reported.

Potential Drug Interactions: None reported.

Therapeutic Indications in Hematology: The major uses are in the treatment of Waldenstroms macroglobulinemia, low-grade lymphomas, CLL, and Hodgkins disease. Except for CLL, its use has been supplanted by newer agents.

Busulfan (Myleran)

Chemistry: Busulfan is an alkylsulfonate bifunctional alkylating agent not chemically related to mechlorethamine. It forms DNA intrastrand and interstrand cross-links.

Absorption, Fate, and Excretion: Busulfan is well absorbed after oral administration. When given by the intravenous route, >90% is cleared from the plasma after 3

minutes. The drug is extensively metabolized to inactive compounds, which are excreted renally. The major metabolite is methane sulfonic acid, although >10 other not fully identified metabolites exist. Virtually no intact busulfan is found in the urine. The biologic half-life of busulfan is approximately 2.5 hours.

Preparation and Administration: The drug is commercially available as 2-mg tablets.

Toxic Effects: Although at low doses the major effect of busulfan is on the granulocytic series, at high doses all three hematologic series are affected. Compared with the other alkylating agents, its nadir of myelosuppression may be relatively late, in a range of 1130 days. Hematologic recovery is also prolonged and may take 54 days. A relatively common side effect is an addisonian-like syndrome characterized by skin hyperpigmentation and weakness, but without abnormalities in adrenal function. Cumulative pulmonary toxicity has been well described and consists of a mixed alveolar and interstitial pneumonitis. As with the other alkylating agents, infertility and leukemogenesis can occur. Nausea and vomiting are rare. At high doses it is associated with hepatic veno-occlusive disease in up to 19% of patients. Seizures may also occur and are controlled by diphenylhydantoin.

Potential Drug Interactions: A metabolic interaction may take place between busulfan and various anticonvulsant medications; however, further description of the specific effects is awaited.

Therapeutic Indications in Hematology: Busulfan is used mainly in the treatment of CML. More recently, high-dose busulfan has been incorporated into preparatory regimens for bone marrow transplantation. Blood level monitoring with adjustment for higher dose levels improved therapeutic outcome and reduced toxicity.

Carmustine (BCNU)

Chemistry: Carmustine, also called BCNU (1,3[bis]2-chloroethyl-nitrosourea), decomposes spontaneously into a chloroethyl hydroxide that can alkylate the DNA, and into an isocyanide molecule, which may produce carbamylation of proteins. Cytotoxicity is due to DNA cross-links.

Absorption, Fate, and Excretion: Intravenously administered carmustine is rapidly metabolized, with a half-life of 70 minutes. Approximately 3080% of metabolites are eliminated in the urine within 24 hours. The drug and/or its metabolites readily cross the bloodbrain barrier, resulting in cerebrospinal fluid concentrations within the range of 1570% of plasma levels. Peak serum levels vary widely in patients treated at 200600 mg/m ^{2} .

Preparation and Administration: Carmustine is available in 100-mg vials as a white lyophilized powder. The drug is reconstituted with 3 ml of absolute alcohol provided by the manufacturer and 27 ml of sterile water, and can be further diluted with normal saline or 5% dextrose in water. It should be used immediately after reconstitution and can be infused over 12 hours. Carmustine is chemically stable for 3 hours at room temperature and for 24 hours when refrigerated.

Toxic Effects: Myelosuppression is the dose-limiting toxic effect and tends to increase with successive cycles of therapy. Leukopenia and thrombocytopenia are characteristically delayed and reach their maximum between the third and sixth weeks after drug administration. Nausea and vomiting can be severe. Abnormal liver function tests may be found in 25% of patients, but the abnormalities are usually mild and reversible. Two rare but serious toxic effects include cumulative pulmonary/interstitial pneumonitis progressing to fibrosis and progressive renal damage, which are dose-related. Secondary leukemias can also occur 510 years after treatment. Patients who receive >1,100 mg/m^2 are at increased

risk of pulmonary fibrosis. Carmustine is not a vesicant, but rapid infusion often produces a burning sensation at the injection site.

Potential Drug Interactions: Cimetidine may enhance the myelosuppressive effect of carmustine. Carmustine may decrease the pharmacologic effects of phenytoin. In rats with intracerebrally implanted tumors, pretreatment with phenobarbital eliminated the antitumor activity of carmustine. The reduction in carmustine antitumor activity correlated with increased carmustine metabolism, which is apparently the result of hepatic microsomal enzyme induction.

Therapeutic Indications in Hematology: Carmustine in combination with other cytotoxic agents may be used in the initial treatment of Hodgkins disease (BCVPP regimen) and multiple myeloma (VBAP regimen). In high-dose therapy, it appears in BEP, for relapsed lymphomas.

Lomustine (CCNU)

Chemistry: Lomustine, also called CCNU, is a nitrosourea derivative with choloroethyl and cyclohexyl side chains.

Absorption, Fate, and Excretion: The drug is rapidly absorbed from the gastrointestinal tract and is rapidly and completely metabolized. Its active metabolites have prolonged plasma half-lives, within a range of 1648 hours. Approximately 50% of an administered dose is detectable (as metabolites) in the urine within 24 hours, and 75% is detectable within 4 days. Active metabolites cross the bloodbrain barrier and can be detected in significant concentrations in the cerebrospinal fluid.

Preparation and Administration: The drug is available in 10-, 40-, and 100-mg capsules.

Toxic Effects: The toxicity profile of lomustine is similar to that of carmustine. Since lomustine can produce vomiting, and the drug is given orally, special attention should be directed to emesis control. If the patient vomits soon after ingestion, the vomitus should be inspected for the presence of intact capsules. The drug should be given again if capsules are identified with certainty. Secondary leukemias are reported 310 years after use.

Potential Drug Interactions: Similar to those of carmustine.

Therapeutic Indications in Hematology: Lomustine is occasionally used as second-line treatment for patients with Hodgkins disease and non-Hodgkins lymphoma, and for childhood gliomas.

Streptozocin (Zanosar)

Chemistry: Streptozocin is a naturally occurring nitrosourea derived from *Streptomyces acromogenes.* The drug is a glucosamine-1-methyl-nitrosourea, which, unlike the other nitrosoureas, methylates DNA and is cytotoxic due to induced mismatch repair.

Absorption, Fate, and Excretion: After intravenous administration, the drug is rapidly metabolized, with no intact drug detectable in the plasma after 3 hours. Its half-life is 40 hours. Within the first 24 hours after administration, approximately 10% of the parent compound is excreted in the urine.

Preparation and Administration: The drug is available in 1-g vials and is reconstituted with either 9.5 ml of normal saline or 5% dextrose in water for injection to form a 100-mg/ml solution. Intravenous infusion of the drug over 3045 minutes usually prevents discomfort at the injection site. Patients should be kept well hydrated to preclude renal tubular toxicity.

Toxic Effects: Although nausea and vomiting have been considered by some investigators to be the limiting toxic effects, in most phase I trials nephrotoxicity was the principal dose-limiting effect. Nausea and vomiting are severe and require aggressive antiemetic support. Streptozocin may also aggravate duodenal ulcers. Renal toxicity frequently occurs and includes mild proteinuria, glycosuria, hypophosphatemia, renal tubular acidosis, and occasionally irreversible azotemia. Although the myelosuppressive effect of streptozocin is mild, it can potentiate the bone marrow suppression of other cytotoxic drugs. Slight increases in hepatic enzymes can also occur. Occasionally, patients (primarily those with insulinomas) may experience transient alterations in glucose metabolism.

Potential Drug Interactions: Streptozocin can potentiate the hyperglycemic effect of glucocorticosteroids. Phenytoin therapy decreases the cytotoxic effect of streptozocin on the pancreatic cells, leading to potential interference with its therapeutic effect in patients with pancreatic islet cell tumors. Steptozocin is a potent

renal toxin, and every effort should be made to avoid concomitant administration of other nephrotoxins.

Therapeutic Indications in Hematology: Streptozocin has been used in the initial treatment of Hodgkins disease and, less commonly, in non-Hodgins lymphomas.

Dacarbazine (DTIC)

Chemistry: Dacarbazine is also called DTIC [5-(3,3-dimethyl-1-triazeno)imidazole-4-carboxamide]. After undergoing metabolic activation by microsomal enzymes in the liver, it acts primarily as an alkylating agent.

Absorption, Fate, and Excretion: After intravenous administration, the drug is extensively metabolized. Activated dacarbazine has an elimination half-life of 57 hours. Approximately 4050% of the parent drug is found in the urine within the first 24 hours after administration.

Preparation and Administration: Dacarbazine is available in 100- and 200-mg vials, which must be protected from light and stored at 28°C. The drug is reconstituted with normal saline or sterile water to produce a 10-mg/ml solution. It can be administered as a slow intravenous push or by infusion over 1530 minutes.

Toxic Effects: Myelosuppression, primarily represented by leukopenia, is the dose-limiting toxic effect. Use of the drug leads to considerable problems with emesis and requires aggressive antiemetic support. A flulike syndrome consisting of fever, malaise, and myalgias may occur. Direct sunlight during the first 2 days after drug administration may result in facial flushing, facial paresthesias, and light-headedness. Hepatotoxicity and diarrhea have also been reported. Pain along the injection site can occur if the drug is rapidly infused, but can usually be lessened by prolonging the infusion rate. Secondary leukemias are reported 310 years after use.

Potential Drug Interactions: Dacarbazine activation may be enhanced by phenytoin or phenobarbital, although the clinical significance of this potential interaction remains uncertain. There may be a potential, as yet poorly characterized drug interaction with levodopa whereby the response to levodopa is diminished.

Therapeutic Indications in Hematology: Dacarbazine is used primarily in the treatment of Hodgkins disease as part of the ABVD (doxorubicin [Adriamycin], bleomycin, vinblastine, and dacarbazine) regimen, and for melanoma.

APPENDIX: Clinical Pharmacology of Antimicrotubule Agents

Vincristine (Oncovin) and Vinblastine (Velban)

Chemistry and Mechanism of Action: Both vincristine and vinblastine are asymmetric dimeric compounds that bind to the protein tubulin at a site distinct from that for the taxanes. At low concentrations, vincristine and vinblastine inhibit microtubule dynamics. At higher concentrations, they disrupt microtubules that constitute the mitotic spindle, resulting in metaphase arrest. They are relatively M phase-specific. Due to their lipophilicity, vinca alkaloids are rapidly taken into cells and achieve several hundred-fold higher intracellular than extracellular concentrations. Overexpression of the multidrug resistance transporters P-glycoprotein or MRP can reduce the intracellular accumulation, while alterations in the or tubulins can affect drugtarget interaction for vinca alkaloids.

Absorption, Fate, and Excretion: After intravenous injection, both drugs are rapidly distributed to the body tissues, especially the red blood cells and platelets. Their elimination follows a triphasic pattern: the elimination half-lives are < 5 minutes; , 50155 minutes; and , 2085 hours. Both vinca alkaloids are primarily eliminated through the liver into the bile and feces, making patients with obstructive liver disease more susceptible to toxic effects. A 50% reduction in the dose is recommended for serum bilirubin concentrations of 1.53.5 mg/dl. Dose modification for renal dysfunction is not indicated. After brief intravenous bolus administration, peak plasma vincristine concentrations of 100400 M are achieved, which decline to <10 M in 24 hours. Continuous infusion doses of 1.0 mg/m ^{2} /day produce vincristine plasma concentrations ranging from 1 to 10 nM.

Preparation and Administration: Vincristine is available in 1-, 2-, and 5-mg vials. Each milliliter contains 1 mg vincristine sulfate, 100 mg mannitol, 1.3 mg methylparaben, and 0.2 mg propylparaben. Vincristine is a powerful vesicant that should be administered only intravenously into a freely running infusion of normal saline or dextrous solution. If the drug is given by continuous infusion, it must be infused through a central intravenous line. In case of extravasation, infusion should be discontinued and any residual drug aspirated through the line. The manufacturer also recommends infiltrating the area with 12 ml of hyaluronidase, 150 U/ml, and then applying warm compresses for 72 hours to facilitate dispersion of the drug. Vinblastine is commercially available as a lyophilized powder and a 1 mg/ml solution in 10-mg vials. The lyophilized drug is reconstituted by adding sodium chloride for injection (which may be preserved with either phenol or benzyl alcohol) to the 10-mg vial. Administration of vinblastine should follow the same guidelines described for vincristine.

Toxic Effects: Vincristines dose-limiting toxic effect is neurotoxicity, which appears to be related to its relative polarity. Peripheral neurotoxicity is usually manifested by sensory impairment, decreased deep tendon reflexes, and paresthesias. Less commonly, severe painful dysesthesias, ataxia, foot drop, and cranial nerve palsy (e.g., affecting the extraocular and laryngeal muscles) can occur. Autonomic neurotoxicities include constipation, abdominal cramps, and ileus, which may be prevented by use of mild laxatives. Alopecia occurs frequently, but myelosuppressive effects are minimal. Rare side effects include inappropriate secretion of antidiuretic hormone and ischemic cardiac toxicity. Vinblastines dose-limiting toxic effect is myelosuppression, with leukopenia more pronounced than thrombocytopenia. Anemia is uncommon. Neurotoxicity can also occur but is significantly less common than with vincristine. Vinblastine is also a vesicant.

Potential Drug Interactions: Both vinca alkaloids have been reported to increase the accumulation of methotrexate and etoposide in tumor cells. Acute shortness of breath and bronchospasm can occur when vincristine or vinblastine is given in conjunction with mitomycin C. Since asparaginase may impair the hepatic clearance of vincristine, it is preferable to give the latter 1224 hours before L-asparaginase administration. Vincristine may decrease the absorption and plasma levels of orally administered drugs such as digoxin. Dilantin may increase the cytotoxicity of vincristine in multidrug-resistant tumor cells; however, this remains to be demonstrated in the clinic. When concurrently administered, erythromycin may increase the toxicity of vinca alkaloids, especially vinblastine.

Therapeutic Indications in Hematology: The vinca alkaloids are among the most important drugs in the treatment of hematologic malignancies. They have a broad spectrum of activity and are often incorporated into many chemotherapy regimens used in the treatment of ALL, Hodgkins disease, non-Hodgkins lymphomas, CLL, and multiple myeloma.

Vinorelbine (Navelbine)

Chemistry and Mechanism of Action: Vinorelbine is a semisynthetic derivative of vinblastine (5-nor-hydrovinblastine) with an eight-member catharanthine ring. Similar to other vinca alkaloids, it also binds to tubulin, inhibits microtubule assembly, and produces a mitotic arrest of cells. This occurs at concentrations that relatively spare axonal microtubules, which may reduce neurotoxicity.

Absorption, Fate, and Excretion: Short (610 minutes) intravenous infusions of 30 mg/m^{2} produce peak plasma concentrations of approximately 1.0 g/ml with a triphase decay. Rapid (<5 minutes) and (49168 minutes) half-lives result in a rapid decline in the plasma concentration in the first hour post-treatment, followed by a prolonged terminal half-life of 1849 hours, reflecting slow efflux from the peripheral compartment. The volume of distribution at steady state is 2075.6 L/kg. The drug is extensively bound to platelets, lymphocytes, and plasma proteins. The major site of metabolism is the liver, with 3380% of the drug excretion in feces and approximately 20% in urine.

Preparation and Administration: Vinorelbine is available for injection in single use as 10 mg/ml in 1-ml or 5-ml vials without preservatives. The calculated dose is diluted to 1.53.5 mg/ml for a slow injection (610 minutes) by a syringe with 5% dextrose or 0.9% saline, or between 0.5 and 2.0 mg/ml in an intravenous bag. Since vinorelbine is a strong vesicant, it should be administered through a freely flowing intravenous access, avoiding all extravasation.

Toxic Effects: Vinorelbine shares many of the principal toxicities of vinblastine. Myelosuppression is dose-limiting but not cumulative, with nadirs occurring 710 days after administration. Anemia and thrombocytopenia occur infrequently. Because of lower affinity for axonal versus spindle microtubules, neurotoxicity is less prominent with vinorelbine.

Mild to moderate peripheral neuropathy and constipation occur in approximately 30% of patients, and the incidence of neuropathy increases with the duration of treatment. Mild to moderate nausea and vomiting is seen in one third of patients. Stomatitis and diarrhea are less frequent. Transient elevations of transaminases have been reported. Among the miscellaneous side effects noted are chest pain with or without electrocardiographic changes (6%; most with underlying cardiac disease), as well as bronchospasm and dyspnea (5%). Alopecia is seen in 10% of patients.

Therapeutic Indications in Hematology: Objective responses have been observed in approximately one third of patients with Hodgkins or non-Hodgkins

lymphomas.

Paclitaxel (Taxol) and Docetaxel (Taxotere)

Chemistry and Mechanism of Action: Both paclitaxel and docetaxel are complex diterpene alkaloid esters consisting of a taxane system linked to an oxetane ring and a C-13 side chain that is necessary for their cytotoxic effects in mammalian cells. After binding to the N-terminal 31 amino acids of the tubulin subunit in the tubulin oligomers or polymers, these taxanes kinetically stabilize microtubule dynamics at plus ends. They also decrease the lag time and shift the equilibrium toward tubulin polymerization into microtubule bundles. The disequilibrium of tubulin-microtubule polymerization results in mitotic arrest and apoptosis of cells. Taxane-induced mitotic arrest is associated with phosphorylation of Bcl-2 protein and increased intracellular levels of free Bax protein, which promote apoptosis. Compared to paclitaxel, docetaxel demonstrates 1.9-fold greater affinity for tubulin binding sites and greater potency in mediating Bcl-2 phosphorylation.

Absorption, Fate, and Excretion: Taxanes generally are administered by intravenous infusion lasting over 3, 24, or 96 hours (paclitaxel) or 1 hour (docetaxel). Depending on the dose and schedule, peak plasma concentrations of paclitaxel range between 0.0515.0 M. Its steady state volume of distribution ranges between 48 and 182 L/m^2 , with rapid uptake in almost all tissues except the central nervous system and 98% plasma protein binding. Plasma decay for paclitaxel is biphasic, with and half-lives of 0.34 and 5.8 hours, respectively. Saturable distribution and elimination appear to be responsible for paclitaxels nonlinear pharmacokinetics. This means that paclitaxel dose escalation in shorter schedules may result in disproportionate increases in area under the concentration time curve and peak plasma concentration. It is metabolized to 6 hydroxy paclitaxel by the CYP3A isoform of the PU50 mixed function oxidases in the hepatic microsomes. Total fecal and urinary excretion of paclitaxel and its metabolites is approximately 70% and 10%, respectively. While dose modification is not necessary for renal insufficiency, a 50% reduction in dose is recommended even for moderate hyperbilirubinemia or significant elevations in hepatocellular enzymes. When administered as a 1-hour intravenous infusion, docetaxel has linear pharmacokinetics that fit a three-compartment model. Similar to paclitaxel, docetaxel also has a high clearance rate (0.36 L/h), steady state volume of distribution (67.3 L/m^2), and terminal half-life of 12 hours. Docetaxel also has high protein binding (97%) and extensive tissue distribution. The drug or its metabolites also have high fecal (80%) and low urinary elimination (5%). Metabolism of docetaxel also primarily occurs in hepatic microsomal P450 mixed function oxidases, CYP3A, CYP2B, and CYP1A.

Preparation and Administration: Paclitaxel is available as a 30-mg/5-ml single-dose vial in polyoxyethylated castor oil (Cremophor EL) 50% and dehydrated alcohol, USP 50%. The contents of the vial must be diluted before use. Docetaxel for injection is available as a concentrate in polysorbate 80 in two vial contents (23.6 mg/0.59 ml or 94.4 mg/2.36 ml), along with the appropriate diluent (1.83 ml or 7.33 ml) in separate vials. Adding diluent that is 13% (w/w) ethanol in water for injection to the concentrate produces a final premix concentration of 10 mg docetaxel/ml. The required amount of premix is transferred by a calibrated syringe into 0.9% saline or 5% dextrose to produce a final concentration of 0.3 to 0.9 mg/ml. The intravenous infusion is administered over 1 hour.

Toxic Effects: Hypersensitivity reaction (HSR) was noted in up to 30% of patients in the early phase I studies. HSR occurs early in the first or second infusion and may be caused by vehicle, Cremophor EL, or paclitaxel itself. HSR consists of dyspnea, bronchospasm, urticaria, and hypotension. Most HSRs regress completely after stopping the infusion and treatment with antihistamines, fluids, and vasopressors. Prolonged infusion (3 hours) and premedication (dexamethasone 20 mg orally, 12 and 6 hours diphenhydramine 30 mg, and ranitidine 150 mg IV 30 minutes before treatment) have reduced the incidence of major HSRs to <3%. Patients with a history of HSR may be rechallenged with paclitaxel at a markedly slower infusion rate, 20 mg dexamethasone IV every 6 hours for 4 doses before treatment. Although not formulated in Cremophor EL, HSRs can occur in up to 25% of patients receiving docetaxel. Most HSRs are minor, consisting of flushing, chest tightness, and low back pain. Premedication with dexamethasone 8 mg PO BID for 3 days, starting a day before treatment with docetaxel, considerably reduces the incidence of HSRs and fluid retention.

Neutropenia is the main toxicity of paclitaxel and docetaxel, but it is not cumulative. With higher doses of paclitaxel (250 mg/m^2 over 24 hours), this can be ameliorated with subsequent administration of G-CSF. Severe thrombocytopenia and anemia are rare. Symmetric, distal, peripheral sensory neuropathy is usually seen with higher doses or multiple doses of paclitaxel. This often limits chronic use of paclitaxel. Diffuse areflexia and neuronopathy are less commonly seen. Higher doses can also cause motor and autonomic neuropathy as well as myalgias, especially in patients with pre-existing neuropathy or when paclitaxel is used with cisplatin. Severe peripheral neuropathy or myalgias are less common after repetitive docetaxel at 100 mg/m^2 . Cardiac rhythm abnormalities, especially bradyarrhythmias and (rarely) heart blocks, have been reported secondary to paclitaxel treatment. A direct causal link between paclitaxel and myocardial ischemic episodes and tachyarrhythmias has not been established. Although noted, a direct link has also not been established between the occurrence of cardiac conductance abnormalities or ischemia and docetaxel treatment. Nausea, vomiting, diarrhea, and stomatitis are uncommon and generally mild to moderate. Alopecia is universal with both drugs. Skin toxicity is more severe and common with docetaxel. It is characterized by an erythematous pruritic maculopapular rash affecting forearms and hands. Onychodystrophy with discoloration, ridging, and brittleness of fingernails also occurs. Docetaxel can cause cumulative fluid retention resulting in peripheral edema, third space fluid collection, and weight gain, which usually resolves slowly after stopping docetaxel. Concurrent treatment with dexamethasone, as noted above, delays the onset and decreases the incidence of these side effects.

Potential Drug Interactions: When paclitaxel infusion (24-hour) is administered following cisplatin, there is a 33% reduction in the clearance rate of paclitaxel. This produces suboptimal antitumor cytotoxicity and more profound neutropenia. Hence, the sequence of paclitaxel followed by

cisplatin is commonly recommended. The use of carboplatin following paclitaxel has been reported to cause less thrombocytopenia than carboplatin alone. Mucositis is more pronounced when paclitaxel is used before doxorubicin, a sequence that reduces the clearance of doxorubicin. Hematologic toxicity is more prominent with the sequence of cyclophosphamide followed by paclitaxel, as compared to the reverse sequence of administration. Anticonvulsants such as phenytoin and phenobarbital induce the metabolism of paclitaxel and docetaxel by the p450 mixed function oxidases. Conversely, in vitro studies have shown that inhibitors of the p450 system can interfere with the metabolism of both drugs. These inhibitors include erythromycin, testosterone, ketoconazole, and fluconazole.

Therapeutic Indications in Hematology: Both paclitaxel and docetaxel have significant activity against previously treated patients with non-Hodgkins lymphomas. Paclitaxel is also very active against HIV-associated Kaposis sarcoma.

APPENDIX: Clinical Pharmacology of Antimetabolites

Cytosine Arabinoside

Chemistry and Mechanism of Action: Cytosine arabinoside (1--D-arabinofuranosylcytosine; Ara-C) is a nucleoside analog that differs from its naturally occurring counterpart (2-deoxycytidine) by virtue of the presence of a hydryoxyl group in the 2- configuration. The altered reactivity of the resulting arabinosyl sugar moiety confers on Ara-C its cytotoxic activity. Ara-C enters the cell by a facilitated nucleoside diffusion mechanism, and is converted to its nucleoside monophosphate form, Ara-CMP, by the pyrimdine salvage pathway enzyme, deoxycytidine kinase. This represents the rate-limiting step in Ara-C metabolism. Ara-C may also be catabolized intracellularly to an inactive form, Ara-U, by the enzyme cytidine deaminase. Ara-C is ultimately converted to its lethal triphosphate derivative, Ara-CTP, by a mono- and diphosphate kinase. Ara-CTP is an inhibitor of DNA polymerases , , and , and is also incorporated into replicating DNA strands, leading to inhibition of chain initiation and elongation, and premature chain termination. The extent of incorporation of Ara-C into DNA closely correlates with lethality in leukemic cells. Although Ara-C is generally thought of as a prototypical S-phase-specific agent, its ability to interfere with DNA repair polymerases (e.g., and) as well as lipid biosynthetic enzymes may account for lethal effects in noncycling cells.

Absorption, Fate, and Excretion: Following intravenous administration, Ara-C is rapidly deaminated to an inactive form, Ara-U, by cytidine deaminase. This enzyme is present in the plasma, liver, and kidney, but is present at very low levels in the central nervous system. The initial plasma half-life of Ara-C has been estimated to be 1012 minutes. Approximately 90% of the administered Ara-C dose is excreted by the kidney as Ara-U or other inactive metabolites. The terminal half-life of Ara-C is 23 hours. Central nervous system Ara-C levels following a 2-hour infusion approximate 50% of plasma concentrations. Steady-state plasma concentrations following standard dose therapy (e.g., 100200 mg/m^2 /d as a continuous infusion) approximate 10^{-7} 10^{-6} M. When Ara-C is given as a highdose bolus infusion (e.g., 13 gm/m^2 over 13 hours), plasma levels as high as 100 M can be achieved.

Preparation and Administration: Ara-C is provided as a sterile, lyophilized powder for reconstitution in vials containing 100 mg, 200 mg, 1 g, or 2 g of material. The powder is reconstituted with sterile bacteriostatic water for injection with benzyl alcohol (0.945%) added as a preservative. When reconstituted in this way, solutions are stable for up to 48 hours under controlled temperatures (e.g., 1530°C). Material reconstituted without preservative should be used immediately. For intrathecal injection, Ara-C should be reconstituted in a diluent that does not contain preservative (e.g., preservative-free 0.9% sodium chloride, USP) and used immediately.

Toxic Effects: Ara-C is primarily toxic to rapidly dividing tissues; consequently, myelosuppression and gastrointestinal toxicity represent the major side effects of this agent. Patients receiving Ara-C regularly experience leukopenia, anemia, and thrombocytopenia, with nadirs appearing 714 days after drug administration. Gastrointestinal toxicity includes nausea and vomiting, abdominal pain, mucositis, and a chemical hepatitis characterized by elevation of liver function enzymes. The latter is generally reversible. Patients receiving Ara-C as a high-dose bolus infusion (e.g., 13 g/m^2 /d q12h × 612 doses) experience, in addition to the standard toxicities, several unique ones. These include alopecia, an exfoliative dermatitis, a chemical conjunctivitis (generally ameliorated by the prophylactic administration of a steroid or saline ophthalmic solution), a respiratory distress-like syndrome (characterized by the appearance of rales, an abnormal radiogram, and pulmonary insufficiency), and cerebellar toxicity. The latter, which is characterized by nystagmus, ataxia, and other cerebellar signs, may be irreversible, and its appearance mandates discontinuation of therapy. Intrathecal administration of Ara-C has been rarely associated with toxicities described for methotrexate.

Potential Drug Interactions: None reported.

Therapeutic Indications in Hematology: Ara-C represents a mainstay in the treatment of acute myelogenous leukemia (e.g., as part of the 7 and 3 regimen in which it is given in conjunction with daunorubicin). It is also incorporated into some induction regimens for acute lymphoblastic leukemia. High-dose Ara-C (HIDAC), either alone or in combination with anthracycline antibiotics, is frequently employed in the treatment of refractory or relapsed AML or ALL. HIDAC has also been used in some salvage regimens for non-Hodgkins lymphoma (e.g., ESHAP). Chronic low-dose Ara-C has been used in the treatment of myelodysplastic syndrome.

Methotrexate

Chemistry and Mechanism of Action: Methotrexate (N-4-[[2,4-diamino-6-pteridinyl)methyl]methylamino]benzoyl]-L-glutamic acid) represents a member of a class of compounds referred to as antifolates. Methotrexate is a potent inhibitor of dihydrofolate reductase, an enzyme responsible for the reduction of dihydrofolates to tetrahydrofolates. The latter are required in 1-carbon transfer reactions involved in

de novo purine and pyrimidine biosynthesis, including conversion of deoxyuridylate (dUMP) to thymidylate (dTMP) by thymidylate synthase. As in the case of most antimetabolites, methotrexate is primarily active against S-phase cells. Methotrexate is transported across cell membranes by an energy-dependent, temperature-sensitive, concentration-dependent process involving folate binding proteins, after which it is polyglutamylated by the enzyme folylpolyglutamyl synthetase (FPGS). Polyglutamylation of methotrexate enhances its intracellular retention and in some studies has been shown to correlate with the sensitivity of leukemia cells to this agent. The mechanism by which methotrexate kills cells may stem from interference with DNA synthesis (leading to a thymine-less death) secondary to DHFR inhibition; disruption of purine biosynthesis; or a combination of these actions. The lethal actions of methotrexate may be reversed by reduced folates such as 5-formyltetrahydrofolate (leucovorin). The possibility that tumor cells may exhibit impaired transport of such reduced folates serves as the basis for strategies involving administration of high-dose methotrexate in conjunction with leucovorin rescue.

Absorption, Fate, and Excretion: In adults, oral absorption is dose-dependent, with mean bioavailability approximating 60% at doses 30 mg/m^2 . At higher doses (e.g., 80 mg/m^2), bioavailability is less. Peak plasma concentrations occur 12 hours following oral administration. Methotrexate bioavailability approximates 100% for parenteral routes of administration; with these routes, peak plasma methotrexate levels are achieved 3060 minutes after administration. For each route, the steady state volume of distribution ranges from 40% to 80% of body weight. Methotrexate tends to accumulate in third space fluids (e.g., ascites, pleural effusions) and can result in prolonged release and accompanying toxicity. Consequently, it is generally not advisable for patients with fluid accumulations to receive methotrexate. Methotrexate competes with reduced folates for transport across cell membranes; however, at high doses (e.g., 100 mg/m^2), passive diffusion is the primary mechanism through which intracellular accumulation occurs. Methotrexate is approximately 50% protein bound, and does not penetrate the CNS barrier when administered orally or parenterally at conventional doses. However, when given by the intrathecal route, high CNS levels are achieved. Administration of high-dose methotrexate with leucovorin rescue can also result in therapeutic CNS levels.

The primary route of excretion is renal, with 8090% of the drug appearing unchanged in the urine within 24 hours following intravenous administration. The terminal half-life of methotrexate is 410 hours for patients receiving low-dose therapy and 815 hours for those receiving high-dose therapy. Because of the primary renal rate

of excretion and the possibility of nephrotoxicity, methotrexate should be withheld or administered at reduced doses in patients with impaired renal function. Patients receiving high-dose methotrexate therapy should be hydrated and their urine alkalinized before administration to reduce the risks of toxicity.

Preparation and Administration: Methotrexate is available in multiple formulations: (a) tablets, containing 2.5 mg methotrexate and inactive ingredients (lactose, magnesium stearate, and pregelatinized starch); (b) methotrexate sodium injection, available in 25-, 50-, and 250-mg vials, containing benzyl alcohol as a preservative, sodium chloride, and water for injection (preservative-containing solutions should not be used for intrathecal or high-dose administration); (c) methotrexate sodium injection without preservative, which can be used for intravenous, intra-arterial, intrathecal, and high-dose administration; (d) lyophilized powder, which is provided in 20-mg vials and is reconstituted with preservative-free sodium chloride or 5% dextrose in water to a final concentration <25 mg/ml.

For intrathecal administration, solutions of 11.5 mg/ml should be prepared using preservative-free 0.9% sodium chloride as the diluent. For high-dose therapy, leucovorin rescue is required to prevent significant toxicity. Leucovorin is administered 1224 hours after the methotrexate at a dose of 1525 mg IV, IM, or PO q6h until the methotrexate dose declines to levels $<5 \times 10^{7}$ M. For patients receiving intermediate- or high-dose methotrexate (e.g., 500 mg/m^2), serum methotrexate and creatinine levels should be monitored at 24-hour intervals. If, after 48 hours, serum methotrexate levels are $>5 \times 10^{7}$ M but $<1 \times 10^{6}$ M, leucovorin is continued at a dose of 25 mg/m^2 q6h × 8 doses until methotrexate levels decline to $<5 \times 10^{7}$ M. If levels are $>1 \times 10^{6}$ M but $<2 \times 10^{6}$ M at 48 hours, the dose of leucovorin is increased to 100 mg/m^2 q6h × 8 doses. For methotrexate levels 2×10^{6} M at 48 hours, the dose of leucovorin is 200 mg/m^2 q6h × 8 doses.

Toxic Effects: Methotrexate primarily exhibits its toxic effects toward proliferating tissues. Consequently, dose-limiting toxicities include bone marrow suppression (leukopenia, thrombocytopenia, anemia), mucositis, and diarrhea. High-dose therapy is occasionally accompanied by transient elevations in liver function tests, whereas chronic low-dose therapy is more often associated with hepatic fibrosis. Standard-dose therapy is rarely associated with nephrotoxicity, but acute renal failure can be seen with high-dose therapy secondary to deposition of 7-OH methotrexate in the renal tubules. The risk of methotrexate nephrotoxicity is significantly reduced by ensuring adequate hydration and alkalinization of the urine. Other reported toxicities include a maculopapular rash, and an idiosyncratic pulmonary toxicity characterized by cough, fever, dyspnea, hypoxia, and interstitial infiltrates.

A necrotizing leukoencephalopathy has been reported in patients receiving methotrexate who have had prior cranial irradiation. Intrathecal methotrexate has been associated with several toxicities, including: (a) chemical arachnoiditis; (b) motor paralysis accompanied by cranial nerve dysfunction, seizures, and coma; (c) chronic demyelinating syndrome. Each of these may be exacerbated by prior craniospinal irradiation.

Potential Drug Interactions: Methotrexate exhibits many potential drug interactions related to plasma protein binding. For example, many compounds are known to displace methotrexate from serum albumin, potentially increasing its bioavailability. These agents include sulfonamides, salicylates, tetracyclines, chloramphenicol, and phenytoin. However, the clinical implications of such interactions are not clear. Nonsteroidal anti-inflammatory drugs should not be administered in conjunction with methotrexate when the latter is given at intermediate/high doses, due to the potential for elevation and prolongation of methotrexate plasma concentrations. Penicillins can reduce renal clearance for methotrexate and should be used with caution in this setting. Probenecid may also reduce renal transport of methotrexate. Administration of methotrexate can also reduce the clearance of theophyllines, and concomitant use of these agents requires careful monitoring. Increases in methotrexate toxicity have been observed in some patients receiving trimethoprim/sulfamethoxazole, possibly as a consequence of enhanced antifolate effects. Administration of folates in vitamin preparations may reduce the efficacy of methotrexate by bypassing DHFR inhibition. Methotrexate may increase the toxicity (and potentially the activity) of various antineoplastic agents in a schedule-dependent manner (e.g., when given prior to 5-FU).

Therapeutic Indications in Hematology: Methotrexate is widely employed in the treatment of acute lymphoblastic leukemia, particularly in the maintenance phase. Methotrexate is frequently administered intrathecally in patients with CNS leukemia, and prophylactically in certain patients with ALL. It also represents a component of various multidrug regimens used in the treatment of non-Hodgkin lymphoma (e.g., M-BACOD, PROMACE-CYTABOM).

Hydroxyurea

Chemistry and Mechanism of Action: Hydroxyurea is an inhibitor of the ribonucleotide reductase system that catalyzes the rate-limiting step in the de novo biosynthesis of purine and pyrimidine deoxyribonucleotides (i.e., the conversion of ribonucleotide diphosphates to their deoxyribonucleoside diphosphate derivatives). Ribonucleotide reductase consists of two subunits: a binding and allosteric effector component and an iron-binding catalytic component. Hydroxyurea binds to and inactivates the catalytic subunit of the enzyme. Like most antimetabolites, hydroxyurea is an S-phase-specific agent and block cells n the G_1/S phase of the cell cycle. Exposure of cells to hydroxyurea leads to a depletion of deoxyribonucleotide triphosphate (dNTP) pools, the extent of which correlates with DNA synthesis inhibition and cell death. Two consequences of hydroxyurea administration include potentiation of the metabolism/cytotoxicity of nucleoside analog (e.g., Ara-C) as a result of dNTP pool depletion, and elimination of amplified genes present extrasomally in double minute chromosomes.

Absorption, Fate, and Excretion: Hydroxyurea is generally administered orally, although intravenous regimens are being investigated. The drug is readily absorbed from the gastrointestinal tract, with peak plasma levels as high as 2.0 mM occurring approximately 2 hours after oral administration. Serum concentrations decline to undetectable levels after 24 hours. The drug is primarily excreted via the renal route, with 7580% of the drug appearing in the urine at 12 hours. The drug penetrates the cerebrospinal fluid, although it has not been established that therapeutic levels are achieved following standard oral administration.

Preparation and Administration: Hydroxyurea is provided as 500-mg capsules. Drug is stored at room temperature in tightly capped containers and protected from heat.

Toxic Effects: The most common adverse reactions include myelosuppression (leukopenia, thrombocytopenia, anemia), gastrointestinal symptoms (e.g., nausea and vomiting, stomatitis, anorexia, appetite disturbances), and dermatologic toxicity, such as rashes, skin ulcerations, and facial erythema. Rarer toxicities, generally seen at high doses, include neurologic disturbances, such as drowsiness, dizziness, headache, and convulsions, altered renal function, and alopecia. The mutagenic potential of hydroxyurea is unknown, and the drug should be avoided when possible in pregnant women.

Potential Drug Interactions: As noted previously, hydroxyurea may increase the toxicity of certain nucleoside analogs. Hydroxyurea may also serve as a radiosensitizing agent; consequently, patients receiving concurrent radiation therapy may experience enhanced toxicity.

Therapeutic Indications in Hematology: Hydroxyurea has become, along with interferon , the mainstay of therapy in patients with chronic or accelerated phase CML. It is currently recommended for initial therapy of CML over busulfan, and may prolong the chronic phase of this disease compared to the latter agent. Hydroxyurea has also been successfully used in the treatment of other myeloproliferative disorders, including myeloid metaplasia and myelofibrosis, polycythemia vera, and essential thrombocytosis. Its leukemogenic potential is uncertain, however, and it should be used with caution, particularly in younger patients. Hydroxyurea has also been shown to reduce the incidence of painful crises in individuals with sickle cell anemia in a subset of patients, a phenomenon that may result from increases in red blood cell fetal hemoglobin levels.

Fludarabine

Chemistry and Mechanism of Action: Fludarabine phosphate is a fluorinated derivative of the nucleotide analog 9--D-arabinofuranosyladenine (Ara-A) that is resistant to deamination by the degradative enzyme cytidine deaminase. It is converted intracellularly to its triphosphate derivative, which inhibits ribonucleotide reductase, as well as DNA polymerase and DNA primase. Fluoro-Ara-ATP is also incorporated into DNA, a process that appears to be essential for the induction of apoptosis in leukemic cells. Fludarabine is toxic to S-phase cells, but its ability to interfere with DNA repair may contribute to lethality in their noncycling counterparts.

Absorption, Fate, and Excretion: Following intravenous injection, fludarabine phosphate is rapidly deaminated (i.e., within minutes) in the plasma to its nucleoside derivative, 2-fluoro-Ara-A, which is then converted intracellularly to its nucleotide form, 2-fluoro-Ara-AMP by the pyrimidine salvage pathway enzyme deoxycytidine kinase. The half-life of 2-fluoro-Ara-A is approximately 10 hours; the primary mode of elimination is renal, with 25% of the total dose appearing in the urine as unchanged 2-fluoro-Ara-A. Total body clearance of fludarabine is inversely correlated with serum creatinine.

Preparation and Administration: Fludarabine is supplied as a sterile powder in 50-mg vials containing 50 mg of mannitol and sodium hydroxide to adjust the pH to

7.7. Material is reconstituted in 2 ml of sterile water to yield a 25 mg/ml solution for injection. The material may be stored atg 4°C; because the reconstituted solution contains no antimicrobial preservative, drug should be administered within 8 hours of formulation.

Toxic Effects: The most common dose-limiting toxicity is myelosuppression (neutropenia, thrombocytopenia, and anemia). Other toxicities include fever, chills, infection, nausea, and vomiting. Rarer toxicities include malaise, fatigue, anorexia, and weakness. Patients with CLL receiving fludarabine have experienced serious opportunistic infections and tumor lysis syndrome. The most serious toxicity of fludarabine when administered at high doses (>40 mg/m ^{2} /d × 5 days) is irreversible neurotoxicity, including cortical blindness, necrotizing leukoencephalopathy, and death. This phenomenon has rarely if ever been seen in patients receiving conventional doses (e.g., 25 mg/m^2 /d × 5 days). Rare reports of interstitial pneumonitis have appeared.

Potential Drug Interactions: Fludarabine has been shown to potentiate the intracellular metabolism and activity of Ara-C, although the toxicity of this combination may also be enhanced. No other interactions have been reported.

Therapeutic Indications in Hematology: Fludarabine has shown marked activity in both untreated CLL and in disease refractory to standard alkylating agent therapy. Fludarabine has also shown activity as a single agent, and particularly in combination with others (e.g., mitoxantrone, cytoxan) in indolent non-Hodgkin lymphoma.

2-Chlorodeoxyadenosine

Chemistry and Mechanism of Action: 2-Chlorodeoxyadenosine (CdA; cladribine) is a derivative of deoxyadenosine that differs from its parent compound by the presence of a chlorine moiety at the 2-position of the purine ring. It is transported intracellularly by facilitated nucleoside diffusion and phosphorylated by the pyrimidine salvage pathway enzyme deoxycytidine kinase. CdA is relatively resistant to deamination by cytidine deaminase. CdA is readily converted to its triphosphate derivative, 2-chlorodeoxyadenosine-5-triphosphate, particularly in cells of lymphoid origin, and is incorporated into tumor cell DNA by DNA polymerase . CdATP is also an effective inhibitor of ribonucleotide reductase, which may contribute to lethal effects. CdA induces cell death (apoptosis) in both cycling and noncycling cells, possibly by promoting DNA fragmentation and by depleting cells of ATP and/or NAD.

Absorption, Fate, and Excretion: Relatively little pharmacokinetic information concerning 2-chlorodeoxyadenosine is available. The drug is most commonly administered as a 7-day continuous infusion or as a 2-hour infusion over 5 days. Bioavailability of CdA following subcutaneous administration approximates that of the intravenous route but is less than that after oral administration. Renal excretion appears to be the major route of elimination. When given as a 2-hour infusion, CdA has a relatively long terminal half-life (e.g., 6 hours), and plasma concentrations following such a schedule may approximate those associated with the continuous infusion. Spinal fluid levels are approximately 25% of plamsa concentrations.

Preparation and Administration: For daily infusions, CdA is diluted under sterile conditions in bags containing 500 ml of 0.9% sodium chloride injection, USP. The use of 5% dextrose solutions is not recommended due to enhanced degradation of the drug. For preparation of longer infusions (e.g., 7 days) the use of bacteriostatic sodium chloride injection, USP, is recommended. Once prepared, solutions should be stored refrigerated at 48°C for 8 hours before administration.

Toxic Effects: The major toxicity is myleosuppression, which is primarily observed following intermittent rather than continuous infusion. Other toxicities include fever, generally beginning several days after initiation of therapy, and increased susceptibility to opportunistic infections. Rare side effects include nausea and hepatic and renal toxicity.

Potential Drug Interactions: None reported.

Therapeutic Indications in Hematology: CdA has shown significant activity in CLL and hairy cell leukemia. However, response rates in the former disorder appear to be somewhat less than those obtained with fludarabine; moreover, patients who have progressed on fludarabine therapy infrequently respond to CdA. Other diseases in which CdA has shown activity include non-Hodgkin lymphoma and Waldenstrom macroglobulinemia.

2-Deoxycoformycin (pentostatin; dCF)

Chemistry and Mechanism of Action: dCF is an adenosine analog that is a highly effective inhibitor of the purine biosynthetic enzyme adenosine deaminase (ADA). It is transported across cell membranes by facilitated nucleoside diffusion, where it binds tightly to ADA. Inhibition of ADA results in accumulation of deoxyadenosine metabolites, most notably dATP. dATP exerts its toxic effects through inhibition of ribonucleotide reductase and induction of global imbalances in deoxyribonucleotide triphosphate pools. These result in interference with DNA synthesis and repair. dCF is particularly toxic to certain lymphoid cells with low levels of ADA activity. It is also toxic to both cycling and resting cells; the mechanism underlying its cytotoxicity toward quiescent cells is unknown.

Absorption, Fate, and Excretion: After intravenous injection of dCF, the plasma clearance follows a biphasic pattern with a terminal elimination half-life of 315 hours. Protein binding is limited. The drug is only partially metabolized, with approximately 6080% of the drug appearing unchanged in the urine after 24 hours. The total body clearance correlates well with creatine clearance. Patients with impaired renal function may require reductions in the dCF dose.

Preparation and Administration: dCF is unstable when reconstituted in solutions of pH <5.0. Consequently, it is customarily reconstituted in normal saline. dCF is provided in vials containing 10 mg of drug, 50 mg of mannitol, and sodium hydroxide to adjust the pH to 7.0. It is administered as an intravenous infusion over 2030 minutes. Hydration is recommended before and after administration.

Toxic Effects: The major toxicities include myelosuppression, nausea and vomiting, immunosuppression, acute renal failure, keratoconjunctivitis, fever, and elevations of liver function enzymes. At high doses, neurologic toxicity, including somnolence, seizures, and coma, has been reported, although these are seen infrequently in patients receiving standard-dose therapy. When administered at such doses (e.g., 4 mg/m ^{2} biweekly), side effects are relatively minor.

Potential Drug Interactions: dCF may augment the toxicity of Ara-A (vidarabine) as a consequence of inhibition of ADA.

Therapeutic Indications in Hematology: dCF is primarily used in the treatment of hairy cell leukemia, where response rates of up to 90% have been reported, even in patients refractory to other therapy, including interferon. Activity has also been reported in other lymphoid malignancies, such as T-cell lymphoma, CLL, prolymphocytic leukemia, and Waldenstrom macroglobulinemia, although its precise role in the treatment of these disorders remains to be fully evaluated.

6-Thioguanine (6-TG)

Chemistry and Mechanism of Action: 6-TG is a guanine analog in which the 6-hydroxyl group is replaced by a sulfhydryl group. It interferes with de novo purine biosynthesis at multiple levels. Following transport across the cell membrane by facilitated diffusion, 6-TG competes with hypoxanthine and guanine for phosphorylation by hypoxanthine-guanine phosphoribosyltransferase (HGPRT) and is converted to its nucleotide form, 6-thioguanylic acid (TGMP), which accumulates within cells. TGMP inhibits several purine biosynthetic enzymes, including glutamine-5-phosphoribosylpyrophosphate amidotransferase and IMP dehydrogenase. 6-TG nucleotides are also incorporated in DNA and RNA, where they function as fraudulent bases. It is unknown which of these actions (interference with purine interconversions, blockade of de novo purine biosynthesis, or nucleic acid incorporation) is primarily responsible for 6-TG cytotoxicity, although DNA incorporation appears to play a significant role. 6-TG is considered to be an S-phase-specific agent.

Absorption, Fate, and Excretion: Following oral administration, the bioavailability of 6-TG is variable, ranging from 14 to 46% of the administered dose (mean = 30%). Peak plasma levels are achieved 8 hours after administration and decline slowly thereafter. The average plasma disappearance of 6-TG is 80 minutes, with a range of 25240 minutes. Relatively little unchanged material appears in the urine; the major

excreted product is the methylated derivative, 2-amino-6-methyl thiopurine. Spinal fluid penetrance after parenteral administration is minimal.

Preparation and Administration: 6-TG is available in tablet form for oral administration. Each tablet contains 40 mg of 6-TG and inactive ingredients including gum acacia, lactose, magnesium stearate, potato starch, and stearic acid. Intravenous preparations are available only in experimental settings.

Toxic Effects: The major dose-limiting toxicity of 6-TG is myelosuppression. Other less common toxicities include gastrointestinal disturbances (nausea and vomiting, anorexia, diarrhea), jaundice, and elevated liver function tests.

Potential Drug Interactions: In contrast to 6-mercaptopurine, the metabolism of 6-TG is not modified by allopurinol, and consequently dose adjustments do not have to be made when these agents are administered concurrently.

Therapeutic Indications in Hematology: The primary indication for 6-TG is in the treatment of AML, generally in conjunction with other agents (e.g., daunorubicin and Ara-C). However, it has not been firmly established that addition of 6-TG to such regimens improves therapeutic efficacy. 6-TG also has activity in CML, although it has been supplanted by other agents (e.g., hydroxyurea, interferon) in this disorder.

6-Mercaptopurine (6-MP)

Chemistry and Mechanism of Action: 6-MP (1,7-dihydro-6*H*-purine 6-thione monohydrate; purinethol) is an analog of the purine bases adenine and hypoxanthine. It is both an antineoplastic and immunosuppressive agent. Like 6-TG, 6-MP and its metabolites act at multiple levels to interfere with purine biosynthesis and interconversions. It competes with hypoxanthine and guanine for HGPRTase, and, following conversion to thioinosinic acid (TIMP), blocks conversion of IMP to xanthylic acid and IMP to AMP. Both TIMP and another metabolite, 6-methylthioinosinate (MTIMP), inhibit glutamine-5-phosphoribosylpyrophosphate aminotransferase. 6-MP is also incorporated into RNA and DNA, thereby functioning as a fraudulent base. It is unknown which of these actions is primarily responsible for the lethal actions of 6-MP, although available evidence points to DNA incorporation as a prime determinant of cytotoxicity.

Fate, Absorption, and Excretion: Following oral administration, the bioavailability of 6-MP is highly variable, presumably due to interpatient differences in gastrointestinal absorption, which averages 50% of the administered dose. Extensive catabolism by hepatic xanthine oxidase also contributes to drug elimination. Approximately 50% of the administered 6-MP or its metabolites is recovered in the urine. The volume of distribution generally exceeds the total body water. Following intravenous administration, the plasma disappearance half-life was 47 minutes in adults. Plasma protein binding is modest (19%), and spinal fluid penetrance is minimal.

Preparation and Administration: 6-MP is supplied as tablets for oral administration. Each tablet contains 50 mg of 6-MP and the inactive ingredients corn and potato starch, lactose, magnesium stearate, and stearic acid. An intravenous preparation containing 500 mg of 6-MP per vial is available for investigational use.

Toxic Effects: The major dose-limiting toxicity of 6-MP is myelosuppression. This is dose-related and is manifested by leukopenia, thrombocytopenia, and anemia. The hematologic effects of 6-MP may be delayed, so it is important to withdraw the medication temporarily at the first sign of unusual hematologic toxicity. Individuals with an inherited disorder of thiopurine methyltransferase deficiency may be particularly susceptible to 6-MP-mediated hematopoietic suppression. Other toxicities include hepatotoxicity (elevated liver function tests, cholestasis, hepatic necrosis, ascites), nausea, vomiting, mucositis, fever, rash, and diarrhea. The hepatotoxicity, which occurs in 1040% of patients, requires close monitoring and discontinuation of therapy until recovery occurs. Patients receiving 6-MP uniformly experience immunosuppression.

Potential Drug Interactions: Allopurinol, an inhibitor of xanthine oxidase, significantly reduces the catabolism of 6-MP when the latter is given by the oral route, leading to major increases in plasma concentrations. Allopurinol does not alter the pharmacokinetics of intravenous 6-MP, presumably because of the absence of first-pass metabolism of 6-MP when administered by this route. When administered in conjunction with allopurinol, the dose of 6-MP should be reduced by 1/3 to 1/4. Increased toxicity has been reported in patients receiving concurrent 6-MP and trimethoprim-sulfamethoxazole. 6-MP may also modify the effects of warfarin.

Therapeutic Indications in Hematology: The major use for 6-MP is in the maintenance phase of treatment for ALL. 6-MP has also been used in the treatment of patients with immune thrombocytopenic purpura (ITP) or autoimmune hemolytic anemia refractory to all other forms of therapy.

5-Azacytidine

Chemistry and Mechanism of Action: 5-Azacytidine is an analog of the nucleoside cytidine, differing from the parent compound by virtue of the presence of a nitrogen at the 5 position of the heterocyclic ring. 5-Azacytidine is transported across the cell membrane by facilitated nucleoside diffusion and is converted to its nucleotide monophosphate form, 5-aza-CMP, by the pyrimidine salvage pathway enzyme uridine-cytidine kinase. 5-Azacytidine is also a substrate for the degradative enzyme cytidine deaminase. It is ultimately converted to its lethal derivative, 5-aza-CTP, which is incorporated into RNA and to a lesser extent DNA. The lethal actions of 5-azacytidine are believed to result from its ability to interfere with protein synthesis through disruption of RNA processing. The chemical instability of the 5-azacytidine ring structure is also thought to contribute to the cytotoxicity of this compound.

Absorption, Fate, and Excretion: The drug distributes into a volume corresponding to the total body water after intravenous administration, and is also well absorbed following subcutaneous injection. It is extensively deaminated in the plasma and liver and displays minimal plasma binding. Peak plasma concentrations following intravenous injection approximate 1.0 mM. The initial half-life of 5-azacytidine (and/or its metabolites) is approximately 4 hours, although the drug is rapidly converted to various derivatives within minutes of administration. There is minimal spinal fluid penetrance.

Preparation and Administration: 5-Azacytidine is an investigational agent provided by the National Cancer Institute as a group C drug for patients with refractory AML. It is supplied in 100-mg vials and is reconstituted in 19.9 ml of sterile water for injection. When further diluted to a concentration of 0.22 mg/ml in normal saline, 5% dextrose in water, or lactated Ringers solution, 10% of the drug undergoes decomposition within 3 hours. Consequently, the drug should be administered immediately after reconstitution and not stored. When administered as a continuous infusion, fresh solutions should be prepared every 34 hours.

Toxic Effects: The major toxicities of 5-azacytidine have been leukopenia and to a lesser extent thrombocytopenia. Nausea and vomiting, often refractory to standard antiemetic therapy, have also been encountered, most frequently in patients receiving bolus infusions. Gastrointestinal toxicity is ameliorated by administering 5-azacytidine as a continuous infusion. Other potential side effects include diarrhea, fever, hepatotoxicity (most frequently in patients with pre-existing hepatic disease), neuromuscular toxicity, rash, and hypotension.

Potential Drug Interactions: None reported.

Therapeutic Indications in Hematology: 5-Azacytidine is primarily used in the treatment of refractory AML, with response rates ranging from 17 to 30% when used as a single agent. 5-Azacytidine has also yielded clinical responses in a subset of patients with the myelodysplastic syndrome when administered as a low-dose continuous infusion. In early trials, low-dose 5-azacytidine has increased fetal hemoglobin levels in some patients with sickle cell anemia and thalassemia.

Gemcitabine

Chemistry and Mechanism of Action: Gemcitabine (2,2-difluorocytidine monohydrochloride) is a nucleoside analog that differs from 2-deoxycytidine by virtue of the presence of fluorine atoms in the 2 and 2 positions of the cytidine ring. It is transported across the cell membrane by facilitated nucleoside diffusion, phosphorylated by deoxycytine kinase, and ultimately converted to its lethal metabolites, dFdCDP and dFdCTP. The diphosphate form (dFdCDP) inhibits ribonucleotide reductase,

leading to disruption of dNTP pools and resultant interference with DNA synthesis and repair. The triphosphate form (dFdCTP) competes with dCTP for incorporation into DNA. Reductions in dCTP pools (secondary to ribonucleotide reductase inhibition) result in self-potentiation of gemcitabine action. Incorporation of gemcitabine into DNA in S phase inhibits elongation of the replicating strand, leading to DNA chain termination. The lethal actions of gemcitabine in leukemia cells have been related to the induction of apoptosis and are not restricted to cells actively engaged in DNA synthesis. Gemcitabine has been shown to be considerably more potent in inducing apoptosis in cultured human leukemia cells than Ara-C.

Absorption, Fate, and Excretion: In studies involving intravenously administered labeled gemcitabine, up to 98% of the drug was recovered in the urine after 1 week. The excreted dose was composed of a minor fraction (gemcitabine; <10%) and inactive metabolites (e.g., 2-deoxy-2,2-difluoruridine). Plasma protein binding was minimal. In studies involving both short and long gemcitabine infusions, pharmacokinetics were found to be linear and best described by a two-compartment model. Plasma half-life and clearance are influenced by both age and gender. For short infusions, half-lives varied from 3294 minutes; for longer infusions, half-lives varied from 245638 minutes. Volume of distribution was 50 L/m^2 for short infusions and 370 L/m^2 for long infusions.

Preparation and Administration: Vials of gemcitabine contain 200 mg or 1 g of the HCl derivative formulated with mannitol (200 mg or 1 g) and sodium acetate (12.5 or 62.5 mg) as a sterile lyophilized powder. HCl or NaOH has been used for pH adjustment.

Toxic Effects: The major dose-limiting toxicity of gemcitabine is myelosuppression, although anemia and thrombocytopenia have also been encountered. Other toxicities include nausea and vomiting, transient elevations in liver function tests, mild hematuria, proteinuria (and in rare cases hemolytic uremia syndrome), fever, rash, dyspnea, edema, and a flulike syndrome. Other infrequent toxicities include alopecia, paresthesias, and bronchospasm.

Potential Drug Interactions: Gemcitabine may function as a radiosensitizing agent and can increase the toxicity of ionizing radiation. No other interactions are known.

Indications in Hematology: The primary indication for gemcitabine is in the treatment of pancreatic carcinoma. However, as an experimental agent, gemcitabine is being evaluated for the treatment of acute leukemia and chronic lymphocytic leukemia.

Arabinofuranosylguanine (Ara-G)

Ara-G is an experimental purine analog that was initially the object of interest due to its resistance to phosphorylysis by purine nucleoside phosphorylase. Its lethal actions stem from formation of Ara-GTP, incorporation of this metabolite into DNA, and interference with DNA synthesis. For reasons that are not yet clear, T cells appear to be particularly sensitive to this agent, a phenomenon that may result from preferential accumulation of the lethal metabolite, Ara-GTP. In a recent clinical trial involving a water-soluble pro-drug (GW506U) in patients with leukemia, cells from patients with T-cell ALL preferentially accumulated Ara-GTP. Phase II studies of Ara-G are ongoing in patients with T-cell ALL and other T-cell malignancies.

APPENDIX: Topoisomerase I and II Inhibitors

TOPOISOMERASE II INHIBITORS
Etoposide (Vepesid), Etoposide Phosphate (Etopophos), Teniposide (Vumon)

Chemistry and Mechanism of Action: *Etoposide* (VP-16), etoposide phosphate, and teniposide (VM-26) are semisynthetic derivatives of epipodophyllotoxin. The mechanism of action of these drugs appears to be related to their ability to stabilize a topoisomerase II/DNA cleavable complex, which acts as a replication fork barrier and leads to the generation of irreversible DNA damage and cell death in proliferating cells.

Absorption, Fate, and Excretion: Etoposide has an oral bioavailability of 2575%. Its terminal half-life is 68 hours, with approximately 3040% excreted in the urine, two thirds as unchanged drug. There is no accumulation with consecutive daily administration, but cytotoxicity has strict schedule dependency. Clinical studies suggest that in patients with a plasma creatinine >130 mol/L, the etoposide dose should be reduced by 25%.

Etoposide phosphate is rapidly and completely converted in vivo to VP-16 by the activity of phosphatase and has been shown to have the same pharmacokinetics as VP-16. Due to

its increased water solubility, etoposide phosphate can be given intravenously in much less volume. In addition, the metabolic acidosis and hypotension seen with the infusion of VP-16 are not seen with this pro-drug.

Teniposide has a multiphasic pattern of clearance from plasma with a terminal half-life of 9.521 hours. Unlike those of etoposide, metabolites of teniposide account for 80% of the drug excreted in the urine. Like etoposide, there is significant interpatient and intrapatient variation in clinical pharmacokinetics. There are currently no formal recommendations for dose modification in patients with renal insufficiency.

Preparation and Administration: *Etoposide* is available as 50-mg capsules and in vials of 50 and 100 mg at a concentration of 20 mg/ml. When the drug is diluted with normal saline or 5% dextrose in water to a concentration of 0.2 or 0.4 mg/ml, it is stable for 96 or 48 hours, respectively. Etoposide must be administered slowly over 30 minutes to prevent hypotension.

Etoposide phosphate is available in single-dose vials containing etoposide phosphate equivalent to 100 mg of etoposide. When it is diluted with water, 5% dextrose, or normal saline to a concentration of 1020 mg/ml, it can be administered without dilution over 510 minutes. Etoposide phosphate when reconstituted is stable for 24 hours at room temperature or under refrigeration.

Teniposide is supplied in 50-mg vials for intravenous use only. The intravenous solution may be taken orally but is unpalatable. Currently, no oral preparation is available on the market; however, for investigational purposes each 50-mg vial may be dissolved in 50100 ml of syrup or juice. A single oral dose of 60 mg/m ^{2} is advised to achieve optimal absorption. It may be repeated at 6-hour intervals. As with etoposide, rapid infusion can produce hypotension.

Toxic Side Effects: Myelosuppression, especially leukopenia, is the dose-limiting toxic effect of *etoposide* and *teniposide*. Nausea and vomiting are usually mild and easily prevented with antiemetics. Rapid infusion of etoposide (<30 minutes) may cause hypotension. Anaphylactoid reactions (e.g., bronchospasm) occur in 2% of patients and may be related to the cremaphor vehicle. Alopecia occurs in approximately 20% of patients treated with etoposide; this side effect is more common with teniposide. When the drug is given in high doses as a component of a preparative regimen for bone marrow transplantation, mucositis and diarrhea are prominent and may be dose-limiting.

Potential Drug Interactions: Theoretically, any drug that increases the S-phase fraction will increase the cytotoxicity of epipodophyllotoxins and other topoisomerase inhibitors. Conversely, drugs that inhibit DNA synthesis antagonize the effect of *etoposide* and *teniposide* (e.g., 5-fluoro-2-deoxyuridine given before etoposide in some human cancer cell lines decreases the cytotoxicity of the latter). More recent in vitro data suggest that synergistic cytotoxic effects are seen when VP-16 is given after a topoisomerase I inhibitor, which appears to upregulate the amount of topoisomerase II enzyme. Antagonistic effects have been reported when a topoisomerase II inhibitor is given before a topoisomerase I inhibitor. In hematology, etoposide and teniposide may inhibit the intracellular Ara-CTP formation, leading to reduced cytosine arabinoside cytotoxicity. Potentiation of teniposide activity has been seen with methotrexate and dipyridamoles. There is at least a twofold increase in the clearance of teniposide with concomitant administration of phenobarbital or phenytoin. Cyclosporine and other P-glycoprotein antagonists (PSC 833) potentiate the cytotoxic effects of etoposide.

Therapeutic Indications:*Etoposide* is employed in the treatment of non-Hodgkin lymphomas and as a second-line treatment for Hodgkin disease. It is also incorporated in the preparatory regimens for bone marrow transplantation of refractory lymphomas (CBV) and acute leukemia. *Teniposide* has been approved as a front-line agent with combination chemotherapy for childhood ALL. Combination chemotherapy with teniposide has been used successfully in some cases of refractory adult ALL and acute monocytic leukemia, but duration of remission is not significantly different from that with other standard salvage regimens. In non-Hodgkin lymphoma, teniposide has shown comparable activity to vincristine. *Etoposide phosphate* has been given in both standard-dose and high-dose (as a single agent) chemotherapy regimens and appears to have the same pharmacokinetics and antitumor activity as VP-16.

Daunorubicin

Chemistry and Mechanism of Action: Daunorubicin is an anthracycline that inhibits DNA topoisomerase II, acting as a poison at lower concentrations and a suppressor of cleavable complex formation at higher doses. Daunorubicin is also a DNA intercalator and generates reactive oxygen intermediates.

Absorption, Fate, and Excretion: After intravenous injection, daunorubicin undergoes rapid tissue uptake and concentration. It is rapidly metabolized in the liver, where approximately 25% of the drug concentrates and has a half-life of 2050 hours. The principal metabolite is daunorubicinol, which also displays antineoplastic activity. Biliary excretion accounts for approximately 75% of the drug and metabolite elimination. Patients with significant hepatic dysfunction should receive an attenuated dose of daunorubicin.

Preparation and Administration: Daunorubicin is supplied with 100 mg of mannitol in 20-mg vials, from which it is reconstituted with 4 ml of sterile water for injection. The vial should be protected from sunlight. Daunorubicin is a powerful vesicant that should be administered into the tubing of a freely flowing intravenous infusion of

either 5% dextrose in water or normal saline. In the event of extravasation, as much infiltrated drug as possible should be aspirated from the tissue, and cold compresses should be maintained on the site for several hours. Despite these measures, skin grafting may be necessary. Daunorubicin is not physically compatible with heparin, and the two drugs should not be coadministered in the same intravenous tubing. The patient should be informed that daunorubicin may impart a red color to the urine for up to 72 hours after administration.

Toxic Effects: Myelosuppression, predominantly leukopenia, is the dose-limiting toxic effect. Mucositis, nausea and vomiting, and alopecia are common. Facial flushing, conjunctivitis, and lacrimation may occur in rare cases. Erythematous streaking near the site of injection occurs as a benign local allergic reaction and should not be confused with extravasation. The drug can produce a severe local reaction (e.g., pneumonitis, esophagitis) in previously irradiated areas, even when both therapies are not administered concomitantly (radiation recall).

Cardiac toxicity is a unique characteristic of the anthracycline antibiotics and can be acute or chronic. In the acute form, abnormal EKG changes such as ST-T wave elevation and arrhythmias may be seen. Transient reduction in the ejection fraction can also occur acutely and is often associated with pericarditis (pericarditis/myocarditis syndrome). The chronic form of anthracycline cardiac toxicity is related to the cumulative dose. The dose limit of doxorubicin is generally considered to be 450500 mg/m^2 , where the risk of clinical cardiotoxicity is 110%. The corresponding cumulative dose limit for daunorubicin is 9001000 mg/m ^{2} . The cardiac

toxicity is clinically characterized by congestive heart failure, usually refractory to medical therapy. Cardiac irradiation or the administration of cyclophosphamide may increase the risk of cardiotoxicity. The cardiotoxic effects appear to be related to the formation of free radicals and not to the inhibition of DNA topoisomerase II. The cardioprotective agent dexrazoxane (Zinecard) is now available and recommended to be started at a doxorubicin cumulative dose >350 mg/m ^{2} .

Potential Drug Interactions: Daunorubicin is not physically compatible with heparin or dexamethasone. The drug interactions described for doxorubicin (see below) probably occur with daunorubicin as well.

Therapeutic Indications in Hematology: Daunorubicin is used in combination with other drugs in the treatment of AML and ALL.

Doxorubicin (Adriamycin)

Chemistry and Mechanism of Action: Doxorubicin is also an anthracycline glycoside antibiotic. It differs from daunorubicin at C-8, where a hydroxyacetyl group replaces an acetyl group. Because of this, doxorubicin is also called hydroxyl daunorubicin. Its mechanisms of action also involve stabilizing DNAtopoisomerase II complexes, DNA intercalation, and free radical formation.

Absorption, Fate, and Excretion: Doxorubicin has a triphasic plasma clearance with a half-life of approximately 30 hours. The drug is extensively metabolized in the liver to yield an active metabolite (doxorubicinol) and a number of inactive metabolites (aglycones). Within 7 days, 50% of an injected dose is excreted in the bile, but only 510% of the drug is excreted in the urine. Penetration into the cerebrospinal fluid is poor.

Preparation and Administration: Doxorubicin is available in 10-, 20-, 50-, 150-, and 200-mg vials. The lyophilized powder is reconstituted with either normal saline or sterile water for injection to yield a 2-mg/ml solution. The reconstituted solution must be protected from sunlight. The drug should be injected slowly into the tubing of freely running intravenous infusion of normal saline or 5% dextrose in water. Erythematous streaking along the vein is often an indication that the administration rate is too rapid. The drug is a powerful vesicant, and in case of extravasation the measures described for daunorubicin should be followed.

Toxic Effects: The toxic effects are similar to those of daunorubicin. Weekly low-dose regimens or administration by continuous infusion can decrease the risk of cardiotoxicity with doxorubicin.

Potential Drug Interactions: When used in combination with other drugs as treatment for leukemia or lymphoma, doxorubicin may decrease the oral bioavailability of digoxin. It is not physically compatible with heparin or 5-fluorouracil. Barbiturates may increase the plasma clearance of doxorubicin and decrease its cytotoxic effect. Doxorubicin is compatible with vincristine, and the two drugs can be administered together in the same intravenous solution.

Therapeutic Indications in Hematology: Doxorubicin is one of the most important drugs in the treatment of hematologic malignancies. It is used in the treatment of Hodgkin disease (ABVD regimen), non-Hodgkin lymphomas (CHOP, MACOP-B), and multiple myeloma (VBAP, VAD).

Idarubicin (Idamycin)

Chemistry and Mechanism of Action: Idarubicin, also called 4-demethoxydaunorubicin (4-DMDR), is an analogue of daunorubicin in which the methoxy group from the aglycone has been replaced with hydrogen. Idarubicin is also a topoisomerase II inhibitor and generates free radicals.

Absorption, Fate, and Excretion: The elimination of half-life of the parent compound is 11.3 hours, and that of the primary metabolite, 13-epirubicinol, is 4060 hours. The major metabolite is as active as idarubicin. The oral bioavailability of this drug is approximately 30%. Eighty percent of the drug is excreted in the urine as 13-epirubicinol.

Preparation and Administration: Idarubicin is supplied in 5- and 10-mg vials, from which it is reconstituted with sterile water or normal saline to obtain a 1-mg/ml solution. The drug should be infused over 1015 minutes through the tubing of a freely running intravenous infusion. Extravasation precautions should be instituted during administration. The oral formulation remains investigational.

Toxic Effects: The side effects of idarubicin are similar to those of daunorubicin and doxorubicin but are of lesser intensity at equal myelosuppressive doses.

Potential Drug Interactions: None reported.

Therapeutic Indications in Hematology: Idarubicin in combination with cytosine arabinoside is equivalent if not superior to combination chemotherapy with daunorubicin in the treatment of adult AML and myelodysplastic syndromes. Idarubicin has been approved for use in combination therapy for adult AML.

Mitoxantrone (Novantrone)

Chemistry and Mechanism of Action: Mitoxantrone is a synthetic anthracenedione. Its mechanism of action appears to involve primarily the inhibition of DNA topoisomerase II. Its reduced potential for free radical formation may explain the decreased cardiotoxicity of this drug.

Absorption, Fate, and Excretion: Mitoxantrone is excreted via the renal and hepatobiliary systems, but hepatobiliary elimination accounts for approximately 30% of active drug elimination and appears to be of greater importance. The half-life is quite variable, with a range of 2342 hours. Patients with severe hepatic dysfunction have been shown to eliminate the drug more slowly.

Preparation and Administration: Mitoxantrone is available as a 2-mg/ml solution in 10-, 12.5-, and 15-ml vials (20, 25, and 30 mg per vial, respectively). The drug is further diluted in normal saline or 5% dextrose in water for injection and is administered over 1530 minutes into the tubing of a freely running intravenous infusion. As with the anthracyclines, erythema or streaking along the vein of infusion indicates that the drug is being infused too rapidly. Although mitoxantrone is not a vesicant, there have been rare reports of tissue necrosis following extravasation.

Toxic Effects: Myelosuppression, principally leukopenia, is the dose-limiting toxic effect. Thrombocytopenia is relatively mild. Nausea, vomiting, and alopecia are usually mild and occur in <30% of patients treated. Rarely, mucositis and elevation of liver enzymes occur. The drug imparts a blue color to the urine of patients

treated. One of the primary advantages of mitoxantrone, in comparison with doxorubicin, is its much-reduced incidence of cardiac toxicity. Occasionally patients develop congestive heart failure after treatment with mitoxantrone in the absence of prior anthracycline exposure, although the incidence appears to be <5%.

Potential Drug Interactions: None reported.

Therapeutic Indications in Hematology: Mitoxantrone is approved for induction therapy of AML in adults.

Amsacrine (AMSA)

Chemistry and Mechanism of Action: Amsacrine, or 4-(9-acridinylamino) methanesulfon-m-anisidide (AMSA), is a synthetic aminoacridine derivative. Amsacrine is a DNA intercalator and also inhibits the activity of DNA topoisomerase II.

Absorption, Fate, and Excretion: When given intravenously, this drug has an initial half-life of 30 minutes and a terminal half-life of 7.9 hours. It is 50% protein bound after 2 hours. It is metabolized by conjugation with glutathione, and approximately 50% of the drug is eliminated in the bile. The remainder of the drug is eliminated via the urinary route as metabolites and parent drug.

Preparation and Administration: Amsacrine is an investigational agent supplied by the National Cancer Institute as a group C drug. It is provided in a dual pack containing two sterile liquids that must be combined prior to use. One vial contains 1.5 ml of 50 mg/ml of AMSA in anhydrous N, N-dimethylactamide, and the other contains 13.5 ml of 0.0353 ml lactic acid diluent. When these are combined, the resulting orange-red solution contains 5 mg/ml of AMSA. Because of the N, N-dimethylactamide solvent, plastic syringes should not be used with the undiluted AMSA solution.

Toxic Effects: The dose-limiting toxic effect is myelosuppression, predominantly affecting granulocytes. Alopecia is common, and nausea, vomiting, and mucositis can occur. Cardiotoxicity, manifested as a decrease in ejection fraction, acute arrhythmias, or EKG changes, was reported in 2.3% of 3,200 patients, but most of these patients had been heavily pretreated with anthracyclines. Hypokalemia seems to enhance amsacrine cardiotoxicity and if present should be corrected prior to administration of the drug.

Potential Drug Interactions: The reconstituted solution is physically incompatible with chloride-containing solutions.

Therapeutic Indications in Hematology: Amsacrine is a group C investigational drug approved for the treatment of refractory AML, although it is being evaluated in combination with other cytotoxic agents in the initial treatment of this disease. As a group C drug, amsacrine must be administered as a single agent.

TOPOISOMERASE I INHIBITORS
Topotecan (Hycamtin)

Chemistry and Mechanism of Action: Topotecan is a semisynthetic derivative of camptothecin that stabilizes a complex between DNA topoisomerase I and DNA. The cytotoxic effect of this drug is believed to result from the collision of DNA replication forks with a ternary complex of topoisomerase I, DNA, and topotecan. The resulting double-strand DNA breaks are lethal. The lactone form of topotecan, which predominates at an acidic pH, is a much more potent inhibitor of DNA topoisomerase I.

Absorption, Fate, and Excretion: At neutral or physiologic pH, the carboxylate form of topotecan is favored, and at a pH <7 the lactone form is favored. Topotecan has been given as a bolus or by continuous infusion. In <1 hour after an infusion, most of the circulating drug in the plasma is in the carboxylate form due to the physiologic pH. The terminal half-life of the lactone form of this S-phase-specific agent is 2.6 hours; the terminal half-life of the total drug is 3.3 hours. Thirty-six percent of an intravenous dose is excreted unchanged in the urine, and there is a 1.5-fold concentration of the drug in bile. CSF levels of topotecan lactone reach approximately 32% of plasma levels. Dose adjustment is required for a creatinine clearance <60 ml/min, but no adjustment is necessary for a bilirubin up to 10 mg/dl.

Preparation and Administration: Topotecan is available in 4-mg vials reconstituted with 4 ml of sterile water. This solution can be further diluted in normal saline or 5% dextrose in water and should be used immediately.

Toxic Effects: The dose-limiting toxicity for topotecan for all schedules is neutropenia. Thrombocytopenia and anemia are less common, although there is an increase in thrombocytopenia with continuous infusion schedules. Other less common and mild toxicities include nausea, vomiting, diarrhea, fever, fatigue, alopecia, skin rash, and increased liver function tests. Mucositis has been seen with prolonged infusion schedules over 5 days or when topotecan is given in higher doses.

Potential Drug Interactions: In vitro data suggest that there may be some synergism if a topoisomerase I inhibitor is given before a topoisomerase II inhibitor. In vitro data also suggest that synergism may be seen if a topoisomerase I inhibitor (topotecan) is given after an alkylating agent, suggesting that topoisomerase I may be involved in the repair of alkylator-induced DNA damage.

Therapeutic Indications in Hematology: Phase II studies suggest that topotecan has activity in myelodysplastic syndromes, AML, and multiple myeloma.

Irinotecan (Camptosar or CPT-11)

Chemistry and Mechanism of Action: CPT-11 is a pro-drug that has a bulky piperidino side chain at C-10 that is cleaved in vivo by carboxylesterase converting enzyme to generate SN-38. SN-38 is approximately 1,000-fold more potent a topoisomerase I inhibitor than CPT-11. The lactone forms of both SN-38 and CPT-11 are more potent inhibitors of topoisomerase I than the carboxylate forms, which is thought to be the mechanism of action of these drugs as described for topotecan.

Absorption, Fate, and Excretion: The terminal half-life of the lactone form of CPT-11 is 7 hours and of the total drug 10.5 hours. The terminal half-life of SN-38 lactone is 8.7 hours and that of the total drug is 14.7 hours. Twenty-two percent of a dose of irinotecan is excreted unchanged in the urine. SN-38 is excreted into the bile and can undergo glucuronidation. The plasma protein binding of CPT-11 is reported to be 3068% and that of SN-38 is 95%.

Preparation and Administration: Irinotecan is available as a 100-mg single-dose vial with 20 mg/ml irinotecan. This preparation also contains 45 mg of sorbitol and 0.9 mg lactic acid per ml with the pH adjusted to 3.5. This solution can be diluted with 5% dextrose in water (preferred) or in normal saline to a final concentration of 0.11.2 mg/ml. The solution is stable for up to 24 hours at room temperature or 48 hours when refrigerated. The dose should be modified for severe diarrhea.

Toxic Effects: The major toxic effect of irinotecan is diarrhea. This can be early-onset diarrhea occurring within hours of administration or during the infusion that can be associated with cramping, vomiting, flushing, and diaphoresis. These side effects are due to the cholinergic effects of CPT-11 and can be managed with atropine. Severe later-onset diarrhea can be treated with high-dose loperamide, which has been found to decrease the incidence of grade 4 diarrhea from 20% to 2%. Diarrhea has been found to be the dose-limiting toxicity when irinotecan is given on a weekly schedule, and neutropenia when the drug is given every 3 weeks. Also seen are alopecia, nausea, vomiting, mucositis, fatigue, increased liver function tests, and rare cases of pulmonary toxicity.

Potential Drug Interactions: As described for topotecan, in vitro data suggest some synergism when topoisomerase I inhibitors precede topoisomerase II inhibitors or follow alkylating agent administration.

Therapeutic Indications in Hematology: Phase I and II studies have shown responses in refractory leukemia and lymphoma.

APPENDIX: Clinical Pharmacology of Platinum Analogs

Cisplatin (Platinol)

Chemistry and Mechanism of Action: Cisplatin [cisdiamminedichloroplatinum(II)] is an inorganic heavy metal complex. This complex can have cis- and trans-isomers; the cis-isomer is the active antitumor drug. In the relatively higher chloride concentrations of plasma, cisplatin is uncharged in the dichloro form and passes through plamsa membranes. Intracellularly, the low chloride concentrations allow the displacement of the chloride ligands by water to form the positively charged aquated complex. This forms covalent cross-links between two nucleophilic atoms of macromolecules such as the N7 positions of guanine and adenine in DNA. The cytotoxicity of cisplatin correlates closely with total platinum binding to DNA, to interstrand cross-links, and to the formation of intrastrand bidentate N7 adducts at d(GpG) and d(ApG), resulting in intrastrand cross-links that bend the DNA helix and inhibit DNA synthesis. Cisplatin damage to DNA induces apoptosis of sensitive cells.

Absorption, Fate, and Excretion: Following its intravenous injection, the drug concentrates in the liver, kidneys, and bowel. Plasma levels of cisplatin decay in a biphasic manner, with an initial half-life of 2549 minutes and a terminal half-life of 5873 hours. Although 15% of the administered cisplatin is excreted unchanged in the urine, up to 90% of the administered dose of the drug can be recovered from urine.

Preparation and Administration: Cisplatin is available as a lyophilized powder, supplied in 10- and 50-mg vials also containing mannitol, sodium chloride, and hydrochloric acid, and as an aqueous solution in 50- and 100-mg vials. Reconstitution of the powder for injection is achieved by adding sterile water to make a 1-mg/ml solution. The reconstituted solution should be further diluted in normal saline (usually 500 ml to 1 L) and administered over 13 hours. To prevent nephrotoxic effects, 2550 g of mannitol is often added to the saline solution, and patients are aggressively hydrated before and after cisplatin infusion. Magnesium sulfate (1224 mEq) is commonly added to the saline solution to preclude the development of hypomagnesemia.

Toxic Effects: Nephrotoxicity is the dose-limiting toxic effect. Cisplatin produces a dose-dependent impairment of renal tubular function, manifested by an increase in serum creatinine as well as potassium and magnesium wasting. The renal dysfunction is usually reversible, but repeated treatments may produce a cumulative and permanent mild to moderate impairment of renal function. Administration of other nephrotoxic agents such as aminoglycosides, even between courses, can potentiate its toxicity. Nausea and vomiting are usually severe and require aggressive antiemetic support. When doses >70 mg/m ^{2} are used, it is also important to protect against delayed nausea and vomiting by administering antiemetic agents (e.g., prochlorperazine plus dexamethasone) for 3 days following therapy. Myelosuppression is usually mild. High-frequency hearing loss, tinnitus, and frank deafness may occur. Peripheral neurotoxicity, characterized by paresthesias or sensory loss in a glove-and-stocking distribution or as muscular weakness, is relatively common in patients who receive total cumulative doses of >500 mg/m ^{2} . The peripheral neuropathy may take many months to resolve, if it does at all. Vestibular toxicity and anaphylactic reactions occur rarely.

Potential Drug Interactions: Aminoglycosides and amphotericin may enhance cisplatin nephrotoxicity. Caution should be exercised when cisplatin is administered with bleomycin and methotrexate, as cisplatin-induced renal damage may delay the excretion and thus increase the toxicity of these agents.

Therapeutic Indications in Hematology: Cisplatin is used in the treatment of refractory lymphomas, usually in combination with cytosine arabinoside and high-dose dexamethasone.

Carboplatin (Paraplatin)

Chemistry and Mechanism of Action: Carboplatin is a second-generation platinum (II) complex. Its mechanism of action is very similar to that of cisplatin. However, the carboxyl ester groups in this platinum complex are less easily displaced and less chemically reactive. The peak level of DNA cross-linking also occurs 612 hours later for carboplatin than for cisplatin.

Absorption, Fate, and Excretion: Carboplatin is eliminated primarily through the kidneys. Its elimination is slower than cisplatin, with a terminal half-life of 26 hours. Following intravenous injection, approximately 60% of the total drug is excreted within 24 hours.

Preparation and Administration: Carboplatin is available as a lyophilized powder in 50- and 150-mg vials containing carboplatin and mannitol. It is reconstituted with sterile water to a final concentration of 10 mg/ml. For injection further dilution with 5% dextrose and water or normal saline to a concentration of 0.5 or 2 mg/ml, it is stable for 8 hours at room temperature. Carboplatin is often administered by intravenous injection over 1530 minutes. Patients with reduced renal function (creatinine clearance <60 ml/min) should have the dose of carboplatin decreased according to the formula described by M.J. Egorin.

For previously untreated patients:
Dosage (mg/m^2)
= (0.091) (creatinine clearance/body surface area)
× ([(pretreatment platelet count
platelet nadir desired)/pretreatment platelet count]
× 100) + 86

For heavily pretreated patients:
Dosage (mg/m^2)
= (0.091) (creatinine clearance/body surface area)
× ([(pretreatment platelet count
platelet nadir desired/pretreatment platelet count)
× 100] 17) + 86

A formula developed by A.H. Calvert also takes into account the patients pretreatment renal function, as follows:
Dose (mg) = target AUC (mg/ml × min)
× [GFR (ml/min) + 25]
where the dose in mg (not mg/m^2 body surface area)

equals target AUC × GFR + 25
where AUC is the area under the plasma clearance curve and GFR is the glomerular filtration rate. In previously untreated adults, the AUC can be estimated at 7 when carboplatin is used alone and 4.5 when used in combination. If the AUC is set lower, less toxicity is expected.

Toxic Effects: The dose-limiting toxic effect is myelosuppression; thrombocytopenia is more significant than leukopenia. Carboplatin leads to less emesis than cisplatin. Although nausea and vomiting are common, they can be easily controlled with antiemetics. At high doses such as those used for bone marrow transplantation, hepatotoxicity, renal dysfunction, and moderate to severe cytotoxicity can occur.

Potential Drug Interactions: None reported.

Clinical Indications in Hematology: Carboplatin has been recently approved for the treatment of ovarian cancer. It is also used to treat small cell lung, testicular, head and neck, and genitourinary cancers. High-dose carboplatin is under evaluation in acute leukemias and lymphomas.

APPENDIX: Clinical Pharmacology of Miscellaneous Agents

Plicamycin

Chemistry and Mechanism of Action: Plicamycin, also called mithramycin, forms complexes with DNA and inhibits DNA-directed synthesis of RNA. Plicamycin also inhibits the effect of parathyrin on osteoclasts. The hypocalcemic effect is independent of the antitumor effect.

Absorption, Fate, and Excretion: The pharmacology of plicamycin has been poorly described. Within 15 hours of intravenous administration, 40% is excreted in the urine. The elimination half-life has been estimated to be approximately 2 hours.

Preparation and Administration: Plicamycin is available as a lyophilized powder in 2.5-mg vials, from which it is reconstituted with 4.9 ml of sterile water for injection. This dose should be further diluted in 1 L of 5% dextrose in water or normal saline and infused over 46 hours.

Toxic Effects: When plicamycin is employed as an antitumor agent, its most common side effects include myelosuppression, elevated liver enzymes, increased serum creatinine and proteinuria, and coagulopathy due to decreased clotting factors II, V, VII, and X. The drug also causes nausea and vomiting, diarrhea, stomatitis, headache, and irritability. Cutaneous toxicity may occur in up to one third of patients, manifested by progressive blushing of the face and thickening and coarsening of the skinfolds. The drug can produce severe local irritation if extravasation occurs.

Potential Drug Interactions: None reported.

Therapeutic Indications in Hematology: Plicamycin is used primarily to treat hypercalcemia of malignancy. Claims of antitumor activity in the blast phase of CML have been made but not confirmed.

Bleomycin

Chemistry and Mechanism of Action: Bleomycin is a glycopeptide. Its antitumor effect correlates with its ability to cause scission of both double- and single-stranded DNA via activated oxygen formed by the iron/bleomycin complex. Bleomycin also affects DNA repair by inhibiting DNA ligase.

Absorption, Fate, and Excretion: Bleomycin is rapidly distributed throughout the body and concentrates in the skin, lung, kidney, peritoneum, and lymph nodes. Its plasma half-life is 24 hours. Within 24 hours of injection, approximately 50% of an administered dose is excreted unchanged in the urine. Bleomycin elimination correlates well with creatinine clearance; accordingly, patients with renal failure should receive a reduced dose. In the tissues, bleomycin is inactivated by bleomycin hydrolase. Tissues lacking this enzyme, such as lung and skin, are more susceptible to the drugs toxic effects.

Preparation and Administration: Bleomycin is available in vials containing 15 U (approximately equivalent to 15 mg), from which it is reconstituted for injection with 35 ml of sterile water, normal saline, 5% dextrose in water, or bacteriostatic water. For intravenous infusion, the reconstituted solution can be further diluted with either normal saline or 5% dextrose in water and administered over 5 minutes. Bleomycin can also be administered by the subcutaneous, intravenous, intramuscular, intracavitary, and intra-arterial routes. Because patients with lymphomas are at an increased risk of anaphylactoid reactions, which may not occur until 12 hours after administration, the first two doses should be intramuscular test doses of 12 mg. If no reactions occur, full doses may be given.

Toxic Effects: The most serious toxic effect is interstitial pneumonitis, which is dose-related and occurs in approximately 10% of patients treated with cumulative doses of >350400 U. The interstitial pneumonitis may evolve into life-threatening pulmonary fibrosis. Pulmonary toxicity is more common in patients >70 years, in those receiving a total dose of >400 U, and in those who received prior radiotherapy to the lung. However, the pulmonary toxicity is unpredictable; it has been reported in patients who had none of these risk factors and has occurred in a patient after administration of only 20 U. Some reports suggest that an increased concentration of

inspired oxygen acts synergistically with bleomycin to produce pulmonary fibrosis. During critical illness and perioperatively, therefore, an attempt should be made to maintain the inspired oxygen concentration at 21%. The early phases of the pulmonary toxicity are clinically manifested by dyspnea and fine rales. Although corticosteroids are often employed in this setting, it is not clear that they are of benefit.

Mucocutaneous toxicity occurs in 50% of patients treated and is manifested by hyperpigmentation, pruritic erythema, mucositis, desquamation of the plantar surface skin of the hands and/or feet, ridging of the nails, and alopecia. The mucositis can be severe and is the acute dose-limiting toxic effect. Febrile reactions, which occur a few hours after bleomycin administration and may last 412 hours, are also common. Fever becomes less frequent with continued use of the drug and can usually be prevented by concurrent administration of glucocorticosteroids (e.g., 100 mg of hydrocortisone). Bleomycin has virtually no myelosuppressive effect. Anaphylactoid reactions are observed in approximately 1% (8% in some series) of patients with lymphomas treated with bleomycin.

Potential Drug Interactions: Bleomycin, administered with other drugs for the treatment of lymphorra, can decrease the oral bioavailability of digoxin and the pharmacologic effect of phenytoin and certain anesthetic drugs.

Therapeutic Indications in Hematology: Bleomycin is often incorporated in the chemotherapy regimens of Hodgkin disease (ABVD and MOPP/ABV hybrid regimens) and non-Hodgkins lymphomas (MACOP-B, PROMACE/ CYTABOM, M-BACOD, and CHOP-Bleo).

Procarbazine

Chemistry and Mechanism of Action: Procarbazine is a substituted hydrazine derivative with a chemical structure similar to that of the monoamine oxidase inhibitors (MAOI). Accordingly, procarbazine exhibits weak MAOI effects. Procarbazine itself is inert and must undergo metabolic activation to generate cytotoxic reactants, the mode of action of which is not clear. They may inhibit transmethylation of methyl groups of methionine into tRNA or may also directly damage DNA. Hydrogen peroxide, formed during the auto-oxidation of procarbazine, may attack protein sulfhydryl groups contained in residual proteins tightly bound to DNA.

Absorption, Fate, and Excretion: Procarbazine is rapidly and completely absorbed by the oral route, peak plasma levels occurring within 60 minutes. It penetrates well into the cerebrospinal fluid. The drug is readily metabolized in the liver and has a plasma half-life of 10 minutes after intravenous injection. The major sites of elimination are the kidneys, where approximately 70% of the drug is excreted as N-isopropylterephthalamic acid and <5% is excreted unchanged.

Preparation and Administration: Procarbazine is available in 50-mg capsules.

Toxic Effects: The usual dose-limiting toxic effect is myelosuppression. Occasionally nausea and vomiting may be dose-limiting, although tolerance to those effects may develop during continued administration. Other less common side effects include paresthesias, headache, dizziness, depression, apprehension, insomnia, nightmares, hallucinations, drowsiness, ataxia, foot drop, decreased reflexes, tremors, coma, confusion, convulsions, skin rash, alopecia, myalgia, and arthralgia. Procarbazine may possibly be leukemogenic.

Potential Drug Interactions: Combination chemotherapy that includes procarbazine may result in a decrease in digoxin plasma levels. Because procarbazine is a weak MAOI, hypertensive reactions could theoretically occur following concurrent ingestion of sympathomimetics, levodopa, tricyclic antidepressants, or foods with high tyramine content (e.g., dark beer, yogurt, cheeses, and red wines). However, such reactions have not been reported. Concomitant use of narcotics or other strong sedatives may result in exaggerated depressant effects, leading to coma and possibly death. Procarbazine also interacts with alcohol, causing a disulfiram-like reaction.

Therapeutic Indications in Hematology: Procarbazine is often used in combination with other cytotoxic agents in the treatment of Hodgkins disease (MOPP and MOPP derivatives) and to a lesser extent in the treatment of non-Hodgkin lymphomas (PROMACE/MOPP).

Asparaginase

Chemistry and Mechanism of Action: Asparaginase contains the high-molecular-weight enzyme L-asparaginase amidohydrolase, type EC-2, derived from *Escherichia coli*. Asparaginase hydrolyzes serum asparagine to nonfunctional asparatic acid and ammonia, depriving tumor cells of a required amino acid; thus, tumor cell proliferation is blocked by the interruption of asparagine-dependent protein synthesis. The drug appears to be most active in the G_1 phase.

Absorption, Fate, and Excretion: Asparaginase is not absorbed orally. Its plasma half-life varies from 8 to 30 hours and is not influenced by dosage, age, sex, surface area, or renal or hepatic function.

Preparation and Administration: Asparaginase is available in vials containing 10,000 IU of asparaginase in 80 mg of mannitol. For intravenous use, the drug should be reconstituted with 5 ml of either sterile water or sodium chloride for injection and injected in the tubing of a freely running infusion of either normal saline or 5% dextrose in water over 30 minutes. For intramuscular or subcutaneous use, each vial should be reconstituted with 2 ml of sodium chloride for injection to obtain a 5,000-U/ml solution. For dosages >2 ml, use of two injection sites is recommended. For both intravenous and intramuscular administration, the drug must be used within 8 hours of reconstitution, and only if it is clear. Because of the possibility of hypersensitivity reactions (particularly in patients with lymphomas), an intradermal skin test is recommended before initial administration of asparaginase or when 1 week has elapsed between doses. For this test, 2 IU should be injected intradermally and observed for a wheal or erythema for 1 hour. A negative skin test, however, does not preclude possible development of a hypersensitivity reaction. It is recommended that oxygen, epinephrine, and corticosteroids be available at the bedside during administration of the drug. For allergic patients, the *E. coli* form of asparaginase should be replaced by the asparaginase derived from *Erwinia carotovora*, provided by the National Cancer Institute as an investigational group C agent.

Toxic Effects: The toxicity of asparaginase is reported to be greater in adults than in children. Anorexia, nausea, or vomiting occurs in approximately one third of patients. Most of the other side effects can be divided into two main groups, those related to hypersensitivity reactions to the foreign protein and those resulting from decreased protein synthesis. The hypersensitivity reaction is characterized by urticaria, laryngeal edema, bronchospasm, or hypotension and may occur with the initial dose of the drug, even if the skin test is negative. More commonly, however, allergic phenomena are observed after multiple courses of treatment. Adverse effects related to the inhibition of protein synthesis include hypoalbuminemia and decreases in serum fibrinogen, prothrombin,

antithrombin III, and other coagulation factors, which may lead to both clotting and hemorrhagic complications; decreased serum insulin with hyperglycemia; and decreased serum lipoproteins. In 25% of patients cerebral dysfunction, characterized by confusion, stupor, and frank coma, can occur. Although the neurotoxic effects resemble those of ammonia toxicity, they are apparently due to low concentrations of either L-asparagine or L-glutamine in the brain. Acute pancreatitis, which may progress to severe hemorrhagic pancreatitis, may occur in 15% of patients. Elevation of liver enzymes and serum bilirubin is almost universal and is histologically represented by fatty metamorphosis. Liver toxicity, although usually not clinically significant, has resulted in occasional fatalities. Asparaginase occasionally produces renal functional impairment with oliguric renal failure.

Potential Drug Interactions: When asparaginase is administered immediately before or with methotrexate, it decreases the cytotoxic effect of the latter. When administered to patients with acute leukemia 910 days before or shortly after methotrexate, however, asparaginase appears to enhance the cytotoxic effect of methotrexate. Concurrent administration of asparaginase with vincristine may increase vincristines neurotoxic effects, but this effect appears to be less pronounced when asparaginase is given after vincristine. The effects of asparaginase on liver function may interfere with the activation or metabolism of other cytotoxic agents.

Therapeutic Indications in Hematology: Asparaginase is used in combination therapy for remission induction of patients with ALL.

Gallium Nitrate

Chemistry and Mechanism of Action: Gallium nitrate is a group IIA metal salt; the mechanism of action is not completely understood. Its selective cytotoxic effects in humans are probably related to its predominant concentration in certain malignant tumors. Gallium nitrate binds to intracellular calcium and magnesium sites. Transferrin binding appears to be necessary to produce the cytotoxic effect.

Absorption, Fate, and Metabolism: Gallium nitrate is primarily eliminated by renal excretion and follows a biphasic pharmacokinetic pattern. The reported half-life is 636 hours.

Preparation and Administration: Gallium nitrate is an investigational agent supplied as a 25-mg/ml solution in 20-ml vials (500 mg per vial), also containing trisodium citrate and sodium hydroxide to adjust the pH. Gallium nitrate can be administered by slow intravenous infusion, although in the treatment of hypercalcemia it is usually given by continuous infusion over 57 days.

Toxic Effects: When given as a single bolus injection, the dose-limiting toxicity is renal impairment. The renal toxicity is significantly minimized when the drug is given by continuous infusion. Other toxic effects include mild myelosuppression, hypocalcemia (when not desired), nausea, vomiting, diarrhea, and mucositis. Rarely, gallium nitrate produces neurotoxic effects such as hearing loss, visual disturbances, paresthesias, and mental status changes.

Potential Drug Interactions: None reported.

Clinical Indications in Hematology: Gallium nitrate has shown promising results in the treatment of hypercalcemia associated with malignancy, in prevention of bone loss in patients with multiple myeloma, and in the treatment of refractory lymphomas.

Glucocorticoids

Chemistry and Mechanism of Action: Glucocorticoids are synthetic compounds derived from the natural adrenal hormone cortisol. Glucocorticoids mediate their biologic actions predominantly by binding to their cytosolic receptor, which then translocates to the nucleus. There, as a homodimer, it binds to specific DNA

sequences located in the regulatory regions of a number of genes. Gene transcription can be up- or downregulated by glucocorticoids. They can also inhibit binding of the AP-1 transcription factor to its DNA consensus sequence site. Lymphocytes treated with glucocorticoids undergo apoptosis mediated by glucocorticoid receptors. An early cytostatic phase is marked by growth inhibition and cessation of proliferation due to inhibition of cellular uptake of glucose, amino acids, and nucleosides as well as inhibition of macromolecular synthesis. This is followed by a cytolytic phase characterized by chromatin condensation and internucleosomal DNA cleavage.

Absorption, Fate, and Excretion: Many synthetic glucocorticoids are available; the three most commonly used in hematology are prednisone, dexamethasone, and methylprednisolone. The glucocorticoids are well absorbed orally and are metabolized primarily in the liver. Unlike the other two glucocorticoids, the activity of prednisone is dependent on hepatic conversion to the 11-hydroxy form (prednisolone). The biologic half-lives of prednisone and methylprednisolone are approximately 1236 hours, whereas dexamethasone has a biologic half-life of 3672 hours. Plasma half-lives for all three drugs are 34 hours. Compared with cortisol, the relative anti-inflammatory potencies of dexamethasone, methylprednisolone, and prednisone are 25, 5, and 4, respectively, for equivalent doses.

Preparation and Administration: Prednisone is available only for oral administration; methylprednisolone and dexamethasone are available in oral and parenteral dosage forms.

Toxic Effects: When glucocorticoids are used for <14 days, as is often done when they are employed in combination with other cytotoxic agents, the most common side effects include euphoria, insomnia, psychosis, hyperglycemia, hypokalemia, increased appetite, metabolic alkalosis, proximal muscular weakness, and fluid retention with edema formation and hypertension. When used on a chronic basis, glucocorticoids also may induce a cushingoid appearance, easy bruisability, peptic ulcers, osteoporosis, subcapsular cataracts, and increased susceptibility to infections related to impaired cellular immunity. Because of this, H_2 blockers, antifungal agents (e.g., ketoconazole), and/or sulfamethoxazole-trimethoprim have been employed in certain glucocorticoid chemotherapy combinations.

Potential Drug Interactions: Glucocorticoids interact with a variety of drugs, including barbiturates, oral contraceptives, erythromycin, hydantoins, rifampin, isoniazid, and salicylates. Given the wide range of doses of glucocorticoids used, however, these interactions are of no major clinical relevance.

Clinical Indications in Hematology: Glucocorticoids have direct anticancer activity in many hematologic malignancies, including ALL and CLL, Hodgkins and non-Hodgkins lymphomas, and plasma cell neoplasms. Because of their efficacy and toxic profiles, which do not overlap with the toxic effects of the other cytotoxic agents, glucocorticoids are employed in many chemotherapy regimens. In addition, they are useful in the management of hypercalcemia secondary to myeloma and lymphomas and are of paramount importance in the treatment of autoimmune hematologic disorders.

Chapter 51 - Clinical Application of Cytokines and Biologic Response Modifiers

Michael S. Gordon
Jeffrey A. Sosman

INTRODUCTION

Cytokines and biologic response modifiers (BRMs) represent a broad class of therapeutic agents that modify the hosts response to cancer or cancer therapy. Table 51-1 summarizes the biologic therapies currently in clinical use or undergoing clinical evaluation (see also Chap. 14). Many of the biologic agents evaluated to date activate natural host immune defense mechanisms. However, the term biologic response modifier is not equivalent to immunotherapy of cancer. Many of these agents exhibit direct biologic effects on malignant cells and may act as

TABLE 51-1 -- Cytokines/Biologic Response Modifiers

Recombinant Cytokine	Molecular Weight (kd)	Principle Cell Source	Biologic Activities	References
IL-1 and IL-1	1417	Monocyte/macrophages DC, B, T, NK cells, fibroblasts, epithelial cells, endothelial cells	Stimulates primitive lymphohematopoietic progenitors; induces secondary cytokine release	[134] [135] [136] [137] [138] [139] [140] [141] [142] , [144]
IL-2	15	T cells	Activates T-cell proliferation; induces cytokine production from NK and T cells; induces proliferation of NK and B cells; induces cytotoxicity in T and NK cells; activates monocyte cytotoxicity	[229] [239] [240]
IL-3 (multi-CSF)	28	T cells, myelomonocytic cells	Induces proliferation of myeloid (including eosinophilic), erythroid, and megakaryocytic progenitors; stimulates early lymphoid development	[143] [144] [145] [146] [147] [148] [149] [150] [151] [152] [153] [154] , [156] [157] [158] [159] [160] [161] [162] [163] [164]
IL-4	1520	T cells, mast cells	Induces T-cell proliferation and cytotoxicity; enhances antigen-specific T-cell responses; enhances growth of mast cells and stimulates monocyte cytotoxicity; stimulates Th2 helper responses; inhibits Th1 helper responses; enhances expression of MHC and adhesion molecules	[284] [285] [286] [287] [288] [289] [290]
IL-5	1218	T cells	Induces proliferation of eosinophils; enhances B-cell antibody production	[11] [12] [13] [14]
IL-6	2129	T cells, macrophages, fibroblasts	Stimulates megakaryocytic maturation and induces thrombopoiesis; stimulates B-cell proliferation and immunoglobulin production; synergistic with early-acting factors for primitive progenitor cell proliferation; induces hepatocyte protein synthesis	[155] , [165] [166] [167] [168] [169] [170] [171] [172] [173] [174] [175] [176] [177] [178] [179] [180] [181] [182] [183] [184] [185] [186] [187] [188] [189] [190] [191]
IL-7	25	Stromal cells (BM)	Co-stimulates T-cell proliferation and cytotoxicity; induces monocyte cytotoxicity; supports growth of B-cell precursors	
IL-8, RANTES, etc.	816	Monocytes/macrophages T cells, fibroblasts	Induces neutrophil chemotaxis; removes proliferating hematopoietic cells from S-phase (similar to other chemokines)	
IL-9	3239	T cells (helper)	Stimulates specific T-cell growth; stimulates mast cells; supports IgE production from B cells with IL-4	
IL-10	1721	T cells, B cells	Inhibits production of cytokines from Th1 cells (IFN; inhibits monocyte activation and cytokine release; inhibits NK cell production of IFN; co-stimulates T-cell proliferation and cytotoxicity	
IL-11	24	Fibroblasts, adipocytes, endothelial cells, monocytes	Induces megakaryocyte maturation and thrombopoiesis; synergistic with early-acting factors for primitive lymphohematopoietic proliferation; induces B-cell Ig production via accessory T cells, inhibits adipogenesis; induces hepatocyte protein synthesis	[192] [193] [194] [195] [196] [197] [198] [199] [200] [201] [202]
IL-12	75 (3540)	B-lymphoblastoid cell lines, activated T cells, monocytes, keratinocytes, mast cells, and DC	Induces TH1 responses; potent induction of IFN from NK and T cells; antimetastatic, anti-angiogenic effects	[307] [308] [309] [310] [311] [312] , [313] [314] [315] [316] [317] [318] [319] [320]
IL-13	132aa	T cells	Induces B-cell activation; induces expression of MHC and CD23 on B cells	
IL-14	468aa	T cells	Induces B-cell proliferation and inhibits B-cell immunoglobulin production	

IL-15	114aa	Monocytes, fibroblasts, epithelial cells, and stromal cells (bone marrow and thymus)	Activation of NK cell proliferation and cytotoxicity; activates T-cell proliferation	[322] [323] [324] [325] [326] [327]
IL-16	56 (tetrameric)	Activated T (CD8+) cells; eosinophils	Chemoattractant for CD4+ lymphocytes; induces proliferation of CD4+ T cells; chemoattractant for eosinophils and monocytes; ligand for CD4; inhibits T-cell receptor activation; inhibits HIV promoter	
IL-17	155aa	CD4+ T cells	Co-stimulation of T cells; induces IL-6 and IL-8 from fibroblasts; induces stromal cells (endothelial cells, epithelial cells, etc.) to secrete G-CSF, IL-6, IL-8, and PGE2	
IL-18	18	Activated macrophages and Kupffer cells	Induces IFN from NK and T and B cells especially with IL-12; inhibits osteoclast activity; augments NK activity; enhances GM-CSF and inhibits IL-10 from activated PBMC	
IFN or IFN	1627	Leukocytes/fibroblasts	Antiproliferative; enhances antigen and MHC class I expression; augments NK activation; anti-viral effects; anti-angiogenic effect; effects expression of adhesion receptors; induces differentiation of tumor cell lines	[338] [339]
IFN	15.525	T cells, NK cells, and monocytes	Induces monocyte activation; induces MHC class II and I and tumor antigen expression; activates CTL; induces B-cell antibody production	
TNF	17/26	Monocytes/macrophages, T cells	Stimulates T-cell proliferation, activates NK cells; activates monocyte cytotoxicity; activates neutrophils; has direct effects on vascular endothelial cells; disrupts lipid metabolism; induces acute phase reactants	[61] [62] [63] [64] [65] [66] [67] [68] [69]
G-CSF	2025	Stromal cells, endothelial cells, and monocytes/macrophages	Induces proliferation and maturation of neutrophilic precursors and progenitors; mobilizes myeloid progenitors into peripheral blood; activates neutrophil function	[12] [15] [16] [17] [18] [19]
GM-CSF	1830	Fibroblasts, stromal cells, endothelial cells, and T cells	Induces proliferation and maturation of neutrophilic, monocytic precursors and progenitors; mobilizes myeloid progenitors into peripheral blood; activates neutrophil/monocyte function; induces eosinophilia; weak activator of NK cell activity	[41] [42] [43] [44] [45] [46] [47] [48] [49] [50] [51] [52] [53] [54] [55] [56] [57] [58] [59] [60] [61] [62] [63] [64] [65] [66]
M-CSF	45	Monocytes, endothelial cells, and fibroblasts	Monocyte differentiation and proliferation; activates monocyte cytotoxicity and ADCC; enhances expression of secondary cytokines and costimulatory molecules on monocytes	[407] [408] [409] [410] [411] [412] [413] [414] [415] [416] [417] [418] [419] [420] [421] [422]
SCF/kit ligand	3035		Induces primitive and committed progenitor cell proliferation; synergistic with other factors for multiple lineage effects; induces activation and proliferation of mast cells	[104] [105] [106] [107] [108] [109] [110] [111] [112] [113] [114] [115] [116] [117] [118] [119] [120] [121] [122] [123] [124]
Thrombopoietin	153332aa	Hepatocytes, kidney, bone marrow stromal cells	Stimulates broad range of megakaryocytic (MK) progenitors and precursors; induces increases in number and maturation of MKs; promotes thrombopoiesis; has indirect effects on myelopoiesis and erythropoiesis	[203] [204] [205] [206] [207] [208] [209] [210] [211] [212] [213] [214] [215] [216] [218] [219] [220] [221]
Flt3 ligand	1829	Stromal cells and stem cells	Stimulates hematopoietic progenitor cells; costimulates colony formation with lineage-specific growth factors; induces proliferation of DC cells and their maturation with other cytokines	[328] [329] [330] [331] [332] [333] [334]
PIXY321	IL-3/GM-CSF fusion protein	Fibroblasts, stromal cells, endothelial cells and T cells; myelomonocytic cells	Enhances in vitro activity on myelomonocytic, erythroid, and megakaryocytic lineages	[125] [126] [127] [128] [129] [130] [131] [132] [133]
Erythropoietin	35	Renal peri-tubular cells	Stimulates erythroid progenitor proliferation and erythroid maturation	[67] [68] [69] [70] [71] [72] [73] [74] [75] [76] [77] [78] [79] [80] [81] [82] [83] [84] [85] [86] [87] [88] [89] [90] [91] [92] [93] [94] [95] [96] [97] [98] [99] [100] [101] [102] [103]

MCH, major histocompatibility complex; PBMC, peripheral blood mononuclear cell.

differentiating, antiproliferative, and/or cytotoxic agents. These effects are independent of their immunomodulatory activities. There has been a considerable focus on cytokines and BRMs in the treatment of cancer patients over the past 12 decades. Advances in cellular and molecular biology have permitted the isolation, identification, genetic cloning, and pharmacologic production of purified recombinant proteins that were previously available only in scant quantities. In addition, significant progress has been made in understanding the regulation of the immune system and the molecular nature of an immunologic response to cell-surface antigens within the context of the major histocompatibility complex (MHC). This has had its greatest effect on the development of vaccine strategies directed at cancer.

Immune cells secrete two major classes of soluble proteins. One is the class of immunoglobulin (Ig) molecules (antibodies) that bind soluble antigens and activate B cells through Ig surface receptors. The other class of soluble molecules secreted by lymphocytes and monocytes are true hormones that act upon many different target cells both within and outside the immune system. The term interleukin denotes the activity between leukocytes. Cytokines represent the class of glycoproteins, which includes interleukins (ILs), interferons (IFNs), and colony-stimulating factors (CSFs). A system for naming cytokines has been developed by the International Congress of Immunology. A cytokine is initially described based on biologic properties, but once the amino acid sequence is defined, an interleukin number is assigned. The system has some exceptions and inconsistencies; for historical reasons, some cytokines retain their original names (i.e., IFNs and CSFs). To date, 18 ILs have been identified.

Over the past 10 years, cytokine therapy has in many ways revolutionized the fields of hematology and oncology. The use of CSFs and hematopoietic growth factors (HGFs) to support patients receiving chemotherapy has permitted the implementation of higher chemotherapy doses with a significant reduction in toxicity. [1] In addition, cytokine therapy has expanded treatment options for patients with various malignancies, particularly hematologic malignancies.

When considering the use of cytokines during the treatment of malignancies, one must be aware of the increasing evidence that some cytokines are aberrantly expressed by malignant hematopoietic cells and may participate pathogenetically through autocrine or paracrine regulatory loops in the expansion of the tumor. [2] IL-1 and tumor necrosis factor- (TNF-) have been found to be constitutively expressed by virtually all leukemias, both myeloid and lymphoid. [3] [4] Receptors for TNF have been detected on the surface of hairy cell leukemia (HCL) and B-cell chronic lymphocytic leukemia (CLL) cells; in vitro studies have shown that TNF promotes survival and induces proliferation of these malignant cells. [5] The mRNA for TNF, IL-1, and IL-6 have been detected in some malignant lymphoid cell lines. [6] Contradictory data have been reported concerning the expression of other cytokines by CLL cells and the consequences of this cytokine production on stimulation of leukemia cell proliferation. [7] With the exception of acute myeloid leukemias (AMLs), cytokines have not been found to have an in vivo proliferative effect on malignant tumors.

GENERAL PRINCIPLES OF THERAPY

Cytokines are low-molecular-weight (1540,000 dalton) glycoproteins that act primarily in a paracrine or autocrine fashion and are therefore short-range mediators. The cytokines in general bind to their cell surface receptors which are part of a family called the hematopoietin (cytokine) receptor superfamily. The receptors that are part of this family are all transmembrane (TM) glycoproteins with four positionally conserved cysteines, a conserved WSXWS motif and Ig, fibronectin type III domains. Intracellular portions of these molecules include two box regions, one with proline and hydrophobic regions, and a second with two charged amino acids and hydrophobic regions. These domains are critical for binding to associated intracellular molecules such as the JAK kinases which lead to signaling mostly through a family of intracytoplasmic molecules called STAT molecules, which then translocate into the nucleus and activate gene transcription. Ultimately, changes in protein synthesis lead to alterations in cellular proliferation, growth inhibition, enhanced cytotoxicity, production of secondary cytokines, and/or modulation of the biologic effects of other cytokines. Many of the cytokines have multiple and overlapping functions. The action of a cytokine may depend on the local concentration of the cytokine, target cell type, available effector cells, and presence of other signal molecules.

Several principles of cytokine therapy are distinct from those used during the administration of traditional chemotherapy. First, for most of the cytokines, a simple dose-response relationship does not exist. It is not clear in many cases whether the optimal biologic dose is the maximum tolerated dose and whether either correlates with antitumor responses. Second, treatment with chemotherapy, if effective, is associated with a prompt response. By contrast, the therapeutic response to cytokines may develop slowly and take months to document. In addition, cytokine therapy is associated with unique toxicities, including fever, rigors, flu-like symptoms, and, for many agents, a capillary leak syndrome at higher doses. The side effects occur acutely, are generally short-lived, and abate with discontinuation of therapy. Long-term chronic toxicities are rare but can occur, and include autoimmune phenomena and cardiac toxicity. [8]

The cytokines approved by the Food and Drug Administration (FDA) for clinical use are still few in number and include granulocyte-CSF (G-CSF) and granulocyte/macrophage-CSF (GM-CSF) which are utilized primarily to accelerate recovery from granulocytopenia following myelosuppressive chemotherapy or bone marrow transplantation (BMT), respectively; erythropoietin (EPO), for the treatment of chemotherapy-associated anemia, human immunodeficiency virus (HIV)-associated anemia and the anemia associated with renal failure; IL-11 for the prevention of severe chemotherapy-induced thrombocytopenia; IFN- for the treatment of chronic myelogenous leukemia (CML), low grade non-Hodgkin lymphoma, hairy cell leukemia (HCL), Kaposis sarcoma in patients with acquired immunodeficiency syndrome (AIDS), and adjuvant therapy for high-risk melanoma and for certain viral syndromes, IFN- for the treatment of multiple sclerosis, IFN- for the treatment of chronic granulomatous disease, and IL-2 for the treatment of metastatic renal cell cancer and metastatic melanoma.

This chapter covers each of the HGFs and BRMs currently in clinical use, or undergoing clinical evaluation with the prospect of finding a significant role in cancer therapy. For a review of the biology of these agents, the reader should refer to Chapter 14 .

HEMATOPOIETIC GROWTH FACTORS

The HGFs are a family of glycoproteins primarily responsible for the proliferation, differentiation, and maturation of the hematopoietic system. Many of these agents have effects not only on blood-forming cells, but also on bone marrow stroma, stimulating the secondary release of cytokines, or enhancing the microenvironment to favor cellular growth. These factors can broadly be divided into early-acting (predominantly proliferative) and late-acting (primarily maturational) agents. The early-acting HGFs act primarily at the level of noncommitted progenitors, resulting in proliferation of these often pluripotential cells. The late-acting factors exert their effects at the level

of committed progenitors. They are responsible for the differentiation of these more mature cells, as well as having effects on terminally differentiated effector cells. The potential clinical effects of HGFs are summarized in Table 51-1 .

The clinical use of the HGFs has concentrated mainly on their ability to stimulate the production of peripheral blood cells. The use of HGFs in the treatment of various diseases, both malignant and nonmalignant, has been studied. HGFs have found their greatest potential application with their use following the administration of intensive chemotherapy with or without progenitor cell support. The primary concern regarding the use of HGFs in patients with cancer is whether cytokines can stimulate malignant cell growth. While in vitro studies have provided some evidence that some HGFs promote tumor cell growth, with the exception of AML, no malignancy has been shown in vivo to be stimulated by HGF therapy. [9] The following sections discuss the clinical development of the clinically applicable cytokines.

Granulocyte-Colony-Stimulating Factor

G-CSF was the first of the myeloid growth factors to be approved by the FDA. Its primary use is in the post-chemotherapy setting, reducing the depth and duration of chemotherapy-induced neutropenia as well as decreasing the incidence of episodes of febrile neutropenia. G-CSF was initially identified and purified by investigators at Memorial Sloan-Kettering Cancer Center during the mid-1980s. [10]

The biologic properties of G-CSF have been well studied, and it appears to be a lineage-restricted HGF, having its principle effect on the neutrophilic granulocyte series. [11] It is present in serum during normal conditions and in disease states. [12] G-CSF is capable not only of reducing the time required for maturation of a committed progenitor pool, but of prolonging the life span of mature effector cells (neutrophilic granulocytes) in the circulation. In addition, G-CSF is an activator of neutrophil function and has been demonstrated to have the ability, both in vitro and in vivo, to prime neutrophils for the activation of the respiratory burst, enhance chemotaxis, and increase phagocytosis. These effects are seen not only on neutrophils of normal subjects, but also in those with hematologic disorders, such as the myelodysplastic syndromes, which are characterized by distinct abnormalities of polymorphonuclear leukocyte function. [13]

Clinical Applications

Phase I trials with G-CSF demonstrated minimal toxicity over a wide range of doses tested. With administration of the agent either intravenously or preferably subcutaneously, dose-related increases in peripheral blood neutrophils were observed, but effects on other nonmyeloid lineages were not evident. Increased bone marrow cellularity with enhanced numbers of committed bone marrow progenitors as well as mobilization of these cells into the circulation was observed following treatment. Side effects of G-CSF include bone pain (due to medullary expansion), elevation of certain serum enzymes representative of increased cellular turnover (leukocyte alkaline phosphatase and lactate dehydrogenase), potential exacerbation of dermatologic conditions such as psoriasis or Sweets syndrome (neutrophilic dermatitis), and with chronic therapy, splenomegaly and hair loss. Fever is not a characteristic side effect of G-CSF.

After Chemotherapy

Following the recognition by Bodey et al. [14] that both the depth and duration of neutropenia correlate with the incidence of infection in myelosuppressed hosts, the need for an agent that could reduce this risk was evident. Because of its ability to promote increases in peripheral blood neutrophil numbers, G-CSF was judged to be an ideal agent to alter the incidence and severity of chemotherapy-induced myelosuppression. Initial studies performed in the post-chemotherapy setting demonstrated an apparent benefit associated with G-CSF therapy. In a phase I trial reported by Gabrilove et al., [15] treatment with G-CSF resulted in a reduction in the severity of neutropenia and the ability to deliver chemotherapy in a more timely fashion in patients with bladder cancer receiving MVAC chemotherapy. These investigators also noted an apparent reduction in the incidence of mucositis in courses of therapy in which G-CSF was administered. Bronchud et al. [16] demonstrated that with the use of G-CSF, doxorubicin chemotherapy for women with breast and ovarian cancer could be intensified from doses of 75 mg/m ^{2} to doses of 150 mg/m^2 administered every 2 weeks. Morstyn et al. [17] studied the relationship between the time of G-CSF administration and the administration of chemotherapy. Although a delay in the initiation of G-CSF therapy was associated with a deeper neutrophil nadir, the neutrophil recovery was essentially the same as that seen in patients for whom G-CSF therapy was initiated 1 day after chemotherapy. It is important to recognize that delayed therapy may be associated with a reduced benefit with regard to eliminating the incidence of febrile neutropenia.

The greatest benefit from the administration of G-CSF occurs after the use of chemotherapy regimens commonly associated with a high risk of developing neutropenic fever (defined as fever occurring during prolonged, severe neutropenia). Neidhart et al. demonstrated that repeated cycles of high-dose chemotherapy can be safely administered without progenitor cell reinfusions with the adjunctive use of G-CSF. [1] Recovery of granulocytes was found to be significantly faster in cycles containing G-CSF than in those without. The benefit of the administration of G-CSF after chemotherapy was tested in two large phase III trials conducted in the United States and Europe. [18] [19] These trials compared the use of G-CSF versus placebo in patients with small cell lung cancer receiving chemotherapy composed of cyclophosphamide, doxorubicin, and etoposide. Although these studies have been criticized for the use of overly intensive doses of chemotherapy, they clearly demonstrate that with adequate myelosuppression, a benefit of G-CSF can be identified. The study by Crawford et al., [18] conducted in the United States, allowed crossover to the G-CSF arm for any patients who received placebo therapy and experienced a neutropenic fever during any course of therapy. For this reason, the maximum data derived from this study are from the first cycle of chemotherapy when all patient therapy was double-blinded. These data demonstrate that the use of G-CSF results in a reduction of the incidence of neutropenic fever by approximately 2530% when the overall incidence of the event approaches 5060%. In addition, the number of days of antibiotics required, as well as the number of days of hospitalization, was reduced by the administration of G-CSF. In the European study, which did not allow crossover and therefore maintained the double-blind format, similar results were observed with regard to the incidence of neutropenic fever. No survival benefit for the patients treated on the G-CSF arm has been seen. Although there is little doubt that G-CSF has the ability to reduce neutropenia following chemotherapy, it is critical to determine which regimens are myelosuppressive enough to warrant routine use of this agent. The American Society of Clinical Oncology has established guidelines stating that the use of a CSF to prevent febrile neutropenia is warranted when the expected risk of such an event is predicted to exceed 40%. [20] To date, no controlled randomized trial has demonstrated a survival benefit for the adjunctive use of any CSF.

Most clinical studies have focused on the use of G-CSF to prevent episodes of neutropenic fever. Two studies have evaluated the use of G-CSF in patients with an established neutropenic fever. [21] [22] In the largest study, 216 patients with solid

tumors, lymphoma, or acute lymphocytic leukemia (ALL) were randomized on admission to receive either G-CSF or placebo by continuous subcutaneous infusion. Although patients treated with G-CSF generally had fewer days of hospitalization, fewer days of neutropenia, and fewer febrile days, the true benefit appeared to be experienced by patients with solid tumors or those with clinically documented or culture-positive infections. Similar results were seen in the second study. Although these two studies appear to define a subset of patients who may benefit from the use of G-CSF in this setting, they also demonstrate the lack of necessity for every patient to be treated in this manner. Timing of G-CSF was studied in a randomized trial conducted by the North Central Cancer Group (NCCG). In this trial, patients were followed and randomized between G-CSF and placebo once their absolute neutrophil count actually fell below 1,000 cells/l. The authors sought to determine whether the initiation of therapy once neutropenia had developed but before a febrile episode had occurred was worthwhile in preventing the latter. In this randomized trial, there was no statistically significant difference in the incidence of febrile neutropenia. Neither the duration of hospitalization or antibiotic therapy though recovery to an ANC >500 cells/l was accelerated by G-CSF (2 days vs. 4 days). [23] Hence, the early initiation of G-CSF is crucial for maximal activity. Late initiation, in general, is no better than no initiation.

The use of G-CSF in patients with acute leukemias has been extensively studied. Ohno et al. [24] published their initial observations in patients with both myeloid and lymphoid leukemias treated with G-CSF following intensive induction chemotherapy. There appeared to be a reduction of chemotherapy-related toxicity in the patients treated on the G-CSF arm. No evidence of increased relapse rate or poorer outcome with G-CSF therapy was seen. The use of G-CSF following induction chemotherapy in elderly patients with myeloid malignancies has been studied. G-CSF resulted in an apparent reduction in therapy-related morbidity and mortality characterized by fewer severe infections compared with historical controls. No negative impact on remission induction was seen but the effect on survival remains unknown. Randomized, placebo-controlled trials in patients with AML undergoing induction and consolidation therapy have demonstrated an apparent improvement in infection rates and a reduction in the number of days of neutropenia. Although several studies have been neutral with regard to the survival benefit of adjunctive G-CSF, no evidence of worsened outcome has been seen. [25] [26] As a result, G-CSF has received an expanded approval covering its use in AML patients.

Following Autologous and Allogeneic Bone Marrow Transplantation

The use of G-CSF following high-dose chemotherapy with progenitor cell support has been shown to reduce the time to engraftment and recovery from neutropenia in patients receiving progenitors derived from either bone marrow or peripheral blood. [27] G-CSF as a single agent, however, does not appear to affect the time for engraftment of either platelets or red cells. The most frequently studied doses of G-CSF in this setting are in a range of 510 g/kg/day, administered predominantly by subcutaneous injection. The benefits of G-CSF in this setting have been seen in patients with solid tumors as well as those with lymphomas. No large randomized trials have been performed using the myeloid growth factors in patients with AML undergoing autologous BMT, though no prospective trial has shown a worsened outcome as a result of G-CSF use in this patient population.

Nonrandomized data regarding the use of G-CSF following allogeneic BMT are limited. Several small series of patients have been reported, demonstrating reduced time to myeloid engraftment, and no increase in the incidence of acute graft-versus-host disease (GVHD). [28] These studies, however, are preliminary and therefore cannot address the larger issue of risk of leukemic relapse in the AML or ALL patients treated. For this reason, it is prudent to consider the use of G-CSF in these patients as investigational.

G-CSF has long been known to have the ability to mobilize progenitor cells into the peripheral blood. The use of these mobilized peripheral blood progenitor cells (PBPC) after chemotherapy has resulted in rapid multilineage engraftment. G-CSF is administered for 710 days, generally by subcutaneous injection at a dose of 10 g/kg/day. This results in mobilization of significant numbers of PBPC which are then collected by leukopheresis on days 57. [29] With the increased use of PBPC for allogeneic BMT, G-CSF has become the preferred mobilizing agent for normal donors. The use of this agent is associated with few short-term and no expected long-term toxicities and allows donors to avoid the inconvenience of a bone marrow harvest and provides an accelerated hematologic recovery. [30]

Bone Marrow Failure States

Negrin et al. [31] [32] evaluated the use of G-CSF in patients with myelodysplastic syndromes (MDSs). Serial dose escalation of G-CSF in patients with <20% blasts resulted in significant increases in white blood cell (WBC) counts and absolute neutrophil counts (ANC). In 18 patients with MDS treated for 68 weeks with subcutaneously administered G-CSF, 16 of the 18 patients demonstrated an increase in both leukocyte and granulocyte counts. There were no changes in platelet counts, while 3 of 12 red-cell-transfusiondependent patients experienced a decrease in their transfusion requirement. All peripheral counts returned to pretreatment values after discontinuation of the agent. Eleven of the patients received chronic administration of G-CSF for >11 months, with persistence of the leukocyte effects. No patients experienced transformation of their MDS to AML while on G-CSF. Studies are focusing on the combination of G-CSF and erythropoietin (EPO) in this patient population. A study performed by Negrin et al. [33] demonstrated that the combination of G-CSF with EPO therapy resulted in neutrophilic responses in all evaluable patients, and erythroid responses in 42% of those treated. Responding patients generally had a lower endogenous serum EPO level than that of nonresponders. Similar responses to G-CSF therapy alone have been seen in patients with other bone marrow failure states, such as aplastic anemia.

Patients with Primary or Secondary Neutropenia

The neutropenic states represent a category of diseases for which G-CSF has become the therapy of choice. Most adults presenting with mild to moderate neutropenia (for whom increased neutrophil margination and drug-induced neutropenia have been ruled out) are categorized as having idiopathic neutropenia. This disorder is characterized by a neutrophil count of <500 cells/l and an increase in infectious complications. Cyclic neutropenia is characterized by cyclical hematopoiesis affecting multiple lineages. Neutrophil counts in these patients oscillate with a periodicity of approximately 21 days, often dropping to levels of near zero and rarely reaching normal levels. During these periods of neutropenia, patients are at increased risk of infectious complications and often develop painful ulcerations of their mucosal surfaces. Finally, congenital forms of neutropenia, such as Kostmann or Schwachmann-Diamond syndrome, are associated with severe neutropenia and infectious complications that are usually manifested in the first year of life and can be life-threatening. The use of G-CSF in each of these states has been studied; therapy results in an increase in the number of circulating neutrophils and reduction in the number of infectious complications. [34] [35] [36] G-CSF should be the initial line of therapy once the appropriate diagnostic

workup has been completed. Although no distinct evidence indicates that chronic G-CSF therapy will result in an increased risk of the emergence of leukemic disorders, such concern exists because it is known that some chronic bone marrow failure disorders (such as aplastic anemia or Fanconis anemia) can evolve into clonal hematologic disorders. Pilot studies in this latter disorder have demonstrated small numbers of multi-lineage responses to G-CSF. [37] Neutropenia that complicates hematologic diseases such as HCL or CLL has been shown to be responsive to G-CSF therapy. [38] Neutropenia of an autoimmune etiology, such as occurs in Feltys syndrome or that associated with systemic lupus erythematosus, tends to respond less well to G-CSF, probably due to the presence of antineutrophil antibodies.

Infectious Disease

Whether G-CSF will be of benefit in patients suffering from severe infections not associated with neutropenia is the focus of a randomized trial in patients with pneumonia. In that study, patients with community-acquired pneumonia are randomized to G-CSF or placebo as an adjunct to antibiotic therapy. No survival advantage was seen for the incorporation of G-CSF, though earlier discharge from the hospital was noted. Overall, the use of G-CSF in patients with community-acquired pneumonia is not yet indicated. It is likely that there are subsets of patients, such as those with severe burns, who may benefit from G-CSF therapy in this setting. The beneficial effect of G-CSF may be a result of its ability to enhance effector cell function and to reduce the mortality due to superinfection in these patients.

The use of G-CSF in patients with AIDS has been studied. G-CSF has been shown to reduce neutropenia related to retroviral therapy, permitting the administration of high doses of antiviral drugs, and is approved for this indication. [39] [40]

Granulocyte/Macrophage-Colony-Stimulating Factor

GM-CSF has been approved by the FDA for its use in patients undergoing high-dose chemotherapy and BMT, as well as for the treatment of neutropenia following induction therapy in elderly patients with AML. GM-CSF is a glycosylated molecule with a molecular weight of 14.532 kD. It is encoded by a gene on the short arm of chromosome 5.

Unlike G-CSF, GM-CSF has effects on multiple stages of hematopoiesis. In vitro, it appears to act synergistically with other factors (e.g., IL-3) to stimulate the production of erythroid and multipotential colonies. [41] In vivo, GM-CSF stimulates the proliferation and maturation of myeloid cells, including neutrophils and eosinophils. In addition, at variable doses, GM-CSF has potent monocyte/macrophage potentiating ability, as well as effects on dendritic cells. Similar to G-CSF, GM-CSF can activate effector cells and enhance their function. GM-CSF primes neutrophils for the respiratory burst and enhances phagocytosis. Unlike G-CSF, GM-CSF reduces chemotaxis. GM-CSF is a locally active factor at the site of inflammation, felt to be responsible for inhibiting the ability of effector cells to migrate away from this site.

Clinical Applications

Phase I trials with GM-CSF demonstrated several important aspects of its use. While it is well-tolerated at clinically effective doses for the treatment of neutropenia, its toxicity at higher doses is composed of arthralgias, myalgias, fever, and serositis (pleuropericarditis). At doses of approximately 5 g/kg/day (250 /m ^{2} /day). GM-CSF appears to have a primarily myeloid effect, promoting increased production of neutrophils and eosinophils. At higher doses, macrophage production and activation become apparent, and it is possible that the toxicity related to GM-CSF is primarily associated with this monocyte macrophage activation (possibly related to a secondary cytokine cascade). Toxicity due to GM-CSF appears to be altered depending on the route of administration. Lieschke et al. [42] reported on the first-dose effect seen in their phase I clinical trial. This toxicity occurred much more frequently in patients treated with intravenous bolus than in those treated with subcutaneous therapy. The first-dose effect is characterized by a constellation of symptoms, including dyspnea, flushing, tachycardia, hypotension, and musculoskeletal pain. It typically occurs several hours after the first dose of GM-CSF in a given cycle and may occur with the first dose of each cycle that a patient receives. It is self-limiting, and patients need only be treated with supportive care. This phenomenon, which may be related to sequestration of neutrophils in the pulmonary microcirculation, appears to be more prevalent with the nonglycosylated bacterially derived formulation of GM-CSF as compared with the glycosylated yeast-derived agent (the FDA-approved formulation).

After Chemotherapy

As with G-CSF, GM-CSF has been studied for its ability to reduce the depth and duration of neutropenia following the administration of chemotherapy. While broad chemotherapy-induced neutropenia is not the primary indication for this agent, several studies address its use in this clinical setting. In a randomized trial of lymphoma patients receiving cyclophosphamide, vincristine, prednisone-bleomycin, leucovorin, doxorubicin, methotrexate (COP-BLAM), GM-CSF reduced chemotherapy-induced neutropenia as well as days of fever and hospitalization. [43] Other randomized trials have been less impressive. Bunn et al. [44] demonstrated an inferior response rate to primary therapy in patients with limited-stage small-cell lung cancer receiving GM-CSF treated with chemotherapy and radiotherapy. Patients treated with GM-CSF, while having a reduction in granulocytopenia, experienced more infections and febrile days as well as a greater degree of thrombocytopenia. The presence of fevers as a possible side effect of GM-CSF confounds the interpretation of randomized trials. For this reason, the ability of GM-CSF to have an impact on chemotherapy-induced neutropenia remains to be proven in a large-scale randomized trial.

A major development in the use of GM-CSF was the demonstration of its ability to reduce the mortality related to induction chemotherapy in patients with AML, Rowe et al. studied GM-CSF administered from the time of documentation of bone marrow aplasia compared to placebo controls. In these patients (>55 years old), the addition of GM-CSF not only accelerated neutrophil recovery but was also associated with a statistically significant improvement in overall survival (GM-CSF 10.6 months vs. placebo 4.8 months, $P = 0.048$).[45] Other randomized trials have failed to show a survival advantage from the use of GM-CSF although the benefit of accelerated neutrophil counts has generally been confirmed. [46]

After Autologous and Allogeneic Bone Marrow Transplantation

GM-CSF has been studied extensively in patients undergoing high-dose chemotherapy with autologous progenitor cell support. Nemunaitis et al. [47] [48] reported on the use of this agent in patients undergoing autologous bone marrow transplantation for lymphoid malignancies. Therapy with GM-CSF following reinfusion of marrow resulted in a shorter time to myeloid recovery, fewer infections, and shorter hospitalizations. This effect has been confirmed by other investigators in similar patient populations.[49] [50] Similar results have been seen in patients with solid tumors undergoing high-dose chemotherapy with autologous BMT. [51] In these settings, the dose of GM-CSF is 250 g/m^2 /day administered intravenously.

GM-CSF was evaluated for its effects in 37 patients with marrow graft failure following allogeneic (15 patients), autologous (21 patients), or syngeneic (1 patient) BMT.[52] GM-CSF was administered as a 2-hour infusion for 1421 days at doses of 601,000 g/m^2 /day. Nine of 15 allogeneic BMT patients, 11 of 21 autologous BMT patients, and 1 syngeneic BMT patient responded with increases of granulocytes to 1500 cells/l. Most patients maintained their granulocyte counts at >500 cells/l after discontinuation of GM-CSF. GM-CSF had no effect on platelet or red blood cell (RBC) counts. Fevers resolved in all responding patients. Toxicities were typical for GM-CSF and included primarily constitutional complaints.

Similar to G-CSF, the use of GM-CSF in the allogeneic BMT setting is under continued investigation. Studies reported to date suggest that GM-CSF is capable of reducing the time to myeloid engraftment without a significant impact on the development of GVHD. [53] Long-term follow-up will be required to determine whether the use of these myeloid agents will affect long-term disease-free survival.

Gianni et al.[54] were the first group to demonstrate that the use of GM-CSF after intensive chemotherapy resulted in the mobilization of PBPCs. Such grafts are highly effective following

WHICH PATIENTS SHOULD RECEIVE HGF THERAPY?

Although it is clear that both G-CSF and GM-CSF can reduce the depth and duration of neutropenia following myelosuppressive therapy, not all patients receiving chemotherapy are candidates for the use of these agents. In general, the use of hematopoietic growth factors benefits patients who are at a high risk of developing neutropenic febrile complications. Most standard regimens used in hematology/oncology do not promote sufficient neutropenia to warrant the routine use of these agents in cancer patients. Regimens associated with an incidence of febrile neutropenia <30% probably will not be affected by the addition of HGFs. In light of this, many cooperative groups as well as the National Cancer Institute are developing guidelines for the routine use of HGFs in clinical medicine.

Patients at high risk for the development of febrile neutropenic complications will generally benefit from the use of HGFs. Such patients include but are not limited to the following groups, and this list is meant to serve as a rough guide for the initiation of HGF therapy.

Patients with prior episode of febrile neutropenia in whom a dose reduction is not planned or patients with febrile neutropenia following dose reduction

Patients receiving intensive chemotherapy, either front line or salvage, with an increased incidence of febrile neutropenia complications (i.e., vinblastine, ifosfamide, cisplatin (VIP) salvage in germ cell tumors with 70% febrile neutropenia incidence)

Elderly or debilitated patients who in the judgment of the clinician will not tolerate a febrile neutropenia episode

Patients who are predisposed to severe myelosuppression (i.e., post-BMT or patients with bone marrow involvement)

For these patients, therapy with G-CSF or GM-CSF can be instituted after completion of chemotherapy.

With regard to the use of thrombopoietic growth factors, clinical judgment must be exercised since an alternative (platelet transfusions) exists for the clinical management of these patients.

GUIDELINES FOR THE USE OF CSFs

Therapy with both G-CSF and GM-CSF should be instituted approximately 24 hours after the last dose of chemotherapy. The use of G-CSF or GM-CSF concomitant with chemotherapy should still be considered investigational pending adequate data regarding toxicity of this approach.

Both G-CSF and GM-CSF can be administered by daily subcutaneous injection.

Both G-CSF and GM-CSF should be administered at a dosage of 5 g/kg/day.

The last dose of G-CSF or GM-CSF or IL-11 should precede chemotherapy by >24 hours.

Since premature discontinuation of G-CSF or GM-CSF can result in a drop in absolute neutrophil count, therapy should be continued until the absolute neutrophil count is >10,000 cells/l.

Monitor CBC and differential counts twice weekly while on therapy.

Interleukin-11 (Neumega) is FDA-approved for the prevention of chemotherapy-induced thrombocytopenia. It may be initiated within 624 hours following the completion of chemotherapy and should be continued until the post-nadir platelet count has exceeded 50,000/l.

high-dose chemotherapy. Since that time, various investigators have used GM-CSF for this purpose. [55] [56] Timing of pheresis has generally been on a schedule similar to that of G-CSF. When the growth factor is administered following chemotherapy administration, pheresis is often initiated when the ANC reaches a minimum of 1,000 cells/l, although some physicians use CD34 counts as an indication of when to harvest. [57]

Bone Marrow Failure States

GM-CSF has been studied in a series of phase I and II trials in patients with MDS. In three studies, GM-CSF was administered intravenously over a variety of doses.[58] [59] [60] Of the 26 patients studied in this manner, 23 demonstrated increases in leukocyte and granulocyte counts. Only 3 displayed any evidence of effect on other hematopoietic lineages. As in the responses seen with G-CSF, peripheral blood counts returned to pretreatment values after cessation of the administration of GM-CSF. Thompson[61] studied the effect of subcutaneously administered GM-CSF on 16 patients with MDS. Of 13 patients treated at doses of 1.0 g/kg/day, 11 demonstrated a significant increase in granulocytes that returned to pretreatment values after completion of therapy. Effects on other hematopoietic lineages were seen in only 2 patients. Progression to acute leukemia occurred in a total of 7 patients and was directly related to the pretreatment bone marrow blast percentage. The results of a randomized trial demonstrate a twofold or greater rise in granulocyte counts in 27 of 28 patients at a dose of 3.0 g/kg/day. [62] [63] No benefit on platelet counts or hemoglobin was detected, and only 1 patient on therapy progressed to acute leukemia.

The use of GM-CSF in patients with aplastic anemia has demonstrated its ability to transiently improve peripheral blood neutrophils but lacks the multilineage effect that was initially sought.[58] In addition, as in patients with MDS, responses in aplastic anemia patients are generally not durable, and counts quickly drop to pretreatment levels following cessation of therapy.

Patients with AIDS or HIV Infection

Patients with HIV infection or AIDS have received GM-CSF either to reduce neutropenia resulting from retroviral therapy or

as a component of a treatment plan in those with Kaposis sarcoma.[64] Levine et al.[65] reported on a small randomized trial in which patients who were hematologically intolerant of zidovudine (AZT) received GM-CSF either before the AZT was restarted or with continued AZT therapy. GM-CSF was administered subcutaneously with intra-patient dose escalation. All patients started at a dose of 1.0 g/kg/day and underwent dose escalation every 2 weeks to 3, 5, and 10 g/kg/day to maintain the ANC >1,000 cells/l. All patients were able to continue AZT therapy without significant neutropenia while GM-CSF was administered. No evidence of HIV proliferation (assayed by p24 antigen levels) was seen, and the regimen did not alter the ability to culture the virus from the peripheral blood mononuclear cells.

GM-CSF has not had demonstrable benefit in patients with congenital neutropenic disorders. It has been studied with some success both alone and in combination with IL-3 in children with amegakaryocytic thrombocytopenia.[66]

Erythropoietin

Erythropoietin (EPO) is a 34-kd glycoprotein whose primary function is the regulation of erythrocyte production. It is essentially lineage-specific in its effects on red blood cells. The regulation of EPO production is under the control of a simple feedback mechanism. EPO production is increased in hypoxemic conditions, and suppressed during times of hyperoxemia.[67] [68] Under normal conditions, the EPO level is maintained at approximately 1020 U/L of plasma. This level can rise exponentially when anemia develops.

The gene for EPO was initially cloned by two separate groups. Depending on the expression vector used, one can obtain either a glycosylated (Chinese hamster ovary cells) or nonglycosylated (*Escherichia coli*) form of the drug. Because native EPO is glycosylated, the mammalian cell-derived product is nearer to the natural product than the latter.[69] [70] In addition, the product derived from *E. coli* appears to have reduced in vivo activity, probably related to the lack of glycosylation.[71]

It was evident very early in the evaluation of the clinical value of EPO that it may have a significant impact on the treatment of anemia. The availability of sensitive radioimmunoassays permitted identification of disorders of EPO deficiency.[72]

Anemia of Renal Failure

Among the patients who were initially designated for the study of EPO were those with chronic renal failure (CRF). The use of EPO in this patient population is one of the most important advances in the field of clinical hematology. As one would expect, patients with nonfunctioning kidneys fail to produce EPO in sufficient amounts to support RBC production. The theory that the anemia related to CRF was at least partially due to EPO deficiency was confirmed by investigators in the United States and United Kingdom.[73] [74] Doses of 25500 U/kg three times per week were administered intravenously and resulted in a dose-dependent increase in hematocrits, while significantly reducing and even eliminating the need for RBC transfusion. In the large multicenter phase III trial reported by Eschbach et al.,[75] patients treated with EPO experienced increases in hematocrits. Those who were treated at initial dose of 300 U/kg three times per week achieved their target hematocrit within 68 weeks of therapy. Patients treated with a dose of 150 U/kg (same schedule) achieved their target hematocrit in approximately 10 weeks. The 333 patients enrolled in this study required 1,030 erythrocyte transfusions over the 6 months before study initiation. Within 2 months of EPO therapy, all patients were erythrocyte-transfusion independent and remained as such with continued EPO maintenance. The only significant toxicities related to EPO therapy were the development of iron deficiency (related to utilization), hypertension, and seizures. The hypertension related to EPO therapy is thought to be secondary to a reversal of the vasodilatory effects of anemia. In the large study by Eschbach et al.,[75] blood pressure increases were noted in 35% of previously hypertensive patients. In addition, 44% of the patients who were not hypertensive before EPO therapy experienced increases in blood pressure, with 32% requiring the institution of antihypertensive therapy. There is no specific etiology for the seizures, although the investigators note that the incidence is not significantly higher than that of an untreated group of CRF patients (EPO 5.4%, untreated 8%). The recommended starting dose of EPO for dialysis-dependent CRF patients is 50100 U/kg body weight IV three times per week. A phase IV study by Nissenson et al.[76] evaluated the treatment practices for patients receiving EPO therapy for CRF. They found that, in general, relatively low doses of EPO were being used with resulting marginal increases in hematocrit levels. This suggests that uniformity is lacking regarding the maintenance of patients with CRF on EPO. Although EPO therapy has produced improvements in hematocrit levels in patients with CRF not requiring dialysis, the degree of anemia in these patients, hence the benefit from therapy, is not great enough to warrant a universal recommendation for this group. Studies have suggested that the subcutaneous route of administration is more efficacious than the intravenous route due to the better pharmacokinetics and length of exposure.[77] Patients treated on this study were able to reduce their dose of EPO by 3050% when the drug was administered subcutaneously compared with their intravenous EPO dose.

Patients with AIDS or HIV Infection

Because of the beneficial effects of EPO therapy in patients with CRF, EPO therapy has been evaluated in other diseases. In addition to the presence of anemia related to chronic illness and opportunistic infections, therapies developed to treat HIV and its related infections are associated with hematologic toxicity. Retroviral therapy, particularly AZT, is associated with the development of significant anemia, which in many patients is the dose-limiting toxicity.[78] Henry et al.[79] reported on four randomized placebo-controlled trials evaluating the effect of EPO on the anemia of HIV infection and AZT therapy. In these studies, patients with endogenous EPO levels of <500 U/L experienced a statistically significant increase in hematocrit and a reduction in RBC transfusion requirements compared with placebo-treated controls. This benefit was associated with an overall improved sense of well-being. Patients with endogenous EPO levels of >500 U/L obtained no benefit. No significant effect of EPO therapy on the incidence of opportunistic infections was found. EPO has subsequently been further studied and has been approved by the FDA for use in this patient population.

Cancer Patients Receiving Chemotherapy

Use of EPO is expanding in patients with malignancies who are receiving chemotherapy. The anemia that develops in these patients is very similar to that of the anemia of chronic disease (i.e., an anemia in the presence of increased circulating levels of EPO). Many cancer patients have elevated levels of circulating cytokines such as TNF, which are negative regulators of hematopoiesis. In addition, chemotherapy, particularly with platinum analogues, is often associated with the development of progressive anemia.[80] [81] Miller et al.[82] previously demonstrated that an impaired EPO response is at least partially responsible for the anemia of cancer and is worsened with subsequent chemotherapy. EPO administration has been studied in patients with malignancies in various settings. Randomized trials have been performed studying EPO in patients receiving chemotherapy. They have demonstrated a reduction in the transfusion requirements,

particularly in platinum-treated patients.[83] [84] This has translated not only into an improvement regarding the ability to reduce red blood cell transfusion requirements but also into an improvement in the overall quality of life of cancer patients.[85] An important issue regarding patients receiving EPO for chemotherapy-induced anemia centers around the timing of initiation of therapy. Early initiation is critical to achieve maximal efficacy. Henry and Glasby have studied prognostic factors in patients with chemotherapy-induced anemia.[86] Early initiation (prior to the need for transfusions), a low observed/predicted endogenous EPO level (<0.825) and evidence for early response (>1 gram rise in hemoglobin within the first 4 weeks) were all associated with increased likelihood of response. Patients meeting all three of these criteria demonstrated an 85% chance of major (>2 gram rise in hemoglobin) response. The use of EPO for the treatment of anemia in patients not receiving chemotherapy has also been studied. In both multiple myeloma and other malignancies with bone marrow infiltration, EPO therapy has resulted in increases in hematocrit levels and reduction in the need for RBC transfusions.[87] [88] As in the anemia of malignancy, the etiology of the anemia associated with diseases such as rheumatoid arthritis is multifactorial. Because one component of the development of anemia in this patient population is a blunted EPO response, the use of EPO has become a therapeutic option in these patients.[89]

Bone Marrow Failure States

Primary bone marrow failure states are often associated with anemia, requiring frequent transfusions and therefore presenting the risk of developing iron overload. Among these, the MDSs have been most aggressively studied with regard to the role of EPO therapy. Circulating EPO levels have been studied in patients with MDS.

Jacobs and coworkers[90] found an inverse relationship between EPO level and degree of anemia. They noted, however, that among patients with the same hemoglobin concentrations, a wide variation existed in EPO levels. Many investigators have studied EPO therapy in patients with MDS. Overall, the results have been disappointing.[91] [92] Responding patients tend to be those who have extremely low EPO levels (<100 U/L). Even at high doses of EPO, although responses can be seen, they are often not durable.[93] [94] EPO alone or with G-CSF[95] has been studied in patients with aplastic anemia with some improvement in RBC transfusion requirements noted. A randomized phase II trial conducted by Hellstrom-Lindberg et al. studied sequential vs. simultaneous administration of EPO and G-CSF. [96] The overall erythroid response was similar, though half of the responding patients in the sequential arm responded to initial EPO administration. The additional responding patients did so following addition of G-CSF therapy. Finally, Hellstrom-Lindberg et al. have performed a meta-analysis of EPO trials in MDS. Patients initiated on therapy prior to requiring RBC transfusions, those with low blast percentages (<5%), and those with low endogenous EPO levels responded best. [97]

Autologous Blood Donation

The use of EPO to prime for autologous RBC donation has been perceived as a major step toward reducing the risks associated with blood transfusions. While the actual risk of contracting a viral infection from a unit of RBC has dropped significantly with improved testing, it still remains a concern. The use of EPO preoperatively has been demonstrated to promote an increase in the number of autologous units of blood donated. In a randomized, placebo-controlled, double-blind trial reported by Goodnough et al.,[98] the mean number of units collected from the EPO-treated group (600 U/kg twice weekly) was 5.4 ± 0.2 compared with 4.1 ± 0.2 in the placebo arm. In addition, the preoperative hematocrits in the EPO-treated patients were 3.4% higher (38.6 versus 35.2) than those of the placebo-treated patients. In a second study, the administration of EPO preoperatively has been shown to increase the amount of blood donated by patients by about 40%. [99] Results of a randomized trial conducted by the Canadian Orthopedic Perioperative Erythropoietin Study Group demonstrated that patients who received EPO preoperatively had a statistically significantly lower incidence of requiring any blood transfusions or of having a hemoglobin level <8 g/dl following hip replacement surgery. [100] Preoperative EPO therapy reduces the need for RBC transfusions and provides a method for autologous red cell donation. EPO is approved for priming for autologous donation as well as for preoperative administration in patients undergoing orthopedic surgical procedures.

Anemia of Prematurity

The use of EPO for the treatment of the anemia of prematurity has been widely studied. In this disorder, EPO levels are low and are not appropriately elevated in response to the anemia. This disorder is usually self-limiting and resolves spontaneously after 12 months. A pilot study with EPO appeared to demonstrate promise for the treatment of this disorder.[101] In a randomized double-blind study, however, Shannon et al.[102] showed no significant benefit from EPO treatment. Although treated patients experienced a more rapid rise in reticulocytes, untreated patients spontaneously recovered, precluding a clinical benefit. This topic has been reviewed elsewhere.[103]

Stem Cell Factor

Stem cell factor (SCF) is the ligand for the proto-oncogene receptor c-kit. [104] [105] [106] Also known as the c-kit ligand, mast cell growth factor, and steel factor (SLF) SCF has the ability to stimulate the proliferation of cells that bear its receptor. Cells that bear the c-kit receptor are ubiquitous, with expression on most normal tissue including melanocytes and gonadal cells. In particular, c-kit is present on the hematopoietic stem cell, and acts to stimulate the proliferation and, in concert with other HGFs, the differentiation of these early cells. The recombinant protein is 165 amino acids long and has a molecular weight of 38 kD. SCF as a single agent appears to have only modest effects on the in vitro growth of hematopoietic progenitors (see Chap. 14). However, when combined with other agents, such as IL-1 or IL-3, or with more lineage-specific factors, such as G-CSF, GM-CSF, IL-6, and EPO, SCF has potent synergistic effects on the proliferative capacity of these cells. [107] [108] [109] [110] Although the receptor for SCF is present on malignant cells, no clear evidence shows that SCF actually stimulates the growth of tumor cells, with the exception of myeloid leukemia cells.[111] [112] SCF may be able to induce apoptosis in some leukemic blasts.[113]

SCF has been studied in several preclinical animal models. The ability of SCF to stimulate the mobilization of hematopoietic progenitors into the peripheral blood is of primary importance. Initial studies by Andrews et al.[114] demonstrated that PBPCs mobilized by SCF at a dose of 200 g/kg/day for 11 days have the ability to engraft and rescue lethally irradiated baboons. This was compared with nonprimed mononuclear cells that failed to engraft in control animals, resulting in their death. Subsequent work by the same investigator has demonstrated that a significantly lower dose of SCF is required (20 g/kg/day) if a standard dose of G-CSF is co-administered to baboons before pheresis.[115] The apparent synergistic interaction between these two agents has led to the investigation of the cytokine combination for use as a stem cell mobilizing regimen.

Clinical Applications

The initial phase I trials of SCF were performed in patients with metastatic breast cancer and nonsmall-cell lung cancer respectively. [116] [117]

In each of the studies, patients received a trial of SCF administration before chemotherapy as part of the study of effects of SCFs on unperturbed hematopoiesis.

In each trial, doses of 10, 25, and 50 g/kg/day were studied. SCF alone demonstrated a modest dose-related increase in peripheral blood neutrophils. Less substantial increases at the higher doses were seen in platelets and reticulocytes, suggesting a possible multilineage effect. At the doses studied, no significant increases in bone marrow cellularity were found. SCF, however, did have substantial effects on bone marrow hematopoietic elements. Immunohistochemical stains of bone marrow biopsies demonstrated significant increases in numbers of cells expressing CD34 as well as Ki-67 and proliferating cell nuclear antigen (PCNA), a proliferation-associated antigen.[118] These results suggest that even at low doses SCF has the ability to stimulate the proliferation of hematopoietic stem cells. This effect was further investigated by Tong et al.,[119] who performed flow cytometric phenotyping of bone marrow and demonstrated statistically significant increases in various subsets of CD34+ cells, including CD34+DR+ and CD34+DRCD15 cells; the latter are believed to include the human hematopoietic stem cell. Additional assays demonstrated significant increases in the number of both primitive (high proliferative potential-colony-forming cells [HPP-CFC], burst-forming unit-megakaryocytes [BFU-MK], and long-term culture-initiating cells [LTC-IC]), as well as committed (colony-forming unit [CFU]-GM, CFU-GEMM, BFU-erythroid [E], and CFU-Mk) progenitors following therapy with SCF. Studies evaluating the ability of SCF to mobilize progenitors into the peripheral blood demonstrated mild increases in the number of BFU-E and CFU-GM at the highest dose levels studied. [119]

Toxicities in these studies were composed primarily of allergic-like reactions related to the ability of SCF to prime mast cells for degranulation. Dose escalation was limited in each study by respiratory (throat tightness, laryngospasm) and/or cutaneous toxicity (systemic urticaria) to 50 g/kg/day. Treatment was delivered by subcutaneous injection daily for 14 days. The effects of SCF following chemotherapy have only been preliminarily reported in the lung cancer study. While a trend toward earlier recovery of neutrophils and platelets was seen at the highest dose, it is unlikely that this agent will have a major impact on postchemotherapy recovery.

Two large phase III trials evaluating the ability of the SCF/G-CSF combination compared to G-CSF alone to mobilize PBPC have been completed and reported. [120] [121] Initial phase I trials demonstrated the ability of the combination to mobilize adequate numbers of progenitors such that a single standard apheresis was adequate to obtain enough PBPC for a course of high-dose chemotherapy. Unlike the phase I trials, severe allergic reactions were not seen in these trials. This was either due to the well-developed prophylactic anti-allergy regimen (H_1 and H_2 blocks with a bronchodilator) or a synergistic interaction between the two HGFs. The phase II/III doses were G-CSF 10 g/kg/day with or without SCF 20 g/kg/day. Both drugs were administered subcutaneously with apheresis performed starting on day +5 and continuing until the target yield of CD34+ PBPC had been obtained. The combination of SCF/G-CSF resulted in a significant increase in the number of patients who achieved the target yield following five aphereses (67% vs. 48%) and the median number of aphereses needed was statistically significantly fewer (3 vs. 6, $P < 0.01$) for the combination. In the second study, heavily pretreated lymphoma patients were mobilized either with the combination or G-CSF alone. Again, the combination of SCF/G-CSF resulted in a statistically significant increase in the number of successfully pheresed patients. Engraftment of the SCF/G-CSF mobilized progenitor cells appears to be at least as good as that of those mobilized by other more standard methods.

The use of SCF to prime bone marrow in vivo before bone marrow harvest is another interesting potential use of this agent. [119] Unquestionably, the two other major areas of interest for this factor are its use in ex vivo expansion of hematopoietic progenitor and stem cells and in patients with bone marrow failure states. Ex vivo expansion of bone marrow could theoretically replace the need to harvest large numbers of PBPCs or bone marrow progenitor cells. Multiple studies of this technique have demonstrated substantial increases in progenitor cells affording the opportunity to generate transplantable quantities of progenitors in the laboratory from a small volume of bone marrow.[122] Initial clinical trials using this approach have been reported. [122] All these studies have demonstrated the importance of SCF as a component of the cytokine cocktail needed for maximal expansion. In addition, SCF has been shown to increase progenitor numbers in vitro from patients with various

bone marrow failure syndromes.[123] A phase I trial of SCF in patients with aplastic anemia demonstrated that in patients treated at doses ranging from 530 g/kg/day, SCF was capable of generating modest trilineage responses in approximately one-third of patients treated with refractory immunosuppressive therapy. [124]

PIXY321

PIXY321 is a genetically engineered fusion protein that links the genes encoding IL-3 and GM-CSF by a flexible amino acid linker. [125] In vitro, PIXY321 appears to have equal, if not superior, effects on hematopoiesis compared with the combination of IL-3 and GM-CSF as individual agents. [125] [126] Preclinical animal studies have demonstrated that PIXY321 has the ability to effect multilineage responses following the administration of radiotherapy. [127]

After Chemotherapy

Several phase I clinical trials with PIXY321 were intially conducted and demonstrated a favorable safety profile for the agent. Vadhan-Raj et al. [128] studied effects of PIXY321 on patients with normal hematopoiesis in patients with sarcoma where PIXY321 was administered subcutaneously in two divided doses (251000 g/m ^{2} /day) for 14 days. PIXY321 treatment was associated with modest increases in peripheral blood WBC count, neutrophils, and platelets. Bone marrow biopsy specimens demonstrated a significant increase in cellularity. In addition, treatment with PIXY321 resulted in increases in assayable committed progenitors, including CFU-GM, CFU-GEMM, and BFU-E, as well as the number of circulating CD34+ cells. At the doses studied, toxicity in this study consisted primarily of local erythema at the injection site.

The effect of PIXY321 on hematologic recovery after the administration of chemotherapy has been studied by a variety of investigators. As a part of their phase I trial in sarcoma patients, Vadhan-Raj et al.[129] examined the effects of PIXY321 following cyclophosphamide, doxorubicin, dacarbazine (CyADIC) chemotherapy. These investigators found that the administration of PIXY321 at doses of >500 g/m ^{2} /day resulted in a reduction in mean nadir neutrophil counts following chemotherapy cycles in which PIXY321 was administered compared with those without PIXY321 therapy (90 cells/l vs. 380 cells/l). The duration of neutropenia was also reduced from 6.7 to 3.1 days by PIXY321. Mean nadir platelet counts were also improved with PIXY321 therapy at doses of >500 g/m ^{2} /day with a reduction in the development of cumulative thrombocytopenia after two cycles of chemotherapy. Small numbers of patients preclude drawing statistical conclusions, but comparison to historical controls treated with GM-CSF reportedly demonstrates trends toward reduced myelosuppression. Additional phase I trials demonstrated less impressive results. Two randomized, placebo-controlled phase II or III trials have been completed. The

first, in relapsed/refractory lymphoma patients, failed to demonstrate a benefit of PIXY321 compared to G-CSF. [130] In the second study, a trial of breast cancer patients receiving 5-fluorouracil, leucovorin, doxorubicin, cyclophosphamide (FLAC) chemotherapy, a superior outcome was seen for patients receiving GM-CSF and not PIXY321.[131]

After Autologous Bone Marrow Transplantation

Initial phase I results in lymphoma patients receiving PIXY321 after transplant suggested a superior outcome compared to historical controls treated with GM-CSF. A subsequent phase III trial comparing GM-CSF to PIXY321 failed to demonstrate a benefit for the investigational agent. [132] A phase I/II trial assessing the mobilization activity of PIXY321 demonstrated only modest activity and this indication was not pursued. [133]

Given the failure of PIXY321 to produce any positive phase II/III data in randomized trials, clinical development with this agent was discontinued.

Interleukin-1

Interleukin-1 consists of two forms, IL-1 and IL-1, that exert their effects via a common receptor. In vitro studies with both agents have demonstrated their ability to stimulate the proliferation of early hematopoietic progenitors and produce a multilineage effect. In addition, their administration in preclinical models results in enhanced hematopoietic recovery following both chemotherapy and radiotherapy-induced myelosuppression. [134] [135] [136]

Clinical Applications

Clinical studies have been performed with both IL-1 and IL-1. The initial phase I trial with IL-1 by Crown et al. [137] demonstrated that a short infusion of IL-1 resulted in a dose-dependent increase in WBC counts (primarily neutrophils) within the first hours of administration. A delayed thrombopoietic effect of IL-1 was seen approximately 34 weeks after administration. Whether this increase in platelet count is a direct effect of IL-1, or indirect through the induction of secondary cytokines, remains unanswered. The major toxic events encountered primarily constitutional symptoms at the lower doses; however, hypotension became the dose-limiting toxicity at a dose of 0.1 g/kg/day. The administration of IL-1 following 5-fluorouracil chemotherapy in subsequent cycles of treatment demonstrated no significant impact on altering chemotherapy-induced leukopenia or thrombocytopenia at the dose levels studied.

IL-1 has been evaluated in various clinical trials as an antitumor agent. In a phase I trial performed by Smith et al. [138] doses of >0.3 g/kg/day were administered by rapid intravenous infusion. Therapy was tolerated, but the principal side effect at these doses was hypotension requiring vasopressor support. Nonetheless, a dose-related increase in WBCs (primarily neutrophils) during therapy, as well as increments in platelet counts occurring 12 weeks after completion of therapy were seen. Serum levels of IL-6, a factor with known thrombopoietic effects, were increased following treatment with IL-1, raising the question of whether the thrombopoietic effects of IL-1 are actually mediated through the induction of IL-6. Regardless, because of the hematologic effects seen in this initial trial with IL-1, a subsequent study was performed in which IL-1 was administered following intensive carboplatin chemotherapy in patients with advanced cancer. [139] In this study, 43 patients received carboplatin at a dose of 800 mg/m^2 . Patients were treated with one of three doses of intravenous IL-1, ranging from 0.030.3 g/kg/day for 3 days. Various schedules of IL-1 administration were used. These patients were compared with a control group who received chemotherapy alone. Treatment with IL-1 resulted in significant blunting of the platelet and WBC nadirs after chemotherapy. The optimal schedule was the administration of IL-1 after the completion of chemotherapy, in an optimal dosage of 0.10.3 g/kg/day. Toxicity was significant, consisting of reversible hypotension (requiring intensive care unit monitoring and vasopressor support), supraventricular tachycardias, and capillary leak syndrome.

After High-Dose Chemotherapy and Progenitor Cell Support

IL-1 has been investigated regarding its potential to accelerate engraftment following high-dose chemotherapy and autologous progenitor cell support. An initial dose escalation study conducted by Vredenburgh et al.[140] examined the effect of 7 days of subcutaneously administered IL-1 following reinfusion of progenitor cells. Doses of IL-1 of 432 ng/kg/day were studied. Of 14 patients, 7 experienced local pain at the injection site; 1 patient, at the highest dose studied, had severe hypotension. No benefit regarding accelerated hematologic recovery was noted, although IL-1-treated patients were found to have greater numbers of bone marrow CFU-GM progenitors on day +21. Similar results and toxicities were seen by Nemunaitis et al. [141] when IL-1 was administered by short intravenous infusion.

Weisdorf et al.[142] studied IL-1 following high-dose chemotherapy and autologous BMT. Patients received IL-1 for 14 days after reinfusion of autologous progenitor cells at doses of 0.110 g/m^2 /day by 6-hour intravenous infusion. Dose-limiting toxicity was hypotension, seen at the 10-g/m ^{2} dose level. Engraftment of neutrophils (ANC >500 cells/l) occurred at a median of 24 days for historical controls, and patients receiving IL-1 at 0.11.0 g/m ^{2} /day compared with 13 days for patients treated with IL-1 at 3.0 g/m^2 /day. Similar trends for platelet engraftment were seen.

In a small study by Walsh et al. [143] IL-1 was administered intravenously in 5-day courses to four patients with severe refractory aplastic anemia. No significant changes occurred in peripheral blood counts or bone marrow morphology associated with the IL-1 therapy. Similar results were seen by Nemunaitis et al. [144]

Although both IL-1 and IL-1 are both potentially capable of reducing the myelosuppressive effects of chemotherapy, neither appears to exert these effects at doses that have been well tolerated. Attempts at using agents such as indomethacin to reduce the hypotension of IL-1 have proved ineffective. [138] Because of its unacceptable toxicity, both forms of IL-1 have been removed from clinical development.

Interleukin-3

IL-3 is the first of the early-acting hematopoietic growth factors to be studied broadly in various clinical trials. IL-3 has its action on early uncommitted progenitor cells and has been shown to act synergistically with various other HGFs, such as GM-CSF, G-CSF, and EPO to support in vitro colony formation. [145] [146] In vivo, IL-3 has been shown to increase WBCs, RBCs, and platelets in normal animals, and to enhance the hematologic recovery of all lineages following chemotherapy or radiotherapy. IL-3 has a molecular weight of 1428 kd and is encoded for by a gene on chromosome 5q23-q31.

Patients with Refractory Malignancy and After Chemotherapy

The multilineage effects of IL-3 in patients with malignancy and following chemotherapy have been the focus of clinical investigation. As a single agent in patients with normal bone marrow, IL-3 results in a dose-dependent increase in neutrophil and

platelet numbers over doses of 0.2510 g/kg/day.[147] Lindemann et al. treated 30 patients with refractory malignancies.[148] IL-3 was administered as a single intravenous bolus on day 1, followed by 14 days of subcutaneously administered IL-3 (days 215). Doses studied were in the range of 60500 g/m ^{2} /day. Dose-dependent increases in WBC and neutrophil counts were seen. Platelets were mildly increased (twofold). Interestingly, significant increases in circulating numbers of basophils and eosinophils were seen. Toxicities were primarily constitutional in nature and consisted of mild fever and headache that were clinically significant. Therefore, Bhatia et al. added propranolol to the IL-3 therapy to ameliorate the headache associated with IL-3. [149] Doses of 604,000 g/kg were evaluated. Hematologic effects were similar to the previously noted trial. No grade III or greater toxicity (including headache) or antitumor activity was reported in either of these studies. The effects of IL-3 on bone marrow and PBPCs were reported by Ottmann et al.[150] These investigators studied the effect of IL-3 administered for 15 days in various patients with normal and abnormal hematopoiesis. Patients were treated with subcutaneous doses of 60500 g/m ^{2} /day. Significant increases in peripheral blood CFU-GM and CFU-GEMM over baseline values were seen after 7 days of therapy (100% and 72% increased respectively). These effects were not seen after the second week of therapy (25% and 28%, respectively). Peripheral blood BFU-E were reduced in nearly all patients with normal hematopoiesis. Cycling rates of progenitors in the bone marrow were increased with therapy, as was bone marrow cellularity. Again, dose-dependent increases in peripheral blood WBC, neutrophil, and eosinophil counts were seen, with peak values at or about day 13 of treatment.

Several studies have been performed using IL-3 as a single agent after chemotherapy. [151] [152] [153] In phase I studies, IL-3 has tolerable side effects below doses of approximately 15 g/kg/day. Above this level, headache and other constitutional complaints have been dose-limiting. Other toxicities seen at lower dose levels include fever, malaise, fatigue, arthralgias, and myalgias. Overall these studies demonstrate that IL-3 does not appear to alter the degree of neutropenia or thrombocytopenia but may, at higher doses, hasten the recovery of these nadirs. At least in one study by Biesma et al., [154] this effect appeared to be associated with a reduction of platelet transfusions. The impact of IL-3 as a single agent, however, appears to be minimal, since equivalent or greater neutrophil effects can be obtained with either G-CSF or GM-CSF, and dose escalation of IL-3 to doses that might affect platelet numbers appears to be limited due to toxicity.

Combinations of HGFs such as G-CSF or GM-CSF with IL-3 have been pursued. Preclinical data suggest that sequential, as opposed to simultaneous, administration of IL-3 with GM-CSF results in increased platelet production via enhanced megakaryocyte maturational effect. [155] Combination HGF therapy, including IL-3, in humans has been studied after chemotherapy. Brugger et al.[152] reported the clinical results of sequential treatment, with 5 days of IL-3 (days 15) and 10 days of GM-CSF (days 515) following intensive VIP chemotherapy. This combination and schedule resulted in neutrophil effects similar to those of GM-CSF alone with additional platelet effects seen only in those patients who were previously heavily pretreated. Other combination trials of IL-3 with G-CSF have been reported with similar results.[156]

After High-Dose Chemotherapy

The use of IL-3 after high-dose chemotherapy and autologous progenitor cell transplants has been investigated. Nemunaitis et al. administered IL-3 as a 2-hour infusion following reinfusion of bone marrow. [157] Doses of 110 g/kg/day were studied; however, doses of >5 g/kg/day were not well tolerated due to constitutional side effects. Compared to historical controls treated with GM-CSF, IL-3 appeared to produce neutrophil recovery at a rate similar to that of GM-CSF. Combinations of IL-3 with later-acting factors have been studied in the autologous BMT setting. Fay et al. performed an initial phase I trial of sequential IL-3 and GM-CSF in patients undergoing autologous BMT for lymphoma.[158] Patients received IL-3 at a dose of 2.5 g/kg/day as a 2-hour intravenous infusion, or subcutaneously. This was followed by GM-CSF at 250 g/m^2 /day as a 2-hour infusion until hematologic recovery. Rapid engraftment was seen in the few patients treated with a median ANC recovery to >1,000 cells/l in 12.5 days. The phase III trial of sequential IL-3/GM-CSF performed by Fay and colleagues failed to demonstrate an advantage for the combination over standard therapy alone.[159]

Other

The multilineage effects of IL-3 make it a potential agent to study alone and in combination with other cytokines in patients with pancytopenia. Ganser et al. studied the effects of subcutaneously administered IL-3 in doses of 250500 g/m ^{2} /day in nine patients with the myelodysplastic syndromes (six refractory anemia, three refractory anemia with excess blasts).[160] Patients were treated for 15 days. Increases in leukocyte counts (consisting of neutrophils, eosinophils, basophils, lymphocytes, and monocytes) were seen in all patients. Increments in platelet numbers occurred in two severely thrombocytopenic patients, while RBC transfusion requirements decreased in one other patient. Therapy was tolerated with acceptable constitutional symptoms. Only one patient experienced an increase in the number of blasts. Other trials with IL-3 in patients with MDS have demonstrated similar findings, with some patients experiencing short-lasting multilineage responses.[161]

While patients with MDS appear to obtain multilineage responses to IL-3, patients with aplastic anemia tend to have less significant hematologic responses. Ganser et al. treated nine patients with aplastic anemia with subcutaneous IL-3 administered for 15 days at doses of 250500 g/kg/day. [162] A platelet response was seen in one patient, and transient leukocyte responses were seen in several others. Two patients were found to have significant increases in bone marrow cellularity without significant increases in peripheral blood counts. This suggests that although IL-3 is capable of stimulating increases in early bone marrow cells, additional factors may be required to produce maturation and peripheral mobilization of these cells. Kurzrock et al. [163] demonstrated similar findings in their phase I trial, which included eight patients with aplastic anemia.

Other uses of IL-3 that have been explored include its use as a single agent in patients with HIV infection. In a phase I trial, Scadden et al. reported on 11 HIV-positive patients who were treated with 14 days of subcutaneous IL-3.[164] Although no significant hematologic improvements were seen, treatment with IL-3 was not associated with increases in HIV replication as measured by HIV p24 antigen levels of quantitative virus cultures.

The failure of IL-3 to demonstrate any positive data from controlled randomized trials resulted in its removal from clinical investigation.

Interleukin-6

IL-6 is a 2130-kd protein that was initially characterized and independently identified by multiple investigators. Investigators have identified this protein as B-cell-stimulating factor-2,[165] IFN-2,[166] hepatocyte-stimulating factor, [167] hybridoma growth factor,[168] T-cell replacement factor,[169] and monocyte granulocyte inducer-2.[170] By international convention, all these factors are now referred to as IL-6.

IL-6 expression and production is increased by various other cytokines, such as IL-1 and TNF, as well as in response to a large number of conditions, including chronic inflammation, autoimmune diseases, and sepsis.[171] [172]

The hematopoietic effects of IL-6 have been well studied in vitro, where its primary effect is on megakaryocyte maturation. IL-6 is a potent megakaryoctye

maturational factor that has demonstrated the ability to increase the number of megakaryocyte progenitors (CFU-Mk) in vitro. [173] Mei et al. demonstrated that IL-6 bioactivity in long-term bone marrow cultures correlated directly with megakaryocyte size and ploidy. [174] However, there was no correlation between IL-6 bioactivity and megakaryocyte number, suggesting that IL-6 acts not to increase megakaryocyte numbers, but rather to influence the maturation of these cells.

IL-6 also has been shown to have the ability to stimulate the generation of granulocyte, granulocyte/macrophage, and megakaryocyte progenitor colonies. [175] These effects, although seen with IL-6 alone, are significantly enhanced by the addition of other cytokines such as IL-3 or GM-CSF. [176] In addition, IL-6 appears to stimulate the proliferation of both murine and human stem cells. These data suggest that in addition to a lineage-specific effect on megakaryocytes, IL-6 may also be an early-acting factor with the ability to activate progenitor cells. [177] [178] [179]

Preclinical studies in both mice and nonhuman primates demonstrated that treatment with IL-6 results in significant increases in peripheral blood platelet counts. [180] [181] [182] The effects of IL-6 on thrombopoiesis appear to be mediated by its action on megakaryocyte maturation. This conclusion is based on the observations that IL-6 increases megakaryocyte ploidy and that the maximal elevation in platelet counts is delayed, occurring primarily after completion of IL-6 therapy. Unlike the effects of G-CSF and GM-CSF on neutrophils, IL-6 does not appear to function as a platelet-releasing factor. IL-6 therapy results in the induction of acute-phase proteins, including C-reactive protein, fibrinogen, and haptoglobin. Following chemotherapy or irradiation, IL-6 enhances the hematologic recovery, thereby reducing the duration of myelosuppression.

Clinical Applications

Thrombopoietic Activity

Clinical studies with IL-6 have been completed and have generally been disappointing with regard to its thrombopoietic activity. In initial phase I trials, IL-6 was studied in patients receiving chemotherapy for sarcoma or advanced malignancies. [183] In the first study, patients were treated with IL-6 before the initiation of chemotherapy to study the effects of this agent on normal hematopoiesis. Patients received 10 days of IL-6 by daily subcutaneous injections at doses of 1.025.0 g/kg/day. IL-6 therapy resulted in significant dose-dependent increases in platelet counts that peaked following completion of the IL-6 therapy. Toxicities of IL-6 included fevers, chills, malaise, fatigue, and a transient therapy-related anemia. This anemia characteristically developed early after the initiation of IL-6 therapy and rapidly resolved after completion of treatment. Plasma volume and chromium-labeled red cell mass studies have confirmed that these effects are related to plasma volume expansion.[184] Dose-related increases in C-reactive protein and fibrinogen were consistent with the known effects of IL-6 on acute-phase proteins; elevations in these parameters can serve as an indicator of IL-6 activity.

The complicating issue regarding the clinical development of IL-6 is related to its poor safety profile. At doses >5 g/kg/day, severe constitutional toxicites result in intolerance to the agent. Unfortunately, it is at these doses that IL-6 appears to be most effective in inducing thrombopoiesis. While single-arm studies at doses of 10 g/kg/day suggested some potentially clinically relevant activity, [185] randomized phase III trials in patients with breast cancer, performed at much lower doses (1 g/kg/day), failed to demonstrate any meaningful thrombopoietic activity. [186] A similar lack of activity was seen for IL-6 whether derived from *E. coli* or mammalian cells. The lack of clinically significant thrombopoietic activity, resulted in IL-6 being abandoned for this indication.

IL-6 was also studied in patients with myelodysplasia and thrombocytopenia. In a phase I trial, 22 patients with refractory anemia, refractory anemia with ringed sideroblasts, or chronic myelomonocytic leukemia with <5% bone marrow blasts were treated with doses of IL-6 ranging from 1.05.0 g/kg/day. [187] Dose-limiting toxicity of malaise and fatigue was reached at 5.0 g/kg/day, and the maximum tolerated dose in this population was 3.75 g/kg/day. Of 22 patients, 5 had transient (3 patients) or lasting (2 patients) responses to IL-6 therapy. Only 1 patient demonstrated progression of MDS to acute leukemia.

Anti-tumor Activity

In addition to its hematopoietic effects, IL-6 has potential anti-tumor activity. IL-6 is synergistic with IL-2 in the generation of cytotoxic T lymphocytes. [188] This action is possible mediated by the ability of IL-6 to up-regulate the expression of the IL-2R on thymocytes. [189] Mulé et al. demonstrated that IL-6 therapy results in the regression of established pulmonary metastases in mice that appears to be mediated via both CD4+ and CD8+ lymphocytes. [155]

Weber [190] treated 11 patients with advanced malignancies with daily subcutaneous injections of IL-6. Patients were treated on an every-other-week schedule for 3 weeks at doses of 3, 10, and 30 g/kg/day. Dose-limiting toxicity of hepatotoxicity and cardiac arrhythmias precluded further dose-escalation by this route of administration. Other side effects included fevers, chills, and malaise. Although no anti-tumor responses were reported in this study, peripheral blood immunophenotyping did demonstrate an up-regulation in the expression of the low affinity IL-2R on CD3+ cells, suggesting the activation of peripheral blood lymphocytes. The Cytokine Working Group performed a phase II trial of IL-6 in patients with metastatic renal cancer that failed to demonstrate any clinically significant anti-tumor activity.[191]

Interleukin-11

IL-11 is a 199-amino-acid polypeptide that was initially cloned from an immortalized and IL-1induced primate bone marrow stromal cell line, PU-34. The human gene was subsequently cloned from a fetal pulmonary fibroblast cell line. [192] IL-11 has effects similar to those of IL-6 and is capable of stimulating the proliferation of the IL-6-dependent plasmacytoma cell line, T1165. IL-11 has the ability in vitro to synergize with other early-acting hematopoietic factors, including IL-3. Studies performed by Yin and Yang demonstrated that IL-11 uses the same signal transduction pathway (GP-130) as IL-6, leukemia inhibitory factor (LIF), and ciliary neurotrophic factor (CNTF) but appears to operate through an independent receptor. [193] [194] In preclinical models, IL-11 results in enhanced recovery of platelets as well as neutrophils after both chemotherapy and lethal irradiation following the infusion of progenitor cell transplants. [195] The preclinical data have been extensively reviewed.[195]

IL-11 has a variety of other interesting activities defined in preclinical models, such as its ability to inhibit adipogenesis and prevent the development of chemoradiotherapy-induced mucositis.[195] Keller et al. demonstrated that IL-11 has the ability to promote myelopoiesis in long-term bone marrow cultures. [196] This effect may be mediated by the inhibition of adipogenesis and promotion of stromal cell and macrophage development by IL-11. These findings could be relevant for the treatment of various bone marrow failure states in which bone marrow microenvironmental

defects could play a role in the pathogenesis of the disorders. The prevention of mucositis extends to IL-11s ability to prevent and/or decrease the degree of inflammatory bowel disease in a variety of models.[197] At low doses, IL-11 has anti-inflammatory activity that may be related to these activities.

Clinical Applications

The phase I trial of IL-11 has been performed in women with locally advanced or metastatic breast cancer. [198] [199] Patients received IL-11 at doses of 10100 g/kg/day. Therapy was administered initially by daily subcutaneous injection for 14 consecutive days during a 28-day prechemotherapy period. Following completion of the prechemotherapy portion of the study, all patients received IL-11 at their assigned dose level after each of four cycles of chemotherapy. Chemotherapy consisted of cyclophosphamide (1,500 mg/m^2 /day) and doxorubicin (60 mg/m^2 /day) given on day 1 of each 28-day cycle. IL-11 was administered for 12 consecutive days on days 314.

Toxicity of IL-11 primarily included reversible grade 2 fatigue, myalgias, arthralgias, and edema of the lower extremities, seen in all patients treated at 75 g/kg/day. In addition, a transient therapy-related anemia which is similar in character to that described for IL-6 and is associated with a similar plasma volume expansion was seen at all doses studied. IL-11 therapy was associated with a dose-related increase in mean peak platelet counts over baseline of 76%, 93%, 108%, 185% (for doses of 10, 25, 50, and 75 g/kg/day, respectively). For all doses studied, maximum platelet counts occurred after the completion of IL-11 therapy. No effect was seen on the WBC count. Acute-phase proteins, including C-reactive protein, haptoglobin, and fibrinogen, were increased at all doses. Platelet aggregation studies performed pretreatment and after 14 days of IL-11 demonstrated no therapy-related changes.

IL-11 administered after chemotherapy was associated with a similar toxicity profile. Compared to patients at the 10-g/kg/day dose level, patients treated at doses of

25 g/kg/day experienced less thrombocytopenia. In addition, cumulative thrombocytopenia appeared to be attenuated by IL-11 therapy. No effect of IL-11 on neutrophil nadirs was seen. A similar therapy-related anemia was seen during chemotherapy cycles. Subsequently, two randomized, placebo-controlled phase II trials have been conducted.

IL-11 was subsequently studied in two randomized, placebo-controlled phase II trials. [200] [201] In the first of these trials, a secondary prophylaxis study, IL-11 at either 25 or 50 g/kg/day or placebo was administered to patients with a history of severe thrombocytopenia. [200] Patients were required to receive the identical doses of chemotherapy they received in the previous nonstudy cycle. For all patients evaluable, only one patient (4%) of the placebo groups did not require a platelet transfusion compared to 30% of the IL-11 patients treated at the 50 g/kg dose level ($p < 0.05$). A dose-related effect was suggested in that the 25 g/kg dose resulted in 18% of patients not requiring a platelet transfusion (p = NS compared to placebo). In addition to the improvement in the number of patients in whom severe thrombocytopenia developed, there was a trend toward fewer transfusion episodes in the IL-11-treated patients compared to placebo, though this difference was not statistically significant.

In the second phase II trial, women with breast cancer (stages 2, 3, and 4) received dose-intensive chemotherapy (cyclophosphamide 3,200 mg/m ^{2} and doxorubicin 75 mg/m^2) with placebo or IL-11 (50 g/kg) following each of two blinded cycles of therapy. [201] Only 15 of 37 patients (41%) in the placebo arm did not develop severe thrombocytopenia compared to 68% of the IL-11-treated patients ($p < 0.02$). This benefit was maximal in the second cycle of therapy. IL-11 also had the ability to reduce the number of episodes of platelet transfusions compared to the placebo arm. Overall, patients receiving IL-11 also tended to recover their platelets faster than the placebo group.

The side effect profile of IL-11 in these studies has been similar to those seen in the phase I trial and the side effects are primarily grade 1 or 2 in nature. In a small number of patients, plasma volume expansion may be associated with edema, dyspnea, and infrequently atrial arrhythmias that are usually asymptomatic and self-limiting. Phase I and II trials of IL-11 in the bone marrow transplant setting have demonstrated a similar safety profile. Data regarding the thrombopoietic activity of IL-11 in that setting is less well-defined, though there is some suggestion of enhanced platelet recovery in a placebo-controlled, randomized, phase II trial. [202] A randomized, placebo-controlled phase III trial using the secondary prophylaxis design is ongoing. On the basis of the preceding randomized phase II data, IL-11 was approved by the FDA in 1997 for the prevention of severe chemotherapy-induced thrombocytopenia. The role of IL-11 in other thrombocytopenic disorders, such as the myelodysplastic syndromes, aplastic anemia, and immune thrombocytopenia, is being considered for investigation.

Other potential applications for IL-11 include the prevention of chemotherapy-induced mucositis and the treatment of inflammatory conditions such as inflammatory bowel diseases and psoriasis. The latter has been studied in early phase I trials in which low doses of IL-11 appear to have some effect on the severity of inflammatory bowel disease. Doses under investigation for these indications are typically lower than those for the thrombopoietic effect.

Thrombopoietin

Thrombopoietin is the ligand for the c-mpl receptor, a proto-oncogene which is the human correlate for the avian myeloproliferative leukemia (v-mpl) receptor. The ligand has been cloned by a variety of investigators. [203] [204] The native molecule is recognized as thrombopoietin (TPO) whereas a truncated, PEGylated form is known as megakaryocyte growth and development factor (MGDF). Both molecules have a similar range of activity. The PEGylation of the latter molecule allows for protein stability and maintenance of half-life. Thrombopoietin has been extensively studied and appears to be a lineage-dominant factor for megakaryocytic progenitor cell proliferation and megakaryocyte maturation and platelet production. Thrombopoietin has also been shown to affect erythropoiesis as well as the proliferation of the pluripotent stem cell. Thrombopoietin has an approximately 20% sequence homology to erythropoietin and is primarily produced by the liver and to a lesser degree, the kidney. The gene for thrombopoietin is located on chromosome 3q27-28. [205] Thrombopoietin levels in hematologic malignancies vary and are related to the presence of the megakaryocyte mass. [206]

When administered to animals in preclinical models, thrombopoietin and MGDF induce rapid platelet production associated with significant increments in both the number of megakaryocyte progenitors as well as the overall number of megakaryocytes. [207] [208] [209] [210] They exert not only a proliferative effect but also a maturational effect on bone marrow megakaryocytes. Following the administration of chemotherapy or radiotherapy, both TPO and MGDF have the ability to accelerate platelet recovery in a wide variety of preclinical animal models. In addition, both agents are potent inducers of peripheral blood progenitor cell mobilization.

Clinical Applications

Phase I studies with both TPO and MGDF have been completed. The former has been studied in patients with soft tissue sarcomas

who received a single dose of TPO intravenously at doses ranging from 0.32.4 g/kg 3 weeks prior to chemotherapy. [211] A single dose of TPO was associated with a dose-related increase in peripheral blood (PB) platelet counts. Rises in platelet counts were noted as early as day 4 though, like many other thrombopoietic agents, the peak platelet count was seen in the second week following therapy. Unlike many other HGFs, TPO has a prolonged half-life following a single IV injection, measured at between 2030 hours. Peak platelet counts exceeded 1,000,000/l at the 2.4 g/kg dose level. Additional biologic effects of TPO administration were seen in the bone marrow, where increases in the absolute number of megakaryocytes (MKs), the number of MK progenitors, and the mobilization of a broad range of PB progenitors was seen. Data following the administration of chemotherapy is scant but it appears that the post-chemotherapy thrombopoietic response is somewhat dependent on the degree of chemotherapy intensity. Hence, multiple-day dosing, scheduled every third day due to the prolonged half-life, is being tested though no definitive data regarding the ability of TPO to reduce the degree of chemotherapy-induced severe thrombocytopenia has been shown. Safety of the single-dose TPO formulation was excellent with mild headache as the only therapy-related adverse event.

MGDF has been studied in two placebo-controlled phase I trials as well as at least one reported randomized, placebo-controlled phase II trial. The initial phase I trial was conducted in patients with refractory cancer by Basser and colleagues in Australia. [212] This trial assessed the effect of MGDF administered subcutaneously at doses ranging from 0.035.0 g/kg/day for 10 days during a prechemotherapy phase. Reproducible increases in PB platelet counts were seen at all doses though these were noted to occur earlier at higher doses of 0.3 and 1.0 g/kg/day. At these doses, a median threefold increase in platelets was seen. Peak platelet counts of 0.8, 1.3, and 1.8 million were seen at the highest dose level. These platelets were not hyperaggregable and appeared to function normally. [213] Following the administration of chemotherapy (cyclophosphamide 1,200 mg/m^2 and carboplatin 600 mg/m^2) MGDF was administered for between 7 and 20 days. Although severe thrombocytopenia was not routinely seen with this regimen, the nadir platelet count occurred earlier in the MGDF patients compared to placebo controls although there was no difference in the depth of the thrombocytopenia. In addition, platelet count recovery to prechemotherapy levels occurred faster in the MGDF patients compared to those in the placebo group.

In the second phase I trial, Fannuchi and colleagues administered MGDF following carboplatin (AUC 9) and paclitaxel (225 mg/m ^{2}) chemotherapy at doses ranging from 0.035.0 g/kg/day. [214] MGDF was given for as few as 3 days at the highest doses due to excessive thrombocytosis with platelet counts exceeded 1.52.0 million in some patients. No significant increase in thromboembolic events was identified. Nadir platelet counts in the MGDF patients were 189,000/l compared to 111,000/l in the placebo group. This difference was statistically significantly improved. In addition, recovery to baseline platelet counts occurred earlier among the MGDF patients.

In a randomized phase II trial, Archimbaud et al. studied the effect of MGDF compared to placebo in reducing the duration of severe thrombocytopenia in patients with AML undergoing induction chemotherapy. [215] In this study, all patients received a standard cytarabine/anthracycline/etoposide-containing induction regimen followed by either placebo or MGDF at either 2.5 or 5.0 g/kg/day for up to 21 days (starting on day 8). The median time to recovery of platelet count of 20,000/l was 21 days in each group with excessive thrombocytosis seen in approximately 50% of the MGDF patients compared to a minority of the placebo patients. No untoward effects were seen in this trial.

Overall, both TPO and MGDF continue to be investigated in the setting of chemotherapy-induced thrombocytopenia and further results are expected.

Other Applications

Results of phase I and phase II trials of MGDF in the autologous transplant setting appear to be dependent on the type of progenitor cell reinfused. Preliminary data suggest that if bone marrow is used as the source of progenitor cells, a modest improvement in platelet count recovery may be seen. [216] In contrast, when PBPC are

used, MGDF was unable to accelerate recovery regardless of being given prior to or following PBPC reinfusion. [217]

As was noted in the phase I trials, both TPO and MGDF have potent PBPC mobilization activity. Studies exploring this as a potential approval indication are underway.[218] [219] [220] Finally, the use of MGDF to mobilize increasing numbers of platelets into the PB for plateletpheresis has been reported by Kuter et al. [221] The administration of a single dose of MGDF at doses of 1.0 and 3.0 g/kg was associated with a statistically significant increase in the percentage of donors who succeeded in donating adequate platelet volumes. In addition, preliminary results suggest that these super-plateletpheresis packs promoted greater increases in platelet counts in their recipients. Larger studies assessing their safety in a nonselected group of donors will be necessary since this has the potential to increase the number of available plateletpheresis donors.

BIOLOGIC RESPONSE MODIFIERS (BRMs)

The rationale for using BRMs for the treatment of malignancies is based primarily on preclinical data and indirect clinical evidence that suggests an important relationship between the immune system and the neoplastic process. These clinical and histopathologic observations include favorable clinical prognosis associated with brisk lymphocytic infiltrate in solid tumors, increased risk of malignancies in the setting of immunodeficiency states or immunosuppression, rare spontaneous regression of metastases after resection of primary tumor, and the presence of antitumor antibodies in sera and specific cytotoxic T lymphocytes in the peripheral blood and at tumor sites of cancer patients.[222] [223] [224] [225] [226] [227] More recently, compelling preclinical animal data have further supported the use of BRMs for the treatment of cancer.[228] Table 51-1 summarizes some of the biologic effects of many of these agents that may be relevant to their potential role in cancer therapy.

Interleukin-2

Interleukin-2 (IL-2) is a 15,000 dalton glycoprotein encoded by a single gene on chromosome 4 which acts in a monomeric form as an autocrine growth factor. [229] IL-2 is critical in allowing T lymphocytes to proceed from G_1 into cell cycle (S phase) following activation of their unique T-cell receptor complex. [229] It also induces the secondary secretion of proinflammatory cytokines from NK-and T lymphocytes and induces the proliferation of NK-and B lymphocytes. [229] [230] [231] It activates the cytotoxic machinery in T cells, NK cells, and monocytes. IL-2 activation of effector cells results in the release of secondary cytokines, including IL-1, TNF-, IFN-, and GM-CSF, which further recruits and activates monocytes.[231] This secondary release of cytokines may account for the therapeutic activity of IL-2 and likely contributes to the toxicity associated with IL-2 treatment.[232] As a biologic agent IL-2 appears to function primarily through host immunomodulation.

IL-2 binds to a heterodimeric receptor composed of three component molecules, , and subunits.[233] IL-2 effects are

mediated through interaction with a specific high-affinity membrane receptor.[233] The IL-2R is composed of three IL-2R peptide chains; the -chain (or Tac molecule), a 55-kd peptide; the -chain, a 75-kd peptide; and the -chain, a 64-kd protein. [233] [234] When all three chains are present in close approximation on the T-cell surface, a high-affinity IL-2R is formed which has 1,000-fold greater binding affinity compared to cells that express only the 55-kd -chain. The high-affinity receptor responds to IL-2 levels 100 times lower than the intermediate affinity receptor (receptor). T lymphocytes have only a high-affinity form of the receptor when activated, whereas NK cells have both an intermediate and high-affinity receptor and monocytes have only the intermediate receptors. [235] [236] [237] The subunit is shared by a number of cytokine receptors and it is critical to effective signal transduction for IL-2, as well as IL-4, IL-7, IL-9, and IL-15. [236] [237] The specificity, duration, and magnitude of a T-cell response is in part regulated by IL-2. [229] [238] IL-2Rs have a fairly restricted pattern of expression (NK cells, T cells, activated B cells, activated macrophages, and on some cells of malignant lymphoproliferative disorders). In addition, IL-2 stimulates a resting population of lymphocytes that, when activated, have cytotoxic activity against isolated tumor cells and tumor cell lines. [229] [230] [238] [239] [240] This cytotoxic activity is not MHC-restricted.[230] These cells have been termed lymphokine activated killer (LAK) cells; although no single effector cell is responsible for LAK activity, cell-surface phenotyping studies suggest that LAK activity is primarily mediated by CD3, CD56+ NK cells.[230] A minor contribution of LAK activity can be derived from cytotoxic T cells under some in vitro conditions.

In addition to the expression of the IL-2R by activated T cells, a fully soluble form of the subunit of this trimeric structure has been described and referred to as soluble p55 IL-2R (sIL-2R). Low levels of sIL-2R have been detected in the sera of healthy individuals and markedly increased levels have been detected in patients with hematologic malignancies.[241] [242] This has been most extensively evaluated in patients with human T-cell leukemia/lymphoma virus-1 (HTLV-1)-associated T-cell leukemia.

Clinical Application

IL-2 has undergone extensive clinical evaluation as a single agent, in combination with effector cells (including LAK cells and tumor-infiltrating lymphocytes) and, more recently, in combination with other cytokines and chemotherapy. [228] [243] [244] [245] Early studies, based on extensive animal experiments, used IL-2 combined with ex vivo IL-2-activated LAK cells.[228] The LAK cells were obtained by daily leukopheresis, and were then cultured in vitro with IL-2. Initial clinical studies, reported in 1986, revealed objective regressions in traditionally unresponsive tumors and therefore generated considerable interest. [243] [245] Since then, numerous studies have been performed to define both the optimal dose and schedule of IL-2 therapy, as well as the overall antitumor activity. IL-2 has shown activity as a single agent and in combination with other cytokines (IFN-) or with chemotherapy in solid tumors, most clearly demonstrated in renal cell cancer and metastatic melanoma. [246] [247] [248] [249] Most importantly, in both of these chemotherapy-resistant diseases, IL-2 induces significant durable complete or near complete remissions in 1020% of patients. These patients can have very durable unmaintained remissions lasting over 5 years. The mechanism of the antitumor effects, and the reason only a small percentage of patients experience these impressive tumor responses is unknown. The most convincing data for durable tumor responses have been reported in patients receiving the high dose bolus IL-2 regimens initially developed at the NCI-Surgical Branch. [242] Lower dose regimens and even outpatient subcutaneous regimens of IL-2 alone or with IFN- have shown similar response rates (1020%), but have failed to demonstrate the durability of their responses. [247] [248] Adoptive cellular therapy with ex vivo activated LAK cells or TIL cells has been too cumbersome and expensive to warrants its continued use. Results with LAK cells or TIL cells were not obviously superior to IL-2 alone.

Therapy of Hematologic Malignancies

Numerous trials have been conducted with IL-2 in hematologic malignancies. These have included trials in both acute and chronic leukemias, non-Hodgkins lymphomas, and multiple myeloma.[250] [255] Trials have been initiated utilizing a variety of schedules and doses of IL-2 and administered in a number of clinical settings including early relapse of acute leukemia, following remission as maintenance therapy, and following hematopoietic stem cell transplantation with autologous or even allogeneic stem cell donors (see Table 51-2). While many of these trials have provided some promising leads, they have largely been difficult to interpret and failed to determine a definitive role of IL-2 in the treatment of hematologic malignancies. Early studies with high-dose IL-2 regimens suggested activity against lymphoma. Weber and colleagues treated 19 patients with either low grade (follicular) lymphomas (8 patients) or intermediate grade lymphomas (11 patients) with high-dose bolus IL-2.[256] There were three partial responses and one complete response among the eight patients with follicular lymphoma and no responses among those with intermediate grade lymphoma. Duggan et al. reported a phase II study of recombinant IL-2 with or without IFN- in patients with relapsed or refractory non-Hodgkins lymphoma.[251] Although designed as an outpatient regimen, toxicity was severe and the response rate was only 17%. A relatively large phase II experience with continuous infusion IL-2 at inpatient dose intensity was reported from France and included 61 patients with lymphoma. [252] Of 23 patients with intermediate- and high-grade NHL, there were 3 CRs and 4 PRS; of 24 patients with low-grade NHL, there was a single CR; and of seven patients with mycoses fungoides, there was 1 CR and 4 PRs. The CR durations were 4, 12, 17, 20, and 23 months.

Several uncontrolled phase II trials in small cohorts of patients suggest antileukemic activity of IL-2. [257] [258] [259] [260] In acute myeloid leukemia (AML) patients with refractory or relapsed disease with between 530% bone marrow myeloblasts, IL-2 administered through continuous intravenous infusion followed by lower dose

subcutaneous IL-2 maintenance led to CRs in 11 of 20 patients with 6 continuing in CR at median follow-up of 50 months (9, 33, 49, 51, 52, and 87 months). [257] These remission durations were all longer than the patients previous remission durations. Although toxicity was significant, there were no deaths and side effects were completely reversible. Intensive bolus IL-2 at 68 MIU/m^2 every 8 hours was administered to 10 AML patients with relapsed disease following prior chemotherapy or autologous stem cell transplant. [258] Two patients had complete remissions of 3 and 4 months in duration. IL-2 has also been administered to AML patients at high risk for recurrence following induction of second remission with chemotherapy or stem cell transplantation. IL-2 has been administered as a bolus infusion, or via polyethylene glycol (PEG) delivery as a means of slow release to simulate continuous infusion. [259] [260] Prolongation of second remissions was suggested, but not proven by the results. IL-2 has potential to enhance the immune state of patients with myelodysplastic syndromes and may be a treatment worth exploring, especially in low-risk MDS patients. [261]

A potentially more promising approach has been the incorporation of IL-2 into BMT regimens to augment immunologic recovery after BMT and, possibly, to stimulate graft-versus-leukemia activity. Defective IL-2 production and defective T-cell proliferation have been reported following BMT. Higuchi et al. reported that IL-2 responsive LAK precursor cells are available in the peripheral circulation as early as 3 weeks after

TABLE 51-2 -- Clinical Trials with Interleukin-2 in Hematologic Malignancies

Patient Population	IL-2 Regimen	Significant Toxicity	Outcome/Findings	References
Lymphoma				
Non-Hodgkin lymphoma Hodgkin disease	Moderate IL-2 IV CI + LAK		15 treated: 1 PR in NHL 1 PR in HD	[114]
Non-Hodgkin lymphoma Hodgkin disease	High dose bolus IL-2 IV + LAK	Hypotension, renal insufficiency, fever	0/15 responses in NHL 2/12 PR in HD	[115]
Non-Hodgkin lymphoma	High dose bolus IL-2 IV + LAK	Hypotension, renal insufficiency, fever	3 PR and 1 CR in 19 NHL (8 low grade and 11 intermediate grade)	[116]
Non-Hodgkin lymphoma Hodgkin disease	IV CI Moderate dose IL-2		1 CR, 5PR in 10 low grade NHL, 0 responses in 7 intermediate NHL and 4 HD	[108]
Non-Hodgkin lymphoma Hodgkin disease Cutaneous T-lymphoma	IV CI Moderate to high dose IL-2	Cardiac, renal VLS, platelets	1 CR-24 low-grade NHL 3 CR, 2PR-23 Int grade NHL 0/7 responses in HD 1 CR, 4 PR in 7 CTCL	[110]
Acute Leukemia				
Early relapsed/refractory AML (<30% BM blasts)	IV CI Moderate dose IL-2	Fever, renal, N/V, platelets, hypotension, sepsis	11/20 CR, 1 SD 6 CCR for 9+ to 87+ mos 1 SD for 18+ mos	[117]
Relapsed (overt) AML	IV bolus high dose IL-2	Fever, hypotension, platelets, renal, liver	2 CR among 10 pts Duration of 3 and 4 mos	117a
2nd remission AML as consolidation	IV 1 hr IL-2	Fever, rash, sepsis, liver	5/21 2nd CR longer than 1st CR 7/21 ongoing 2nd CR Others 2nd CR < 1st CR	[118]
2nd remission IL-2	PEG IL-2 weekly IV	Fever, chills, fatigue, VLS (mild)	3/7 2nd CR longer than 1st CR	[119]
Adult ALL: phase III of autologous BMT ± IL-2 in 1st CR versus allogeneic BMT	IL-2 CI IV moderate dose after engraftment		30 IL-2 vs. 30 with no IL-2: median CR, 3 yr CCR no different and inferior to allogeneic BMT	[120]
Hematologic malignancies: CML, AML, ALL, NHL, MDS following T-depleted allogeneic-BMT	Low dose CI IL-2 after engraftment	Fatigue, fever, N/V, infection, rash, diarrhea	In 25 patients: relapse of IL-2 treated similar to controls with no-IL-2 with GvHD and superior to no IL-2 without GvHD	[121]
Relapsed AML post autologous BMT	CI IV IL-2 + LAK moderate dose post engraftment	Fever, rash, platelets	10/14 in CCR for 15+ to 50+ mos (median 36+ mos) 71% 4 yr DFS actuarial	[122]
High-risk AML ex vivo IL-2 activated BMT + IL-2	Ex vivo IL-2 BM activation + sc IL-2 low to moderate dose	Fever, malaise, hypotension, delayed engraftment	5/10 in CCR for 18 to 32+ mos	[123]
Multiple Myeloma				
Multiple myeloma	Low dose sc IL-2 (1.8 MIU/m2/d)	Fever, splenomegaly, herpes zoster, eosinophilia	2/17 objective responses 4/17 stable disease	[124]
Multiple myeloma	SC IL-2 (4.5 MIU) + IFN (4.5 MU) TIW	Headache, anorexia, nausea	0/17 objective responses	[125]

ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; BM, bone marrow; BMT, bone marrow transplant; CI, continuous infusion; CML, chronic myeloid leukemia; CR, complete remission; CCR, continuous complete remission; CTCL, cutaneous T-cell lymphoma; DFS, disease-free survival; GvHD, graft-versus-host disease; HD, Hodgkin disease; IV, intravenous; LAK, lymphokine-activated killer cells; MDS, myelodysplastic syndrome; NHL, non-Hodgkin lymphoma; N/V, nausea and vomiting; PEG, polyethylene glycol; PR, partial remission; SC, subcutaneous; SD, stable disease; TIW, thrice weekly; VLS, vascular leak syndrome.

autologous BMT. [262] [263] Fefer and colleagues hypothesized that IL-2 may be most effective as a consolidative immunotherapy for lymphoma and AML early after ABMT. [264] [265] This was based on the in vitro and in vivo activity of IL-2 in NHL and AML and the minimal disease state following ABMT; treatment of clonogenic malignant cells within the graft with IL-2; activation of the recovering immune system with IL-2; and the ability of IL-2 to induce a cutaneous graft-versus-host disease (histologically and clinically) which has been associated with a graft versus tumor effect in allogeneic transplants. [253] [264] Two preliminary trials of IL-2 with and without LAK cells administered shortly after hematologic recovery (1491 days after BMT) have appeared promising, with a majority of AML patients remaining in a prolonged disease-free-remission far longer than historical controls. [253] [265] These preliminary trials have led to ongoing randomized phase III trials in cooperative groups for NHL with consolidative immunotherapy of IL-2 alone following ABMT. In a small randomized trial in adults (1555 years) with ALL, 135 previously untreated patients, 126 who went into a complete remission with BFM induction chemotherapy either received an allogeneic BMT if they had an HLA-matched sibling or underwent an autologous stem cell transplant with or without post-transplant IL-2. [266] Only 60 patients were randomized between IL-2 or observation following their autologous transplants. The patients undergoing allogeneic BMT (68% vs. 26%) had a far better DFS, whereas IL-2 did not appear to improve the results in patients receiving autologous transplant (29% vs. 27%). The dose of IL-2 was defined by a prior phase I trial. IL-2 was administered a median of 80 days post-autologous transplant, which may have had a relationship to the high early relapse rate and the few patients randomized to IL-2 or observation. Earlier administration of IL-2 may be critical to the

treatments efficacy. Others have cultured stem cells ex vivo with IL-2 as a means of purging residual leukemic cells and to induce immune effectors within the graft. [261] [262] [263] [264] [267] [268] [269] In these trials IL-2 was administered to patients immediately following stem cell infusion in the hope of activating these immune cells within the graft. Engraftment of platelets and neutrophils appeared to be significantly delayed by this approach and a number of manageable toxicities were observed. Slavin and colleagues have reported on the use of both IL-2 and IFN following autologous stem cell transplantation for both NHL and Hodgkins disease. [270] [271] Results of post-transplant immunotherapy in 56 patients again appeared superior to historical controls in terms of disease-free survival. The regimen was self-administered,

outpatient, and subcutaneous.

Others have explored the feasibility of administering IL-2 following allogeneic BMT as a means of enhancing the existing graft-versus-tumor effect. [254] [272] [273] Soiffer and colleagues at the Dana Farber Cancer Institute have treated patients with hematologic malignancies who underwent a T cell (CD6) depleted HLA-matched sibling allogeneic BMT with a low dose regimen of continuous IL-2 following recovery from the BMT for a period of 3 months. [272] T-cell depleted allogeneic BMT has been an effective approach at limiting GvHD, but increases the risk for disease relapse. The schedule of low dose continuous IL-2 was able to activate and expand endogenous NK cells, with minimal toxicity. Results from the 25 patients who received IL-2 for greater than 30 days suggest a better outcome (relapse rate) compared to historical controls who did not develop GvHD. Robinson and colleagues have administered IL-2 following HLA-matched sibling allogeneic BMT in children with acute leukemia.[273] Patients without GvHD off immunosuppressive agents received IL-2 by continuous infusion. At higher doses of IL-2, pulmonary toxicity and chronic GvHD was observed. Severe acute GvHD was not observed. This may set the stage for further trials of IL-2 in unmodified allogeneic BMT where GvHD is not observed. Another modification of this approach has been explored by Slavin and colleagues, who treated relapses post-allogeneic BMT with donor lymphocytes activated in vitro and/or in vivo with IL-2. [270] The allogeneic cell therapy may be enhanced by further activation with IL-2 in these studies.

Finally, IL-2 has shown promise in patients with HIV disease as an immunostimulant capable of increasing CD4 cell counts, without changing HIV viral load. [274] Bernstein and colleagues have also treated patients with HIV-associated malignancies and demonstrated large in vivo expansion of NK cells without increases in HIV viral levels.[275] Most striking was the absence of opportunistic infections during the 50 months of IL-2 therapy, far fewer than would be expected for this highly immunosuppressed population.

IL-2 Associated Clinical Toxicity

Most of the toxicities associated with IL-2 have been reported in patients receiving the high dose intravenous bolus (600,000720,000 IU/m ^{2}) or continuous infusion regimens.[8] [276] The adverse effects of high dose IL-2 resemble sepsis and include fever, rigors, oliguria, and hypotension that frequently requires vasopressor support.[276] The vascular leak syndrome is believed to be due to the induction of proinflammatory cytokines such as IL-1, TNF-, IFN-, and the induction of nitric oxide which acts to mediate the vascular and organ toxicities. [231] [232] [277] A variety of hematologic, hepatic, neurologic, renal, cutaneous, and gastrointestinal toxicities have also been well described. [276] [279] [280] [281] All patients experience a reversible malaise and flu-like syndrome with fever, chills, and gastrointestinal symptoms. Other end-organ toxicities have included hepatic dysfunction manifested as elevated bilirubin due to intrahepatic cholestasis. Several autoimmune processes have been reported including thyroiditis, vitiligo, and inflammatory bowel changes. [8] [276] Finally, infectious complications such as catheter-associated bacteremias have been associated with skin changes due to IL-2. [8] Most of the deaths occurring in patients while receiving IL-2 were due to sepsis, prior to institution of prophylactic antibiotics in all patients with central venous catheters. Cardiopulmonary effects have been most prominent among the multiple sequelae of IL-2. Initially, mortality associated with myocardial infarctions, cardiac arrythmias, and pulmonary edema requiring intubation and mechanical ventilation were reported in 210% of patients receiving high dose IL-2 with or without LAK cells. [276] [278] This initial experience led to more rigid selection criteria of patients, thereby excluding those at risk for cardiac problems. In addition, management changes were instituted that led to discontinuation of IL-2 if any of the following occurred; excessive vasopressor support, neurologic toxicity, significant cardiac arrhythmias, or respiratory distress requiring significant oxygen support. [276] In more recent series, there were no deaths from treatment and no myocardial infarctions. [278] Hypotension requiring vasopressors occurred in 53% of courses and intubation occurred in four patients (1.2% of courses). Only one patient required intubation for respiratory distress; the other three patients required protection of the airway because of obtundation. Atrial arrhythmias occurred in 5.2% of courses, but were associated with hypotension in only two courses (0.6%). This decreased toxicity was associated with a large reduction in doses to approximately 15 doses administered of a maximum total of 28 for a course (two cycles) with 720,000 IU/kg per dose. Several patients also demonstrated a transient rise in CPK-MB without definitive findings of myocardial infarctions. In addition, the use of prophylactic antibiotics and aggressive therapy of infection may have led to a decline in cardiopulmonary complications. Renal toxicity including azotemia, oliguria, and weight gain due to fluid retention was frequent, but completely reversible without long-term renal dysfunction. [279] It was more prevalent in association with prior renal compromise from a nephrectomy. Finally, hematologic toxicities including anemia, severe thrombocytopenia and lymphocytopenia, rebound lymphocytosis, and eosinophilia have all been reported. [280] [281] The lymphopenia occurs early in therapy and may be the result of margination. Thrombocytopenia has been relatively rare, requiring transfusions or resulting in hemorrhage in very few cases. Virtually all the side effects of IL-2 are rapidly reversible with discontinuation of therapy. Several attempts to limit IL-2 toxicities with inhibitors of secondary cytokine induction such as pentoxyfilline, lysofilline, and ciprofloxacillin, or inhibitors of TNF function have shown only marginal benefit in limiting toxicity or allowing greater dose intensity. [282] [283]

Interleukin-4

Interleukin-4 (IL-4) is a 20,000 dalton glycoprotein produced by activated T cells, first described as a B-cell stimulatory factor. [284] More recent studies have demonstrated a broad range of regulatory activities for IL-4. [285] [286] [287] [288] [289] [290] IL-4 induces T-cell proliferation and enhances cytotoxicity of T cells. It enhances the generation of antigen-specific T lymphocytes from tumor-infiltrating lymphocytes. [289] IL-4 enhances the growth of mast cells and stimulates macrophage antitumor cytotoxicity.[284] Interleukin-4 is a pluripotent cytokine that has the ability to activate T cells in combination with IL-2 or by itself; to stimulate T-helper type 2 (Th2) responses; enhance expression of MHC class II, CD23, CD40, LFA1/LFA-3; and enhance antibody-dependent cellular cytotoxicity (ADCC) responses of human mononuclear cells.[285] [286] [287] [288] It is composed of a single 129-amino-acid chain and predominantly produced by the Th2 CD4+ subset of T cells. Preclinical studies of IL-2 and IL-4 in combination resulted in inhibition of IL-2-induced LAK activity. In addition, IL-4 inhibits cytokine production and certain effector functions in human monocytes.[291] [292]

IL-4 can antagonize some of the responses induced by IFN- and TNF-. [291] Therefore, IL-4 appears to play an important role in the down-regulation and resolution of an inflammatory response. IL-4 has also been shown to inhibit megakaryocyte colony formation in a dose-dependent fashion and to suppress CFU-GM proliferations.[293] The high-affinity IL-4 receptor can be found on T cells, mast cells, macrophages, and hematopoietic progenitors, as well as fibroblasts, brain cells, and most epithelial cells. The IL-4 gene is found on human chromosome 5. IL-4 has been shown to modulate tumors directly by changing surface phenotypes by modifying MHC class II expression and tumor-associated ganglioside expression, inhibiting proliferation, and inhibiting secretion of autocrine growth factors (IL-6) for some cancers (e.g., myeloma); and, in combination with GM-CSF, may enhance the ex vivo induction of potent antigen presenting cells (dendritic cells). [294] [295] IL-4 transfected murine cancers have been shown to protect hosts from subsequent tumor challenge from parental untransfected tumor cells through activation of host immune cells and eosinophils.[296] [297]

Phase I and II trials with IL-4 have been performed in patients with solid tumors. [298] [299] [300] These trials have demonstrated no significant anti-tumor activity in patients with renal cancer or melanoma. IL-4 has the unique ability to inhibit the release of proinflammatory cytokines and induce inhibitors to IL-1 (IL-1ra). These anti-inflammatory effects differ greatly from IL-2. Toxicity of IL-4 has differed from IL-2 in terms of frequent development of gastritis, nasal congestion, and myocardial inflammation and dysfunction in IL-4 treated patients, while still exhibiting common cytokine toxicities including fever, rash, myalgias, and headaches. [300] The in vitro effects of IL-4 on human lymphoid and plasma cell malignancies have been investigated. [294] IL-4 inhibits the in vitro growth of most tumor specimens, with <10% of specimens studied demonstrating a proliferative response. The addition of IL-4 to chronic myeloid leukemia (CML) cell cultures has resulted in divergent effects with suppression of CFU-GM in some patients and stimulation in other samples. [295] IL-4 has also been shown to inhibit the growth of Philadelphia-chromosome positive ALL cells in vitro and is being explored in the treatment of relapsed ALL. [301] [302] More recently, IL-4 has demonstrated promising preclinical effects in tumor models of Burkitts lymphoma, B-cell precursor acute leukemia, and high risk acute lymphoblastic leukemia. [303] [304] These effects may be due to direct antiproliferative effects or induction of programmed cell death (apoptosis) of the leukemic cell or via indirect effects on the host effector cells. Trials in myeloma and low grade lymphoma are anxiously being awaited. Finally, IL-4 has been used in combination with GM-CSF in clinical trials to ex vivo expand dendritic cells as a means to enhance tumor vaccines with these potent antigen-presenting cells. [305] [306]

Interleukin-12

Interleukin-12 (IL-12) was initially known as cytotoxic lymphocyte maturation factor (CLMF) or natural killer cell stimulatory factor (NKSF). [307] [308] Once characterized and cloned, its profound effects on the proliferation, cytolytic activity, and cytokine induction of both T and NK cells became apparent. [309] [310] It plays a profound role in regulating the induction of the T-helper (CD4+) type 1 (Th1) subset and is an important component of the immune response to foreign antigens. [309] [310] [311] [312] [313] IL-12 is unique among cytokines in that it is composed of two different disulfide-linked protein subunits: p40 with sequence homology to the cytokine receptors of the gp130 family; and p35 which is structurally similar to the IL-6 family of cytokines. [314] IL-12 is postulated to have arisen from a disulfide linkage between a receptor and its ligand. The disulfide-linked heterodimer is required for optimal biologic activity. IL-12 can be produced from a variety of cells including EBV-transformed B-cell lines (from which it was first isolated), B lymphocytes, monocytes, macrophages, mast cells, keratinocytes, dendritic cells, and thymic stromal cells. Its surface receptor is

still poorly characterized, but at least one of its subunits is a member of the cytokine receptor superfamily and is associated with members of the JAK kinase family (JAK2 and TYK2).[314] IL-12 can augment both T-cell and NK-cell cytolytic activity, but most impressively induces the activation of T- and NK-cell secretion of Th1 type cytokines, especially IFN.[315] This shift to a Th1 functional phenotype may be important in the induction of cell-mediated responses against tumors. IL-12 has been shown to have potent antitumor effects in animal tumor models. It also has antimetastatic activity in various tumor models. [315] These activities appear more dependent upon T cells than on NK cells or monocytes/macrophages. It is active in mediating antitumor effects when delivered directly to tumor sites. [315] In some tumor models, IL-12 appears more active when combined with IL-2.[316] IL-12 has been shown to be capable of suppressing experimental tumors through an indirect anti-angiogenic effect through its effect on IFN- and IP-10, an early response gene induced by IFN-. [317] Additional studies have demonstrated that peripheral blood lymphocytes from patients with metastatic cancer or following allogeneic BMT are activated by IL-12. [318] Future clinical studies with IL-12 will focus the potent immune-enhancing properties of this cytokine both alone and in combination with IL-2. Phase I trials of IL-12 in cancer and HIV patients have been completed. [319] The major toxicities have been oral stomatitis and transient hepatic dysfunction. Serum IFN- is markedly increased in these patients. Interestingly, when IL-12 proceeded into phase II trials, a single test dose was removed from the treatment schedule.[320] Without the single test dose of IL-12, toxicity of the 5-day course of IL-12 was much more severe with life-threatening systemic toxicities including gastrointestinal hemorrhage, acidosis, dyspnea, and severe fatigue. The single dose of IL-12 abrogated the toxicity, as well as the IFN- induction. This unique biologic activity was found to be reproducible in animals, as well. [320] Phase II trials are now underway with the added understanding of these unique biologic effects of IL-12 and its scheduling dependence. These trials are anticipated with great promise in solid tumors, hematologic malignancies, and in the stem cell transplant setting.

Interleukin-15

Interleukin-15 (IL-15) has been isolated based on the T-cell stimulatory activity of supernatant from an epithelial cell line. [321] It shares a number of biologic activities with and has structural similarities to IL-2 in its four-helix bundle structure, but virtually no sequence homology exists between the two cytokines. IL-15, unlike IL-2, is not predominantly produced by activated T lymphocytes, but abundant levels are produced by monocytes, fibroblasts, epithelial cells, and stromal cell lines derived from the bone marrow and thymus.[322] IL-15 is abundantly secreted from monocytes and macrophages and can then induce the proliferation of activated and antigen-dependent T cells, induce the proliferation of NK cells, co-stimulate the secretion of cytokines from NK cells in combination with IL-12, and induce cytolytic effector cell activity from T and NK/LAK cells.[321] [323] [324] IL-15 may act to recruit T lymphocytes to sites of inflammation by changing their polarity and enhancing expression of adhesion molecules. IL-15 also appears to induce the proliferation and cytokine release from peripheral blood mononuclear cells (PBMC) and CD4+ T cells from HIV-infected individuals.[325] IL-15 appears critical to the survival of resting NK cells. [323] Its absence leads to apoptotic cell death of NK cells. The abundant release of this cytokine by stromal and antigen-presenting cells (APC) suggest that its presence maintains NK cells to a much greater degree than IL-2. The IL-15 receptor shares the and subunits with the IL-2 receptor, but has a different and unique

receptor.[321] It has been shown that IL-15 mediates proliferation of both CD3+ and CD3 granular lymphocytes from patients with lymphoproliferative disorders of granular lymphocytes.[326] The presence of mRNA for IL-15 and its receptor in the peripheral blood mononuclear cells of these patients suggests a role in the expansion of granular lymphocytes.[326] Similar findings have been described for B-cell malignancies such as hairy cell leukemia and B-cell CLL. [327] IL-15 has not yet entered clinical trial development, but may ultimately be a component in therapy for immunodeficiency states or cancer. Antagonists to IL-15 may have a role in T- and B-cell chronic leukemic conditions.

Flt3 Ligand

Flt3 ligand (flt3L) is a novel hematopoietic growth factor and the ligand for the flt3 tyrosine kinase receptor, a member of the tyrosine kinase (TK) receptor family involved in hematopoiesis (i.e., c-kit and c-fms). [328] [329] Primitive CD34+ cells from bone marrow, cord blood, and fetal liver in human and mouse respond to flt3L to form colonies and flt3L synergizes with other more lineage-specific colony-stimulating factors promoting in vitro colony formation. [328] [329] In vitro colony assays show that flt3L has activity in regulating both primitive multipotential and lineage-committed hematopoietic progenitor cells. Studies also suggest that the presence of flt3L may enhance the ability to genetically transduce human and murine hematopoietic progenitor cells. [329] Normal expression of flt3L is limited to CD34+ stem/progenitor cells. Overexpression of flt3L and its receptor appears common in many cases of AML, ALL, and CML blast crisis, regardless of whether CD34 is expressed. [328] [330] Flt3L alone or with other cytokines (IL-7) can induce the in vitro proliferation of ALL and AML cells. [330] This finding suggests a potential role for flt3L in the pathophysiology of acute leukemia. Patients with aplastic anemia, and patients undergoing intensive marrow ablative chemotherapy have large increases in flt3L levels, which return to baseline following hematologic recovery or remission. [331] Flt3L appears to be a critical regulator of early hematopoiesis. Daily subcutaneous administration of flt3L has been shown to induce large numbers of dendritic cells in lymph nodes, spleen, and other tissue. [332] These dendritic cells are antigen-presenting cells capable of stimulating primary T-cell responses to antigen. The dendritic cells expanded in vivo or ex vivo by flt3L are functionally active and capable of stimulating antigen-specific T-cell responses. Based on this dendritic cell activation, flt3L was examined as an anti-tumor agent in murine tumors. These experiments revealed that in vivo tumor rejection and specific immunologic memory can be induced. [332] Therefore, administration of flt3L alone or in combination with other colony-stimulating factors may not only lead to mobilization of hematopoietic progenitor cells, but also to the generation and mobilization of dendritic cells. These effects may enhance hematologic recovery and immune recovery, and potentially mediate a direct or indirect anti-tumor effect. Flt3L-stimulated cells could also be utilized for the induction of more optimal protein- or peptide-based vaccines. These concepts will soon be tested in various clinical trials. [333] [334]

Interferons (IFN- and - and -)

Interferons are produced in response to various stimuli, including viral infection, double-stranded RNA, mitogens, and antigens. [335] The IFNs are a family of glycoproteins that were initially discovered in 1957 and named for their ability to interfere with viral replication. It has since become clear that IFNs have pleotropic biologic effects, including immunostimulatory effects, direct antiproliferative effects, and antiviral properties. [335] The three major types are IFN-, IFN-, and IFN-. IFN- and IFN- bind to the same type I receptor and are stable at pH 2. IFN- binds to a type II receptor and is labile at pH 2. IFN- is produced by a variety of cells including macrophages and lymphocytes. Virtually every nucleated cell produces IFN- in response to a variety of stimuli, including viruses, other pathogens, and double-stranded RNA. IFN- is produced by fibroblasts and epithelial cells and IFN- is produced by T lymphocytes and NK cells. IFN- is a potent activator of monocytes and macrophages, enhances NK-cell cytotoxicity, and results in the up-regulation and expression of both class I and class II MHC antigens. [336] [337] The other biologic activities of IFNs include antiviral activities; ability to interfere with cell proliferation; inhibition of angiogenesis; and regulation of differentiation and enhancement of expression of cell surface antigens, including tumor-associated antigens, MHC antigens, or adhesion molecules. [335] In part, IFNs mediate their action by enhancing the expression of IFN-inducible genes. [338] The biologic role for most of the proteins activated by IFNs is unknown, but two of the best-characterized molecules regulate protein translation. [338]

Both IFN- and IFN- are derived from a single gene, whereas 23 genes exist for IFN-, all located on the short arm of chromosome 9. The IFN- gene is also located on chromosome 9, and the gene for IFN- is located on chromosome 12.[339] Interestingly, some malignant hematopoietic cell lines have been shown to have homozygous deletions of type I IFN genes on chromosome 9, suggesting that these genes may function as tumor suppressor genes; therefore, their loss may be associated with tumor progression.[339] The interferons have activity in a variety of malignancies. Anti-tumor activity has been demonstrated in hairy cell leukemia (HCL), chronic myeloid leukemia, cutaneous T-cell lymphomas, multiple myeloma, and other indolent lymphomas.

Clinical Application

The IFNs were the first of the cytokines to undergo extensive clinical evaluation, and most of the trials have studied IFN-. Initial clinical studies began in the 1970s with partially purified IFN preparations. Over the previous decade, numerous phase II studies of IFN- have been completed, with antitumor activity primarily being demonstrated against hematologic malignancies. Limited studies have been conducted with IFN-, and results to date demonstrate little role for this cytokine as a therapeutic anticancer agent. IFN- is administered at a wide range of doses and schedules depending on the clinical setting. The toxicities associated with IFN- are dose-related. The most common side effects include fever, chills, fatigue, headache, myalgias, arthralgias, and a flu-like syndrome. [335] Patients generally develop tolerance to the fever and chills after repetitive administration. However, there is no tolerance to the other constitutional symptoms, which are usually dose-limiting. Higher doses of IFN are associated with neurologic toxicity (depression, confusion, seizures); cardiac abnormalities (atrial arrhythmias), and laboratory abnormalities, including transaminase elevation, leukopenia, thrombocytopenia, and anemia. [340] Bone marrow suppression must be monitored closely in patients with compromised marrow reserve due to underlying malignancy, concomitant drug administration (AZT), and/or chemotherapy. The salient features of IFN therapy in hematologic malignancies are discussed in the following sections.

Chronic Myelogenous Leukemia (CML)

IFN- produces hematologic responses in 5080% of patients with chronic phase CML. [341] [342] A major difference from chemotherapy is the induction of cytogenetic responses (suppression of the Ph+ cells) by IFN therapy. [341] [342] Cytogenetic responses can be observed in up to 50% of patients with major cytogenetic

responses (<35% Ph+ cells) in 1525% of patients. In 1994, the Italian Study Group randomized 218 patients between IFN- and hydroxyurea and found that IFN-treated patients had a significantly longer survival (>72 vs. 52 months), time to transformation (>72 vs. 45 months), and increased incidence of major cytogenetic responses (19% vs. 1%). [342A] This was achieved with regimens administering IFN daily at doses of 5 MIU/m^2 or 9 MIU daily. Based upon the experience at M.D. Anderson, the development of a major cytogenetic response was associated with improved survival even with landmark analyses performed 12 months into therapy. [341] Most studies suggest the benefit of IFN- is limited to patients who develop a cytogenetic response. A medical research council trial reported improved survival compared to chemotherapy alone in the IFN--treated cohort of patients who did not demonstrate cytogenetic response. [343] The presence of splenomegaly and bone marrow basophilia were poor prognostic factors for outcome. Most studies suggest that higher doses of IFN- are required for this beneficial effect. However, a trial performed at the University of Colorado among 41 patients with newly diagnosed CML reported a 70% complete hematologic remission rate with 22% major cytogenetic responses using IFN- at 2 MIU subcutaneously three times a week. [344] This activity appears similar to IFN activity with higher, more frequent dosing, but with less toxicity and much lower overall cost. These results will require confirmation and even randomized trials to define the role of lower dosing. Most patients treated with IFN do not eliminate their minimal disease state defined by positive RT-PCR for bcr-abl mRNA. [345] [346] [347] [348] However, recently patients in complete cytogenetic remission on IFN for many years have been found to be RT-PCR negative for the transcript. The minimal disease state is generally only eliminated in patients following an allogeneic BMT. Toxicity of the higher-dose standard regimen of IFN is significant in patients over 60 years of age with up to 65% requiring dose modification due to toxicity (frequently neurotoxicity and fatigue). [349] Response rates appear similar to younger patients with 26% experiencing major cytogenetic responses and a median survival of 64 months and 5-year survival of 62%. Finally, a study from France combined IFN- with cytarabine (Ara-C) and compared it to IFN- alone in newly diagnosed CML patients. Ara-C was administered at 20mg/m^2 /day for 10 days while IFN- was administered in both cohorts at 5 MIU/m^2 /day daily. [350] Those receiving the combined IFN plus Ara-C had significantly greater cytogenetic responses (41% vs. 24%); higher hematologic remission rate ($P = 0.003$), and at 3 years a significantly better survival (85.7% vs. 79.1%). After a short follow-up, the combined arm appears superior in terms of overall survival. This appears to be a step forward in the treatment of chronic phase CML.

IFN is most effective when used to treat patients with early-stage CML, with very little activity in accelerated phase disease, and no benefit when used in blast crisis. [351] Many patients experience significant side effects from IFN, as relatively high doses are generally utilized to induce responses. IFN- has also been evaluated in patients with CML, but the available data suggest that IFN- has greater activity in CML, and the incidence of toxic events has been greater with IFN-. [352] [353] Additional approaches currently being explored include combining IFN with chemotherapy and the use of maintenance IFN after allogeneic BMT for CML.

In limited pilot studies, IFN- has been used to treat patients with polycythemia vera, agnogenic myeloid metaplasia, and primary thrombocythemia with activity in subsets of patients. [354] [355] [356] [357] [358] Similar to the effects seen in CML, IFN- has the ability to suppress hematopoiesis of affected lineages, thereby reducing peripheral blood counts. Clearly, IFN- has potential clinical application for the treatment of myeloproliferative disorders, in addition to CML.

Hairy Cell Leukemia (HCL)

Since the initial report in 1984 by Quesada that IFN--induced improvement in the hematologic parameters of patients with HCL, it has become well established that IFN- is an active agent in its treatment. [359] [360] HCL is extremely responsive to IFN- therapy, with an overall response rate of 8090%. IFN- has only a 1015% complete remission rate. These results can be obtained with relatively low doses of IFN, 23 MIU subcutaneously three times a week, but require continued therapy to maintain the hematologic remission. Recovery of the platelet count can occur within 2 weeks; reduction in spleen size and improvement in peripheral blood counts usually occur within 23 months of therapy. Responses to IFN have been reported in splenectomized and previously untreated patients. [361] Progression of HCL has been associated with the development of neutralizing anti-IFN antibodies. [242] Survival in patients treated with IFN- is excellent. However, the development of newer agents, pentostatin and 2-chlorodeoxyadenosine, have replaced IFN as front line therapy because of their durable and frequently complete remissions. [361]

The precise mechanism of IFN activity against HCL is not entirely clear, but its antitumor activity may involve direct effects, modification of oncogene expression, modulation of cytokine expression, or specific alterations in protein synthesis leading to partial differentiation of the malignant leukemia cells. [3] [7] [335] Interesting preclinical and clinical data suggest that TNF may act as an autocrine growth factor for some cases of CLL and HCL. [3] Digel et al. [7] found increased circulating levels of soluble TNF-binding proteins (TNF-BP) in the sera of patients with B-CLL and HCL compared with human sera from healthy controls. Levels of TNF-BP have been reported to be decreased after effective therapy with IFN-. [362] [363] In addition, preclinical studies have shown that IFN- can inhibit TNF-dependent HCL growth with decreases in TNF mRNA occurring after IFN treatment. [362] [363]

Multiple Myeloma

IFN- has been known to bind to myeloma cells and cell lines and to mediate anti-proliferative effects. [364] Despite years of evaluation, the role of IFN in the treatment of multiple myeloma remains unclear. Early studies explored the activity of IFN- as a single agent and resulted in response rates of only 2025%. [364A] [364B] [364C] This was considerably less than that achieved with chemotherapy. Clinical effects in end stage refractory myeloma patients have been observed, but only in few patients for limited periods of time. Many more clinical trials have utilized IFN- either in combination with chemotherapy during the induction phase of treatment or following achievement of a maximal treatment effect. [365] [366] [367] [368] [369] [370] [371] Treatment during the plateau phase with maintenance IFN to prevent tumor cell cycling has been explored. Results of these studies have been contradictory. The Nordic Myeloma Group randomized 583 patients to chemotherapy (melphalan plus prednisone) with or without IFN during all phases of treatment including induction, plateau phase, and even relapse. [366] The IFN had no effect on overall survival or response rate, but it did increase the duration of response and plateau phase. On the other hand, a Canadian study randomized 176 patients following a response to melphalan and prednisone to either observation or IFN- at 2 MU/m^2 /d three times a week. [371] This trial showed a benefit in overall median survival (4335 months) that was significant only when adjusted for baseline characteristics. Progression-free survival greatly favored those randomized to IFN maintenance. Other trials, including the Swedish and Southwest Oncology Group trials, showed no survival benefit from maintenance treatment with IFN. [368] [370] The continuation of IFN at relapse has been proposed

as a reason for the different outcomes between some of the trials. [372] Several small randomized trials showed that IFN can maintain remission following autologous BMT and even improve overall survival in post-transplant patients. [373]

Non-Hodgkin Lymphoma (NHL) (Including Cutaneous T-Cell Lymphoma and HTLV-Associated T-Cell Lymphoma)

IFN- studies in patients with non-Hodgkin lymphoma have also examined the single-agent activity, effects of maintenance therapy after induction chemotherapy, and use of IFN- in combination with chemotherapy. [374] [375] [376] [377] [378] [379] [380] [381] For the most part, these studies have been limited to indolent lymphomas in which the overall response rate is approximately 2540%. [374] [375] [376] Patients with intermediate-grade non-Hodgkin lymphoma tend to have fewer objective responses. [374] IFN has also been studied in combination with cytotoxic chemotherapy in patients with low-grade lymphomas. The results of a prospective randomized trial designed to evaluate the role of IFN- with a multidrug cytotoxic therapy (COPA [cyclophosphamide, vincristine, prednisone, doxorubicin]) have been reported. [377] Two hundred ninety-one patients with low-grade lymphoma were randomized. The regimens produced comparable objective response rates, but the addition of IFN resulted in prolongation in the time to treatment failure, in duration of complete response, and in overall survival. [377] A follow-up report at 5 years failed to confirm the overall survival advantage. [380] A trial reported by a French cooperative multicenter group enrolled 242 eligible patients with advanced low-grade follicular NHL and randomized them between cyclophosphamide, doxorubicin, vinblastine, prednisone (CHVP) with or without IFN-. [381] Those receiving CHVP plus IFN- had a better response rate, event-free survival, and overall survival. CHVP and IFN- were administered simultaneously and for prolonged periods of time. In contrast, the preliminary results of a large prospective trial in which patients with follicular low-grade lymphoma were randomized to chemotherapy alone or with IFN- suggests no difference in complete response rates and overall survival between the two groups. [378] The results of ongoing randomized trials should address whether the combination of IFN and chemotherapy increase response rates, disease-free time, or overall survival time in patients with low-grade lymphoma. IFN has also been

added following both autologous and allogeneic stem cell transplants for both non-Hodgkin lymphoma and Hodgkin disease. [382] The treatment is associated with an increase in cytopenia thereby limiting doses of IFN to 23 MIU/m ^{2} three times a week. Whether it improved the remission duration or overall survival is unclear and randomized trials will be required to definitively answer this question.

Mycosis fungoides and Sezary syndrome are categories of cutaneous T-cell lymphomas that can be controlled by a variety of modalities including psoralen ultraviolet A (PUVA), electron-beam whole skin irradiation, and topical chemotherapy. [383] Responses are best achieved while the disease is confined to the skin. Nodal and systemic disease is poorly controlled by these measures and systemic chemotherapy has only transient palliative effects. The use of IFN- in cutaneous T-cell lymphomas (CTCL) was first reported by Bunn in 1984. [383A] Initial reports utilized the maximal tolerated doses of IFN administered intravenously and showed a 45% response rate. [383] As further trials were performed and reported, it became clear that the high doses were not necessary for responses and lower more tolerable doses (510 MIU/m^2 three times a week) could induce responses. [383] Response duration generally lasts 35 months for partial responses and longer for complete responses. Response rates appear superior in patients with stage IAIIB and lower; those with stage IV and those with large cell histology or visceral disease are less likely to respond to IFN-based therapy. IFN has been combined with various chemotherapy agents with generally unimpressive results. Some promising results have been observed when IFN was combined with PUVA phototherapy. [384] A high percentage of complete responses were seen in previously treated patients and these responses were quite durable. The responding patients had stage IB to IVA, whereas no responses were seen in patients with stage IVB disease. In this trial IFN was administered with PUVA at 12 MIU/m^2 three times a week.

HTLV-1-associated adult T-cell leukemia/lymphoma can be chronic and indolent with >2 year median survival, or very aggressive with median survivals of <6 months. Therapy with systemic combination chemotherapy has been quite unsatisfactory. Recent reports have combined IFN with the antiretroviral nucleoside inhibitor AZT and shown remarkable effects. [385] [386] Some of the 19 patients reported by Gill et al. had failed prior combination chemotherapy. [386] There were 11 major responses out of 19 patients with 5 complete responses. Six of the patients had survived longer than 12 months. Another report described clinical responses to IFN and AZT in all five patients treated with high-dose AZT and IFN at 9 MIU/m ^{2} /d three times a week. [386]

Chronic Lymphocytic Leukemia

IFN- produces responses in early stage CLL and immunomodulatory activity has been documented in patients with CLL who were treated with IFN-. [387] Attempts have been made to use IFN to maintain remissions in patients with CLL who have been induced into a remission with fludarabine. [388] The hypothesis to be tested was that patients with low CD4 counts are frequently anergic and have low IgG levels, and that uniform disease progression may be halted by either the direct antitumor effects or immunomodulatory effects of IFNs. In a trial of 22 patients, no beneficial immune effects were observed with IFN at 3 MIU subcutaneously three times a week. [388] Furthermore, the time to progression did not appear any different from that in a historical control group not maintained with IFN. It is possible that the immune defects within the T-cell compartment following fludarabine may limit the effectiveness of IFN in CLL.

Solid Tumors

Therapy of melanoma has been drastically changed by the results of a randomized trial of high dose IFN- as adjuvant therapy of high-risk patients with either deep melanoma primary lesions (>4.0 mm) or regional lymph node disease. [389] Patients treated with 4 weeks of intravenous IFN at 20 MIU/m^2 /day, 5 days a week, followed by 11 months of 10 MIU/m^2 /day three times a week had a significant improvement in progression-free survival and overall survival. While toxicity was significant, with many constitutional symptoms, most patients completed over 80% of the intended treatment and there were only 2 early deaths of 143 patients treated with IFN. The deaths were due to liver failure, which was not observed later in the trial when liver function tests were more rigorously monitored. Other solid tumors including renal cancer and colon cancer have been studied with IFN in combination with other cytokines, or chemotherapy. The actual role and benefit achieved by the addition of IFN is still poorly defined in most solid tumors.

Interferon-

IFN- has not found a definite role in the treatment of either hematologic malignancies or solid tumors. Based on its many immunomodulatory effects compared to type I IFNs, there was much hope for this agent as a component in the immune-based therapy of cancer. [336] [364] [390] [391] IFN- has antiproliferative effects in myeloma cell lines and may inhibit IL-6 mediated growth of these same myeloma cells. [392] In addition, it has been utilized in

combination with cyclosporin A to induce an autologous graft-versus-host-like syndrome in patients with breast cancer undergoing autologous stem cell transplantation. [393] It may help induce this syndrome through its ability to enhance MHC class I and II expression on tissues. The induction of a graft-versus-host syndrome is one of many attempts to induce a concomittant antitumor response (graft-versus-tumor). Attempts have been made to activate host antitumor immunity with IL-2 and IFN- in acute leukemic patients at high risk for relapse following autologous stem cell transplantation. [394] The addition of IFN- to IL-2 may allow a lower dose of IL-2 to stimulate NK cells and also stimulate MHC expression by target leukemic cells. IFN- can also induce the production of a number of other cytokines, some of which appear to mediate antitumor effects by themselves. [336] [337] IP-10 is an IFN- inducible protein with anti-angiogenic properties capable of inducing tumor necrosis. Mig is a chemokine induced in monocytes by IFN- that also mediates antitumor effects through vasculature damage and necrosis. [336] IL-18 is a recently described cytokine produced by monocytes in response to IFN- that can co-stimulate T and NK cells and stimulate Fas-ligand-mediated tumor cell cytotoxicity by NK cells. IL-18, like Mig and IP-10, has antitumor effects on its own, through the activation of NK cells and CD4+T cells. [337]

Tumor Necrosis Factor- (TNF-)

TNF- and lymphotoxin (TNF-, LT) are closely related cytokines that share common receptors and have similar biologic effects with a central role in immune and inflammatory responses. [395] [396] Release of TNF- and LT is stimulated by endotoxin, and other cytokines, including IFN-, IL-1, and GM-CSF. [397] Monocytes/macrophages are the primary producers of TNF-, and activated T cells are the primary source of TNF-. In humans, the genes for TNF- and LT are closely linked on the short arm of chromosome 6. [395]

Interest in the use of TNF for the treatment of human cancers stems from intriguing animal studies in which TNF resulted in dramatic regression and hemorrhagic necrosis of tumors. [398] In addition, the in vitro antitumor effects of TNF are very specific for malignant cells, with very few cytotoxic effects observed against normal cells. [395] The biologic effects of TNF include profound effects on immune effector cells and hematopoietic cells, inhibition of enzymes involved in adipocyte differentiation and lipid metabolism, and stimulation of both collagen production and collagenase activity. [397] TNF specifically induces a number of proteins in vascular endothelial cells, which may be closely linked to its hemostatic properties. Although mature neutrophil activity is stimulated by TNF, it suppresses the colony growth of CFU-GM and CFU-E. The inhibitory effects of TNF on hematopoietic progenitor cells depend on prolonged exposure and high concentrations. In addition, TNF activates macrophages and is an important inducer of acute-phase reactants. [399] TNF- is identical to the protein associated with cachexia, hence the alternative name, cachetin. Importantly, TNF also induces secretion of a number of cytokines, including GM-CSF, IL-1, and IL-6, as well as other mediators of inflammation. [395] The precise mechanism whereby TNF mediates its antitumor activity is unclear, but evidence suggests that direct cytotoxicity against malignant cells is one important mechanism that may be due to free radical formation. TNF- has indirect effects on the vascular supply of tumors with platelet aggregation, erythrocytosis, and endothelial and vascular destruction. The tumor vascular bed may be the most critical target for TNFs antitumor effects.

Phase I and II studies with TNF have been completed with limited single-agent activity demonstrated against hematologic malignancies or solid tumors. [400] [401] [402] However, in studies to date, only modest doses of TNF have been administered due to considerable toxicity, including fever and hypotension. [400] [401] [402] Systemic toxicity (hypotension) in humans allows only 1/201/50 the effective dose administered in the murine tumor models. Thus, therapeutically inadequate doses of TNF have been administered due to the significant toxicity associated with the systemic administration of TNF. Strategies designed to overcome this limitation have included the use of agents to reduce hypotension associated with TNF, such as nitric oxide inhibitors and the use of effector cells (tumor-infiltrating lymphocytes) transfected with the gene for TNF augmenting the local delivery of TNF to tumors and limiting systemic exposure. [403] [404] TNF has been combined with chemotherapy and IFN- in isolated limb perfusion (ILP) therapy of extremity sarcomas and melanoma. [405] [406] The isolated perfusion of an extremity with this combination has allowed very high regional levels of TNF with little exposure for the systemic circulation. In a series of 55 patients with sarcomas (30 primary and 25 recurrent), all with bulky disease and many with multiple sites, there were 36% pathologic complete remission and 51% pathologic partial remission with limb salvage feasible in >80% of patients. [406] Systemic toxicity was mild to moderate with some leakage of TNF- into the central circulation. Compared to prior studies of melphalan alone, these results appear far superior. A similar approach has shown promising effects for in-transit melanoma with a number of complete responses. [405] Higher doses of TNF were more toxic and not more effective. Trials are now underway to more definitively demonstrate the benefit of addition of TNF- to the ILP chemotherapy in melanomas

with regional lesions.

Monocyte/Macrophage-Colony-Stimulating Factor (M-CSF)

M-CSF, or CSF-1, is a homodimer composed of two proteins of approximately 45 kd molecular weight, linked by a disulfide bond. Produced primarily by monocytes, fibroblasts, and endothelial cells, M-CSF stimulates the proliferation, differentiation, and activation of the monocyte/macrophage lineage. [407] [408] The receptor for M-CSF is the product of the proto-oncogene c-*fms*, a member of the tyrosine kinase family of receptors. M-CSF is detectable in the serum at low levels in normal healthy adults.

When administered to mice, M-CSF results in an initial increase in cycling rates of bone marrow and splenic committed progenitors. Further treatment with M-CSF (>2 doses) leads to a reduction in cycling rates. [409] The precise mechanism of this effect is unclear. M-CSF is a potent activator of monocyte/macrophage function. [410] The mechanism by which macrophages promote their antitumor activity following exposure to M-CSF may involve the elaboration of secondary cytokines such as IL-1 or TNF or the promotion of oxygen free radicals. Activation of monocytes/macrophages by M-CSF significantly enhances their antibody-dependent cellular cytotoxicity (ADCC).[410]

M-CSF stimulates the differentiation of hematopoietic progenitor cells into mature monocytes and enhances their proliferation, survival, the production and release of other cytokines (colony-stimulating factors, IL-1 IFNs) from mature monocytes, and the enhanced surface expression of proteins which act as important costimulatory molecules.[411] M-CSF can also act to enhance the differentiation of cytotrophoblasts into syncytotrophoblasts which produce human chorionic gonadotropin and can enhance LDL-receptor clearance of cholesterol from the serum by other cell types. The op/op osteopetrotic mouse has a mutation in the structural gene for M-CSF making it inactive.[412] M-CSF appears to enhance antibody-independent lysis of tumors through activation of reactive nitrogen intermediates. [410] [413] These effects on mature monocytes may be relevant to both infectious and tumor targets. In vitro experiments comparing M-CSF to GM-CSF and to G-CSF have demonstrated that lysis of various human tumor cell lines (glioma, lymphoma, colonic, and melanoma) by either peripheral mononuclear cells or granulocytes were enhanced by M-CSF and GM-CSF.[413] Only M-CSF enhanced the spontaneous lysis of tumors, while GM-CSF and

M-CSF enhanced ADCC-mediated lysis. M-CSF transfection of murine melanoma tumor cell lines (B16) induced a protective antitumor response and prolonged the mouses survival.[414] Both monocyte and T-cell activation occur secondary to the transfected tumor vaccines and may be involved in tumor rejection. Therefore, M-CSF is a candidate cytokine for gene therapy, as well.

Munn et al. studied the effects of parenteral M-CSF on the ADCC of monocytes of nonhuman primates. [408] M-CSF administered by continuous intravenous infusion or subcutaneous injection daily for 14 days at doses of 50100 g/kg/day resulted in significant increases in peripheral blood monocyte number. ADCC of monocytes from treated animals incubated for 3 days with M-CSF demonstrated significantly enhanced tumoricidal activity against a melanoma cell line (SKMel-1) in the presence of the monoclonal antibody 3F8. M-CSF therapy was associated with a mild decrease in peripheral blood platelet counts. No other significant toxicity was noted.

Anti-tumor Agent

Several phase I and phase II trials of M-CSF have been completed and reported. [410] [414] [415] [416] [417] The first, performed by Sanda et al., evaluated intravenous bolus M-CSF administered every 8 hours for 7 days over a range of doses from 10100,000 g/m^2 /day with ocular toxicity (iritis), periorbital inflammation, and malaise as the dose-limiting toxicities at the 30,000 and 100,000 g/m^2 dose levels.[410] Pharmacokinetics revealed levels up to 1,000 baseline of M-CSF with a $t_{½}$ of 16 hours. Monocyte counts were increased in those patients who received >1000/g/m^2 /day and platelets declined during M-CSF administration, but platelet counts remained above 100,000/l. One patient with renal cell carcinoma had regression of his disease for a prolonged period of time. M-CSF was also administered in a phase I trial by continuous intravenous infusion for 14 days at doses of 50150 g/kg/24 hours. [417] Dose-limiting toxicities were both iritis and thrombocytopenia. The maximum tolerated dose was 1,000 g/kg/day for 14 days and 7-day infusions were recommended as more tolerable. Monocyte counts increased and peaked at days 79 of the 14-day course. A subcutaneous dosing schedule was evaluated in a phase I trial by Bukowski and his colleagues in 42 cancer patients. [416] These investigators explored a dose range from 10025,600 g/m^2 /day of M-CSF on days 15 and 812 every 4 weeks. Dose-limiting toxicities at the highest dose tested were thrombocytopenia and iritis as observed in the previous trials. Monocytes in the blood were increased in number and appeared stimulated (primed) based on their in vitro release of TNF and IL-1 following LPS exposure (in vitro). Pharmacokinetics revealed increased clearance of M-CSF following the initial week of therapy.

Much of the interest surrounding M-CSF has centered on its ability to enhance monocyte function in mediating ADCC. Adoptive immunotherapy in the SCID mouse with a human melanoma xenograft (M-14 melanoma cell line) combined R24, an anti-melanoma (anti-GD2) antibody with M-CSF. [418] These studies revealed that activated T cells could be targeted to infiltrate human tumors and mediate anti-tumor effects when exposed ex vivo to antibody and M-CSF. Other cytokines such as GM-CSF and/or RANTES chemokine were unable to target tumors and mediate antitumor effects. A phase II trial of M-CSF was performed with the agent administered at 80 g/kg/day by continuous intravenous infusion for 14 days with monoclonal antibody D612, a murine IgG2a antibody directed at a glycoprotein expressed on cancer of the gastrointestinal tract. [419] Biologic activity was observed, characterized by monocytosis and elevated serum neopterin (a product of activated monocytes). No anti-tumor activity was observed in 14 patients with metastatic gastrointestinal malignancies. Eleven of 14 patients developed low to moderate levels of anti-D612 antibodies. Finally, a phase I trial by Weiner et al. combined M-CSF with IFN- in an attempt to optimally expand and activate tumoricidal mononuclear phagocytes.[420] M-CSF could be combined with IFN- without increasing the toxicity of M-CSF. However, there was no significant increase in peripheral blood monocytosis. Although monocyte phenotype changes suggested activation superior to M-CSF alone, there was no other evidence for superior effects with the combination of agents as compared to either agent alone.

Infectious Diseases

Because of its ability to prime and activate monocytes and macrophages, M-CSF is a potentially attractive agent in diseases in which enhanced effector-cell function may improve therapy. M-CSF has been shown to enhance antifungal activity of its target effector cells, making invasive fungal infections ideal targets on which to test its clinical potential. [409] [411] In phase I and II trials conducted at the Fred Hutchinson Research Cancer Center after the documentation of progressive fungal infection M-CSF was administered at 1002,000 g/m^2 daily for 28 days in 46 patients. [421] [422] The initial 24 patients were reported in a phase I trial of M-CSF and the subsequent 22 treated at the maximally tolerated dose of 2,000 g/m^2 /day. [422] These were all BMT patients with a historical morbidity of 80% due to their invasive fungal infection. These 46 patients, compared to a historical matched group of 58 patients, had a better survival of 27% versus 5% in the control patients. Those with candidal infection and performance status greater than a Karnofsky score of 20 benefited from the therapy (50% survival), although those with aspergillus infection and poor PS (20%) had a dismal outcome with or without M-CSF. There was some thrombocytopenia that complicated the 2,000 g/m^2 /day dosing. Determining whether M-CSF definitively enhances monocyte function, thereby improving therapy of fungal disease, will require randomized trials.

Osteopetrosis

Another particularly interesting application for M-CSF is in osteopetrosis. Osteopetrosis is a heterogeneous family of disorders characterized by the inability of osteoclasts to resorb bone.[423] This results in failure of the remodeling of bone, and obliteration of the medullary cavity that leads to extramedullary hematopoiesis. Since osteoclasts and macrophages are thought to be derived from a common hematopoietic precursor, M-CSF could possibly enhance osteoclast function or recruit new osteoclasts into bone with resultant normalization of bone resorption. [424] [425] Although Orchard et al. demonstrated that serum levels of biologically active M-CSF are normal in patients with osteopetrosis, other investigators have shown absence of bioactive M-CSF in *op/op* mice (an animal osteopetrosis model).[412] [426] For this reason, a phase I trial of intravenous M-CSF has been performed in this disease setting. [427] Although doses of M-CSF were low (1002,000 g/m^2 /day), some clinical benefit, defined as reduced bone density, eruption of new teeth, and improved bone architecture, was seen in several of the patients suggesting that more prolonged therapy beginning at an earlier age may be of considerable benefit.

Monoclonal Antibodies

The successful use of monoclonal antibodies as a therapeutic approach in the treatment of cancer depends on two basic principles; that cancer cells are immunologically distinct from normal cells and that recognition of these differences can result in an effective antitumor response through specific binding to target antigens expressed on tumor cells. Ideally, one can identify tumor-specific antigens (i.e., an antigen expressed solely on the tumor cell, but not on normal cells) as a

antibody. Unfortunately, truly tumor-specific antigens are rare and limited to B-cell and T-cell malignancies in which the variable region of the immunoglobulin molecule or T-cell receptor serves as a unique marker referred to as the idiotype determinant. [428] [429] Most currently identified tumor antigens represent differentiation antigens and are therefore expressed on both malignant cells and normal cells, albeit the expression of these antigens may be at lower levels on nonmalignant cells.[222] [223] [430] In addition, the products of cellular oncogenes have been defined as cell-surface receptors (i.e., platelet-derived growth factor, epidermal growth factor) and represent potential targets for monoclonal antibodies. [431] [432] [433]

Because technologic developments allowed for the production of monoclonal antibodies specific for antigens of choice, these monoclonal antibodies promised a revolution in human diagnostics and therapy. The antibodies could be used unmodified or naked, bound to radioisotopes or toxins, or modified to provide two different specificities (bispecific). Their potential to home in on tumor cells specifically led to them being identified as magic bullets. New second- and third-generation antibodies have been created that are now humanized to reduce immune reactions in patients and simplified into a single variable chain construct. The distinct problems associated with murine antibodies (immunogenicity) and human antibodies (limited availability) have led to the construct of these so-called chimeric antibodies, which retain the murine antigen-binding sites of the murine antibody, but closely resemble the constant region of the human immunoglobulin. [434] Chimeric antibodies have been shown to be less immunogenic, with longer half-lives than murine antibodies. Future directions in research include the production of more effective antibodies with single-chain antibody-derived components (Fsv). In addition, researchers are attempting to identify better targets in tumors or associated cells and even to use the monoclonal antibodies to disrupt growth signals. Although the initial expectations for monoclonal antibodies were unrealistic and many of the initial claims overstated, the perspective now appears to be more realistic and balanced. Now a variety of antibodies including those which are unmodified, humanized, and linked to radioisotopes, and toxins that inhibit specific steps in protein synthesis are demonstrating efficacy in phase II and III trials. These may be close to becoming a component of standard therapy for malignancies. New targets for monoclonal antibodies may boost their efficacy by binding to an antigen that is a growth factor receptor on the surface of the cancer cell, or by blocking the signal that induces the formation of blood vessels in tumors, or antibodies directed at the stroma of tumor cells.[434] [435] These alternate targets may lead to more sustained tumor regression and may avoid resistance by the cancer cells through their ability to constantly mutate and escape detection.

Considerable obstacles to the therapeutic use of monoclonal antibodies have been identified and include the short half-life of administered antibody due to the presence of free circulating antigen and the development of neutralizing antibodies to the murine antibody (human anti-mouse antibody). Tumor cells can escape the monoclonal antibody through the phenomenon of antigenic modulation, in which binding of the antibody to the antigen results in the transient disappearance of the antigen. In addition, only a proportion of the cancer cells express the relevant antigen due to antigenic heterogeneity, again limiting efficacy. Other barriers to this approach include poor affinity of the antibody to the tumor target antigen and impaired delivery of the antibody due to poor tumor vascularity and necrotic centers. [436]

Clinical Application

Naked Antibodies

Numerous phase I and II studies of monoclonal antibodies have been completed in patients with solid tumors and hematologic malignancies. [432] [435] [437] [438] [439] [440] [441] Initial studies focused on the safety and pharmacology of unconjugated murine antibodies in patients with leukemia and lymphoma. The tumor-associated antigens identified were differentiation surface markers expressed by both malignant and normal lymphoid cells. Generally, the side effects of unconjugated monoclonal antibodies have been mild and include fever, chills, urticaria, bronchospasm, and pain. Rarely patients have developed symptoms of anaphylaxis and serum sickness, which have been reversible in all reported cases.

One strategy for testing immune intervention in patients with hematologic malignancies is to target cytokine receptors, such as the IL-2R. [438] [442] Waldmann et al. developed a murine monoclonal antibody, anti-Tac, which binds to IL-2R and prevents interaction of IL-2 with this subunit. [442] The rationale for this approach is that resting normal T cells do not express the high-affinity IL-2R, whereas expression of this receptor is found on a proportion of lymphoid neoplasms, including HCL, large and mixed-cell lymphomas, T-cell and B-cell monocytic leukemias, T-cell lymphoma, and some Reed-Sternberg cells in Hodgkin disease. [442] In addition, virtually all patients with HTLV-1 associated adult T-cell leukemia express the IL-2R. Therefore, initial clinical studies with the anti-Tac antibody have been directed at patients with HTLV-1 associated T-cell leukemia.[442] Preliminary results with 19 patients have shown that therapy is well-tolerated. Seven patients had partial or complete remission, lasting 9 weeks to >3 years. The elimination of clonal malignant cells was confirmed by molecular genetic analysis of HTLV-1 proviral integration and T-cell receptor rearrangements. The mechanism of action of anti-Tac is not clear, but it does not appear to be mediated by ADCC.

One very intriguing and labor-intensive approach has involved the use of anti-idiotype monoclonal antibodies for the treatment of indolent lymphomas. [435] Levy and his colleagues[437] generated monoclonal antibodies that recognize the specific idiotype of surface immunoglobulin on the patients lymphoma cells. Initial clinical trials reported a 5070% reduction in the tumor size with some patients obtaining complete responses. [437] [443] The mechanism of antitumor effects remains unknown. Treatment with anti-idiotypic murine antibodies either alone or in combination with other treatment modalities such as IFN- or chlorambucil have produced up to 70% partial or complete responses in patients with B-cell NHL. It has been generally accepted that host effector systems, such as complement or antibody-dependent cellular cytotoxicity, that interact with the Fc-portion of the antibody are required for the generation of an antitumor effect. Studies have shown that the degree of in vitro stimulation of tyrosine phosphorylation of intracellular proteins correlated with direct antiproliferative effects and very strongly with tumor regression in vivo. [443] Expression of bcl-2 did not correlate with tumor regression.

Anti-CD20 monoclonal antibody IDEC-C2B8 has shown significant activity in recurrent or refractory B-cell lymphomas leading to its approval by the FDA. [440] [444] This is a nonmodulated antigen that mediates complement and antibody-dependent cellular cytotoxicity in vitro. Toxicity due to a single dose of therapy includes fever, chills, nausea, and mild hypotension. These were all very tolerable and easily managed. The $t_{½}$ was quite long, with persistent levels after 14 days following a single dose of treatment. CD20+ B cells were rapidly depleted from the blood and chimeric antibody could be found within the biopsied lymph node cells. Significant tumor regression was observed after a single dose. No significant infections were observed. The pivotal trial in relapsed low grade lymphomas included 166 patients and showed a response rate of 48% with a median duration of responses greater than 9 months (not reached yet). This humanized chimeric antibody has also shown promise in combination with chemotherapy such as cyclophosphamide, doxorubicin, vincristine, prednisone (CHOP). T-cell

lymphomas such as mycoses fungoides have been treated with chimeric humanized anti-CD4. Clinical responses to anti-CD4 were induced with low-level immunogenicity, some immunosuppression, but no tolerance to foreign antigens. [441]

Although encouraging results have been described with antibodies against leukemia and lymphoma, little success has been reported with naked monoclonal antibodies against solid tumors. One apparent exception has been a report on Dukes C colon cancer treated with a murine monoclonal antibody. [445] This antibody, 17-1A, is directed at a surface glycoprotein present on epithelial carcinoma cells, which can induce antibody dependent cellular cytotoxicity and prevent colorectal cancer growth in human xenografts in nude mice. Patients with Dukes C colorectal cancer were randomized to observation (before the proven benefit of 5-FU based regimens) or 17-1A administered intravenously postoperatively (2 weeks after surgery) and then monthly for 4 months. [445] Patients receiving the antibody in their minimal disease state had a significantly better relapse-free and overall survival. The improvement was in the range of 2530% and most of the benefit appeared to be based on the decrease in distant metastases. Toxicity was minimal with only four controllable allergic reactions to the antibody infusion. These results are being confirmed in other trials and would certainly be a major step forward for antibody-based therapy of cancer.

Her-2/neu, a proto-oncogene, encodes a transmembrane protein that is a receptor for a growth factor peptide and is amplified and overexpressed in 2040% of breast cancer.[446] It appears to be associated with a poor prognosis. A murine monoclonal antibody directed at the extracellular domain of p185-Her-2/neu is a potent inhibitor of growth of human breast cancer in vitro and in vivo in animal xenografts. [432] A humanized recombinant anti-p185her2 monoclonal antibody was produced for further phase I and II trials. [432] [447] When the anti-p185her2/neu antibody was administered by intravenous injection weekly, 5 of 43 patients with advanced, chemotherapy-resistant breast cancer experienced objective tumor responses. The one complete and four partial responses lasted from 1 to >24 months. Toxicity was minimal with mild fever and chills and only one grade 3 toxicity. More than 90% of patients had trough antibody levels above the targeted 10 g/ml level. An additional 16 (37%) patients had minor responses or stable disease at 11 weeks. Serum levels of extracellular domain (ECD) of Her2 appeared to correlate with poor

pharmacokinetics and a short $t_{½}$ for the antibody. Combination of anti-p185her2/neu with chemotherapeutic agents may more effectively induce tumor responses. This has been reported in abstract form for the combination of anti-p185 her 2 antibody (Herceptin) and chemotherapy (paditaxol or Adriamycin plus cyclophosphamide) in advanced breast cancer.[447A]

Angiogenesis is critical for the growth of tumors and is mediated by substances produced by tumors, such as VEGF (vascular endothelial growth factor), which is a key regulatory paracrine growth factor for endothelial cells. [448] A neutralizing monoclonal antibody specific for human VEGF has the capacity to inhibit growth and angiogenesis of human tumors in SCID mice.[448] The neovascularization of microscopic tumors is inhibited by anti-VEGF leading to suppression of tumor growth at less than 1 mm^3 . A rapidly proliferating human rhabdomyosarcoma cell line, A673 changes its growth characteristics and enters an apparent dormant state simply by exposure to anti-VEGF, thereby inhibiting tumor angiogenesis. This has potential application in a variety of solid tumors, especially renal cell cancer, in which VEGF levels are increased in association with a common genetic alteration of the VHL gene.

Antibodies against CD44 (the major receptor for hyaluronic acid), a surface molecule involved in the adhesion of tumor cells and their implantation, appears to effect the in vitro binding of ovarian cancer cells to peritoneal mesothelial layers. [449] Animal studies with human ovarian cancer cells exposed to anti-CD44 suggest that in vivo implantation in the murine peritoneal cavity is greatly impaired, significantly decreasing the number of tumor implants.

Antibodies may also be used as cytokine antagonists or cytokine binding proteins. Anti-IL-6 can neutralize the activity of IL-6, which has been postulated as a growth factor in multiple myeloma, HIV-associated lymphomas, and possibly in renal cell cancer. [450] In multiple myeloma, elevated serum levels of IL-6 have been associated with a high proliferative phase index for the malignant plasma cells and a short survival. Initial trials with anti-IL-6 (murine antibody) in 13 patients with multiple myeloma and renal cell cancer were able to demonstrate a decrease in the fever and hypercalcemia associated with the disease states. [451] However, patients who had very high production of IL-6 were not effectively inhibited with the doses of anti-IL-6 administered. The reduction of C-reactive protein (CRP) was a good indicator of effective IL-6 inhibition.[451] While the proliferative index of some patients plasma cells could be reduced, this was not of significant clinical benefit to most patients with advanced disease. Therapy with antibodies to cytokines may not be a practical way to effectively inhibit tumor-associated cytokines, and better approaches that can overcome the high levels of cytokines are needed.

Bispecific antibodies/ligands have been used as a strategy to target molecules on the tumor cell surface, while the other antibody specificity/ligand binds to an immune cell and is capable of activating it (anti-CD3, anti-CD16, anti-CD64, or SEA [staphylococcus enterotoxin-superantigens] or is a cytokine (IL-2), itself. [452] [453] [454] [455] [456] [457] [458] Bispecific molecules bring targeted cells or cytokines directly to the tumor site and overcome the systemic toxicity by linking them to an antibody that has specificity for tumor cells. An example of such a bispecific molecule is SEA (staphylococcal enterotoxin A)-C242 (Fab), which shows promise in animal studies. [459] The SEA binds and activates large numbers of T lymphocytes through their V T-cell receptor in an MHC class II-independent manner. The attachment of antibodies to the superantigens allows the tumor-infiltrating lymphocytes to be activated and release cytokines at the tumor sites alone. This approach has been used in conjunction with antibodies directed at epithelial surface antigens (C242) and at B-lymphocyte lineage markers such as CD19. These approaches have been effective in animal trials and initial clinical trials have revealed tolerable toxicities with fever and hypotension, cytokine release, and decrease in peripheral monocyte counts. [453] Another approach taken by several investigators with antibodies to the Her2/neu surface receptor, is linking them to antibodies directed at Fc-receptors (CD16), thereby activating NK cells, monocytes, and neutrophils.[455] These trials have also been initiated with similar toxicities including thrombocytopenia in heavily pretreated patients.[455] [456] Bispecific antibodies with either CD3 or CD16 as the activating moiety and CD19 (for B-cell lymphomas) and CD30 (for Hodgkins disease) for tumor targeting have undergone preclinical and some clinical testing. [457] [458] Anti-CD30 monoclonal antibodies react with the CD30 surface antigen on Reed-Sternberg cells of Hodgkins disease and the malignant cells of anaplastic large cell lymphoma (ALCL). [460] [461] CD30 is a member of the nerve growth factor receptor family including CD27, CD40, tumor necrosis factor receptor, and Fas, all of which are involved in cellular activation or apoptosis. [461] Activation of T or NK cells with IL-2 ex vivo appears to generate more effective immune cells and allows for better subsequent activation by antibody. A phase I trial of anti-CD16/CD30 administered every 34 days with dose escalation of antibody from 1 mg/m^2 to 64 mg/m^2 resulted in only mild, nondose limiting side effects.[457] A number of patients developed human anti-mouse antibody (HAMA) responses and several had allergic reactions when rechallenged. In this phase I trial, one complete remission, one partial remission, and three minor

responses were observed at various dose levels with durations of 111 months. Finally, bispecific ligands may be promising compounds in delivering cytokines directly to tumors. IL-2 bound to antibodies against epidermal growth factor (EGF) or gangliosides appears to allow release and activation of cytokine at the tumor site that expresses the targeted antigens.[459] This has proven effective in animal studies and against human cancers in SCID-human chimeras. These effects are superior to antibodies and cytokines administered together, but not linked covalently. This approach may avoid the systemic toxicity of IL-2 (hypotension, fevers, etc.), while increasing the dose of IL-2 at the tumor site similar to cytokine-transfected tumor vaccines.

Attempts have been made to combine antibody-based therapy with cytokines that activate host immune effector cells. [452] [462] [463] [464] [465] Based on murine experiments utilizing anti-CD19 or anti-CD20 with IL-2 or GM-CSF, it was apparent that the combination of IL-2 with anti-CD20 was superior to all other combinations of cytokine and antibody in inducing remission of human B-cell lymphomas.[462] Clinical trials have combined IL-2 or GM-CSF with antibodies such as R24 (anti-GD2 murine antibody).[463] These attempts to activate immune effector cells with a cytokine and then add an antibody capable of triggering ADCC have successfully activated immune effector cells in vivo. Whether this approach enhances the clinical benefit of the cytokine or the antibody is not clear. Additionally, bispecific antibodies that bind to immune effector cells, such as T cells (anti-CD3) or NK cells (CD16), may be expanded and activated in vivo with cytokines such as IL-2. A bispecific antibody directed at CD3 and EGP-2 (a 40 kD pancarcinoma antigen) has been combined with subcutaneous IL-2 in renal cancer patients with some evidence that T cells were more effective at tumor cell killing in the presence of the bispecific antibody following in vivo IL-2. [452]

Monoclonal antibodies have also been utilized to deplete neoplastic cells from the bone marrow grafts of patients with leukemia and lymphoma undergoing autologous BMT.[464] Early trials focused on non-T-cell ALL and B-cell non-Hodgkin lymphoma and confirmed the value of antibodies and complement for purging bone marrow with very little toxicity against hematopoietic progenitor cells. [464] Thus, hematologic engraftment has not been affected; however, relapse of leukemia and lymphoma remains a significant problem. Monoclonal antibodies have also been used to prevent GVHD in patients undergoing allogeneic transplants for hematologic malignancies.[465] However, the use of anti-T-cell monoclonal antibodies for the treatment of donor marrow to decrease GVHD has been associated with reduced frequency of bone marrow engraftment and a higher incidence of leukemia recurrence. [466]

Radioisotope-Conjugated Antibodies

For a number of years, antibodies have been sought as targeting vehicles to deliver radioactivity specifically to tumor sites. [436] Advances in the chemistry and conjugation of isotopes to proteins and the development of monoclonal antibodies with relative tumor specificity have been critical to advancing the field. Radioisotopes have two advantages over conjugation to toxins or chemotherapy agents; beta-emitting compounds can kill adjacent targets and radioisotopes are not subject to multidrug resistance. Iodine [131] , yttrium [90] , a pure beta emitter, and Cu [67] are the most widely used isotopes in cancer therapy. Dosimetry of radioimmunotherapy is dependent on the uptake of the antibody and its clearance; the distribution of the antibodies; and the radioisotope used. Imaging of tumors can be improved by use of positron-emission tomography (PET) scanning. More than 100 radioimmunotherapy trials have been reported. The most promising results have been in hematologic malignancies.

Numerous pilot trials have demonstrated the efficacy of radioimmunotherapy in chronic lymphocytic leukemia, T-cell leukemia/lymphoma, and acute myelogenous leukemia (see Table 51-3).[467] [468] [469] [470] [471] [472] [473] [474] M195, a monoclonal antibody directed at CD33 (a myeloid antigen expressed by many AML cells) has been labeled with I [131] and used in the treatment of AML in combination with high-dose chemotherapy and allogeneic bone marrow transplantation and also in relapsed acute promyelocytic leukemia (APL) patients following an ATRA-induced remission. [473] [474] Results in both populations appear promising, but are early and other complicating issues in the transplant patients make the findings difficult to interpret. A few of the APL patients no longer had the PML/RAR transcript while on therapy with radiolabeled antibody. The investigators at the Fred Hutchinson Cancer Center have studied another antibody, BC8, that binds to CD45, a common leukocyte antigen present on most cells of the lymphoid and hematopoietic lineages in 8590% of AML and ALL cases. [475] BC8 was labeled with I [131] and administered to patients undergoing cyclophosphamide with total body irradiation (TBI) and allogeneic or autologous transplants. [475] Twenty patients were treated with no obvious increase in toxicity above what was expected with cyclophosphamide plus TBI. Eleven of the twenty patients were alive and in remission at 8 to 41 months. This may be a way to enhance the delivery of radioactivity as part of a transplant therapy without dose-limiting systemic exposure. The major issues continue to be tumor relapse and the development of HAMA.

The experience with radioimmunotherapy in B-cell lymphoma is even more promising. B-cell non-Hodgkin lymphoma is an especially attractive target for this therapy

since it is relatively radioresponsive. Patients have a depressed humoral immune response which makes them mount a diminished, if any, human anti-mouse immune response, and lymphoma cells may be more accessible than many solid tumors to antibody delivery.[436] This has been elegantly demonstrated by the work of Press and Kaminski utilizing anti-CD20 radiolabeled I[131] antibody.[467] [468] Press utilized this antibody at myeloablative doses with stem cell support.[467] These patients generally had minimal disease and a favorable dosimetry for tumor site accumulation. The results show a very high response rate with durable CRs in over 50% of the patients. Of 25 patients, 22 had favorable antibody biodistribution (delivery of higher doses of radioactivity to tumor compared to normal tissue). Twenty-one patients received therapeutic treatment with the anti-CD20-I[131] . Those with bulky disease or splenomegaly did not initially have favorable biodistribution. Eighteen of 21 had objective responses to the treatment, with 16 complete responses and overall progression-free survival at 2 years of 62% and survival at 2 years of 93%.[467] All patients received 2.5 mg/kg of radiolabeled antibody and tumor sites received an estimated 2792 Gy of radioactivity; all patients received stem cell support. Kaminski also observed a very high response rate with a lower nonbone marrow ablative dose of antibody, which followed a trace dose of labeled antibody given to assess radiolabeled antibody distribution.[468] The therapy was limited by hematologic toxicity and of 28 patients, there were 14 CRs and 8 PRs. The median duration of the complete responders was over 16 months. Low-grade, intermediate-grade, and transformed lymphomas all showed evidence of a response. A number of patients had large tumor burdens (>500 gm). Additionally, studies of cutaneous T-cell lymphomas with an anti-CD5 (T101) I[131] labeled radioimmunoconjugate have shown activity with partial and minor clinical responses.[471] These patients have developed HAMA that have interfered with treatment. Finally, patients with refractory Hodgkin disease have also shown promising results when treated with [90] Y-anti-ferritin polyclonal antibodies.[472] Both partial and complete responses were observed in over 50% of patients. Bone marrow toxicity did require autologous stem cell support in several patients.

Radioimmunotherapy of solid tumors has not been nearly as promising as that used to treat hematologic malignancies,

TABLE 51-3 -- Clinical Studies of Radioimmunoconjugates in the Treatment of Hematologic Malignancies

Patient Population	Radioimmunoconjugate	Target Antigen	Toxicity	Results	References
B-cell non-Hodgkin lymphoma	I[131] IgG2a anti-B1	CD20	Severe myelosuppression, stem cell rescue, infections, nausea, mild mucositis	18/21 with objective responses, 16 CRs, 15 progression-free at 3+ to 23+ mos	[291]
B-cell non-Hodgkin lymphoma	I[131] IgG2a anti-B1; trace labeled Ab, unlabeled AB, then full dose	CD20	Fever, rash, hematologic toxicity grade 34 WBC, plat	22/28 with objective responses, 14 CRs, CR median duration >16 mos, 6 DFS 16+ to 31+ mos	[292]
B-cell non-Hodgkin lymphoma	Y[90] anti-idiotype	Ig idiotype specific to B-cell NHL	NV, mucosal congestion, arthralgias, pain Fever, arthralgias	2CR, 1PR, 1 MR, 2 SD of 9 pts TTP 112 mos	[293]
B-cell non-Hodgkin lymphoma	I[131] Lym-1	HLA-DR variant		8 CRs, 5PRs of 24 patients	[294]
Cutaneous T-cell lymphoma	I[131] T101	CD5	Fever, pruritis, dyspnea, cytopenia	2PRs, 4MRs of 7 patients	[295]
Hodgkin disease	Y[90] anti-ferritin polyclonal	Ferritin receptor	BM toxicity, stem cell support required in some patients	10CRs, 10 PRs of 39 patients median survival 6 mos	[296]
Acute myelogenous leukemia	I[131] Hu M195 +Bu/CY+ allogeneic BMT	CD33 early myeloid Ag	BMT toxicity, GvHD, urticaria	1st BMT-14/15 CR, 3 CCR-18+ to 29+ mos 2nd BMTall died of transplant complications	[297]
Acute promyelocytic leukemia	I[131] Hu M195 following ATRA in relapsed disease	CD33 early myeloid Ag	Myelosuppression	2/7 molecular remission, 8 mos median PFS	[298]
Acute myelogenous leukemia	I[131] BC8 antibody + Cytoxan and TBI + BMT (allogeneic or auto-4HC)	CD45 pan-leukocyte marker	Cyt/TBI toxicity, infection, cardiac	9/13 AML/MDS and 2/7 ALL DFS at 841 mos (median 17 mos)	[299]

ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; ATRA, all-*trans*-retinoic acid; BM, bone marrow; BMT, bone marrow transplant; CR, complete remission; CCR, continuous complete remission; DFS, disease-free survival; MDS, myelodysplastic syndrome; MR, molecular remission; NHL, non-Hodgkin lymphoma; NV, nausea and vomiting; PFS, progression-free survival; TBI, total body irradiation; WBC, white blood cells.

excluding thyroid cancer. Therapy of breast cancer, brain tumors, and intraperitoneal therapy for ovarian cancer has limited clinical activity with occasional durable responses.[476] [477] [478] [479] Trials in human breast cancer with anti-mucin antibodies labeled with Y[90] has already been initiated. Therapy directed at the carcinoembryonic antigen (CEA) expressed on colorectal cancers, as well as normal colonic and small bowel mucosa with radiolabled I[131] antibody, A33 was escalated to sufficient levels to lyse colon cancer in vitro without significant gastrointestinal toxicity.[476] In some trials the level of serum CEA (antigen) and the degree of tumor bulk led to more rapid antibody clearance and a shorter $T_{½}$ for anti-CEA labeled with I[131] .[479] Intraperitoneal administration of a Lu[77] -labeled murine antibody, CC49, directed at TAG-72 tumor-associated glycoprotein expressed by the majority of common epithelial cancers, has been used to treat ovarian cancer.[478] Among 27 patients who had failed prior chemotherapy, 13 had measurable disease, 9 had disease <1 cm^2 , and 5 had microscopic disease only. Of those with microscopic disease only 1 of 5 relapsed with four being progression-free at >6 to 35 months. Regional therapy in patients with small-volume disease may be a more effective route of radioimmunotherapy.

Overall toxicity issues include allergic reactions, myelosuppression, and more rarely with extremely high doses of radioisotope, pulmonary, cardiac, or hepatic toxicity. Future directions include the production of more effective antibodieschimeric, CDR-grafted, or single-chain antibody-derived components.[436] Use of cytokines to enhance antigen expression (interferons) on tumor cells, or to enhance immune effector cell function (IL-2) is also being explored with radioimmunotherapy. Finally, the use of agents to improve radiotherapy, such as hypoxic cytotoxins (radiosensitizers) and local hyperthermia, could be incorporated into therapy.

Toxin-Conjugated Antibodies

Immunotoxins allow for the targeting of a variety of highly cytotoxic molecules to cancer cells.[480] [481] Additional modifications are made to prevent nonspecific binding and normal cell killing. These toxins include ricin, modified with a chemically blocked -chain or only a single -chain that has been deglycosylated; gelonin toxin, which is naturally without the chain and therefore associated with less nonspecific binding; saporin or PAP-S, a potent type I ribosome-inactivating protein (RIP); pseudomonas exotoxin modified to remove domain I (binding domain); or diphtheria toxin without receptor binding domain. The toxins may be linked either to antibodies (murine or humanized) or ligands (cytokines or growth factors) that will both target the delivery to the site of the antigen or cytokine receptor on the cancer cell.

Patients with advanced, refractory Hodgkins disease were treated with anti-CD25 (IL-2 R) bound to ricin chain and toxicities included a vascular leak syndrome, mild allergic reactions, some dyspnea, and relatively frequent induction of both anti-mouse and anti-ricin antibodies.[482] Three of 15 patients had signs of clinical tumor regression. Both anti-CD25 and anti-CD30 have been bound to ricin chain and utilized for targeting Hodgkins disease (Reed-Sternberg cells). In a phase I trial of pseudomonas exotoxin conjugated with an antibody (B3) directed at the carbohydrate antigen (LeY) present on many

solid tumors, 38 patients were treated every other day intravenously with doses from 10 to 100 g/kg. [483] Dose-limiting toxicities observed above 75 g/kg were a vascular leak syndrome, hypoalbuminemia, fluid retention, and peripheral edema. Five patients with breast and colon cancer had objective tumor regressions. Neutralizing antibodies to the immunotoxin limited therapy developed in almost all patients. Small-cell lung cancer (SCLC) has been treated with N901, an immunotoxin composed of an antibody directed at CD56 (N-CAM) linked to ricin with a blocked chain. [483] A continuous intravenous infusion for 7 days defined toxicity as a vascular leak syndrome. Cardiac and neurologic toxicity was acceptable and one clinical response was observed among 21 refractory or relapsed patients with SCLC. Again, most patients developed either human anti-ricin antibodies or human anti-mouse antibodies. Both anti-CD33 (humanized M195) and anti-CD30 have been linked to immunotoxins (gelonin toxin and PAP-S) and shown impressive activity in human leukemias and lymphomas engrafted in mice. [484] [485]

Another strategy involves the use of chimeric toxins, in which bacterial toxin genes are fused with cytokine genes or growth factors. The first such construct for clinical use involved the gene for IL-2 fused to a gene for diphtheria or pseudomonas exotoxin. [486] [487] These fused proteins recognize cells bearing the IL-2R, and are subsequently internalized by receptor-mediated endocytosis, and result in cell lysis mediated by the toxin. Clinical studies of malignancies are now underway in which the malignant cells express the IL-2Rs, including HTLV-1-associated leukemia, T-cell leukemia and lymphoma, and Hodgkins disease. [487] IL-2-diphtheria A chain toxin (DAB) has shown the most promise with documented clinical remissions in Hodgkins disease and cutaneous T-cell lymphomas. [487] Again, toxicities, including hepatic enzyme elevation, were observed. DAB EGF is being targeted for therapy of breast cancer where EGF-R is overexpressed. [433] The fact that these receptors are linked to critical signaling pathways with tyrosine kinases may make them especially critical to the clonogenic cancer cell growth. Finally, IL-4-pseudomonas exotoxin may have efficacy in cancers such as renal, lung, gastric, colon, as well as Burkitts lymphoma, T-cell leukemia, glioblastoma, and melanoma, which all express IL-4R. [488]

Tumor Vaccines

Numerous vaccine-based strategies aimed at cancer have entered the clinic over the past several years. The concept of active specific immunotherapy has been of interest in the treatment of both hematologic malignancies and solid tumors for a long period of time. The use of autologous tumor cells, allogeneic tumor cell lines, or tumor cell lysates in combination with a nonspecific immune-stimulating substance (adjuvant) have been attempted in numerous clinical trials with suggested, but still questionable benefit. Only with the enhanced understanding of the process of immune recognition and T-cell activation have more defined and potentially effective approaches been identified. Two major advances have moved the field of tumor immunology and tumor vaccines forward. First, antigens recognized by T lymphocytes are processed from endogenous or exogenous peptides, which are then presented on the antigen-presenting cell surface to a T cell. [489] This critical interaction can take place if the antigen is appropriately processed and binds to the MHC antigens and the T-cell repertoire includes receptors that bind to this complex. [490] Therefore, tumor antigens may include a variety of surface and intracellular molecules including viral-induced genes (HPV, EBV), mutated (ras) or nonmutated oncoproteins (her-2/neu), fusion proteins derived from translocations (bcr-abl), differentiation antigens from the tissue-specific proteins (gp-100, gp-75 tyrosinase), and other normal or abnormally expressed proteins. [489] [490] Work on human melanoma has led to the isolation of a variety of genes that express tumor-regression antigens and are recognized by tumor-infiltrating lymphocytes (TIL) cells which can lyse tumor targets and lead to in vivo tumor regression. [489] These tumor regression antigens have been primarily found to be tissue differentiation antigens that are normally expressed by the melanocyte lineage, including MART-1, gp-100, and tyrosinase. [489] Peptides derived from these proteins can bind to MHC molecules and subsequently be recognized by T cells from melanoma patients. The second finding critical to improved vaccines is the need for presentation of the antigen in a setting which will break tolerance, enhance recognition, and lead to the danger response. [491] This may be achieved by the release of certain cytokines at the site of a vaccine, either through genetic delivery or local injection. The delivery of local cytokines such as IL-2, IL-12, GM-CSF, lymphotactin, and IL-4 may allow the enhanced recruitment and activation of T lymphocytes or the activation and recruitment of dendritic cells to the tumor site where antigen can be presented with the appropriate second signal to the T cell. [492] [493] [494] [495] In addition, the presentation of peptide antigen by activated dendritic cells may allow resting T cells in the repertoire to be activated and expanded in response to either foreign or self antigens. It is clear that these maneuvers can enhance the stimulation of T lymphocytes and allow a relatively weak tumor antigen to be a more effective target. Therefore, many of the present vaccine trials are aimed at utilizing defined proteins or peptides with the simultaneous delivery of cytokines to better locally stimulate the host. Use of autologous tumor or allogeneic tumor cell lines that have been genetically modified to secrete critical cytokines such as GM-CSF or IL-2 is actively being pursued. [496] These trials can incorporate biologic intermediate endpoints, but in the end will require randomized trials to prove their efficacy.

Cell Products-Proteins

Serologically defined gangliosides are a major cell surface component of various neoplasms, especially melanoma, sarcoma, and small-cell lung cancers. [495] [497] The gangliosides include GM2, GD2, and GD3, which are specific to the malignant phenotype and have been isolated by monoclonal antibody purification. Vaccine-induced or natural antibodies directed at GM2 appear to confer an advantage in survival as well as relapse-free survival in patients with melanoma. [498] Human antibodies induced by vaccination can be directly cytotoxic for melanoma tumor cells that express GM2. A trial in patients with stage III melanoma (involved, resected regional lymph nodes) showed that patients vaccinated with GM2 plus an adjuvant BCG with cyclophosphamide had a marginal improvement in relapse-free survival compared to patients receiving BCG and cyclophosphamide alone ($P = 0.09$). This benefit was much more apparent and reached statistical significance if all patients with natural GM2 antibodies were excluded from the analysis ($P = 0.02$). Further modifications of the vaccine protocol with linkage of GM2 to a protein carrier KLH and the use of a superior adjuvant, QS21, has led to much better induction of both IgM and IgG antibodies with higher titer levels. A trial is now ongoing to evaluate the efficacy of this vaccine compared to IFN- in high-risk melanoma patients.

Another protein antigen that has been the target of a number of clinical efforts is the Her-2/neu molecule, which is overexpressed in a large number of patients with both breast and ovarian cancer. [446] A growing literature indicates that patients with Her-2/neu overexpressing cancers have an endogenous antibody, helper, and cytolytic T-cell response directed at Her-2/neu protein as a whole or to component peptide fragments. [446] The presence of natural immunity to Her-2/neu heightens the expectations that vaccine strategies can increase the host immune response. Data is only now being collected to determine the significance of endogenous host responses to Her-2/neu

and whether its presence is associated with a better or a worse outcome. Several investigators have now demonstrated the presence of cytolytic T cells in the blood and at tumor sites of patients with breast and ovarian cancer and have shown that the T cells specifically recognize a peptide derived from Her-2/neu and can lyse tumor cells expressing the appropriate HLA molecules and Her-2/neu molecules. [446] This has led to several vaccine protocols enrolling patients at various stages of breast and ovarian cancer with Her-2/neu protein plus adjuvant, Her-2/neu peptides plus GM-CSF, Her-2/neu peptides presented by autologous dendritic cells, or Her-2/neu expressing viral or vaccinia vectors to deliver the protein.

The unique portions of the surface immunoglobulin on each B-cell lymphoma determine idiotypes that are unique tumor-specific antigens. Active immunotherapy in patients with their idiotypes coupled to a protein carrier such as KLH, in combination with an immunologic adjuvant or with autologous antigen-presenting cells such as dendritic cells (DC) isolated from peripheral blood have been utilized in clinical trials. [499] [500] Specific T-cell responses against idiotypes were induced in numerous patients, especially when DC were used in the vaccination. [499] Several patients experienced objective tumor regressions, and many patients had prolonged progression-free periods post-vaccination. Patients who developed idiotype-specific immune responses had superior progression-free periods compared to those patients who were unable to develop specific immunity. [500] Although this is not a practical strategy for all lymphoma patients because of the cost and time required to produce the specific protein for immunization, it is a model for effective tumor-specific vaccination. Finally, others have utilized anti-idiotype antibodies themselves as antigens. [501] The anti-antibodies are evidently somehow viewed by the immune system as similar to the initial antigen used to generate them. This concept of mirror image may allow for better recognition and stimulation than the original antigen itself. [501] [502] This approach has been used in melanoma (GD3), colon cancer (CEA), and small-cell lung cancer.

Peptide Vaccineswith or Without Adjuvants

Numerous peptide components of defined protein antigens expressed by malignant cells have now been defined in terms of their HLA-binding capacity and their ability to induce T-lymphocyte responses (cytolytic [class I] and helper [class II]). [489] [490] Peptides from the melanoma differentiation antigens (MART-1, gp-100, tyrosinase, TRP-1), melanoma fetal-embryonic antigens (MAGE), Her-2/neu, PSA, CEA, p53 (mutant and wild-type), and ras have all been shown to stimulate T cells [489] [490] However, in many cases the endogenous protein expressed in the malignant cell is not processed in a manner that allows the peptide to be presented on its surface and therefore, the cancer cell will not be a target for the peptide-induced T cell. Nevertheless, examples of peptide-induced T-cell responses to endogenously expressed proteins have been the basis for numerous trials with MART-1, gp-100, tryosinase, PSA, CEA, Her-2/neu peptides in their native form or

modified to enhance their MHC-binding capacity (gp-100 peptide 209-2M). These trials have utilized peptides with adjuvants, cytokines (e.g., GM-CSF, IFN, IL-2, IL-12), helper peptides, or antigen-presenting cells (APC) such as dendritic cells. Other approaches have included DNA expression of the peptide and direct transfection of cells via liposomal transfer, gene gun, virus, or vaccinia. [502] Finally, approaches may include peptide vaccine administered with systemic cytokine or use of ex vivo-stimulated T cells expanded with peptide, cytokines, and APC.

Genetically Modified VaccinesCytokine Modified

Attempting to modify either autologous tumor cells or allogeneic tumor cell lines to allow a high level of cytokine expression and release at the site of the tumor cell vaccine has been a popular strategy. [296] [492] [493] [494] [496] [503] These studies have been based on the evidence that cytokine expression at sites of tumor antigens may allow the migration and activation of immune effector cells, such as T lymphocytes or natural killer cells, to the tumor site. [503] This may be accomplished by genetically transfecting tumor cells with IL-2, IL-4, or lymphotactin. In addition, the transfection of tumor cells with GM-CSF appears especially effective in promoting the recruitment and activation of the premiere antigen-presenting cell, the dendritic cell. [305] [496] Once at the tumor vaccine site, these dendritic cells can capture antigens and present them to the host T cells. Work with GM-CSF has been attempted in renal cancer and melanoma using autologous tumor cells transfected ex vivo. [496] Tumor responses have been observed and tumor deposits have exhibited marked inflammatory responses characterized by massive numbers of infiltrating eosinophils. Finally, preclinical studies suggest that expression of more than a single cytokine can lead to more effective immune activation and antitumor effects. This is exemplified by studies in A20 lymphoma with IL-2 (activation of T and NK cells) with lymphotactin (Lptn) (recruitment of T lymphocytes) or in B16 melanoma intracerebrally with IL-4 and GM-CSF (dendritic cell activation). [493] These studies have numerous obstacles, including inefficient transfection of autologous tumor cells to obtain effective cytokine level and the frequent difficulty in obtaining fresh autologous tumor to allow for transfection.

Cellular Therapy

It has been known through experimental models of leukemia and analysis of allogeneic transplant data that cells within the donor graft are capable of mediating a graft-versus-leukemia effect.[504] Recent data have demonstrated conclusively that the infusion of donor leukocytes can induce prolonged, complete remission in patients with CML who relapse following an allogeneic BMT. [505] [506] This effect of donor leukocytes can be observed in patients with cytogenetic and hematologic relapse of CML, as well as in select patients with relapse of their acute leukemia. Patients with multiple myeloma also may respond to donor leukocyte infusion if they are relapsing after an allogeneic BMT. [506] Several variations of this approach have included the addition, either in vivo or in vitro, of cytokines such as IL-2 or IL-2 and IFN to activate these donor leukocytes further. [507] [508] [509] Responses have been seen among patients with myelodysplastic syndromes, ALL, and AML. A modification of this form of cellular therapy has involved the genetic modification of the allogeneic donor leukocytes via transduction with herpes simplex thymidine kinase (HSV-TK) suicide gene.[510] Therefore, patients who developed graft-versus-host disease following infusion of donor leukocytes had their graft-versus-host disease controlled by treatment with ganciclovir which was cytotoxic to cells transduced with the HSV-TK gene. [510] This type of gene therapy may increase the safety and efficacy of donor leukocyte infusions and ultimately may be applied to allogeneic BMT in general.

Another type of cellular therapy being incorporated into cancer therapy involves dendritic cells that provide effective antigen presentation to naive T cells in situ and are critical for effectively stimulating T-cell activation to a variety of antigens, including many tumor antigens. [305] [306] The development of a better understanding of DC progenitors and how to induce their maturation and proliferation has allowed investigators to expand their numbers for use in clinical trials. Furthermore, the use in vivo of cytokines to mobilize hematopoietic progenitor cells and newer cytokines such as Flt3L has allowed the isolation from peripheral blood of DC in larger numbers capable of stimulating immune responses.[333] [334] Dendritic cells are now being applied to vaccine therapy of cancer by pulsing them ex vivo with the proteins or peptides that are being targeted. Idiotype vaccines for B-cell lymphomas have already been used as

a paradigm for this type of cancer vaccine and both immune and clinical responses have been observed. [499] Other approaches, including the acid stripping of peptides from fresh tumors or the use of known specific peptides or proteins (such as mutant oncogenes [ras, p53, etc]), viral proteins, or tissue-restricted peptides expressed by cancer cells, could all be pulsed onto DC, which are derived and expanded from the autologous cancer patients and then used as active immunotherapy.

APPENDIX: Approved Agents

Trade name: Proleukin

Generic name: Interleukin-2

Other names: Aldesleukin

FDA status: Approved

Current approved indications: Indicated for adult patients with metastatic renal cell cancer and metastatic melanoma

Investigational uses: Bone marrow transplantation, hematologic malignancies

Dosing: 600,000 IU/kg administered IV over 15 minutes, every 8 hours, for two 5-day treatment cycles (days 15 and 1519)

Toxicity: Fever, chills, hypotension, capillary leak syndrome, oliguria, pulmonary edema, anemia, elevated liver function studies, atrial and ventricular cardiac arrhythmias

Trade name: Actimmune

Generic name: Interferon-

Other names: None

FDA status: Approved, limited indication

Current approved indications: Reducing the frequency and severity of serious infections associated with chronic granulomatous disease

Investigational uses: Anticancer agent, immunomodulator

Dosing: 50 g/m^2 for patients whose body surface area is >0.5 m^2 and 1.5 g/kg/dose for patients whose body surface area is 0.5 m^2 ; injections should be administered subcutaneously three times weekly

Toxicity: Flu-like or constitutional symptoms such as headache, fever, chills, myalgias

Trade name: Roferon-A, Intron-A, Alferon N

Generic name: Interferon-$_{2a}$, interferon-$_{2b}$, human leukocyte-derived (interferon-$_{n3}$)

Other names: None

FDA status: Approved

Current approved indications: Indicated for use in hairy cell leukemia and AIDS-related Kaposi sarcoma; non-Hodgkins lymphoma; chronic myeloid leukemia; Alferon N approved for refractory or recurrent external condylomata accuminata.

Investigational uses: Malignant melanoma, carcinoid

Dosing: Hairy cell leukemiainduction dose is 3 million IU/day for 1624 weeks, administered as a subcutaneous or intramuscular injection; recommended maintenance dose is 3 million IU, three times per week; dose reduction by one-half or withholding of individual doses may be needed when severe adverse reactions occur; use of doses >3 million IU is not recommended in hairy cell leukemia.

Kaposis sarcomarecommended induction dose is 36 million IU/day for 1012 weeks, administered as an intramuscular or subcutaneous injection; recommended maintenance dose is 36 million IU, three times per week; dose reduction by one-half or withholding of individual doses may be required when severe adverse reactions occur

Condylomata accuminatarecommended doses of Alferon N injection (interferon-$_{n3}$) for treatment is 0.05 ml (250,000 IU) per wart; Alferon N injection should be administered twice weekly for 8 weeks

Toxicity: Flu-like syndrome, fever, fatigue, chills, arthralgia, anorexia, and headache

Trade name: Neupogen

Generic name: Filgrastim

Other name: G-CSF

FDA status: Approved

Current approved indications: Chemotherapy-induced neutropenia, idiopathic/cyclic neutropenia, PBPC mobilization, HIV infection

Investigational uses: Bone marrow failure

Dosing: 5 g/kg/day by subcutaneous injection or intravenous infusion; check CBC twice per week; discontinue Neupogen when absolute neutrophil count >10,000 cells/l

Toxicity: Elevation of serum chemistries (lactate dehydrogenase, leukocyte alkaline phosphatase), hair thinning, and splenomegaly (with chronic use), exacerbation of pre-existing vasculitis, bone pain

Trade name: Leukine, Prokine

Generic name: Sargramostim

Other names: GM-CSF

FDA status: Approved

Current approved indications: High-dose chemotherapy with autologous bone marrow transplantation; post-chemotherapy for AML

Investigational uses: Chemotherapy-induced myelosuppression, bone marrow failure states, HIV infection

Dosing: 5 g/kg/day administered by subcutaneous injection or intravenous infusion; continue therapy until neutrophil count has recovered; decrease dose by 50% if absolute neutrophil count >20,000 cells/l; check CBC twice per week

Toxicity: Fever, chills, arthralgias, myalgias, pericarditis, pleuritis, first-dose effect, bone pain, fatigue, malaise

Trade name: Procrit, Epogen

Generic name: Erythropoietin

Other names: Not applicable

FDA status: Approved

Current approved indications: Anemia associated with chronic renal failure, chemotherapy-induced anemia, anemia associated with HIV infection, and pre-operative orthopedic surgeries

Investigational uses: Anemia of prematurity, bone marrow failure states

Dosing: Chronic renal failurestarting doses 5100 U/kg three times per week; dose is usually administered by intravenous bolus to patients on dialysis; dose may be increased at intervals of 25 U/kg three times per week until target hematocrit level is reached (36%); maintenance dosing can be either at a lower dose, or increased interval of therapy

HIVbefore initiating therapy, check endogenous erythropoietin level, since most patients with erythropoietin levels >500 mU/ml will not respond to erythropoietin therapy; recommended starting dose for patients with erythropoietin levels <500 mU/ml and AZT doses <4200 mg/wk is 100 U/kg three times per week for 8 weeks; dose can be increased by 50100 U/kg three times per week every 48 weeks and response monitored; erythropoietin therapy should be held when the hematocrit is >40% and resumed at 25% dose reduction when the hematocrit is <36%

Toxicity: Iron deficiency, hypertension, seizures, thrombotic events, headache, allergic reaction

Trade name: Neumega

Generic name: Oprelvekin

Other names: Interleukin-11

FDA status: Approved

Current approved indications: prevention of severe chemotherapy-induced thrombocytopenia

Investigational uses: Bone marrow failure states, BMT

Dosing: 50 g/kg/day SC starting within one day of last dose of chemotherapy

Toxicity: Plasma volume expansion, anemia, edema, constitutional symptoms

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

APPENDIX: Investigational Agents

Name: Stem cell factor

Other names: c-kit ligand, mast cell growth factor, steel factor

FDA status: Investigational

Current approved indications: None

Investigational uses: Peripheral blood progenitor cell mobilization, bone marrow failure states, bone marrow priming

Dosing: To be established; 530 mg/kg/day, subcutaneous administration only

Toxicity: Allergic-like reactions, including urticaria, shortness of breath, laryngospasm

Name: Interleukin-12

Other names: None

FDA status: Investigational

Current approved indications: None

Investigational uses: Immunotherapy of renal cell carcinoma, melanoma

Dosing: To be established

Toxicity: Constitutional toxicity, liver function abnormalities, mucositis

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

Chapter 52 - Pathobiology of Acute Myeloid Leukemia

Wendy Stock
Michael J. Thirman

INTRODUCTION

The development of acute myeloid leukemia (AML) is the consequence of a multistep process resulting from a series of genetic changes in a hematopoietic precursor cell. These genetic changes produce an uncoupling of normal hematopoietic growth and differentiation, with an accumulation in the bone marrow and blood of large numbers of abnormal immature myeloid cells that retain the capacity to divide and proliferate but have lost the ability to differentiate terminally into mature hematopoietic cells. As in other malignancies, the genetic alterations in AML include the loss of tumor suppressor genes and mutation of oncogenes. In contrast to most solid tumors, many hematologic malignancies can be categorized on the basis of a single characteristic cytogenetic abnormality. The identification of specific recurring chromosomal abnormalities, including translocations, has provided great insight into the pathobiology of AML and its heterogeneous nature. This chapter discusses the molecular genetic events involved in the pathogenesis of AML.

HETEROGENEITY OF AML

The classification of AML has relied to a large extent on the morphologic and cytochemical criteria of the French-American-British (FAB) classification, which attempts to assign a single lineage to each leukemia (divided into eight subgroups, M0 through M7). [1] Use of the FAB classification has improved the reproducibility of AML diagnosis and classification and has allowed AML to be separated from acute lymphoblastic leukemia (ALL) on the basis of morphology and cytochemical analysis, supplemented by immunophenotyping, which is fundamental to the treatment of acute leukemia. [2] [3] In addition, some FAB AML subgroups correlate with selected disease features. As examples, megakaryoblastic differentiation with marrow fibrosis (M7), monocytic differentiation with gingival infiltrates (M4, M5), and the morphologic subgroup acute promyelocytic leukemia (M3) each correlate closely with a specific genotype and specific clinical characteristics. [1] [4] However, the morphologic features of the large population of leukemic cells typically give few insights into the pathobiology of AML and do not necessarily correlate with the treatment outcome, biologic features, or genetic markers of these diseases.

Several modifications have been proposed to improve the classification of AML and make it more relevant to clinical decision making through incorporation of biologic and genetic data, including sophisticated immunophenotyping data and the recurring chromosomal abnormalities that characterize subgroups of AML. A comprehensive classification system that has been recently proposed subdivides AML into two groups not recognized by traditional classificationAML evolving from prior myelodysplastic syndromes, and true de novo AMLand incorporates pathogenetic mechanisms and treatment responses, in addition to morphology and cytogenetics. [5]

Establishment of a correlation between specific morphologic subtypes and recurring chromosome translocations that result in the creation of novel fusion genes in AML has provided insight

TABLE 52-1 -- Correlation Between Morphologic Subtypes of AML and Recurring Chromosomal Translocations

FAB Subtype	Cytogenetic Aberration	Molecular Aberration
M0, M1, and ALL	t(10:11)	*CALM-AF10*
M1	Trisomy (11)	Partial duplication of *MLL*
M2	t(8;21)	*AML1-ETO*
M3	t(15;17), t(11;17), t(5;17)	*PML-RAR*, *PLZF-RAR*, *NPM-RAR*
M4Eo	inv(16)	*CBF-MYH11*
M4 with erythrophagocytosis	t(8;16)	*MOZ-CBP*
M5	11q23 translocations	*MLL* fused to one of its partner genes
M6	t(3;5)	*NPM-MLF1*
M1, M2, M4, and MDS	t(6;9), ?t(9;9)	*DEK-CAN, SET-CAN*
Multiple FAB subtypes, MDS, and CML	t(16;21)	*TLS/FUS-ERG*
M2, M4, CML	t(7;11)	*NUP98-HOXA9*
MDS, de novo/t-AML	inv(11)	*NUP98-DDX10*
MDS, t-AML, CML	t(3;21)	*AML1-EAP/MDS1/EVI1*

into the potential mechanisms of leukemogenesis and has led to important clinical observations (Table 52-1). Examples of this correlation include the association of FAB-M3 morphology with acute promyelocytic leukemia with a t(15;17)(q22;q1112) and the *PML-RAR* fusion gene involving the retinoic acid receptor- gene on chromosome 17 and the *PML* gene on chromosome 15. This observation provides a rationale for the highly effective treatment of acute promyelocytic leukemia with all-trans-retinoic acid. [6] [7] [8] [9] A subgroup of FAB-M2 leukemias associated with prominent Auer rods and salmon-colored granules in the myeloblasts have a t(8;21)(q22;q22) and the *AML1-ETO* fusion gene, and a subgroup of M4 leukemias with atypical eosinophilic cytoplasmic granules in the blasts (M4Eo) have the inv(16)(p13q22) and the *CBF-MYH11* fusion gene. Both of these leukemias have a very favorable prognosis when patients receive consolidation treatment that includes high doses of cytarabine. [10] Interestingly, the fusion genes created as a result of these translocations both contain components of the core-binding factor complex (*AML1* and *CBF-*), which may render these leukemia cells more sensitive to the effect of high-dose cytarabine. Efforts are under way to elucidate the mechanism of drug sensitivity in these leukemias. These fusion genes, and other AML-associated chromosomal translocations, are reviewed in detail below. Because these and other specific recurring chromosomal abnormalities in AML have prognostic relevance, [3] [11] [12] current AML trials are attempting to stratify treatment based on the presenting cytogenetic abnormalities and known response to treatment of a specific subtype.

CLONAL ORIGIN OF AML

AML cells exhibit characteristic maturation defects that correspond to various stages in hematopoietic differentiation; therefore, to begin to understand the pathogenesis of this heterogeneous group of diseases, it is useful to review the stages of normal hematopoiesis. Mature blood cells of multiple lineages, including erythrocytes, platelets, neutrophils, monocytes, and lymphocytes, are derived from a pluripotent hematopoietic stem cell. [13] To sustain hematopoiesis, stem cells are part of a developmental hierarchy capable of three basic functions: (1) maintenance in a noncycling state; (2) self-renewal capacity, to allow the production of additional stem cells; and (3) the production of progenitor cells with more limited development potential. These progenitor cells commit to subsets of myeloid and lymphoid lineages and ultimately to single developmental pathways, resulting in the expression of the terminally differentiated stage of each cell type. [14]

Normal hematopoiesis is a dynamic yet highly regulated process controlled by the combined effects of growth factors, which permit cellular proliferation, and nuclear transcription factors, which activate specific genetic programs resulting in lineage commitment and terminal differentiation. In the past few years many of the regulatory growth factors and a number of specific transcription factors have been identified that play critical roles in lineage commitment and in the subsequent development of the mature lymphoid and myeloid (erythroid, granulocytic/monocytic, and megakaryocytic) lineages (Fig. 52-1).[5] [16] Some of the genes encoding these transcription factors

Figure 52-1 Transcription factors essential for normal hematopoietic development as defined by gene targeting studies in murine embryonic stem cells. Transcription factors known to be involved in human leukemias are highlighted in red, whereas transcription factors involved in mouse leukemia models are highlighted in pink. Transcription factors essential for normal hematopoiesis but not known to be involved in leukemogenesis are shown in gray. The primitive hematopoietic stem cell gives rise to nucleated erythroid cells at the yolk sac stage of development. Subsequently, multilineage hematopoiesis is thought to be derived from the definitive hematopoietic stem cell. The origins and relationships of the primitive and definitive hematopoietic stem cells remain controversial. Experimental evidence suggests that a common precursor to the primitive and definitive hematopoietic stem cell may exist (blast cell colony-forming cell). The precise hematopoietic pathways remain to be defined. (*From Kennedy et al.*[275] *Reprinted by permission Nature, copyright 1997, Macmillan Magazines Ltd.*)

are involved in the recurring chromosomal translocations of AML, leading to the concept that these leukemias occur because of alterations in master regulatory proteins that control hematopoietic growth and differentiation programs. [17] The novel fusion genes created by these translocations are reviewed in detail later in the chapter.

A large body of evidence supports the development of acute leukemia from a single transformed hematopoietic progenitor cell. Initial studies of glucose-6-phosphate dehydrogenase (G6PD) isoenzyme restriction in the leukemic myeloblasts of heterozygous females demonstrated the clonal origin of AML. [18] [19] In these studies, X-chromosome inactivation mosaicism was used to determine clonality. The G6PD locus is on a portion of the X chromosome that undergoes inactivation in XX somatic cells (Lyonization). Females who are heterozygous at this locus produce two isoforms of the enzyme (A and B) and, because their normal tissues are composed of mixtures of cells, these tissues manifest both forms of the enzyme. Approximately one-half of the cells in normal somatic tissue will have randomly inactivated one of the X chromosomes, allowing expression of the A isoform, and the other half of the cells will have inactivated the other X chromosome, resulting in expression of the B isoform. Cells of clonal origin, however, express only one type of G6PD. In each of the G6PD heterozygous females with AML who were studied, both types of enzyme were found in normal tissues, but only a single type was observed in the leukemic myeloblasts. [18] [19] [20] Similar conclusions about the clonal origin of AML have been reached using X-linked recombinant DNA probes, standard cytogenetics, and fluorescence in situ hybridization (FISH). [21] [22] [23]

Leukemic Transformation: Cell of Origin

The precise cell of origin of leukemic transformation in AML has been the subject of intense investigation. Two models have been proposed to explain the heterogeneity of the disease that is observed at the molecular, cytogenetic, phenotypic, and clinical levels (Fig. 52-2A). One model proposes that *many cell types in the stem cell/progenitor cell hierarchy are susceptible to leukemic transformation*, resulting in the expansion of abnormal cells that are blocked at a particular stage of differentiation. According to this model, the transforming event(s) in AML may occur during different stages of hematopoiesis, from the stage of primitive multipotent stem cells to lineage-committed progenitor cells. The level of commitment of the transformed target cell defines the characteristics of the resulting leukemic blast cells; therefore, this model predicts that the phenotype of the leukemic stem cells from patients with AML restricted to the granulocytic-monocytic series differs from the phenotype of the leukemic stem cells from AML patients with involvement of erythroid, megakaryocytic, and granulocytic-monocytic lineages.

The correlation of specific cytogenetic and molecular genetic aberrations with the morphologic appearance of leukemic cells suggests that the transforming event occurs at different stages of myeloid differentiation. This hypothesis is underscored by the FAB criteria, which distinguish different subtypes of AML based on the stage of apparent differentiation. [1] Evidence in support of this model also comes from a variety of studies of clonal hematopoiesis in AML. [21] [22] [23] [24] Although these clonality studies demonstrate that the majority of cells derived from the leukemic clone undergo variable degrees of differentiation to cells of the granulocytic-monocytic lineage, clonally derived cells from some AML patients also may differentiate into cells of the erythroid and/or megakaryocytic pathways. Multilineage involvement has been noted more frequently in elderly patients with AML, in patients in whom AML arose after a documented prior preleukemic (myelodysplastic) phase, or in patients in whom AML developed after treatment for another malignancy; [23] [24] multilineage involvement was noted to a lesser degree in younger adults and children with AML. [22] [24]

A second model for leukemogenesis challenges this concept and proposes that mutations responsible for *leukemic transformation and progression occur only in primitive multipotent cells* (Fig. 52-2B).[25] According to this model, the heterogeneity seen in AML results from the variable ability of these primitive stem cells to differentiate and acquire specific phenotypic lineage markers. The heterogeneity noted is a direct consequence of the transforming gene itself. Depending on the nature of the transforming gene(s), in some patients, the pluripotent stem cells have lost the capacity for erythroid and megakaryocytic differentiation, whereas in other patients the pluripotent stem cells retain the capacity for multilineage differentiation.

A number of studies support this model of a hierarchical development of AML originating from a primitive, multipotent stem cell. Hematopoietic stem cells express a characteristic cell-surface antigen, classified as CD34, and can be further subdivided by the expression of additional cell surface antigens, including CD38 and HLA-DR.[26] [27] CD34+/38/HLA-DR cells are multipotent hematopoietic stem cells, whereas CD34+/CD38+/HLA-DR+ cells define a committed population of myeloid progenitor cells.[28] Using fluorescence-activated cell sorting techniques, it has been possible to specifically sort these subpopulations of hematopoietic cells from bone marrow samples of patients with different phenotypic and cytogenetic subtypes of AML. CD34+/CD38 and CD34+/CD38+ cells have been obtained from patients with AML that evolved from a prior myelodysplastic syndrome and from patients with AML without any antecedent hematologic disorder (de novo AML). Cytogenetic and FISH studies of sorted stem cell compartments from these patients have shown that the characteristic cytogenetic abnormality in both leukemia sample groups was present in the CD34+/CD38 multipotent stem cell compartment.[29] [30] These data support the idea that the target cell for leukemic transformation in phenotypically

diverse AML cases arises from a similar primitive, multipotent stem cell in all cases studied by these investigators.

More compelling evidence in support of the CD34+/CD38 (multipotent) stem cell as the target for leukemic transformation in most, but not all, cases of AML comes from recent studies in which purified AML subpopulations were transplanted into mice with severe combined immunodeficiency disease (SCID). [31] These experiments have defined a SCID mouse leukemia-initiating cell (SL-IC) in the bone marrow of patients with AML. SL-ICs compose approximately 1 in 10^5 AML cells and can repopulate immune deficient mice with leukemia cells that are phenotypically identical to those of the AML patient from which they were derived. [31] In several AML patient samples studied, the SL-ICs resided in the most primitive compartment of cellsthose that are CD34+/CD38. CD34+/CD38 cells purified from normal marrow give rise to mixed-lineage granulocytic-erythroid-megakaryocytic colonies in culture and can repopulate immune deficient mice with normal cells. Therefore, these experiments indicate that the SL-ICs share an immunophenotype expressed by normal multilineage stem cells and that the target for leukemic transformation resides in this primitive pluripotent population of cells rather than in a lineage-restricted cell.

Using nonobese diabetic mice with SCID (NOD/SCID), a modified SCID mouse,[32] it has been shown recently that in AML patient samples, the SL-ICs reside only in the CD34+/CD38 fraction, and not in the CD34+/CD38+ fraction. [33] The SL-IC phenotype was consistent regardless of the FAB subtype (M1, M2, M4, M5), lineage markers, or percentage of leukemic blast cells expressing the CD34 antigen. The SL-ICs also demonstrated self-renewal capacity, a requirement for maintenance of the leukemic clone, assessed by their ability to be serially transplanted into secondary recipient mice. The uniformity of the

Figure 52-2 Two models to explain the heterogeneity of AML. Hatched lines

represent the leukemic transformation event for the different AML subtypes. **(A)** This model proposes that the transforming event(s) occurs at any one of several stages of differentiation in the stem cell / progenitor cell hierarchy. **(B)** In this model, the transforming event almost always occurs in a primitive, pluripotent progenitor cell. The heterogeneity of the disease is then determined by the specific molecular transforming event(s). Acute promyelocytic leukemia (AML M3) is an exception to the model shown in **B** as it appears to arise from a more differentiated myeloid progenitor cell.

leukemic stem cell phenotype, together with the observation that normal stem cell repopulating cells are also found in the CD34+/CD38 fraction, strongly suggests that the leukemia-initiating transformation- and progression-associated genetic events always occur in primitive cells and not in committed progenitors. As a result of the specific transforming event(s) itself, the leukemic multipotent stem cells in some patients may have lost the capacity for erythroid and platelet differentiation. This would explain the conflicting results of clonality studies, which demonstrate multilineage (erythroid, megakaryocytic, granulocytic-monocytic) involvement in some AML cases and lineage-restricted disease (granulocytic-monocytic) in other cases. Interestingly, an exception to these findings may be acute promyelocytic leukemia (APL). In the NOD/SCID mice, peripheral blood leukocytes from patients with APL did not engraft. In addition, flow cytometric/molecular analysis of APL patient samples suggests that the leukemic stem cell arises in a committed lineage-restricted, CD34+/CD38+ progenitor cell. [34] This contrasts with the CD34+/CD38 fraction observed in the other subtypes of AML.

MULTISTEP PATHOGENESIS

Progression to acute leukemia may require a series of genetic events that begins with clonal expansion of a transformed leukemic stem cell. [35] The specific mutational events required for leukemic progression are not well defined; however, insights into the multistep pathogenesis of human AML have been obtained from mouse models of leukemia and from several lines of evidence in human leukemias. For example, in chronic myeloid leukemia (CML), the leukemia cells contain the t(9;22) transposition, resulting in the *BCR-ABL* fusion gene at the time of the clinical diagnosis of chronic phase disease. [36] This fusion gene product has been demonstrated to be critical in the pathogenesis of CML. [37] As the disease progresses, additional cytogenetic abnormalities [38] are acquired that include loss of important tumor suppressor genes such as *p53*.[39]

Additional evidence for a multistage pathogenesis comes from study of clonal remissions after treatment for AML. A variety of clonality studies using X-linked polymorphisms, identical to those described above that demonstrate a clonal origin for AML, have shown that patients in clinical remission may still have clonal rather than polyclonal hematopoiesis. [21] [40] [41] [42] This finding supports a multistep process, since the clonal remission marrow may represent the preleukemic stem cell that has undergone an initial transforming event but has not acquired the additional mutation(s) essential to progression to overt leukemia. In these cases, it is presumed that the transformed, overt leukemic cell responded to chemotherapy and probably represented a subclone of the original preleukemic stem cell that had acquired the genetic mutations required for the definitive block in differentiation and manifestation of the frank leukemic phenotype. Although some recent studies suggest that these clonal remissions may actually be the result of skewed Lyonization (preferential inactivation of one X chromosome over another), [43] [44] more carefully controlled studies suggest that clonal remissions do occur after treatment for AML. [45] [46] Bone marrow samples from patients in remission from de novo AML (FAB-M2) with a t(8;21)(q22;q22) transposition and the *AML-ETO* fusion transcript (described below) have been found to harbor the aberrant fusion transcript as long as 8 years after cessation of all chemotherapy. [47] Recently, the *AML-ETO* fusion transcript has also been detected in remission bone marrow samples from patients who underwent allogeneic bone marrow transplantation for AML and have remained in clinical remission. [48] These data suggest that expression of the chimeric protein is only one of the genetic modifications necessary for the development of cancer and leukemia, and that the affected clone would require additional mutation(s) to express the transformed phenotype.

THERAPY-RELATED AML

The development of AML after chemotherapy administered for a variety of other malignancies, ranging from Hodgkin's disease to breast cancer, is an unfortunate complication of curative treatment strategies.[49] Leukemia develops after a latency period of varying length, which suggests that the initial mutations resulting in clonal hematopoiesis may occur without any obvious hematologic change (no dysplasia or cytopenia). The subsequent acquisition of a variety of additional genetic lesions may be essential for the development of a preleukemia (myelodysplasia) or overt leukemia.[35] Clonal chromosomal abnormalities have been reported in the majority of cases of therapy-related AML (see Chap. 48). The most frequently reported abnormalities involve complete loss or interstitial deletions of the long arm of chromosome 5 or 7 (or both). Typically these leukemias develop after alkylating agent-induced damage a median of 35 years after therapy for the primary malignancy and are associated with an antecedent myelodysplastic disorder.[50] A second group of therapy-related leukemias is associated with rearrangements of the *MLL* gene in chromosome band 11q23.[51] 11q23-associated AML often develops after treatment with drugs that target DNA-topoisomerase II (e.g., epipodophyllotoxins, anthracyclines), with a very short latency of 1218 months after treatment, and is not typically associated with an antecedent myelodysplastic syndrome.[52] [53] [54] Of concern are recent reports of the development of myelodysplastic syndrome and AML after dose-intensive therapy with (and without) autologous stem cell and hematopoietic growth factor support for the treatment of Hodgkin's and non-Hodgkin's lymphoma and breast cancer.[55] [56] [57] [58] The identification of an increasing incidence of therapy-related AML consequent on attempts to improve cure rates for other malignancies emphasizes the importance of understanding the underlying pathogenetic mechanisms.

The genetic damage induced by chemotherapeutic agents can result in clonal proliferation, which may be an essential early step in leukemogenesis, occurring before the development of clinical abnormalities. Clonal hematopoiesis has been demonstrated in clinically asymptomatic patients who received prior cytotoxic chemotherapy for a variety of non-Hodgkin's lymphomas.[59] [60] [61] Recently it has also been shown that sequential X-linked clonality assays may help predict subsequent evolution to frank myelodysplasia or AML.[62] The specific genetic events induced by chemotherapeutic agents remain unknown; nevertheless, the resultant clonal proliferation and observed cytogenetic abnormalities provide a valuable model for multistep leukemogenesis.

ETIOLOGY

In addition to certain chemotherapeutic agents that are associated with the development of therapy-related leukemia, exposure to a variety of environmental agents has been implicated in the pathogenesis of AML. Ionizing radiation shares with the alkylating agents the ability to damage DNA, usually by inducing double strand breaks that may cause critical mutations, genomic deletions, or the chromosomal translocations required for hematopoietic stem cell transformation. [49] [63] An increased incidence of AML has been noted in atomic bomb explosion survivors. [64] This risk may be directly proportional to the radiation exposure. [65]

Ionizing radiation used in the treatment of malignancies such as Hodgkin's disease has also been linked to the development of AML, although this risk appears to be quite low when radiation alone is used as treatment and is associated with age of the patient and doses of more than 2,000 cGy. [66] [67] Whether irradiation adds to the risk of therapy-related AML associated with chemotherapy remains controversial. Although some studies suggest that the risk of development of AML is significantly

increased when the two modalities are combined, other studies have demonstrated that the combination of high-dose radiation therapy confined to small volumes and chemotherapy did not significantly increase the leukemogenic risk. [68] [69] [70] [71]

Chemical exposure to organic solvents such as benzene and occupational exposure to petroleum products have been associated with a higher risk of developing AML;[72] [73] however, case-control studies of leukemia have demonstrated only a slight increase in risk of disease for persons with occupational or chemical exposures. Except for special groups exposed to high levels of benzene or radiation, the reported risks associated with occupational and chemical exposure have generally been less than twofold, making these exposures of questionable pathogenetic significance. [74] The presence of *ras* mutations in patients with AML has been associated with specific occupational exposure to chemicals, suggesting that these exposures may induce genetic damage that may culminate in acute leukemia. [75] In a case-control study, cigarette smoking was associated with only a modest increase in risk for leukemia; however, a twofold increase in risk for AML was noted in participants over the age of 60.[76]

In a number of animal models, retroviruses have been demonstrated to play an important role in leukemogenesis, and these are reviewed later in the chapter. The human T-cell leukemia retrovirus (HTLV-I) is associated with acute T-cell leukemia in adults. [77] In human AML, however, despite extensive investigation, there has been no clear association of a retrovirus with leukemogenesis. [78]

Familial leukemia occurs rarely, but, as with other cancer family syndromes, study may lead to the identification of genes involved in the pathogenesis of the far more common sporadic cases of AML. Familial leukemia can occur in the context of a medical syndrome where it is one component of the overall disease, or it can occur as isolated leukemia not specifically associated with co-morbid conditions. [79] Several illnesses have leukemia as a component of the syndrome. These include a rare constitutional trisomy 8 syndrome associated with a characteristic facial and skeletal muscle dysmorphism; the development of hematologic disorders, including aplastic anemia, myelodysplasia, and acute and chronic myeloid leukemia; [80] and Down's syndrome, trisomy 21, in which there is a 10- to 18-fold increased risk for leukemia.[81] Potential chromosome 8 genes associated with the development of AML (reviewed later) include the *ETO* gene, involved in the t(8;21)(q22;q22) translocation, and the *MOZ* gene, involved in FAB M4/M5 leukemias with a t(8;16)(p11;p13) translocation. [82] [83] In individuals with Down's syndrome who are less than 3 years old, the leukemia is most frequently AML, of the FAB M7 subtype; after age 3, the development of ALL is more common. [84] [85] Interestingly, from the study of atypical Down's karyotypes, it has been possible to narrow the critical region for leukemia, and this region includes the *AML1* locus on 21q22.3, which encodes the -subunit of core-binding factor (CBF) and is the site of recurrent t(8;21)(q22;q22) translocations in AML. [82] [86]

Defective DNA repair syndromes have also been associated with a high incidence of hematologic malignancies, including AML. These familial disorders include Bloom's syndrome, in which AML, ALL, lymphoma, or other malignancies occur in about 25% of affected individuals, [87] [88] Fanconi's anemia, in which approximately 52% of patients develop AML or myelodysplasia by the age of 40; [89] neurofibromatosis, which results from mutations in the neurofibromin tumor suppressor gene on chromosome 17q11.2 and which is associated with the development of juvenile CML, ALL, lymphomas, and a disproportionately high rate of myelodysplastic syndrome evolving into AML in young patients; [90] [91] Li-Fraumeni syndrome, which occurs as a consequence of dominantly inherited germline mutations of the *p53* tumor suppressor genes and is associated with the development of multiple types of tumors, occasionally including leukemia; and Wiskott-Aldrich syndrome, an X-linked immunodeficiency syndrome associated with the occasional development of lymphomas, AML, and ALL. [92] Other syndromes associated with high rates of AML include Kostmann's infantile genetic agranulocytosis, an autosomal recessive disorder that has been associated with mutations in the G-CSF receptor on chromosome 1p35p34.3, [93] [94] and the Blackfan Diamond syndrome, consisting of congenital hypoplastic anemia and growth retardation. [95]

There have also been reported cases of familial leukemias not associated with any defined syndrome. Several families have been reported in which multiple siblings have developed childhood-onset myelodysplasia with bone marrow monosomy for chromosome 7 with evolution to AML.[96] The inheritance pattern is autosomal recessive. Autosomal dominant patterns of inheritance of leukemia have also been reported, with a variety of morphologic and cytogenetic subtypes. [97] [98] [99] [100] Some are associated with an antecedent myelodysplastic syndrome, while others appear to arise as de novo AML.

Although the environmental and hereditary conditions described above serve as excellent models for obtaining insights into the molecular pathogenesis of AML, it must be emphasized that the vast majority of patients with de novo AML show no evidence of any of these risk factors, and the etiologic factors contributing to the development of AML remain unknown.

HEMATOPOIETIC GROWTH FACTORS

The role of hematopoietic growth factors in promoting the growth and differentiation of leukemic blood cells has been studied extensively. With in vitro clonogenic assays it has been possible to demonstrate that leukemic cells proliferate in response to many of the endogenous hematopoietic growth factors critical for normal hematopoiesis, including granulocyte, granulocyte-monocyte, macrophage, stem cell colony-stimulating factors (G-CSF, GM-CSF, M-CSF, SCF), interleukin-3 (IL-3), and Flt3 ligand (Flt3-L). [101] [102] [103] [104] [105] It appears that a combination of these factors can produce a synergistic growth response in clonogenic assays.

Disruption of normal hematopoietic growth factor signal transduction pathways could also play a role in leukemogenesis. Mutations in the G-CSF receptor gene have been described in some children with Kostmann's syndrome and with nonfamilial severe congenital neutropenia (see previous discussion). [94] [106] The high incidence of AML in these patients supports the hypothesis that defective signaling function by the aberrant receptor increases susceptibility to AML. These data are intriguing; however, outside of these cases, mutations in critical hematopoietic growth factor receptors have not been reported as a general pathogenetic mechanism for AML.

In a substantial number of patients with AML, autonomous growth has been reported to occur as a result of autocrine or paracrine stimulation of a number of factors, including G-CSF, GM-CSF, IL-1, and IL-6. [107] [108] Several investigators have noted that the presence of autonomous growth characteristics in AML cells grown in vitro correlates with lower remission rates and poor survival. [109] [110] Recently it was demonstrated in a multivariate analysis that expression by leukemic blasts of c-*mpl*, the receptor for thrombopoietin, correlates with a significantly decreased duration of remission in patients with AML. [111] Several explanations for these observations have been proposed. One possibility is that the acquisition of autonomous growth capability allows AML cells to become more aggressive by making them independent of stromal cell production of essential growth factors. [110] Others have suggested that autonomous production of growth factors such as GM-CSF may reduce the cytotoxicity of chemotherapy agents by altering intracellular drug metabolism. [112] Some data suggest that exogenously administered

hematopoietic growth factors not only stimulate in vitro growth and proliferation but also inhibit apoptosis of cultured AML cells. [113] [114] It is possible that the autonomous production of hematopoietic growth factors by leukemia cells may also inhibit apoptosis.

As a result of these in vitro data demonstrating the growth-promoting effects of a variety of cytokines on AML cells, one of the recent controversies in the treatment of AML has centered on the use of hematopoietic growth factors during or after induction chemotherapy. The desired goal of reducing the toxicity of treatment and the duration of cytopenia with exogenous administration of G-CSF or GM-CSF was tempered by concerns about the leukemogenic potential of these growth factors. A number of large randomized clinical trials in AML demonstrate variable clinical efficacy of these growth factors with respect to significant decreases in morbidity and mortality. [115] Although different conclusions have been reached regarding clinical efficacy, there is consensus about the safety and lack of increased leukemogenic potential of these growth factors when they are administered after induction or consolidation chemotherapy.

Two early trials demonstrated that either G-CSF [116] or GM-CSF [117] could be administered safely after induction chemotherapy without increased toxicity or an increased rate of relapse. In addition, these early trials demonstrated that cytokine support was efficacious, with a reduction in neutropenia and early death rate and a trend toward an improvement in the rate of complete remission. Since that time, a number of phase III trials testing the role of GM-CSF or G-CSF in patients with newly diagnosed AML have been concluded. [118] [119] [120] [121] [122] [123] A primary objective of these randomized trials was to evaluate the potential role that these growth factors might play in decreasing the neutropenic phase; however, these studies are difficult to evaluate as a whole since the trial designs varied considerably with respect to the time of administration of growth factor. Only two of these trials required documentation of marrow hypoplasia before CSF use. [118] [120] Despite these differences, administration of either GM-CSF or G-CSF was found to be safe, without an increase in acute toxicity or an increase in relapse rate. Most of the studies demonstrated a significant improvement in neutrophil recovery, and two demonstrated an improvement in complete remission or overall survival rates. [118] [122]

In contrast, the clinical use of cytokines prior to induction chemotherapy in an attempt to recruit leukemic cells into the S phase of the cell cycle to enhance chemotherapeutic effect remains investigational. Several clinical trials in patients with relapsed or refractory AML have attempted to evaluate this concept with a variety of cytokines, including GM-CSF, G-CSF, IL-3, and PIXY321. [124] [125] [126] [127] [128] Most studies incorporated either 24 or 48 hours of cytokine priming before chemotherapy, and some were able to demonstrate the ability to recruit leukemia blast cells into the cell cycle before chemotherapy administration. [125] [126] All but one of these trials demonstrated that cytokine administration prior to chemotherapy was safe; however, one trial [124] found that prolonged infusion of GM-CSF before chemotherapy was associated with severe toxicity, including the development of leukostasis.

MOLECULAR GENETICS OF AML

Tumor Suppressor Genes

Several of the known tumor suppressor genes have been well characterized in myeloid leukemias, such as the association of *p53* mutations with progression to blast crisis in CML.[129] [130] [131] In AML, *p53* mutations occur less frequently. Only about 7% of cases have known *p53* mutations at the time of diagnosis. The incidence of *p53* abnormalities may be slightly higher in patients with AML evolving from a prior myelodysplastic syndrome [132] and in cases with 11q23 translocations.[133] [134] The *p16INK4* gene is another critical cell cycle regulatory gene that has been shown to be inactivated by a variety of mechanisms in a number of tumors, including frequent deletion in ALL but only very rarely in AML. [135] Similarly, overexpression of the *BCL-2* gene occurs in a wide variety of lymphoid malignancies as a result of the t(14;18) translocation, which juxtaposes *BCL-2* with the immunoglobin (Ig) heavy chain locus. In AML, *BCL-2* overexpression in AML has been reported only rarely; however, in one study of patients with newly diagnosed AML, a multivariate analysis showed that *BCL-2* overexpression was associated with lower complete remission rates and a significantly shorter survival. [136] As noted above, patients with neurofibromatosis and mutations of the *NF1* tumor suppressor gene have a high rate of developing neoplasms, including progression of myelodysplastic syndrome to AML. [90] [91] The Wilms' tumor suppressor gene, *WT1*, has been found to be overexpressed in the leukemic blasts of approximately 75% of cases of newly diagnosed AML. [137] [138] The *WT1* gene, located in the 11p13 region, encodes a transcription factor normally expressed in a time- and tissue-dependent manner, mainly in the kidneys and gonads, [139] [140] although it is also expressed in normal CD34+/CD38 hematopoietic progenitor cells.[141] In AML, high *WT1* levels at diagnosis correlate with lower remission rates and overall survival. [137] [138]

Certain genetic alterations are specific to AML. These include loss of the long arms of chromosomes 5, 7, and 20, which occurs commonly in therapy-related AML and AML associated with prior myelodysplastic syndrome, and is associated with a poor prognosis. [50] [53] [67] These deletion events are discussed in detail in Chapter 48 . The involved genes have not yet been cloned, although novel tumor genes are likely to be identified at these loci.

Oncogene Mutations

Mutations of three closely related *ras*(H-*ras*, K-*ras*, N-*ras*) proto-oncogenes occur in human malignancies.[142] Each of these genes encodes a structurally similar 21-kd protein that localizes to the inner plasma membrane and plays an important role in signal transduction. [143] Specific point mutations occur characteristically in each of the three genes, although no consistent karyotypic abnormalities have been associated with *ras* mutations and result in its activation. [144] Mutations of *ras* have been identified in approximately 25% of cases of AML [144] [145] and are observed with higher frequency in myelodysplastic syndrome (35%). [146] [147] The majority of the mutations in AML and myelodysplastic syndrome are in the N-*ras* gene; K-*ras* and H-*ras* mutations occur less frequently. In both AML and myelodysplastic syndrome, *ras* mutations have been reported more frequently in cases with a monocytic morphology, FAB M4 and chronic myelomonocytic leukemia (CMML) respectively. [148] An association between cases of AML in patients with a variety of occupational exposures and *ras* mutations has been observed.[75]

The pathophysiologic and clinical significance of these mutations in AML remains unclear. Mutations in *ras* have been reported at diagnosis but not at relapse in some AML cases.[149] Conversely, cases have been reported in which *ras* mutations were acquired at the time of relapse or disease progression. [148] [150] It is therefore possible that activation of *ras* may be important in the initiation but not in progression of disease in some cases, whereas *ras* mutation may play an important role in disease progression in other cases of AML and myelodysplastic syndrome. The presence of *ras* mutations has been associated with improved survival in patients undergoing treatment for AML.[145] This improvement in outcome may be related to the fact that these mutations were also associated with a lower leukemia burden in the bone marrow at presentation of AML, thus rendering the cells more susceptible to chemotherapy. Alternatively, it has been suggested that cases of AML with *ras* mutations are more sensitive to chemotherapy with cytarabine,

one of the most active drugs employed in chemotherapy regimens for AML.[151]

CHROMOSOME TRANSLOCATIONS

Chromosome translocations can affect the cell by one of two main mechanisms: by juxtaposition of an intact transcription unit from one chromosome to an enhancer element from a gene on another chromosome, or by the formation of chimeric fusion proteins (Fig. 52-3). [17] For example, in the t(14;18) translocation in non-Hodgkin's lymphoma, the *BCL-2* gene translocates into the *IgH* locus, leading to the inappropriate expression of *BCL-2*. However, the *BCL-2* gene product is identical to the wild-type protein. Alternatively, chromosome translocations can disrupt two different genes within their coding sequences, leading to the creation of a chimeric protein. For example, t(9;22) in CML results in the formation of a chimeric *BCR-ABL* fusion protein. In AML, the vast majority of chromosome translocations result in the generation of chimeric fusion genes that are never expressed in wild-type cells (Table 52-1). With the development of positional cloning techniques, identification of the genes involved in these chromosomal breakpoints has occurred rapidly. In addition, the application of sophisticated techniques such as the polymerase chain reaction (PCR) and FISH has revealed an expanding number of molecular rearrangements in leukemia.

Characterization of the genes involved in these translocations has led to the elucidation of essential transcriptional regulatory pathways in hematopoiesis. [16] [152] [153] For example, the - and -subunits of core-binding factor have been found to be required for definitive hematopoiesis, and both of these subunits are involved in chromosome translocations in AML. The involvement in chromosome translocations of several other classes of transcription factors has been recognized, including those that contain zinc fingers, ring fingers, leucine zippers, basic helix-loop-helix (HLH) motifs, and ETS domains. [154] Often, homologs of these transcription factors have been well characterized in model organisms such as *Drosophila*, including the *AML1* homolog, *runt*, and the *MLL* homolog, *trithorax*. Several other proteins with well-defined functions in normal hematopoiesis have been recognized at chromosome translocation breakpoints, including retinoic acid receptors and Hox genes. However, structural proteins that do not appear to be specific to myeloid cells have also been identified, including members of the nuclear pore complex and nucleolar phosphoproteins. The functions of many other genes involved in chromosome translocations remain to be elucidated. The heterogeneity of the classes of genes involved in different translocations underscores the complexity of normal hematopoietic differentiation and provides insight into the disrupted regulation of these pathways that result from the formation of chromosome translocations.

With the intensive investigation of molecular genetic alterations in leukemia cells, it has become clear that many genes are capable of participating in translocations that involve multiple alternative partner genes (Fig. 52-4). For example, the *MLL* gene has been found to form chimeric fusion genes with at least 14 known partners and an additional 1015 that have not yet been cloned. Moreover, although the *RAR* gene classically fuses to *PML* in acute promyelocytic leukemia, its fusion to other partner genes, including *PLZF* and *NPM*, has recently been identified. These alternative fusions provide an opportunity to contrast the contributions of each component of the fusion gene and thus dissect the motifs within these genes that are critical to leukemogenesis. The cloning of new genes at translocation breakpoints often leads to the identification of family members of genes previously identified in other translocations. Examples include the *AF10* and *AF17* genes as well as the *TLS/FUS* and *EWS* genes. In addition, certain classes of genes have been identified in different translocations such as the nucleoporins, *CAN* and *NUP98*, each of which is involved with two other fusion partner genes. In the majority of cases, the contribution to different fusion genes from members of the same family is usually similar. However, in the t(12;21), the contribution of *AML1* to the *TEL-AML1* fusion differs from the pattern observed in the t(8;21) and the t(3;21). The involvement of the same genes in multiple different translocations leads to great difficulties in the development of classification schemes for the genes involved in leukemia. For example, the fusion of *NPM* to *ALK* is a frequently recurring abnormality in anaplastic large cell lymphoma. However, *NPM* also fuses to *RAR* in APL and to *MLF1* in other subtypes of AML. In addition, rearrangements of *AML1* and *MLL* occur in both ALL and AML. We will discuss specific fusion genes in the context of other similar families of fusions that share common features. The recurring involvement of the same genes in multiple different translocations has two important implications. First, it suggests that the genomic structure of these genes may contain hot spots for chromosomal breakage. Second, it indicates that disruption of the normal pathways regulated by these genes results in malignant transformation rather than death of the hematopoietic cell in which that chromosome translocation first arises.

Figure 52-3 Two potential consequences of chromosome translocations. In (I), the chromosomal breakpoints occur within the transcription units, leading to the formation of chimeric genes and thus to the expression of fusion proteins. In (II), an intact transcription unit is juxtaposed to regulatory elements from a gene on another chromosome, leading to its inappropriate expression.

Figure 52-4 Branching networks of genes involved in chromosome translocations. Each line represents a pair of genes that form chimeric fusion proteins. The myeloid-specific fusion genes are highlighted in black and the lymphoid-specific fusions in red. The fusion genes highlighted in pink are involved in chromosome translocations in sarcomas and are shown because of their overlap with fusion genes involved in the myeloid leukemias.

CBF Family of Leukemias

Chromosome aberrations in AML commonly involve subunits of the core-binding factor (CBF) group of transcription factors. Characterization of the functions of this family of transcription factors was pioneered by study of their roles in leukemogenesis. [82] The members of the CBF group function as heterodimeric complexes to regulate diverse target genes involved in differentiation in many tissues (Fig. 52-5).[155] CBF factors consist of an -subunit that binds DNA, and a -subunit that does not bind DNA directly but enhances binding by the -subunit. Because of the discovery of the various subunits in different contexts, their nomenclature is somewhat confusing. Three -subunits have been identified: *AML1/CBFA2/PEBP2B, AML2/CBFA3/PEBP2C,* and *AML3/CBFA1/PEBP2A.* In view of its pivotal role in both normal hematopoiesis and leukemia, we will refer to *AML1/CBFA2/PEBP2B* as *AML1*. At their N-terminus, the -subunits of CBF contain a DNA-binding domain that is highly homologous to the *Drosophila melanogaster runt* gene.[156] In *Drosophila, runt* functions as a pair-rule segmentation gene involved in body pattern development and the regulation of other segmentation genes. The consensus binding site for the -subunit, TGPyGGT, was identified initially in enhancers of polyoma and murine leukemia viruses.[157]

Figure 52-5 Core-binding factor (CBF) consists of a heterodimer that contains an DNA-binding subunit and a -subunit that does not bind DNA directly but enhances DNA binding by the -subunit. Each of the components of the CBF heterodimer is involved in chromosome translocations in AML. These fusion genes are highlighted in red. Formation of these fusions may disrupt the normal regulation of target genes that contain CBF regulatory sites.

In hematopoietic cells, CBF-binding sites have been observed in genes specific to both the lymphoid lineage (T-cell receptor enhancers, CD3epsilon, and LCK proximal promoter) and genes specific to the myeloid lineage (M-CSF receptor, IL-3, GM-CSF, myeloperoxidase, granzyme B, and neutrophil elastase). [16] [158] The -subunit of the CBF complex appears to contribute to the tissue specificity of CBF gene regulation. For example, the *AML3/CBFA1/PEBP2A* gene has been found to

be a critical factor in the regulation of osteoblast differentiation, and disruption of this gene in mice has demonstrated it to be essential for the development of bone. [155] The *AML1* subunit has been studied extensively in hematopoiesis. Multiple splice variants have been identified; *AML1B* contains the *runt* domain and a trans-activation domain, whereas *AML1A* lacks the trans-activation domain.[159] Disruption of *AML1* by gene targeting in embryonic stem cells results in embryonic lethality at embryonic day 12.5 due to an absence of fetal liver hematopoiesis and to central nervous system hemorrhage. [160] Strikingly, the knockout of *CBF* results in a very similar phenotype, indicating that both the - and -subunits of CBF are essential for definitive but not primitive hematopoiesis. [161] [162] Because these knockouts affect the earliest stages of hematopoiesis, the role of CBF in later stages of hematopoietic differentiation is not yet clear.

AML1-ETO in the t(8;21)(q22;q22)

The t(8;21)(q22;q22) translocation is associated with the M2 subtype of AML and was the first recurring chromosome translocation in AML to be identified. [82] The clinical and morphologic correlations of this subtype of AML include a high incidence of development of extramedullary collections of leukemic blasts known as granulocytic sarcomas. The blasts have a characteristic morphology, including prominent Auer rods, salmon-colored granules, and large cytoplasmic granules and vacuoles. When the characteristic histologic appearance of these cells is identified in AML blasts that do not contain a t(8;21), the *AML-ETO* fusion can be identified by PCR, indicating that formation of the molecular fusion is responsible for the morphologic and clinical features of this subtype of AML. [163]

The *AML1* gene was first identified by cloning the chromosome 21q22 breakpoint junction in the t(8;21)(q22;q22) in the M2 subtype of AML. [164] Although no function could be ascribed to *AML1* at the time of its initial cloning, the identification of the homology to the *Drosophila runt* gene has enabled a series of researchers to determine the normal functions of CBF transcription

factors in hematopoiesis. In t(8;21), *AML1* fuses to the *ETO* gene on the der(8) chromosome to form a chimeric fusion protein.[165] The normal functions of the *ETO* gene are not yet known; however, it contains regions of homology to the *Drosophila nervy* gene.[166] The chimeric protein fuses the N-terminus of *AML1*, including the *runt* homology domain but excluding the trans-activation domain to nearly all of *ETO* except for a few N-terminal amino acids. The *AML1-ETO* fusion gene has pleiotropic effects in reporter gene assays as it appears to repress several *AML1* target genes but to activate the M-CSF receptor promoter.[167] By engineering a knock-in of the *ETO* cDNA into the murine *AML1* locus, a mouse model of the t(8;21) has been generated. These mice exhibit a midgestation embryonic lethality with an absence of fetal liver hematopoiesis and central nervous system hemorrhage that is quite similar to what is seen in the *AML1* and *CBF* knockout mice.[168] This result suggests that the *AML1-ETO* fusion gene can act as a dominant negative of normal *AML1* function. The embryonic stem cells containing the *AML1-ETO* knock-in do not contribute significantly to hematopoiesis in the chimeric mice; thus these mice do not develop leukemia. Thus, a mouse model that would recapitulate the leukemia awaits the development of an inducible expression system that can bypass the early block in hematopoietic development caused by *AML1-ETO* in the knock-in mice.

AML1-EAP, MDS1, EVI1 in the t(3;21)(q26;q22)

The t(3;21)(q26;q22) translocation has been observed in the blast crisis of CML and also in therapy-related MDS and AML. The *AML1* gene has been found to be rearranged in these cases, leading to the formation of alternative fusion transcripts involving the *EAP, MDS1*, and *EVI1* genes.[169] [170] The fusions contain the N-terminus of *AML1*, including its *runt* homology domain fused to alternative C-terminal sequences derived from its partner genes on 3q26. A complex pattern of these fusion transcripts has been identified. The fusion to *EAP* is out of frame, and thus the chimeric transcript would encode a truncated form of *AML1* that contains only a few additional amino acids from *EAP*. By PCR analysis of cases with this translocation, independent fusions of *AML1* to *MDS1* and *EVI1*, as well as a combined *AML1/MDS1/EVI1* fusion transcript, have been identified.[171] *EVI1* is also involved in the inv(3)(q21q26) and the t(3;3)(q21;q26) in AML. [172] However, the consequence of these chromosome aberrations is the inappropriate expression of the *EVI1* transcription unit, whereas in the t(3;21), *EVI1* participates in the formation of a fusion gene with *AML1*. Sequences from another transcription unit, *MDS1*, are also observed in the t(3;21). Although mapping data indicate that the exons of *MDS1* and *EVI1* are separated by several hundred kilobases, they have been found to be spliced together not only in cases with the t(3;21), but also in normal tissues. A mouse model of the t(3;21) has not yet been generated. However, the *AML1-MDS1* fusion has been shown to transform the Rat1A fibroblast cell line. [173]

TEL(ETV6) and *AML1* in the t(12;21)(p13;q22)

AML1 is involved in the t(12;21)(p13;q22), resulting in the generation of a chimeric protein with the *TEL(ETV6)* gene.[174] The t(12;21) fusion is observed commonly in pre-B-cell ALL. The *TEL(ETV6)* gene was originally cloned from a t(5;12)(q33; p13) in CMML, where it fuses to the *PDGFR* gene, and it has also been found to fuse to the *ABL* gene in a t(12;22) in AML. [175] [176] *TEL(ETV6)* is a member of the ETS family of transcription factors that contain an HLH motif and an ETS DNA-binding domain. In the t(12;21), the structure of the fusion protein differs from that of other fusion genes involving *AML1*. The HLH domain of *TEL(ETV6)* comprises the N-terminus of the fusion, whereas sequences from *AML1*, including both the *runt* homology domain and the trans-activation domain, are located at the C-terminus of the chimeric protein.[177] *TEL(ETV6)* has also been found to fuse to *MDS1/EVI1* in the t(3;12)(q26;p13) (Fig. 52-4).

CBF-MYH11 in the inv(16)(p13q22) and the t(16;16)(p13;q22)

The aberrations of the inv(16)(p13q22) and the t(16;16)(p13;q22) are observed primarily in the M4Eo subtype of AML. These patients, similar to those with the t(8;21), have a relatively good prognosis and a high likelihood of responding to high-dose cytarabine-containing chemotherapy regimens. [10] In contrast to the t(8;21), the inv(16) is not typically associated with the development of granulocytic sarcomas. The -subunit of CBF, located at 16q22, is disrupted as a result of either this chromosomal inversion or a translocation leading to the formation of a fusion transcript with the gene for smooth muscle myosin heavy chain, *MYH11*, located at 16p13.[178] Thus both the - and -subunits of CBF are disrupted in common subtypes of AML and form chimeric fusion transcripts with genes not normally expressed in hematopoietic cells. The CBF-MYH11 chimeric protein contains nearly all of *CBF*, including the heterodimerization domain for *AML1*, fused to the C-terminal sequences of *MYH11*, including its coiled-coil dimerization motif. The chimeric CBF-MYH11 protein thus retains its ability to bind to *AML1* and is also capable of forming high-molecular-weight multimers through the coiled-coil domain of *MYH11*. The *CBF-MYH11* fusion has been shown to interfere with the trans-activation capacity of the normal CBF heterodimer.

By inserting the *MYH11* cDNA into the murine *CBF* locus, a mouse model for inv(16) leukemia has been generated through a knock-in approach. [179] These mice exhibit a midgestation embryonic lethality, an absence of fetal liver hematopoiesis, and central nervous system hemorrhage. The chimeric mice generated from embryonic stem cells containing *CBF-MYH11* did not develop leukemia. However, there was no contribution by the embryonic stem cells to hematopoiesis. Thus, a striking similarity has been observed for the knockouts of *AML1* and *CBF*, as well as the *AML1-ETO* and *CBF-MYH11* knock-in mice. This convergence in phenotypes from seemingly disparate gene-targeting experiments indicates that *AML1* and *CBF* are both essential for definitive hematopoiesis and are both required for the function of the CBF heterodimer. In addition, although there are two other -subunits of CBF, they cannot compensate for *AML1* in hematopoiesis. Further, the fusion genes formed as a result of chromosomal aberrations involving either the - or the -subunits of CBF appear to act as dominant negative inhibitors of CBF function.

RAR Family of Leukemias

The cytogenetic hallmark of acute promyelocytic leukemia (APL), the M3 subtype of AML in the FAB classification, is a translocation involving the *RAR* locus on chromosome 17.[180] The vast majority of these cases contain a t(15;17)(q22;q1112), although several variant translocations involving *RAR* have been identified. These include *PLZF* in a t(11;17)(q23;q1112) and *NPM* in a t(5;17)(q35;q1112). *NPM* is also involved in the t(2;5)(p23;q35) in anaplastic large cell lymphoma (Fig. 52-4).[249] These translocations lead to the formation of chimeric fusion transcripts from each of the derivative chromosomes. Retinoic acid is a critical ligand in the differentiation pathway of multiple tissues. The diverse effects of retinoids are mediated through binding to a retinoic acid receptor (RAR). RARs belong to the nuclear steroid/thyroid hormone receptor superfamily and possess a modular structure with discrete ligand-binding and DNA-binding domains. Of the three isoforms of RARs, *RAR* is expressed primarily in hematopoietic cells. *RAR* heterodimerizes with retinoid X receptor (RXR) and binds to retinoic

Figure 52-6 Retinoic acid receptor- (RAR-) and retinoic acid X receptor (R × R) bind as heterodimers to retinoic acid receptor response elements (RARE). The fusions of RAR- to its partner genes in leukemia are highlighted in red. These RAR- fusion proteins disrupt the regulation of genes that contain RARE regulatory elements.

acid-responsive elements to regulate transcription of target genes (Fig. 52-6).[181]

The capacity of retinoids to induce myeloid differentiation was recognized prior to the identification of the involvement of *RAR* in APL. Retinoic acid had been shown to enhance the growth of normal myeloid progenitors, to induce differentiation of the HL-60 promyelocytic cell line, and to induce terminal differentiation of primary human APL cells cultured in vitro.[182] [183] [184] Subsequently, the use of all-*trans*-retinoic acid (ATRA) was found to induce complete remissions in patients with APL. Rather than inducing cell death from cytotoxicity, ATRA induces differentiation of the malignant promyelocytic clone, an effect that can be observed by serial morphologic examination of the peripheral blood of patients undergoing treatment. [185] Although patients with APL can achieve a complete remission with ATRA alone, it has become clear that without additional cytotoxic chemotherapy, most patients will ultimately relapse. The basis for the development of ATRA resistance remains unclear but it appears that additional genetic events might occur in APL cells that confer resistance. The use of arsenic trioxide has also been shown to induce remissions in APL, possibly by inducing the degradation of PML-RAR-.

PML-RAR in the t(15;17)(q22;q1112)

The *PML* gene was first identified by its fusion to *RAR* in the t(15;17).[186] [187] It is expressed ubiquitously, and multiple alternative splice variants have been isolated. *PML* contains a cysteine-rich ring finger motif and an -helical coiled-coil region. The normal function of *PML* is not yet known, but overexpression of *PML* inhibits growth in cell lines. As a result of the t(15;17), a reciprocal fusion transcript is formed from each derivative chromosome. The *PML-RAR* fusion contains the N-terminus of *PML*, including its ring finger and part of the coiled-coil domain fused to the DNA-binding and ligand-binding motifs of *RAR*. The reciprocal *RAR-PML* fusion is much smaller and contains the N-terminal activation domain of *RAR* fused to the C-terminus of the coiled-coil motif of *PML*. In addition, a truncated version of *PML* is also formed as a result of the fusion of N-terminal sequences of *PML* to an exon of *RAR* that is out of frame. The contribution of each of these transcripts has been the focus of intense investigation. Whereas the *PML-RAR* fusion is found consistently in all cases of the t(15;17), the reciprocal *RAR-PML* fusion can be detected in approximately 80% of cases.[188] Although this suggests that the *RAR-PML* fusion may not be essential, its expression has been postulated to represent a potential second genetic event that contributes to the leukemic phenotype.

The PML-RAR- protein has been shown to function as an aberrant retinoid receptor that possesses altered DNA-binding and transcriptional regulatory properties compared to wild-type RAR-.[189] PML-RAR- can heterodimize with RXR and bind to retinoic acid-responsive elements in target genes. In addition, PML-RAR- can form homodimers and is also capable of forming heterodimers with PML. Expression of *PML-RAR* has been shown to block retinoic acid-induced myeloid differentiation. [190] In addition, PML-RAR- can block RAR--mediated trans-activation in a dominant negative manner. In line with the hypothesis that translocations affecting the *RAR* locus act as dominant negative inhibitors of normal RAR--mediated functions, a dominant negative mutation of RAR- has been observed to affect myeloid differentiation. When this mutation was introduced into a murine FDCP multipotent hematopoietic cell line by retroviral infection, a block in differentiation along the neutrophil and monocytic lineages was observed and a switch to the development of mast cells and basophils occurred. [191] Because PML-RAR- contains most of PML, the fusion protein may also be acting as a dominant negative inhibitor of potential PML target genes that have not yet been defined.

The PML protein is a component of a novel nuclear structure referred to by several names, including PODs (PML oncogenic domains), NBs (nuclear bodies), or ND10 (nuclear domain 10).[192] [193] This nuclear structure was initially discovered by immunohistochemical analysis of the targets of autoantibodies obtained from patients with primary biliary cirrhosis. The Sp100 protein was the first component of this structure to be identified. Type I and II interferons induce the expression of both PML and Sp100. Infection of cells with adenovirus or herpesvirus leads to the delocalization of Sp100 and PML. In APL cells, the integrity of the nuclear body is disrupted and a microspeckled distribution of PML-RAR- is observed (Fig. 52-7). Treatment of APL cells with ATRA causes the nuclear bodies to regenerate, with proper relocalization of PML. Recently, arsenic trioxide has also been found to target PML and PML-RAR- to nuclear bodies and to induce degradation of these proteins. [194] Thus, the restoration of nuclear body structures by either ATRA or arsenic trioxide correlates with the ability of these agents to induce remission of APL.

Several groups have generated transgenic mice that express *PML-RAR* under the control of various myeloid-specific promoters. The phenotype in these mice depended on the stage of myeloid differentiation when the transgene was expressed. In mice with the transgene expressed under the control of the human MRP8 promoter, which drives expression in early myeloid progenitors as well as in mature neutrophils and monocytes, neutrophil numbers were normal but differentiation was impaired. Approximately 30% developed acute leukemia, with a latency period of 39 months, and remission of the leukemia could be induced by ATRA. [195] Two groups have generated transgenic mice expressing *PML-RAR* under the control of the human cathepsin G promoter, which drives expression in promonocytes and promyelocytes. In contrast to the MRP8 transgenics, these mice develop elevated numbers of immature myeloid cells in the bone marrow and peripheral blood. Approximately 1030% of the cathepsin G transgenic mice develop leukemia, with a latency period of 1214 months. [196] [197] Treatment of these mice with ATRA caused apoptosis of myeloid precursors rather than differentiation. Transgenic mice expressing *PML-RAR* under the control of the CD11b promoter have also been generated.[198] This promoter drives expression in later stages of myeloid differentiation. The CD11b transgenic mice do not develop leukemia and have normal numbers as well as normal maturation of myeloid cells. However, the ability of these mice to recover granulocytes following sublethal irradiation was impaired. Comparison of the phenotypes observed in the different transgenic mice reveals that the timing of *PML-RAR* expression during myeloid differentiation is a critical determinant in the development of leukemia. In addition, the relatively low frequency and long latency period to the development of leukemia imply that other genetic events, in addition to the expression of *PML-RAR*, are necessary for APL to occur.

Figure 52-7 In normal cells, PML and Sp 100 are localized in PODs (PML oncogenic domains), whereas RAR- is in the nucleoplasm. As a result of t(15;17), PML-RAR- is delocalized from the PODs. Treatment with all-trans-retinoic acid (ATRA) or arsenic trioxide restores proper subnuclear localization.

PLZF-RAR in the t(11;17)(q23;q1112)

The *PLZF* (promyelocytic zinc finger) gene fuses to *RAR* in APL with the variant (11;17)(q23;q21) translocation. [199] *PLZF* is a member of the *Drosophila Kruppel* family of transcription factors that contains nine zinc fingers. *PLZF* is expressed in myeloid but not lymphoid lineages, and its expression has been found to be down-regulated during differentiation. Unlike *PML, PLZF* is not a component of nuclear bodies, but it is localized in smaller, more numerous nuclear subdomains. Reciprocal fusion transcripts are expressed from each of the derivative chromosomes that are similar to the structure of the t(15;17) fusions. The *PLZF-RAR* fusion transcript consists of the first two zinc fingers of *PLZF* fused to the DNA-binding and ligand-binding domains of *RAR*, and the reciprocal *RAR-PLZF* fusion transcript contains the activation domain of *RAR* fused to the last seven zinc fingers of *PLZF*. PLZF-RAR- can either homodimerize with itself or heterodimerize with RXR. Similar to PML-RAR-, PLZF-RAR- can inhibit the activity of wild-type RAR- in a dominant negative manner. [200] In contrast to APL with the t(15;17), patients with the t(11;17) appear to be resistant to treatment with ATRA.[201]

NPM-RAR in the t(5;17)(q35;q1112)

Recently, another variant translocation in APL has been described. In the t(5;17)(q35;q21), the *NPM* gene has been found to fuse to *RAR*.[202] *NPM* is a nucleolar phosphoprotein that is involved in ribosomal ribonucleoprotein processing and transport. Two alternatively spliced *NPM-RAR* fusion transcripts have been isolated that differ by 129 bases in the contribution of *NPM* sequences to the fusion. The sequences in the fusion transcript derived from *RAR* include its DNA-binding and ligand-binding domains, similar to what is observed in the *PML-RAR* and *PLZF-RAR* fusions. In transcriptional assays, NPM-RAR- has been shown to trans-activate retinoic acid response element reporter constructs at similar levels to wild-type RAR-. The localization of the NPM-RAR- fusion protein has not yet been determined. *NPM* is also involved in the t(2;5)(p23;q35) in anaplastic large cell lymphoma, where it fuses to the *ALK* gene. In addition, *NPM* has been found to fuse to the *MLF1* gene in the t(3:5)(q25.1;q35) in AML.

MLL Family of Leukemias

Translocations involving chromosome band 11q23 occur frequently in both AML and ALL and have several unique features in comparison with other subtypes of leukemia. There are at least 30 different partner chromosomes involved in recurring reciprocal 11q23 translocations. [51] This exceeds the number of known translocations affecting the immunoglobulin loci, suggesting that the 11q23 breakpoint region may contain genomically unstable sequences that lead to chromosomal

recombination events. Translocations involving 11q23 are the single most common cytogenetic abnormality in infants with acute leukemia, regardless of phenotype, occurring in approximately 7080% of these cases. 11q23 translocations are also observed frequently in therapy-related leukemias in patients who have previously been treated with chemotherapy drugs that inhibit topoisomerase II, especially the epipodophyllotoxins.

The chromosomal partners in 11q23 translocations are usually lineage specific. In AML, the t(9;11)(p22;q23), the t(11;19)(q23;p13.1), and the t(6;11)(q27;q23) are the most common, and in ALL, the t(4;11)(q21;q23) and the t(11;19)(q23;p13.3) occur predominantly. The *MLL* gene was isolated from the 11q23 breakpoint by several groups and is referred to by other names, including *HRX, ALL-1*, and *Htrx*.[203] [204] [205] [206] 11q23 translocations have been observed in several FAB subtypes but occur most commonly in the M4 myelomonocytic and M5 monoblastic leukemias. Myeloid leukemias with 11q23 translocations often coexpress lymphoid markers, whereas 11q23 lymphoid leukemias often express myeloid or monocytoid markers in addition to B-cell markers. These observations suggest that rearrangement of *MLL* may affect a pluripotent stem cell or, alternatively, that disruption of *MLL* may affect a common differentiation pathway shared by lymphoid and myeloid progenitor cells.

MLL encodes a large protein, with a predicted molecular weight of 430 kd, that contains two regions of extensive homology to the *Drosophila trithorax* gene.[207] The regions that are conserved with *trithorax* include a series of Cys4-His-Cys3 zinc fingers in the middle portion of the protein that have been referred to as PHD or LAP domains.[208] [209] The C-terminus of MLL contains a conserved motif, named the SET domain, because it is present in several proteins, including Su(var)3-9, enhancer of zeste, and trithorax.[210] At the N-terminus of *MLL*, there are three AT-hook motifs similar to those present in the HMG-I(Y) proteins that bind to AT-rich sequences in the minor groove of DNA.[211] There is also a region of homology to mammalian DNA methyltransferases. Neither the AT hooks nor the DNA methyltransferase domain are present in trithorax. The MLL protein also contains transcriptional activation and repression domains.[212] In *Drosophila*, trithorax is essential to maintain the proper expression of homeotic genes but not to initiate their expression.[213] Targeted disruption of *Mll* in mice causes lethality at embryonic day 10.5.[214] *Mll* heterozygous mice also exhibited a phenotype with growth retardation, bidirectional homoeotic transformations of the axial skeleton, and sternal malformations. In the *Mll* homozygous deficient mice, expression of *Hoxa-7* and *Hoxc-9* was abolished, whereas in *Mll* heterozygous

Figure 52-8 Potential consequences of 11q23 translocations. As an example, t(11;19)(q23;p13.1) results in the formation of a fusion gene involving the *MLL* gene from chromosome band 11q23 and the *ELL* gene from chromosome band 19p13.1. Motifs within *MLL* are shown on the upper line and those in *ELL* on the bottom line. Two potential fusion genes encoded by each of the derivative chromosomes can be formed and are shown in the middle. In 11q23 translocations, the fusion transcript encoded by the derivative (11) chromosome has been implicated in leukemogenesis.

mice, the anterior boundaries of expression of these genes were shifted posteriorly. These findings indicate that MLL is a positive regulator of *Hox* gene expression.

In 11q23 translocations, the chromosomal breakpoints of both de novo and therapy-related leukemias cluster within an 8.3-kb genomic *Bam*HI fragment within *MLL*. As a result, all *MLL* gene rearrangements can be identified on Southern blot analysis with a 0.74-kb *Bam*HI cDNA fragment that contains the exons that span the breakpoint cluster region.[51] [215] 11q23 translocations result in the formation of two derivative chromosomes that each encode chimeric fusion transcripts. The fusion transcript encoded by the derivative 11 chromosome contains the N-terminal sequences of *MLL*, including its AT hooks, DNA methyltransferase motif, and repression domain, fused in frame to C-terminal sequences from the partner gene (Fig. 52-8). The reciprocal fusion contains the N-terminal sequences of the partner gene fused to the C-terminal sequences of *MLL*, including the zinc fingers, activation domain, and the SET domain. However, the C-terminal sequences of *MLL* that would be contained in the reciprocal fusion transcript are deleted in the formation of the translocation in approximately 2530% of cases, suggesting that its expression is not essential to leukemogenesis.

Fourteen genes at 11q23 partner chromosomal breakpoints have been cloned. These are *AF4* in the t(4;11)(q21;q23),[204] *ENL* in the t(11;19)(q23;p13.3),[205] *ELL* in the t(11;19)(q23;p13.1),[216] *AF9* in the t(9;11)(p22;q23),[217] *AF6* in the t(6;11)(q27;q23),[218] *AF1p* in the t(1;11)(p32;q23),[219] *AF1q* in the t(1;11)(q21;q23),[220] *AF-X* in the t(X;11)(q13;q23),[221] *AF10* in the t(10;11)(p12;q23),[222] *AF17* in the t(11;17)(q23;q21),[223] *EEN* in the t(11;19)(q23;p13),[224] and *CBP* in the t(11;16)(q23;p13.3).[225] [226] [227] Two *MLL* partner genes are involved in other chromosome translocations. *AF10* has been shown to fuse to the *CALM* gene in the t(10;11)(p13;q14), and *CBP* fuses to the *MOZ* gene in the t(8;16)(p11;p13). The functions of many *MLL* partner genes are not yet known. Although no consistent homologies or motifs among the partner gene sequences have been identified that might explain how their fusion to *MLL* results in leukemia, certain partner genes have similar features (Fig. 52-9). *ENL* and *AF9* contain transcriptional

Figure 52-9 Motifs in *MLL* partner genes. The partner genes can be grouped into several classes that share common motifs.

activation domains and share extensive homology at their C-termini. *AF10* and *AF17* contain leucine zipper and zinc finger motifs and also share extensive homology with each other. In addition, *AFX* and *AF6q21* contain forkhead domains and also share other regions of homology. Three *MLL* partner genes have well-characterized functions. *ELL* has been shown to function as an RNA polymerase II transcriptional elongation factor. It serves to increase the catalytic rate of RNA polymerase II by suppressing transient pausing by the polymerase along the DNA template.[228] *CBP* and *p300* are transcriptional co-activators that mediate interactions between multiple transcription factors and the basal transcriptional machinery. The pattern of protein-protein interactions of *MLL* partner genes may provide insight into the nature of the aberrant functions of MLL fusion proteins in leukemia.

In a subset of patients with AML and either trisomy 11 or a normal karyotype, a unique pattern of rearrangement of the *MLL* gene has been observed. As in the translocations that affect *MLL*, a fusion occurs involving one of the exons in its breakpoint cluster region. However, rather than fusing to a partner gene, the fusion is to 5 sequences from *MLL* itself.[229] [230] For example, the structure of the partial duplication might contain *MLL* exons 17 fused to exon 2 through the 3 end of the gene. The largest duplication identified contains exons 29, and the smallest, exons 46. The region of the duplication contains the AT hooks, methyltransferase, and repression domains of *MLL*. In several cases, the 5 and 3 genomic breaks within *MLL* occur at similar points within *Alu* repetitive sequences, suggesting that partial duplications may be generated as a result of homologous recombination. In contrast to the reciprocal translocations involving *MLL*, the partial duplications of *MLL* appear to occur primarily in older patients and are infrequent in childhood and therapy-related leukemias. The morphology of the leukemias also differs in that the partial duplication patients usually are classified as FAB-M1 or -M2, rather than the M4 or M5 typically observed in cases with *MLL* translocations. The basis for the correlation of the partial duplication event with the trisomy for chromosome 11 remains unknown.

Two different strategies have been used to generate mouse models of 11q23 leukemias. To create an *Mll-AF9* knock-in mouse, the *AF9* cDNA was targeted into the murine *Mll* genomic locus by homologous recombination in embryonic stem cells.[231] The chimeric mice generated from these embryonic stem cells all developed AML within 69 months. Chimeric mice that expressed only the N-terminal sequences of *Mll* did not develop leukemia. In addition, retroviral bone marrow infection has been used to express another 11q23 fusion gene, *MLL-ENL*, in hematopoietic cells.[232] In serial replating assays on methylcellulose, the *MLL-ENL*-transduced cells could be immortalized, whereas constructs containing either N-terminal *MLL, ENL* alone, or vector controls could not maintain proliferative capacity beyond three passages. After transplantation of *MLL-ENL*-transduced bone marrow, syngeneic recipient mice developed AML. These models have established proof of the principles that (1) the expression of *MLL* fusion genes contributes to leukemogenesis, and (2) the *MLL* partner genes are essential to this process.

Other Fusion Genes in AML

DEK-CAN in the t(6;9)(p23;q34) and *SET-CAN*

The t(6;9)(p23;q34) translocation is usually observed in the M2 and M4 subtypes of AML but has also been identified in patients with the M1 subtype and in myelodysplastic syndrome. This translocation is associated with a younger age and a poor prognosis. The 9q34 chromosome breakpoint junction was cloned by chromosomal walking from the nearby *ABL* gene, resulting in the identification of the *CAN* gene at this breakpoint.[233] [234] Subsequently, a chimeric transcript was isolated that contained 3 *CAN* sequences fused to 5 sequences of a gene named *DEK* at 6p23. The *CAN* gene was also found to be rearranged in a patient with acute undifferentiated leukemia and a normal karyotype. A chimeric transcript containing an alternative *CAN* partner gene, named *SET*, was isolated in this case.[235] The

SET gene was also localized to 9q34, suggesting that this fusion results from an inversion of chromosome 9 or a cryptic translocation.

DEK and *SET* are both nuclear proteins with little homology to each other, except that both contain highly acidic regions. The structure of the *DEK-CAN* and *SET-CAN* fusions are similar, with nearly all of either *DEK* or *SET* fused to the C-terminal two-thirds of *CAN*.[236] The *CAN* gene has been localized to the nuclear envelope at both its nuclear and cytoplasmic faces. *CAN* contains a coiled-coil domain and a leucine zipper N-terminal to the breakpoint in the t(6;9), and a second coiled-coil domain that flanks the breakpoint. In addition, *CAN* contains a number of repeat sequences, including 35 FG repeats (repeats of the amino acids phenylalanine and glycine) at its C-terminus, which are retained in the formation of the fusions to *DEK* and *SET. CAN* has been found to belong to a family of nucleoporins.[237] These are nuclear pore complex-associated proteins that are involved in the transport of RNA and proteins across the nuclear membrane. The fusion of *CAN* to *DEK* or *SET* disrupts its normal nuclear envelope localization, as both the *DEK-CAN* and *SET-CAN* fusions are located exclusively in the nucleus.

Knockout of the *CAN* gene results in embryonic lethality at embryonic day 4 to 4.5. The embryo is capable of survival until that stage with maternally derived *CAN*. Day 3.5 embryos exhibit impaired nuclear protein import and mRNA export, consistent with the function of *CAN* as a nucleoporin. Recently, *CAN* has been found to interact with two proteins, NUP88 and hCRM1. NUP88 is another member of the nuclear pore complex.[238] In yeast, CRM1 is required for maintenance of correct chromosome structure. Although NUP88 does not interact with the DEK-CAN fusion protein, hCRM1 has been found to associate with DEK-CAN. Thus, aberrant protein-protein interactions may contribute to the leukemogenic properties of the *CAN* fusion proteins.

TLS/FUS-ERG and the t(16;21)(p11;q22)

The t(16;21)(p11;q22) translocation has been observed in several FAB subtypes of AML, in blast crisis of CML, and in myelodysplastic syndrome.[239] [240] In this translocation, the *TLS/FUS* gene at 16p11 fuses to the *ERG* gene at 21q22 to generate a chimeric protein. Both *TLS/FUS* and *ERG* are involved in chromosome translocations with other partner genes in sarcomas. *TLS/FUS* fuses to the *CHOP* gene in the t(12;16)(q13;p11) in myxoid liposarcoma, and *ERG* fuses to the *EWS* gene in the t(21;22)(q22;q12) in Ewing's sarcoma and PNET tumors.[241] [242] *EWS* has also been shown to fuse to the *CHOP* gene in myxoid liposarcoma.[243] In addition, *EWS* has been identified in chimeric fusion proteins generated as a result of several different chromosomal translocations in other distinct types of sarcomas (see Fig. 52-4). These include fusions to the *ETS* family members *FL11, ETV1, FEV*, and *E1AF*, and fusions to the *WT1, CHN/TEC*, and *ATF1* genes. *TLS/FUS* and *EWS* share extensive homology with each other.[244] [245] [246] Both contain a polypeptide repeat SYGQQS and have the capacity to bind to RNA. *ERG* is a member of the *ETS* family of transcription factors that is homologous to *FLI1* and contains an N-terminal activation domain and a C-terminal DNA-binding domain. In the t(16;21), the N-terminal sequences of *TLS/FUS*, including the SYGQQS motif, are fused to the C-terminal sequences of *ERG*, including the ETS DNA-binding domain. This is quite similar to the structure of the other fusion proteins involving *TLS/FUS* and *EWS* and their myriad partner genes in leukemia and sarcomas. The TLS/FUS-ERG fusion

protein exhibits alterations in both DNA binding and transcriptional activation when compared with the wild-type proteins.[247] The striking similarity of the *TLS/FUS-ERG* fusion gene in AML to the sarcoma-associated fusion genes suggests that disruption of a common differentiation pathway may lead to transformation in multiple cell types.

NPM-MLF1 in the t(3;5)(q25.1;q35)

The t(3;5)(q25.1;q35) translocation has been observed in several FAB subtypes of AML, especially in M6 or erythroleukemia, and also in myelodysplastic syndrome.[248] The *NPM* gene at 5q35 was found to be rearranged in patients with this translocation, resulting in the formation of a fusion gene with the *MLF1* (myelodysplasia-myeloid leukemia factor 1) gene at 3q25.1. Previously, the involvement of *NPM* was identified in the t(2;5) (p23;q35) in anaplastic large cell lymphoma, in which it fuses to the *ALK* gene.[249] NPM is also rearranged in the t(5;17)(q35;q21) in APL, in which it fuses to *RAR*, as discussed above. *MLF1* contains no known structural motifs and its functions are not yet known. The *NPM-MLF1* fusion transcript contains 58 more amino acids of *NPM* than the *NPM-ALK* and *NPM-RAR* fusions. The metal-binding motif at the N-terminus of *NPM* is retained in all three types of *NPM* fusions. However, in the *NPM-MLF1* fusion, the additional contribution from *NPM* includes an acidic cluster and a nuclear localization signal. The MLF1 protein localizes to the cytoplasm, whereas in leukemia cells with the t(3;5), the NPM-MLF1 fusion protein is observed primarily in nucleoli. Thus, the normal subcellular localization of MLF1 is altered as a result of its fusion to NPM. The involvement of *NPM* in chromosome translocations involving three different partner genes, resulting in three discrete types of hematologic malignancies, suggests that *NPM* plays an important role in normal hematopoietic differentiation.

EVI1 in the inv(3)(q21q26) and the t(3;3)(q21;q26)

EVI1 (ecotropic virus integration site 1) was initially cloned as the gene at a common site of retroviral integration in murine myeloid leukemia. The *EVI1* gene is normally expressed only in the kidney and ovary, and not in hematopoietic cells. In mice, retroviral integration at the murine *Evi-1* locus leads to its inappropriate expression. A similar phenomenon occurs in human AML with the inv(3)(q21q26) and the t(3;3)(q21;q26).[172] As a result of these cytogenetic aberrations, the *EVI1* gene is juxtaposed to enhancer elements of the ribophorin gene, leading to inappropriate activation of the *EVI1* transcription unit. In contrast to the majority of chromosome translocations in AML, the inv(3)(q21q26) and the t(3;3)(q21;q26) do not result in the formation of a fusion gene. However, in the t(3;21)(q26;q22), *EVI1* is a component of the complex fusion transcripts that involve the *AML1* gene.

MOZ-CBP in the t(8;16)(p11;p13)

The t(8;16)(p11;p13) translocation has been recognized in the M4 and M5 subtypes of AML that exhibit a characteristic erythrophagocytosis. This translocation has been observed in both de novo and therapy-related leukemias. The *CBP* (CREB-binding protein) gene was identified at the 16p13 breakpoint, and a novel gene, *MOZ* (monocytic zinc finger), was cloned at the 8p11 breakpoint.[250] *CBP* is a transcriptional co-activator that coordinates signals between sequence-specific transcription factors and the basal transcription machinery. It interacts with multiple proteins, including CREB, Fos, Jun, ATF1, YY1, E1A, TFIIB, p53, and myb. CBP can function as a histone acetyltransferase and thus modulate transcription. *MOZ* contains two Cys4-His-Cys3 and one Cys2-His-Cys zinc fingers. *MOZ* also contains a putative acetyltransferase domain. The *MOZ-CBP* fusion contains the zinc fingers and acetyltransferase domain of *MOZ* fused in frame to nearly all of *CBP*. Several variant translocations involving 8p11 have been recognized in monocytic leukemias with erythrophagocytosis, but the genes involved in these translocations have not yet been cloned. *CBP* is also involved with a fusion to *MLL* in the t(11;16)(q23;p13).[225]

CALM-AF10 in the t(10;11)(p13;q14)

The t(10;11)(p13;q14) translocation has been recognized in both ALL and AML. In AML, the cases are primarily M0 and M1. This translocation has also been observed in the U937 cell line.[251] The *AF10* gene was identified at the 10p13 breakpoint, and a novel gene, *CALM*, was cloned from the 11q14 breakpoint.[252] *AF10* is also one of the partner genes of MLL in translocations and insertions with 10p12 and 11q23 breakpoints. *AF10* is highly homologous to another MLL partner gene, *AF17. AF10* and *AF17* both contain a zinc finger and a leucine zipper motif. The *CALM* (clathrin assembly lymphoid myeloid leukemia) gene has a high homology to the murine *ap-3* gene, a clathrin assembly protein. The CALM-AF10 fusion protein contains virtually all of the coding sequence of the involved genes.

NUP98-HOXA9 in the t(7;11)(p15;p15), *NUP98-DDX10* in the inv(11)(p15q22)

The t(7;11)(p15;p15) translocation is observed in the M2 and M4 subtypes of AML and also in CML. The *HOXA9* gene was identified at the 7p15 breakpoint and the *NUP98* gene at the 11p15 breakpoint.[253] In BXH-2 mice, the *Hoxa9* gene has also been implicated in myeloid leukemia as a result of its activation by proviral insertion. In addition, other homeobox proteins, such as *PBX1* in the t(1;19) and *HOX11* in the t(10;14), have been identified in chromosome translocations in lymphoblastic leukemia. *NUP98* is a member of the FG repeat nucleoporin family. Another nucleoporin, the *CAN* gene, is involved in the fusion to *DEK* in the t(6;9). The *NUP98-HOXA9* fusion contains the FG repeats of *NUP98* fused to the homeobox domain of *HOXA9. NUP98* has also recently been found to be involved in the inv(11)(p15q22) in AML. This cytogenetic aberration has been recognized in both de novo and therapy-related MDS and AML. The *DDX10* gene, which is a putative RNA helicase gene, was identified at the 11q22 breakpoint.[254] The *NUP98-DDX10* fusion contains the FG repeats of *NUP98* fused to the RNA helicase domain of *DDX10*.

ANIMAL MODELS OF AML

There are several examples of naturally occurring animal models of AML that are caused by retroviruses. There are two mechanisms of retroviral transformation: a retrovirus can encode for an oncogene that leads to transformation, or, alternatively, the retrovirus can inappropriately activate the expression of a gene adjacent to its integration site. The characterization of these processes has revealed a number of genes that are critical to both normal hematopoiesis and to human myeloid leukemias. In addition, these animal models have demonstrated the multistage nature of the evolution of leukemia and have provided reagents for analyzing the transformation of hematopoietic cells. Moreover, the naturally occurring models of leukemia have provided the basis for generating mouse models of human acute leukemia.

MYB Leukemias

The v-*MYB* gene is involved in two different avian retroviruses that induce leukemia in chickens. The v- *MYB* gene was originally identified as the transforming element in the avian myeloblastosis virus (AMV). In the E26 retrovirus, a fusion gene

consisting of *gag*, v-*MYB*, and v-*ets* has been identified.[255] The formation of a fusion gene containing sequences of two transcription factors is reminiscent of the fusions that result from chromosome translocations in human acute leukemia. In chickens, AMV causes monoblastic leukemias and transforms only myelomonocytic cells in vitro, whereas E26 induces erythroleukemias but is capable of transforming myeloid, erythroid, and megakaryocytic lineages in vitro. [256] C-*MYB*, the normal cellular counterpart of v-*MYB*, has been shown to be essential for definitive hematopoiesis in gene targeting studies. [257] Activation of the c-*MYB* gene has also been identified in murine myeloid leukemias. Promonocytic leukemias have been induced by priming mice with intraperitoneal injections of Pristane followed by infection with the Moloney murine leukemia virus.[258] The majority of the mice that develop leukemia have undergone insertional mutagenesis at the c- *MYB* locus.[259] The role of Pristane is unknown but appears to promote leukemogenesis by mediating an inflammatory response. At this time, there is no evidence for the rearrangement of c-*MYB* in human leukemias.

Friend Virus/SFFV Erythroleukemia

The erythroleukemia induced by infection with the Friend viral complex is the culmination of a three-step process that has become a paradigm for multistage neoplastic transformation.[260] Infection of susceptible mice with the Friend murine leukemia virus/spleen focus-forming virus (SFFV) complex induces, within 48 hours, a polyclonal proliferation of erythroid progenitors. This expansion of erythroid precursors has been shown to be secondary to the expression of the SFFV *env* gene product, the GP55 glycoprotein, which has the capacity to bind and activate the erythropoietin receptor. These erythroid cells are not transformed and retain the ability to undergo terminal differentiation. After approximately 2 weeks, however, a clonal population of transformed erythroblasts emerges that can be transplanted into syngeneic recipients. The evolution from a polyclonal proliferation of normal erythroid cells to a clonal population of transformed erythroblasts has been shown to depend on two additional independent genetic events. One of these is the inactivation of the *p53* tumor suppressor gene either by deletion, mutation, or proviral insertion.[261] [262] In addition, activation of either the *PU.1* gene, also referred to as *Spi-1* (SFFV proviral integration 1), or of the *Fli-1* gene occurs as a result of proviral integration adjacent to these loci. [263] [264] *PU.1* and *Fli-1* are members of the ETS family of transcription factors. In gene-targeting studies, *PU.1* has been shown to be essential for both myeloid and lymphoid development. [265] Thus the Friend/SFFV erythroleukemia model depends on three events: (1) polyclonal proliferation induced by a cytokine, (2) inactivation of a tumor suppressor gene, and (3) oncogenic activation of a gene involved in normal hematopoiesis.

BXH-2 Leukemias

BXH-2 mice are an inbred strain of mice derived from a cross of C57BL/6J and C3H/He mice. Although these parental strains have a low incidence of leukemia, more than 95% of BXH-2 mice develop myeloid leukemia by 1 year of age, one of the highest rates of spontaneous leukemia in any inbred strain of mice. This high incidence of leukemia has been shown to be caused by the expression of an ecotropic murine leukemia virus that is horizontally transmitted in this strain. [266] These retroviruses induce leukemia by insertional activation or mutation of proto-oncogenes adjacent to the viral integration site. One of the most frequent viral integration sites to be characterized is EVI2 (ecotropic viral integration site 2). The EVI2 was localized to a large intron within the *NF1* tumor suppressor gene.[267] The consequence of this integration event is disruption of the normal expression of *NF1* in the affected mice. In humans, the neurofibromatosis type I autosomal dominant disorder is caused by mutation of the *NF1* gene.[268] In addition to neurofibromas, patients with neurofibromatosis have an increased risk of developing several types of solid tumors and also malignant myeloid disorders, especially juvenile chronic myelogenous leukemia (JCML) and the monosomy 7 syndrome. [269] Gene-targeting studies of *NF1* revealed that mice heterozygous for the *NF1* allele developed myeloid leukemia with loss of the wild-type allele, indicating that *NF1* acts as a tumor suppressor gene.[270] The *NF1* gene product, neurofibromin, has been shown to accelerate GTP hydrolysis on ras proteins. In JCML patients without neurofibromatosis, activating *ras* mutations are frequently identified. The consequence of either the disruption of *NF1* or the activation of *ras* has been shown to be an inability to negatively regulate GM-CSF signaling in hematopoietic cells. [271] [272]

Because viral integration within the *NF1* gene has been observed in only 15% of BXH-2 mice, the identification of additional mutations within other genes associated with myeloid leukemias has also been pursued. A proviral tagging approach has been used to identify additional viral integration sites that alter the expression of three genes, *Hoxa7, Hoxa9*, and *Meis-1*. [273] [274] The *HOXA9* gene is involved in the t(7;11)(p15;p15) in AML, resulting in the formation of a fusion gene with *NUP98. Meis-1* is a member of the *PBX1* family of homeobox proteins that bind to DNA cooperatively with Hox proteins. *PBX1* is involved in the t(1;19) in ALL, where it fuses to the *E2A* gene. This underscores a recurring theme: the involvement of similar families of genes in both human and spontaneous animal models of AML.

Chapter 53 - Clinical Manifestations of Acute Myeloid Leukemia

Kenneth B. Miller
Philip R. Daoust

INTRODUCTION

Acute myeloid leukemia (AML) is not a single disease but a group of neoplastic disorders characterized by the proliferation and accumulation of immature hematopoietic cells in the bone marrow and blood. These malignant cells gradually replace and inhibit the growth and maturation of normal erythroid, myeloid, and megakaryocytic precursors. If untreated, AML is usually fatal within weeks to months from the time of diagnosis.

The clinical evaluation, therapy, and prognosis of patients with AML has changed dramatically over the last two decades. The initial evaluation of a patient with acute leukemia should be directed at defining the factors that are important in planning therapy and assessing the long term prognosis. Molecular, cytogenetic, and immunologic studies have contributed to our understanding of the pathogenesis and prognosis of the acute myeloid leukemias. Knowledge of environmental or occupational exposures to known or suspected leukemogenic agents or prior illnesses that predisposes an individual to develop AML must be considered in planning treatment and evaluating the response to therapy.

HISTORY

Velpeau in 1827 reported the first accurate description of a case of leukemia. [1] The patient was a 63-year-old florist who developed an illness characterized by fever, weakness, urinary stones, and massive hepatosplenomegaly. Velpeau reported that the blood of this patient was like gruel. He found no infectious cause for this disorder and speculated that the elevated number of white corpuscles and the unique appearance of the blood may not have been the result of infection.

In 1845, Bennett, a brilliant and controversial pathologist from Edinburgh, published a report of a series of patients who died with enlarged spleens and changes in the color and consistency of their blood. [2] While he also found no infectious etiology for the peculiar appearance of the blood, he attributed these changes to the presence of purulent material in the blood and introduced the term *leucocythemia*. Virchow, the noted German pathologist, reported a similar case. [3] Virchow commented on the reversal of the normal ratio of pigmented, red, to colorless, white cells, in his patient but did not attribute these changes to an infection. Unsure of the etiology of his finding, he was content to simply describe his observations and used the descriptive name white blood. Later, in a monograph entitled *Die Leukemia*, Virchow introduced the word *leukemia*, which he derived from the Greek meaning white blood. [4]

The name and the interpretation of this new pathologic condition were acrimoniously debated by Virchow and Bennett, the two leading pathologists of the day. Virchow noted that the leukemias were not one disorder but a heterogeneous group of disorders, and he attempted to subdivide them into a splenic, probably myeloid, and a lymphatic type. In addition, he noted that some patients had a chronic or indolent course, while others presented with a rapidly progressive fatal illness. Virchows and Bennetts observations and interpretations were remarkable in view that neither had the tools to stain blood smears and that little was known about the mechanisms of hematopoiesis or the fate, origin, or function of the various cellular elements.

Neumann and Konigberg in the 1870s were the first to suggest that the colorless white cells were made in the bone marrow independently of red cells. [5] Ehrlich in 1877 developed the first aniline-based stains that permitted the clear definition of cellular detail in air-dried films of blood. He was then able to

accurately describe and differentiate the various types of normal and abnormal white blood cells. Ebstein in 1889 introduced the term acute leukemia to describe a rapidly fatal illness that failed to respond to available therapy. [6] Neumann in 1869 first suggested that the white blood cells were made in the bone marrow and not the spleen. This concept gave rise to the term myeloid, meaning marrow-derived. Mosler in 1879 described the aspiration of bone marrow as a means to diagnose leukemia. [7] Naegeli in 1900 described the myeloblast and divided the leukemias into a myelocytic and a lymphocytic type. [8] Hirschfeld, DiGuglielmo, and Schilling described the granulocytic, erythroid, and monocytic leukemic variants, respectively. [9] [10] [11]

The development of histochemical stains and cytogenetic, immunologic, molecular, and biochemical markers have helped to further define the lineage of the leukemic cell and to classify the leukemias. Effective therapy and advances in supportive care have resulted in dramatic changes in the approach to the patient with AML. The treatment and prognosis of patients with AML has changed AML from a disease that formerly was uniformly fatal to one that responds to chemotherapy and is potentially curable.

ETIOLOGY

AML causes approximately 1.2% of all cancer deaths in the United States, an annual death rate of 2.2 per 100,000. There are approximately 9,200 new cases of AML each year. The incidence increases with age and has remained remarkably steady since the late 1960s. In adults AML represents approximately 90% of all acute leukemias[12] (Fig. 53-1).

Genetic predisposition, drugs and environmental exposures, and occupational factors have been implicated as possible leukemogenic agents in children and adults.[13] [14] Leukemogenesis is a multistep process that requires the susceptibility of a hematopoietic progenitor cell to inductive agents at multiple stages. The different subtypes of AML may have distinct causal mechanisms, suggesting a functional link between a particular molecular abnormality or mutation and the causal agent.[15] No one factor has been shown to cause leukemia in all individuals exposed.

Evidence supporting a genetic predisposition for human leukemia has come from epidemiologic and family studies. [16] The highest incidence of AML in adults is in North America, Western Europe, and Oceania, and the lowest in Asia and Latin America. [17] [18] In contrast, the highest rate of childhood AML is in Asia and the lowest is in North America and India.[18] [19] There are numerous reports of multiple cases of both acute lymphocytic leukemia (ALL) and AML occurring within the same family.[20] [21]

Figure 53-1 Relative incidence of ALL versus AML (ANLL) in different age groups.

The concordance of each of the leukemia subtypes in families is also more common than could be expected on the basis of chance alone. [22] [23] Reports of familial leukemia suggest that dynamic mutations of unstable DNA sequence repeats could be a common mechanism of inherited AML.[24] For all types, there is a threefold increase in leukemia incidence among first-degree relatives of patients with acute leukemia. [24]

In monozygotic twins there is an increased concordance for childhood leukemia. If one twin develops leukemia before the age of 6 years the risk of leukemia occurring in the second twin is up to 25%.[25] [26] The clinical presentation of AML in monozygotic twins is atypical: the leukemia usually occurs before 2 years of age; it occurs in both twins in close succession, typically in the same year; and it is of the same morphologic and cytogenetic subtype. [27] [28] [29] The twin studies are compatible with a genetic or a nongenetic intrauterine postzygotic event, which affects both twins simultaneously. [30] [31] [32] Moreover, no similar excess of leukemia has been observed in nonidentical twins of children with leukemia, and adult twin studies do not demonstrate such a high concordance for acute leukemia. [33] A possible explanation for these observations is that a single leukemogenic event occurring in utero leads to involvement of both twins as a result of the shared placental fetal circulation of monozygotic twins.[34]

The existence of a genetic predisposition to develop AML is suggested by the increased leukemia incidence associated with a number of congenital disorders, including Downs syndrome and Klinefelter syndrome.[35] [36] In Downs syndrome the incidence of acute leukemia is 10 times that of the general population. [37] [38] [39] The incidence of megakaryoblastic leukemia (M7) is 500 times higher than expected in children with Downs syndrome. [40] Moreover, families that have a Downs syndrome child may have an overall higher incidence of acute leukemias in the genetically normal family members. [41] Parents of children with Downs syndrome may also have an increased incidence of AML. [41] [42] [43] [44] These reports of familial clustering of Downs syndrome and leukemia have led to the speculations that a familial tendency to meiotic nondisjuction may be a risk factor for leukemia.[37] However, the familial association of Downs syndrome and acute leukemia remains controversial. [45]

In addition, the risk of childhood AML appears to increase with increasing maternal age, independently of the presence of Downs syndrome. [46] [47] [48] [49] Disorders associated with chromosomal instability and increased chromosome breakage, including Fanconis anemia, ataxia telangiectasia, and Blooms syndrome, are associated with an increased incidence of AML.[50] [51] [52] The development of leukemia in these disorders appears to be a multistep process and not a single transforming event. The genetic disorders give rise to a cellular environment that results in chromosomal instability, a hypersensitivity to DNA damage, and an increased susceptibility to mutations.[53] Von Recklinghausens disease, congenital neurofibromatosis, is associated with an increased incidence of childhood AML. [54] In case-controlled studies a maternal history of fetal loss was associated with an increased risk for childhood AML. Mothers of children with AML diagnosed before 2 years of age had a five-fold increase in previous fetal loss and a 12-fold increase in two or more fetal losses. [49]

Exposure to ionizing radiation and to a number of chemicals has been linked to the development of acute leukemia. The evidence linking radiation exposure and leukemia comes in part from the long-term follow-up of survivors of the atomic bomb explosions in Hiroshima and Nagasaki. [55] [56] [57] [58] The latency time from exposure to the development of leukemia was between 5 and 21 years, and the risk was related to age at the time of exposure and to radiation dose. [56] The development of leukemia was predictable and dose-related. In Hiroshima there was a 30-fold increase in the incidence of both AML and chronic myelogenous leukemia (CML). The highest rates were observed in persons younger than 10 or older than 50 years at the time of exposure.

In Nagasaki, where victims were exposed to a higher amount of gamma radiation, the incidence of AML was even greater. [57] All variants of AML except the M3, acute promyelocytic leukemia subtype, were observed. [59]

Exposure to even moderate doses of radiation therapy appears to be associated with an increased risk for developing AML. Workers at radium plants and military personnel exposed to ionizing radiation during nuclear test explosions have a higher than expected incidence of AML. [60] [61] Patients who received low doses of radiation for benign disorders such as ankylosing spondylitis, [62] [63] menorrhagia,[64] tinea capitis,[65] benign thymic enlargement,[65] and rheumatoid arthritis,[66] develop AML at a greater than expected rate. Exposure to thorotrast, a colloidal suspension of thorium dioxide used widely in the 1940s as a radiographic contrast medium, has been associated with an increased risk of AML, specifically the acute erythroleukemia subtype. [67] [68] The principal thorium isotope is ^{232}Th which, on decay, exposes the individual to chronic low dose alpha particles. The thorotrast-associated leukemia occurred 10 to 30 years after exposure. [67] The incidence of alpha particle-induced AML after thorotrast exposure was related to the combined effects of the amount of thorotrast administered, the exposure time, and the attained age of the individual.[67] Exposure to extremely low frequency electromagnetic fields generated by high voltage power lines has been reported to be associated with an increased incidence of acute leukemia, but this association remains controversial and is not clearly proven. [69] [70] The incidence of AML is increased in workers with chronic magnetic and electric field exposures, including telegraph, telephone, and other communication equipment operators. [71] [72] There appears to be an association between the duration of electric field exposure and the risk for the subsequent development of AML. [73] Workers exposed to extremely low frequency magnetic fields also have an increased incidence of AML. [74] Childhood leukemia has been linked to exposure to electromagnetic radiation associated with certain wiring configurations of a childs home.[75] These observations remain controversial and it is unclear from the reported case-controlled studies if the exposure to

electromagnetic radiation generated from wiring and power lines is physiologically, clinically, or epidemiologically important. [76] [77]

Chronic exposure to a number of chemicals has been associated with the development of acute leukemia.[78] Benzene is the best studied and has been the most widely used chemical leukemogenic agent.[78] [79] [80] [81] [82] Leather and rubber industry workers chronically exposed to benzene and benzene derivatives have a significantly increased incidence of AML.[83] Case-controlled studies have found that truck drivers, filling station attendants, workers in petroleum and gas plants, and painters have an increased incidence of AML, which is perhaps related to their chronic exposure to benzene and other hydrocarbons. [84] [85] [86] [87] [88] Persons exposed to embalming fluid, ethylene oxides, and herbicides also appear to be at an increased risk for acute leukemia. [89] [90] [91] Workers exposed to organic solvents used in the processing of medical radiographs and the manufacturing of electrical wiring may have an increased incidence of AML. [92] [93] Cigarette smokers and those chronically exposed to cigarette smoke appear to be at an increased risk of developing AML. [94] [95] [96] [97] Heavy cigarette smoking is associated with the development of clonal, nonrandom, cytogenetic abnormalities.[98] Metabolites of benzene are found in the urine of chronic cigarette smokers. [99] [100] Moreover, cigarette smoke contains measurable quantities of other known and suspected leukemogenic agents and mutagens. [100] [101]

An increased incidence of acute leukemia has been reported in patients who have received chemotherapy for a number of malignant and nonmalignant disorders. The nitrosoureas, the alkylating agents, and procarbazine appear to have the highest leukemogenic potential. [102] [103] [104] The development of AML following exposure to chemotherapy is usually preceded by a myelodysplastic syndrome.[105] [106] All the commonly used alkylating agents including cyclophosphamide, mechlorethamine, chlorambucil, busulfan, lomustine, and semustine have been associated with an increased risk for AML. The combination of chemotherapy and radiation therapy further increases the risk of developing leukemia. [107] [108]

The risk of developing AML is proportional to the age of the patient and the cumulative dose of the administered alkylating agent. In Hodgkins disease the cumulative risk of developing AML after treatment with alkylating agents increases steadily from 1 year after the start of treatment and reaches a peak of 13% at 7 years. [108] [109] The post-treatment incidence of AML increases most markedly in the first 2 years and plateaus after 8 to 10 years; [108] [109] this increase is related to the administration of a chemotherapy regimen that contains an alkylating agent. The incidence of AML in patients treated with the mechlorethamine-Oncovin-procarbazine-prednisone (MOPP) regimen containing the alkylating agent mechlorethamine, is 3, 4, and 7% at 3, 5, and 7 years, respectively. This is in contrast to a less than 1% incidence of treatment-related AML in patients treated with a regimen that does not include alkylating agents, or with radiation therapy alone. AML occurs after autologous bone marrow and stem cell transplants. Patients who are greater than 40 years of age at the time of transplant and receive total body irradiation are at highest risk for AML.[110] [111] The actuarial risk for secondary AML following chemoradiation therapy and autologous transplantation for Hodgkins disease is between 9 and 18%. [111]

An increased incidence of leukemia has been reported in patients receiving alkylating agents for small-cell lung cancer, [112] ovarian cancer,[113] germ cell tumors,[114] [115] [116] breast cancer,[117] non-Hodgkins lymphoma, [118] chronic lymphocytic leukemia,[119] multiple myeloma,[120] [121] polycythemia vera,[122] [123] and other malignancies.[102] [124] [125] Patients with non-neoplastic disorders such as nephritis, rheumatoid arthritis, psoriasis, multiple sclerosis, systemic lupus erythematosus, and Wegeners granulomatosis who have received alkylating agents also have a increased incidence of AML. [125] [126] [127] [128]

Therapy-related leukemias now represent between 10 and 20% of all cases presenting with AML. [129] These treatment-related, or so-called secondary leukemias are clinically and prognostically different from AML that occurs de novo. The secondary leukemias are frequently preceded by a variable period of anemia, neutropenia, or thrombocytopenia. Dysplastic changes are common and can be found in all cell lines. Circulating platelets may be large, with abnormal granulation; neutrophils may be hypogranular or agranular with pseudo-Pelger-Huet nuclei; and the red cells may demonstrate coarse basophilic stippling with prominent anisocytosis. The bone marrow early in the course may demonstrate dysplastic changes characterized by megaloblastic erythroblasts, micromegakaryocytes, ringed sideroblasts, and an increased number of myeloblasts (5 to 25%) with abnormal maturation. These morphologic abnormalities may also be accompanied by functional defects. Platelet and neutrophil function may be markedly impaired, which results in excess bleeding and recurrent infections despite an adequate number of circulating platelets and granulocytes. These findings in the peripheral blood and bone marrow may precede the development of overt AML by many months. [129] [130] Clonal, nonrandom, cytogenetic abnormalities involving chromosomes 7, 5, and 8 occur in 50 to 90% of patients with therapy-related leukemia. [129] [131] [132] These leukemias are associated with an overall poor prognosis. Although some patients may attain a complete hematologic remission with intensive chemotherapy, these responses are usually of short duration.[129] [133] [134]

A clinically and cytogenetically distinct group of secondary leukemias have been reported in individuals who have received one of the topoisomerase II inhibitors. [116] This group includes the epipodophyllotoxins, etoposide and teniposide, and the anthracyclines,

daunomycin and doxorubicin. The topoisomerase II inhibitors cause DNA damage via the intranuclear enzyme topo II. In contrast to alkylating agentrelated AML, the topoisomerase II therapyrelated leukemias typically lack a preceding myelodysplastic phase and are characterized by a shorter latency of onset, generally less than 23 years.[135] [136] [137] Most of the patients reported have received combination therapy that has included alkylating agents and/or radiation therapy. [138] [139] These topoisomerase IIrelated secondary leukemias are associated with chromosomal rearrangement involving chromosomes 3, 11, and 21, characterized by a balanced translocation involving bands 11q23 and 21q22. The MLL gene (mixed lineage or myeloid-lymphoid leukemia) located on chromosome 11 band q23 is the most frequent site of the leukemogenic translocation induced by topoisomerase II inhibitors. Most of the patients develop morphological M4 or M5 leukemias and present with a rapidly progressive disease with an elevated blast count. The treatment outcome for these patients is much worse than patients with de novo AML with similar clinical and cytogenetic abnormalities. In children with ALL the incidence of secondary AML after exposure to one of the epipodophyllotoxins is approximately 5%. [138] However, in children treated for a T cell ALL the incidence of secondary AML approaches 19% after exposure to one of the topoisomerase II inhibitors. [138] Cytogenetic studies suggest that the second leukemogenic event occurs in a normal hematopoietic progenitor and not in the initial leukemic clone. The outcome for these children with standard treatment remains poor. Topoisomerase II inhibitors have also been associated with a secondary acute promyelocytic leukemia with the characteristic 15;17 translocation.[139] It appears that the topoisomerase II inhibitors are leukemogenic by themselves and the effect may be amplified by the addition of other agents, such as prior or concomitant administration of alkylating agents or radiation therapy.

Drugs other than the cytotoxic agents that have been reported to be associated with the development of acute leukemia include chloramphenicol, [140] phenylbutazone,[141] chloroquine,[142] methoxypsoralen,[143] and LSD.[144] The strength of such associations, however, remains unclear.

Certain acquired diseases are associated with transformation to AML. Patients with the myeloproliferative disorders, including polycythemia vera, primary thrombocythemia, and agnogenic myeloid metaplasia, have an increased incidence of leukemic transformation. [123] [145] [146] [147] In polycythemia vera the incidence of AML is approximately 1% for patients treated only with periodic phlebotomies; the addition of chemotherapy or radiation therapy significantly increases this incidence.[148] [149] Moreover, the incidence of acute leukemia is related to the intensity and duration of alkylating agent therapy. The relative risk for AML was 410 times as great for those patients treated with daily continuous doses of an alkylating agent as for those treated by intermittent pulse therapy. [123] A similar phenomenon has been observed in patients with multiple myeloma and Waldenstroms macroglobulinemia. [124] Aplastic anemia is associated with late development of acute leukemia.[147] In patients with aplastic anemia treated successfully with antithymocyte globulin, 26% developed AML or one of the myelodysplastic syndromes after 8 years. In patients with aplastic anemia who were treated successfully with cyclosporin and recombinant granulocyte colony stimulating factor, 22% developed AML or a myelodysplastic syndrome.[147] The risk for AML appears higher in patients with aplastic anemia following irradiation or chemical exposure. [150] AML occurs in patients with paroxysmal nocturnal hemoglobinuria, and appears to involve the same clone from which the abnormal erythrocytes are derived. [151] Multiple myeloma is associated with the development of AML.[152] The association between AML, multiple myeloma, and administration of multiple alkylating drugs is well documented, but AML can occur in patients with myeloma who have not received prior chemotherapy or radiation therapy. [153]

Primary nonseminomatous mediastinal germ cell tumors are associated with the development of AML.[154] The acute megakaryocytic leukemia (M7) subtype is a frequent type of AML following these germ cell tumors. This secondary leukemia appears associated with the primary disease and is unrelated to prior treatment for the germ cell neoplasm.

CLINICAL MANIFESTATIONS

The presenting signs and symptoms of AML are usually nonspecific and are related to the decreased production of normal hematopoietic cells and invasion of other organs by the leukemic cells. Patients usually complain of a brief viral-like illness characterized by fatigue and malaise or may present with a progressive skin infection after a minor abrasion. While anorexia is common, weight loss is unusual, generally reflecting the acute onset of the disease. Diffuse bone tenderness involving the long bones, ribs, and sternum is the initial clinical manifestation in 25% of patients. Joint pain and swelling, localized to large joints, may antedate other symptoms by weeks. The bone pain, which can be severe, is caused by the expansion of the intramedullary space or direct involvement of the periosteum by the leukemic cells.

The findings on physical examination relate to the interference with normal hematopoiesis by the leukemic cells. Typically, all three cell lines are affected. Anemia results in pallor and the onset of cardiovascular symptoms. Thrombocytopenia produces hemostatic defects, which result in petechiae and ecchymosis. Oozing from the gums, epistaxis, and excess bleeding after dental procedures or minor trauma are common initial manifestations. Petechiae are most prominent in the lower extremities and may appear suddenly after minor physical activity or standing for prolonged periods of time. Splenomegaly occurs in up to 50% of patients with AML, but the splenic enlargement is usually modest and rarely extends more than 5 cm below the left costal margin. A very large spleen suggests that the leukemia has evolved from an underlying prior myeloproliferative disorder. Lymphadenopathy is rare in AML, in contrast to ALL in which peripheral lymphadenopathy may be a prominent presenting finding. Involvement of the thymus or hilar nodes is very uncommon in AML. Skin involvement, leukemia cutis, occurs in about 10% of patients and usually presents as violaceous, raised, nontender plaques or nodules, which on biopsy are found to be infiltrated with myeloblasts (Plate 53-1). There may also be diffuse involvement of the skin. On biopsy there may be a prominent diffuse infiltrate involving deep dermal surface but with preservation of the superficial dermis.[155] Skin involvement is more common with the monocytic subtypes, including the acute monocytic and myelomonocytic leukemias.[156] Sweets syndrome, acute neutrophilic dermatosis, is a cutaneous paraneoplastic syndrome that is associated with AML and other hematologic disorders. [157] It is characterized by tender red plaques and nodules usually on the upper or lower extremities and may precede the diagnosis of AML by several months (Plate 53-2). The histological finding in Sweets syndrome is a dense infiltrate primarily composed of mature neutrophils located predominantly in the mid- and upper dermis. [158] The pathogenesis of Sweets syndrome in AML is unknown. It has been postulated that leukemia-related growth substances or antigens may directly or indirectly stimulate epidermal or dermal cells.[159] Sweets syndrome may occur in patients with normal, low, or elevated white blood counts. Similar lesion have been noted in patients with inflammatory disease and associated with the use of granulocyte colony stimulating factors. [160] [161] The use of topical or systemic steroids is the treatment of choice for Sweets syndrome.[162]

Chloromas, local collections of blasts, may present as isolated subcutaneous masses and may therefore be confused with a primary or metastatic carcinoma. [163]

Chloromas, granulocytic

sarcomas, are extramedullary solid aggregates of blast forms. The term chloromas is related to the greenish appearance on sectioning, which is secondary to the presence of myeloperoxidase granules in the myeloblasts. Granulocytic sarcomas are more common in M2-AML with the 8;21 translocation and leukocytosis. [156] [164] The presence of extramedullary leukemia is associated with a generally poorer response to treatment and shorter overall survival. [165] Gingival hyperplasia caused by leukemic infiltration is more frequent in the monocytic leukemias (Plate 53-3) but may occur in all the leukemic subtypes. The patient may present initially to a dentist complaining of painful gums, rapidly progressive gingival disease, and gum bleeding after dental brushing.

Central nervous system (CNS) involvement in AML is an uncommon presenting finding, but 5 to 7% of all patients have asymptomatic central nervous system involvement, as determined by positive cerebrospinal fluid cytology. [166] Magnetic resonance imaging (MRI) also appears to be a more sensitive and specific imaging modality than the computed tomography (CT) scan to detect dural involvement in suspected cases of CNS leukemia. [167] The finding of asymptomatic central nervous system disease does not alone appear to predict a poor prognosis. [168] [169] [170] Patients at highest risk for developing central nervous system leukemia include those with a high circulating blast count, elevated lactate dehydrogenase activity, and one of the monocytic leukemic subtypes. [166] [171] Of note is the very high frequency of central nervous system leukemia, up to 35%, in AML with increased eosinophils, the M4EO variant, which is associated with an inversion of chromosome 16. Leptomeningeal leukemia and intracerebral myeloblastomas are common in this otherwise prognostically favorable subtype. [172] Unless there are signs of overt central nervous system involvement that requires therapy, it is preferable to defer a lumbar puncture until the peripheral blasts have been cleared with chemotherapy in order to prevent the possibility of accidentally contaminating the spinal fluid with circulating leukemic cells. [173]

The majority of patients with leukemic involvement of the central nervous system are asymptomatic.[174] Some patients, however, present with meningeal signs and symptoms caused by increased intracranial pressure. In these patients a lumbar puncture is required and typically reveals an elevated opening pressure with an increased protein and a low glucose concentration in the cerebrospinal fluid. The cell count may be low, and therefore a Millipore filter technique or cytocentrifuge preparation of the cerebrospinal fluid is required to detect the presence of leukemic cells. Cranial nerve palsies secondary to leukemic infiltration of the nerve sheath are rare in AML. When they do occur, the Vth and VIIth cranial nerves are most frequently involved. [175] [176] Patients may present with the sudden onset of facial muscle weakness, which rapidly progresses to paralysis. Optic nerve infiltration can result in papilledema, eye pain, blurred vision, or the sudden onset of unilateral blindness. Retinopathy can occur and result in progressive impairment of vision. [177] Cranial nerve involvement can occur in the absence of overt central nervous system disease, and therefore the cerebrospinal fluid can be negative for leukemic cells in these cases. [178] A CT scan or preferably MRI of the affected nerve root may demonstrate thickening of the nerve sheath, which is suggestive of leukemic involvement. To prevent permanent loss of cranial nerve function, the affected cranial nerve roots should be irradiated as soon as possible after the onset of symptoms to prevent permanent loss of function. [176] Patients presenting with neurologic findings and a greater than 50,000/mm^3 concentration of circulating leukemic cells are at high risk for a major central nervous system event and require emergency intervention to rapidly lower the blast count. [179] [180] The high number of circulating blasts increases the blood viscosity and is associated with small-vessel leukoblastic emboli, resulting in leukostasis in the cerebral vessels. The leukemic blasts can infiltrate the arteriolar endothelial

Figure 53-2 Head CT scan of a patient with a presenting WBC count of 100,000/mm ^{3} and a massive intracranial hemorrhage secondary to leukostasis.

walls and cause a secondary hemorrhage (Fig. 53-2). Suspected or developing central nervous system leukostasis requires emergency efforts to rapidly lower the blast count. Patients may complain of diffuse headaches and fatigue, which rapidly progress to confusion and coma. Leukostatic hemorrhage clinically resembles a major cerebrovascular accident. The adhesion and aggregation of leukemic cells as well as local anatomical factors appear to play a role in development of CNS leukostasis.[180] Leukostasis is more intensive in the white matter and leptomeninges with involvement of medium-sized vessels. The risk of CNS leukostasis rapidly increases when the blast count is greater than 50,000/mm^3 . Despite most efforts to rapidly lower the white blood count and the blood viscosity, the prognosis for patients with central nervous system leukostasis remains very poor. [180]

Metabolic and electrolyte derangements are common in patients with AML.[181] Hyperuricemia is the most frequent leukemia-related biochemical abnormality and results from the increased turnover of the proliferating leukemic clone and subsequent purine catabolism. Hyperuricemia and hyperuricuria can develop before therapy is started. Typically, however, the uric acid level rises rapidly once therapy is initiated as a result of release of intracellular nucleic acids by the lysis of large numbers of cells. Urate crystals can precipitate in the renal tubules and ureters, causing acute renal failure. To prevent the development of urate nephropathy, all patients should receive intravenous hydration and should be started on allopurinol before beginning chemotherapy. Allopurinol, by inhibiting xanthine oxidase, causes an increase in the urine xanthine and can produce xanthine crystalluria and calculi.[182] Therefore, it is important to maintain adequate hydration in addition to administering allopurinol before and during induction chemotherapy. Rarely, leukemic cells produce an obstructive uropathy as a result

of direct infiltration of the prostate gland.[183] Direct bilateral cortical, medullary, and interstitial kidney involvement with myeloblasts may result in renal failure.[184] [185] However, in AML, in contrast to ALL, kidney involvement is uncommon. Hyperkalemia may occur as the result of rapid cell breakdown.[186] Hypokalemia, however, is a more common presentation in patients with AML.[187] The hypokalemia, which can be profound and require large doses of intravenous potassium, is most pronounced in the myelomonocytic and monocytic leukemias, in which intracellular levels of the lysozyme muramidase, which is toxic to renal tubular cells, are high.[188] [189] [190] Ineffective myelopoiesis or destruction of the leukemic cells with therapy causes the release of large amounts of this enzyme, which produces a proximal renal tubular dysfunction and leads to renal potassium wasting. In most cases, however, muramidase-induced tubular damage is not the sole mechanism of the hypokalemia.[190] Attempts to directly correlate the elevated serum and urinary muramidase lysozyme level with the leukemic subtype and the development of hypokalemia and the renal tubular defect have produced conflicting results.[191] [192] Leukemic cells can synthesize other factors with renin-like activity that may contribute to the development hypokalemia.[193] Antibiotics and chemotherapy-induced nephropathy, diarrhea, vomiting, and the development of hypomagnesemia all contribute to the development of potentially life-threatening hypokalemia during and before induction therapy for the AML.[192] [194]

Hypercalcemia has been reported in association with AML.[195] The mechanism is unclear, but may be related to the release of parathyroid hormone or parathyroid hormone-like fragments produced by the leukemic cells.[196] [197] The hypercalcemia may be caused by direct bone involvement or stimulation of osteoclasts and the resultant lytic bone lesions.[198] In these instances the blood calcium level parallels the activity of the disease. Hypocalcemia presumably a result of release by the leukemic cells of factors that result in accelerated bone formation has been reported. The hypocalcemia can be profound, and patients can present with tetany and potentially fatal cardiac arrhythmias.[198] The hyperphosphatemia and hyperphosphaturia associated with underlying renal insufficiency can also contribute to the hypocalcemia.

The rapid lysis of leukemic cells can acutely precipitate a number of serious metabolic problems as a result of the release of intracellular phosphate, potassium, and urate.[199] This so-called tumor lysis syndrome is characterized by the rapid development of hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia.[200] The consequences of tumor lysis syndrome are directly related to the metabolic abnormalities: the hyperuricemia produces a urate nephropathy and acute renal failure; the hyperkalemia is associated with potentially lethal cardiac arrhythmias; and the hyperphosphatemia causes a reciprocal depression of the serum calcium and progressive renal insufficiency, with further reduction of the excretion of potassium and phosphate. The hypocalcemia, a result of the hyperphosphatemia, can cause tetany, cardiac arrhythmias, and muscle cramps. The tumor lysis syndrome occurs in patients with a rapidly rising or very high blast count.[201] [202] [203] It is important to recognize those patients at risk for this syndrome and to address and correct metabolic and electrolyte abnormalities before starting therapy. Allopurinol and intravenous hydration should be started early, before beginning chemotherapy. Serum electrolytes, including potassium, calcium, phosphate, and uric acid, and renal function should be carefully monitored. Renal function can rapidly deteriorate, and patients should be monitored daily to correct developing electrolyte abnormalities. Dialysis may be required and should be considered early in the course to prevent the complications of rapidly rising serum potassium, phosphate, and uric acid.[204] [205] In many patients recovery of renal function after tumor lysis occurs early and patients can be supported through the relatively brief period of renal insufficiency.[206] [207] With careful attention to electrolytes and the use of intensive hydration, the tumor lysis syndrome remains a complication in the treatment of AML. In the majority of patients with AML the development of renal insufficiency is associated with acute tubular necrosis, sepsis, and the use of nephrotoxic drugs.[205] The use of nephrotoxic antibiotics and other medications are frequent contributing factors for the development of renal failure during induction therapy. Many of the renal complications of AML and its treatment can be prevented with close attention to the medications given and the fluid status of the patient.

Lactic acidosis has been associated with AML.[208] The etiology of this metabolic acidosis is unclear but may result from anaerobic glycolysis by the leukemia cells. When lactic acidosis occurs, it is usually associated with a very high blast count, extramedullary disease, and leukostasis. The lactic acidosis parallels the disease activity in these cases.[209]

Hypocholesteremia and a reduction in total low-density lipoproteins in the plasma are frequently noted in untreated patients with AML.[210] The mechanism of the reduced lipoproteins is unclear but may involve the leukemic cells use of cholesterol for membrane synthesis. Alternatively, the leukemic cells may secrete growth factors that are associated with changes in the concentration of cholesterol.[211]

A spuriously low serum glucose level and arterial oxygen saturation can occur in the presence of high numbers of circulating blasts.[212] These spuriously low values reflect use by the leukemic blasts of the glucose and oxygen and typically reflect a delay in processing the test sample. A spurious elevation of blood potassium levels may occur with hyperleukocytosis as a result of the release of potassium from leukocytes undergoing lysis during clotting or as a result of prolonged storage of the sample before analysis.[186] This phenomenon is more common in patients with a high blast count. If a spuriously elevated potassium is suspected, the serum electrolyte studies should be repeated with an anticoagulated blood sample that is rapidly analyzed to prevent the in vitro lysis of leukemic blasts.[213]

Ophthalmic problems occur in patients with AML.[214] All portions of the eye may be involved including the optic nerve, choroid, and retina.[177] Chloromas, which are collection of blasts, can occur anywhere in the eye. Leukemia can involve the optic disc and optic nerve, resulting in the sudden onset of blurred vision, which can rapidly progress to total blindness.[215] This diagnosis should be suspected when the funduscopic examination reveals papilledema and disc pallor. Iritis may present with photophobia, excess lacrimation, and orbital pain. Ophthalmic involvement is very suggestive of meningeal leukemia. Ophthalmic involvement can occur in all the leukemic subtypes and is associated with a higher relapse rate and shorter survival as compared to patients without eye involvement.[177] [216]

Cardiorespiratory symptoms are common in patients with acute leukemia, pneumonias being the most common pulmonary problems. At presentation gram-positive and gram-negative bacteria are the major pathogens. However, patients who have a history of prolonged neutropenia or abnormal neutrophil function or who are receiving broad-spectrum antibiotics are at an increased risk for pulmonary infection with fungi or other opportunistic organisms. Pulmonary leukostasis is a serious potential problem for patients who present with a blast count greater than 50,000/mm ^{3} .[217] [218] In this setting leukocyte thrombi and plugging of pulmonary microvascular channels lead to vascular rupture and infiltration of the lung parenchyma. Patients may note the sudden onset of shortness of breath and progressive dyspnea, and on physical examination they are tachypneic, with diffuse bilateral rales. The chest radiograph usually demonstrates a diffuse interstitial infiltrate (Figure 53-3). Fever is common. Hypercapnia, hypoxemia, and progressive respiratory acidosis are signs of a very poor prognosis despite intensive efforts to rapidly lower the blast count

Figure 53-3 Pulmonary leukostasis in a patient with monoblastic leukemia and a presenting WBC count of 150,000/mm ^{3} .

and institution of ventilatory support. Pulmonary leukostasis and the hyperleukocytosis syndrome are more common in patients with one of the monocytic subtypes and the microgranular variant of acute promyelocytic leukemia.[218]

Pulmonary hemorrhage and leukostasis may mimic the signs and symptoms of a bacterial or fungal pneumonia. Pulmonary hemorrhage may be diffuse, involving both lungs, or localized to a single segment or lobe. Patients typically complain of the sudden onset of shortness of breath. Hemoptysis may occur, and hypoxemia and hypercapnia are common. The presentation may be similar to other forms of noncardiogenic pulmonary edema.[219] On physical examination there may be few objective pulmonary findings, although the chest radiograph typically reveals an interstitial pattern in the area of the hemorrhage. The use of high-resolution CT scan may help in differentiating fungal infections from other causes of respiratory failure.[220] The prognosis of patients with AML and respiratory failure is poor.[221] Progressive pulmonary infiltrates caused by either leukostasis or pulmonary hemorrhage are associated with a poor prognosis.[222] The treatment of suspected

pulmonary hemorrhage should be directed at correcting the underlying coagulopathy.

Cardiovascular abnormalities are usually a result of derangements in metabolic, electrolyte, and pulmonary function. Leukemic infiltration of the heart or great vessels is rare, but there are reports of leukemic involvement of the conduction system, pericardium, and myocardium, as well as involvement of the arterial endothelial wall with monoblasts and subsequent formation and rupture of an aortic aneurysm.[223] [224] Chemotherapy-related toxicities produce the majority of the cardiovascular problems in patients with AML. The cardiotoxicity of the anthracyclines is dose-related, and these agents act synergistically with other cardiotoxic agents. Cardiac function should be assessed before beginning therapy. The left and right ventricle ejection fractions should be measured in all patients who have received a known cardiotoxic drug or who have a history of cardiac disease before they are given an anthracycline. An echocardiogram may be more helpful in assessing wall motion abnormalities. A pretherapy baseline ejection fraction or echocardiogram is not, however, warranted for all patients before starting induction therapy. Unless the patient has a known or suspected cardiac disease that would alter the chemotherapy regimen, treatment need not be delayed pending the result of ejection fraction.

Gastrointestinal abnormalities are frequent in AML patients. Dysphagia is common and is usually a result of oral or pharyngeal infections, mucosal involvement with leukemia, or chemotherapy-induced mucositis. Oral candidiasis is a common presenting finding and may involve the tongue and/or the soft or hard palate. Esophageal candidiasis can produce substernal pain and a midepigastric burning sensation, and dysphagia is common with oral and esophageal candidiasis. These symptoms may be severe and interfere with the patients ability to eat and to take oral medications. A barium swallow is usually sufficient to confirm the diagnosis of candida esophagitis. For patients who fail treatment, atypical cases, or cases in which the barium swallow is not diagnostic, an upper endoscopy is helpful. Obtaining a culture at the time of endoscopy is important. The clinical appearance of the lesions may be deceptive, and mixed fungal and viral infections are common. [225] [226] Candida infections can obscure an underlying herpes simplex or cytomegalovirus infection, and herpes simplex virus reactivation frequently occurs during therapy for AML. Viral lesions may be atypical, and superinfection with bacteria or fungi is common. Viral cultures for herpes simplex should be obtained on all atypical lesions in and around the oral cavity. Serologic viral studies are usually not helpful, since the majority (>80%) of patients will have had prior exposure to the herpes virus and have a positive serology. Patients with microbiologically documented or clinically suspected herpes simplex virus infection should be treated with acyclovir while undergoing induction therapy. Gingival involvement can occur in any of the subtypes of AML. Gingival hypertrophy is most frequent in the well-differentiated monocytic types. Gastrointestinal involvement with AML is rare, but chloromas or granulocytic sarcomas can form in the esophagus and small intestine and produce obstructive symptoms.[227] [228] [229]

In patients with leukemia the anal and perirectal areas are important potential sources for infection, the first signs of which may be induration and tenderness in the perirectal area without other signs of inflammation or infection. Patients may initially only complain of pain on defecation and diffuse anal tenderness. It is important to recognize and treat these potential sources of infection early. Perirectal abscesses are usually due to gram-negative bacteria and in the setting of granulocytopenia can rapidly progress to perirectal cellulitis and septicemia. While digital rectal examinations are generally avoided in patients who are granulocytopenic, the perirectal area should be carefully and gently examined.

Patients should be instructed on the importance of perirectal hygiene. Constipation should be avoided in order to prevent small mucosal tears. Diarrhea and drugs or agents that cause diarrhea should be carefully monitored and the use of harsh laxatives or agents that cause prolonged diarrhea should be avoided. The use of contrast agents that are cathartics must be critically evaluated before their use in patients with AML. The perirectal and oral area are two important portals for infection, and patients should be to instructed on how to perform daily oral and perirectal care.

The use of more intensive chemotherapy regimens has resulted in an increase in the incidence of gastrointestinal complications. [230] The use of broad-spectrum antibiotics and mucosal damage from chemotherapy has increased the incidence of fungal infections originating in the gastrointestinal tract. [231]

Typhlitis, a fulminant necrotizing colitis related to granulocytopenia and cytotoxic therapy, occurs in up to 10% of patients with leukemia who are undergoing intensive therapy.[232] This entity may present a diagnostic and therapeutic dilemma. Patients present with the sudden onset of abdominal pain, fever, and a distended and tense abdomen. Bowel sounds are decreased, and abdominal radiographs are nonspecific, usually revealing an incomplete small bowel obstruction, a questionable right lower quadrant mass, pneumatosis, or no appreciable abnormality. CT scanning frequently demonstrates an edematous

right colon with spiculation of the pericolic fat and subcutaneous edema. The clinical presentation frequently mimics that of acute appendicitis. The diagnosis of typhlitis is usually made on clinical findings. The CT scan may be helpful in differentiating appendicitis from other causes of abdominal pain and fever. [233]

Treatment of typhlitis is controversial, and for many patients the prognosis is poor. [234] [235] [236] [237] Medical management includes bowel rest, broad-spectrum antibiotics directed at bowel pathogens including anaerobes and fungi, intravenous fluid replacement, total parental nutrition, and transfusion support. [230] Surgical intervention, usually a hemicolectomy, should be reserved for patients with localizing peritoneal signs suggesting an abscess or clear evidence of perforation, as well as for those who do not respond to medical therapy. Patients who are neutropenic and thrombocytopenic can tolerate an exploratory laparotomy, but their postoperative course is more complicated.[236] The morbidity and mortality of surgery must be carefully weighed against the risk of medical therapy and support therapy in the individual patient. A majority of the patients with typhlitis can be managed medically with intensive supportive therapy and antibiotics, with only a minority of patients requiring surgical intervention.

DIAGNOSIS

The presumptive diagnosis of acute leukemia is usually apparent after examining the patient and reviewing the blood smear. Most patients present with pancytopenia and circulating blast forms, which are apparent on the peripheral blood smear. The total white blood count may range from less than 1,000/mm ^{3} to more than 200,000/mm^3 , with the majority of patients having a total white blood count between 5,000 and 30,000/mm ^{3} . The blood smear is usually sufficient to make the presumptive diagnosis of AML, but in the 10% of patients who may present with only a modest thrombocytopenia, low-grade anemia, and a normal WBC without circulating blast forms, a bone marrow examination is required to make the diagnosis. The bone marrow aspiration and biopsy should be performed at a time when the necessary pretherapy studies can be obtained. While many patients and physicians feel compelled to start treatment for AML immediately, in most instances emergency therapy is not needed. Treatment can usually be delayed until the necessary clinical and laboratory evaluations are available. Patients may also need time to accept the diagnosis and address personal, financial, and family needs. As part of the initial evaluation the psychological and emotional needs and concerns of patients and their families must be considered. Moreover, prior medical and dental problems and intercurrent illnesses need to be evaluated or treated before starting induction chemotherapy.

Even in the severely neutropenic and thrombocytopenic patient, a bone marrow biopsy and aspiration can be safely performed. Local bleeding or infection at the site of the procedure is very rare. The posterior iliac crest is the preferred site unless the patient has received prior radiation therapy to the pelvis or has evidence of an active infection at the site. The sternum is an alternate site for performing a bone marrow aspirate. A bone marrow biopsy cannot be performed by the sternal route.

Bone marrow smears from the aspirate and touch preparations from the biopsy should be prepared at the bedside for best results. Slides should be made for Wright/Giemsa and cytochemical stains. Cytogenetic studies are important prognostic indicators and should be performed at the time of the initial bone marrow aspiration and biopsy. Cell surface markers, molecular studies, and enzyme studies are helpful if there is a possibility that a lymphoid or a biphenotypic leukemia may be present. The bone marrow aspirate allows the qualitative assessment of bone marrow cell morphology. The bone marrow biopsy allows quantitative assessment of bone marrow cellularity, megakaryocyte number, and reticulin fibrosis and should be performed on all patients. [238] When insufficient aspirate material is available, circulating blasts in the blood may be used for cytogenetic studies, surface markers, and cytochemical stains. Immunohistochemical stains may be performed on the biopsy specimen to aid in the diagnosis, especially when the marrow smear or imprint material is scant or absent.

The bone marrow aspirate should be evaluated for cellularity, number and morphology of megakaryocytes, myeloid to erythroid ratio (M:E), cellular maturation, and the presence of dysplasia or asynchronous maturation. The blast percentage should be determined on at least a 200-cell differential of the bone marrow aspirate. Iron stores should be assessed with the Prussian blue stain, and the presence or absence of ringed sideroblasts specifically noted. Evaluation of the cellularity of a bone marrow aspirate is a qualitative assessment and may reflect the number of spicules obtained, slide preparation technique, and volume of diluting blood. Despite these limitations, a number of criteria have been adopted by cooperative groups to evaluate the cellularity of a bone marrow aspirate. Marrow aspirate cellularity is grouped into five broad categories, from 0 to +4: aplastic, hypocellular, normal cellular, hypercellular, and intensely hypercellular.

The initial bone marrow in a patient with AML is typically hypercellular, with absent or decreased megakaryocytes. However, elderly patients or those with secondary or treatment-related AML may have a normal cellular or hypocellular bone marrow. [239] Dysplastic myeloid and erythroid maturation may be noted. Myeloid precursors may be morphologically bizarre with asynchronous granulation. The prognostic significance of dysplasia in de novo AML is controversial. [240] [241] Trilineage dysplasia is associated with other poor prognostic features including unfavorable chromosomal abnormalities. Trilineage dysplasis appear to be a marker for a high-risk goup of patients and is associated with a less-favorable response to treatment. [242] [243] In addition, prominent dysplasia may suggest prior exposure to hematotoxins or that the patients leukemia evolved from a prior myelodysplastic syndrome or is secondary to prior cytotoxic chemotherapy. Features of dysplasia at presentation are not a negative prognostic feature unless there are other features to suggest a prior myelodysplastic syndrome. [244] Auer bodies or rods, which are reddish rodlike filaments of aggregated primary granules, may be present in the leukemic cells. These bodies, or rods, first described by Joseph Auer, are derived from incorporation of primary azurophilic granules into autophagic vacuoles. The term *phi bodies* has also been used to describe small spindle-shaped Auer bodies, and single cells containing multiple Auer bodies are sometimes referred to as *faggot cells* (from the term meaning bundle of sticks). Auer rods are faintly birefringent in polarized light. Ultrastructurally they have a defined three-dimensional crystal structure with a characteristic 6-nm to 13-nm periodicity, which is different for each of the leukemic subtypes.[245] Auer rods have been considered virtually pathognomonic of AML. The French-American-British Cooperative Group, however, does not place this degree of importance on the Auer rods and in fact includes the presence of Auer rods as part of the definition of one of the myelodysplastic syndromes, which it terms refractory anemia with excess blasts in transformation. [246] [247] Auer rods should therefore not be considered as unequivocal evidence of AML but as a manifestation of a myeloid malignant disorder with abnormal maturation. Auer rods are found in approximately 50% of newly diagnosed patients with AML and are found most frequently in the M1, M2, M3, and M4 subtypes.[247] The M2 subtype has characteristically thin and elongated Auer rods which may help in the diagnosis of this generally favorable subtype. The remission rate and duration of remission may be higher in patients whose leukemic cells demonstrate Auer rods. [248]

The number of blasts in the blood and bone marrow is the defining criterion to distinguish myelodysplastic syndromes

Figure 53-4 Definition of acute myeloid leukemia. TNC, total nucleated cells; NEC, nonerythroid cells.

from acute leukemia as well as subclassifying the acute leukemias. The diagnosis of acute leukemia requires that at least 30% of either total nucleated cells or nonerythroid cells in the bone marrow are blast forms[247] (Fig. 53-4). Blast cells must be distinguished from promyelocytes in the bone marrow count because the latter are included with differentiated granulocytes. The determination of the number of blasts in the bone marrow is crucial and the distinction between a blast and a promyelocyte can be difficult. The French, American, British Group (FAB) has recognized three types of myeloblasts [249] (Table 53-1). The type I blasts lack granules, have open chromatin, a high nucleocytoplasmic ratio, and prominent nucleoli. The type II blasts have a granulated basophilic cytoplasm with few (up to 20) azurophilic granules and nuclear features similar to the type I blasts except for the presence of azurophilic granules and a lower nucleocytoplasmic ratio. These type II blasts can be confused with early promyelocytes. Type III blasts have a heavily granulated basophilic cytoplasm with numerous azurophilic granules and nuclear features similar to Type I myeloblasts. Myeloid precursors are classified as promyelocytes when they have moderately basophilic cytoplasm with numerous azurophilic granules and an eccentric nucleus. The promyelocytes has a defined perinuclear region of pallor or clear Golgi zone, nucleoli, and a low nuclear-cytoplasmic ratio. [247] In a patient with acute leukemia the most important initial morphologic evaluation is to distinguish between AML, ALL, or one of the myelodysplastic syndromes. The prognosis and therapeutic strategies remain very different for adults with these disorders. In most cases the morphologic evaluation and cytochemical stains will define the appropriate lineage. It may, however, be difficult to differentiate between one of the myelodysplastic syndromes, refractory anemia with excess blasts in transformation, and AML. The myelodysplastic syndromes are most frequently confused with the M6 variant, acute erythroleukemia, or a hypoplastic AML. [250] In

TABLE 53-1 -- Blast Types in Acute Leukemia

Type	Description
Type I myeloblast	Agranular basophilic cytoplasm, fine structured chromatin, and two to four distinct nucleoli.
Type II myeloblast	Granulated basophilic cytoplasm with few (20) azurophilic granules, and nuclear features similar to type I blasts.
Type III myeloblast	Heavily granulated basophilic cytoplasm with numerous (>20) azurophilic granules, and nuclear features similar to type I blasts.
Promyelocyte[a]	Large with a lower nuclear-cytoplasmic ratio than myeloblasts, moderately basophilic cytoplasm with numerous azurophilic granules, an eccentric nucleus with some chromatin clumping, distinct nucleoli, and a perinuclear region of pallor or Golgi region.

[a]For the purposes of diagnosing acute leukemia, promyelocytes are included in the count of differentiating granulocytes. [247] [253]

TABLE 53-2 -- Laboratory Differential Diagnosis of Subtypes of AML

Subtype	Differential Diagnosis
AML-M0	ALL-L2, AML-M5A, AML-M7
AML-M1	ALL-L2, AML-M5A, AML-M7
AML-M2	AML-M1, AML-M4, AML-M6, RAEB-T, agranulocytosis, leukemoid reaction
AML-M3	AML-M5B, AML-M4, AML-M2, agranulocytosis
AML-M4	AML-M2, AML-M5B, CMML in transformation
AML-M5A	AML-M3V, AML-M4
AML-M5B	AML-M3v, AML-M4
AML-M6	AML-M2, AML-M5A and AML-M1, AML-M7, ALL; L2
AML-M7	AML-M1, AML-M5A, AML-M0, ALL-L1, ALL-L2, myelofibrosis, agranulocytosis

cases in which the nucleated erythroid cells constitute greater than 50% of all bone marrow nucleated marrow cells the diagnosis may be difficult. In these cases, if the combined total of all blasts, type I, II, and III is less than 30% the case is classified as a myelodysplastic syndrome. [247] If the nucleated red cells comprise less than 50% of bone marrow cells the percent of blasts is calculated as the percent of all nucleated cells. In many cases the difference between one of the myelodysplastic syndromes and AML can represent a difficult diagnostic problem (Table 53-2; Fig. 53-4). Cytogenetic studies may help define specific abnormalities associated with AML or MDS. In some cases, the morphologic distinction between an undifferentiated myeloblastic leukemia and a lymphoblastic leukemia can be difficult. The acute myeloblastic leukemias with no or minimal differentiation, the monoblastic leukemias without differentiation, and some of the acute megakaryocytic leukemias can be difficult to differentiate from ALL by morphology or cytochemical stains alone. In these instances the use of monoclonal antibody markers for lineage-associated markers is important. When the blasts demonstrate less than 3% positivity with either myeloperoxidase or Sudan black stain, immunologic markers are needed to define the lineage of the leukemia. In the majority of cases of acute leukemia, morphology and cytochemistry are sufficient to assign the correct lineage. In approximately 15% of cases, however, the distinction between an immature AML variant and ALL can not be made morphologically. The use of monoclonal antibodies that identify myeloid and lymphoid associated antigens is very useful in these cases [251] [252] (Table 53-3). A number of monoclonal antibodies have been generated that react with specific antigens expressed on the surface of normal and leukemic myeloid and lymphoid cells. To identify AML the percentage of positive reacting blasts should be greater than 20%, with one or more of the myeloid-associated antigens, CD33, or CD14. [253] [254] The determination of cellular terminal deoxynucleotidyl transferase (TdT) activity, in combination with other markers of lymphoid differentiation may be useful

TABLE 53-3 -- Monoclonal Antibodies Commonly Used to Distinguish AML from ALL

AML	ALL
CD11 (Anti Mo1)	CD10 (CALLA)
CD13 (MY7)	CD2 (T11, Leu 5)

CD15 (VIM-D5)	CD5 (Leu 1)
CD33 (MY 9)	CD3 (T8, Leu 2)
CD41	CD19 (Anti B4)
CD61	CD20 (Anti B1)

CD, cluster designation.

in selected cases.[255] However, TdT activity is not lineage-specific and can be found in 1550% of myeloblasts. [256]

In ALL the immunologic markers are important in assigning cell lineage, defining leukemic specific subsets, and assessing prognosis. In AML biochemical and immunologic markers have been less widely applied. The expression of these antibodies corresponds to the normal stages of myeloid and monocytic differentiation. None of the currently available myeloid monoclonal antibodies identifies leukemia-specific determinants. The monoclonal antibodies have been useful tools for defining the maturation and differentiation of normal myeloid and monocytic precursors. [257] However, leukemic cells frequently express markers of multiple levels of maturation and different lineages. Therefore, unlike morphologic classifications that attempt to place the predominant cell type within a specific defined group, immunophenotyping marker studies have demonstrated that AML cells are antigenically and morphologically heterogeneous. [258] [259] Immunophenotyping has been most useful in distinguishing between AML and lymphoid leukemias and in defining hybrid or biphenotypic leukemias. In ALL the immunophenotyping studies have defined functionally and prognostically relevant subgroups that are unrelated to both morphology and cytochemistry. Although a number of the individual antibodies correlate well with the morphologic classification, as in the expression of CD34 with M0 and M1, but not M3; CD14 (MY4) in the M4 and M5 subtypes; and the absence of HLA DR in the M3 subtype, the overall expression of surface antigens on myeloblasts does not entirely agree with either morphology or cytochemical staining.[260] [261] [262] The use of multiple monoclonal antibodies has identified certain phenotypic groups that may be clinically important, such as the association of the M2 subtype a t(8;21) cytogenetic abnormality, the expression of CD34 and the B-cellassociated cell surface antigen CD19 the expression of CD33, but not CD34, in M3 leukemias[263] [264] (Table 53-4). The use of immunophenotyping markers has demonstrated that the majority of myeloid blast cells express differentiation markers asynchronously and that the unusual coexpression of normal differentiation antigens is common. Moreover myeloid blasts frequently express lymphoid associated antigens. A meaningful proportion, 2045%, of myeloid blasts express lymphoid-associated antigens, most frequently CD2, CD7, and CD19. [265] The CD2 antigen, known as the sheep erythrocyte receptor, which is characteristic of mature T cells, is expressed on approximately 30% of defined myeloid leukemias. CD7, a T-cell marker, is found in up to 32% of AML blasts.[263] [265] [266] The CD19, found on B cells, is frequently noted in association with the 8;21 translocation in M2-AML, and is found in up to 34% of newly diagnosed myeloid leukemias.[263] [265] [266] The myeloid blast cells frequently express both myeloid and lymphoid differentiation antigens. The prognostic significance of this phenotypic heterogeneity is unclear, but is not associated with a uniformly adverse prognosis. [258] [259] [260] [267] [268] The use of immunophenotyping is particularly important for the identification of AML with minimal differentiation (M0), erythroleukemia (M6) and megakaryoblastic leukemia (M7).[269] [270] In addition, immunophenotyping may be helpful for detecting minimal residual disease following intensive chemotherapy. [267] The role of immunophenotyping to identify high-risk patients remains controversial. [262] [265] [271] Immunophenotyping may help in identifying subsets of patients who are at risk for shorter remission durations and resistant disease such as CD34+ AML, but the role of immunophenotyping as a independent prognostic indicator is unclear. At the present time the use of immunophenotyping in the diagnosis of AML is most appropriate for the evaluation of morphologically atypical or undifferentiated leukemias or

suspected hybrid leukemias. CD13 and CD33 are the most useful markers to identify myeloid leukemias. [271] Immunophenotyping has demonstrated the phenotypic heterogeneity and mixed lineage differentiation of many myeloid leukemias. [272]

USE OF CYTOCHEMICAL STAINS IN THE EVALUATION OF AML

The acute leukemias are classified according to the predominant neoplastic cell type. The FAB Cooperative Group in 1976 introduced a classification system for the AML subtypes.[273]

The initially proposed classification system was based solely on morphology and cytochemical stains and did not include the use of cytogenetics, molecular markers, or immunophenotyping markers. The FAB has periodically updated its proposed classification system to incorporate these additional studies. The recommendations of the FAB group have gained wide acceptance and are now used to classify AML in most cooperative groups, cancer centers, and international workshops involved in clinical trials and studies on AML.

The FAB group divides the myeloid leukemias into eight broad categories based upon the morphology, cytochemical staining, and immunological phenotype of the predominant cell type (Table 53-5 and Plates 53-4 , 53-5 , 53-6 , 53-7 , 53-8 , 53-9 , 53-10 , 53-11 , 53-12 , 53-13 , and 53-14). The classification system was initially proposed solely to define morphologically the subtypes of the acute leukemias. However, it has subsequently been expanded to include ultrastructural morphology, cytogenetics, immunophenotyping, and immunohistochemistry markers. This classification system has been shown to be both clinically and prognostically useful. The FAB criteria are based on a Wright-Giemsa stained blood smear and the bone marrow aspirate or biopsy. Four basic histochemical stains are employed, including periodic acid-Schiff (PAS), reagent Sudan black, peroxidase, and esterase (specific and nonspecific) (Table 53-6).

PAS stains carbohydrates, including monosaccharides, polysaccharides, mucoproteins, and phosphorylated sugars. Myeloblasts

TABLE 53-5 -- Classification and Incidence of Subtypes of AML

Cell Line	Classification		Subtype	Incidence
Myeloid	AML	M0	Acute myeloblastic leukemia, minimal differentiated	35%
		M1	Acute myeloblastic leukemia, without maturation	1520%
		M2	Acute myeloblastic leukemia, with maturation	2530%
	APL	M3	Acute promyelocytic leukemia, hypergranular	510%
		M3v	Acute promyelocytic leukemia, variant, microgranular	20%
Myeloid and monocytic	AMML	M4	Acute myelomonocytic leukemia	2030%
		M4e0	Acute myelomonocytic leukemia with eosinophilia	1530%
Monocytic	AML	M5a	Acute monoblastic leukemia, poorly differentiated	29%
		M5b	Acute monocytic leukemia, differentiated	
Erythroid and myeloid	AEL	M6	Acute erythroleukemia	35%
Megakaryocytic		M7	Acute megakaryoblastic leukemia	312%

are PAS-negative, while a majority of lymphoblasts are PAS-positive with a distinctive pattern. PAS-positive lymphoblasts usually demonstrate a concentric ring of coarse granules or heavy blocks against a negative cytoplasmic background. Because not all lymphoblasts on a bone marrow sample will stain with PAS, it is the pattern of the staining rather than the number of positive cells that suggests the diagnosis of ALL. Promyelocytes show a faint diffuse PAS-positive tinge, often with fine cytoplasmic granules; Auer rods are usually negative; and monoblasts stain variably with PAS, resulting in a diffuse and granular pattern. Immature monoblasts are usually PAS-negative, while more differentiated monoblasts and monocytes may react as do normal mature monocytes with a diffuse reddish background superimposed on fine or coarse granules. Erythroblasts generally demonstrate strong PAS-positivity, with a diffusely coarse granular reaction. Maturing erythrocytes may also show heavy PAS-positivity, with concentric annular rings of moderately coarse cytoplasmic granules. Megakaryoblasts stain variably with PAS; the mature megakaryocyte is positive but the megakaryoblast may be negative, and therefore the PAS stain is not a reliable marker for this subtype. The PAS stain is most useful for differentiating a lymphoid from a nonlymphoid leukemia and less helpful in defining the AML subtype.

Sudan black B is a lipophilic dye, which stains phospholipids and lipoprotein complexes. The Sudan black staining pattern is similar to the profile of the peroxidase reactivity, but the reaction is usually more strongly positive in myeloblasts and shows a different distribution from the peroxidase reaction in monocytes and monoblasts. Myeloblasts, promyelocytes, and myelomonocytes

M7		±[d]

[a]ALL may show granular staining that differs from the diffuse staining of monoblasts and fails to inhibit with sodium fluoride.
[b]In 1520% of cases of APL, some atypical promyelocytes stain weakly for NSE.
[c]In 2025% of cases of monoblastic leukemia, monoblasts are weakly reactive or nonreactive for NSE.
[d]Megakaryocytes/megakaryoblasts may show weak focal positivity for NSE.

are positive while erythroid, megakaryocyte, and lymphoid precursors are negative. Myeloblasts are usually positive, with coarse heavy granules. Myeloblasts without azurophilic or specific granules on Wright-Giemsa stain may stain with Sudan black, and the myelomonocytic leukemias demonstrate both coarse and fine granules. Pure monoblasts are usually Sudan blacknegative. Auer rods stain prominently with Sudan black even when not apparent on the standard Wrights preparation. In general, the Sudan black B stain represents a sensitive marker of myeloblasts and myelomonocytes. It is most helpful in differentiating immature cells that appear undifferentiated on smear and give a negative peroxidase reaction.

The esterase stains are biochemically complex and based on the reaction of a specific substrate with a cellular enzyme. The nomenclature is confusing and depends on the substrate used. In hematopoietic cells nine esterase isoenzymes have been identified, all of which cleave the alpha-naphthyl acetate or alpha-naphthyl butyrate substrate; this activity is referred to as nonspecific esterase activity. The substrate in the chloroacetate esterase stains is the chloroacetate of alpha-naphthol or naphthol AS; which react with enzymes peculiar to the myeloid series at all stages of maturation, and the reaction is therefore referred to as a specific esterase reaction.

The chloroacetate esterase reaction gives sharply localized granular staining in the cytoplasm of nearly all granulocytes and mast cells. The reactivity of this stain increases with cell maturity, and myeloblasts without granules are specific esterase-negative. Thus, this reaction is less sensitive than the peroxidase or Sudan black stain for the diagnosis of acute myeloid leukemia without maturation AML (M1). The chloroacetate stain is intensively positive in promyelocytic leukemia (M3), but monoblasts, lymphoblasts, erythroblasts, megakaryocytes, eosinophils, basophils, and monocytes are chloroacetate esterase negative.

The nonspecific esterase stain has a markedly different spectrum of reactivity; the naphthyl acetate and butyrate reactions are largely confined to cells of the monocytic lineage, including monoblasts and monocytes. Monocytes contain two isoenzymes that react strongly with the nonspecific esterase substrate but are dramatically inhibited by addition of sodium fluoride. Therefore, a positive esterase activity that is inhibited by sodium fluoride is characteristic of monocytic differentiation. The two subclasses of the monocytic leukemias, the M5a undifferentiated and the M5b differentiated types, react with the nonspecific esterase stain. Neutrophil precursors and B lymphocytes are nonspecific esterase-negative, and other cells may show varying patterns of positivity that are not inhibited by sodium fluoride. Lymphoblastic leukemias may show a granular nonspecific esterase activity that is resistant to fluoride inhibition. The nonspecific esterase reaction aids in recognizing a monocytic component to the leukemia.

THE USE OF MORPHOLOGY, CYTOCHEMISTRY, AND IMMUNOPHENOTYPING TO DEFINE ACUTE LEUKEMIA

Morphology, cytochemistry, and immunophenotyping are used to define the lineage of acute leukemias. The blast cells in a Wright-Giemsa stained bone marrow aspirate demonstrate either no definable myeloid differentiation or features of myeloid differentiation. The blast cells of the undifferentiated myeloid leukemia (M0), minimally differentiated myeloid leukemia (M1), undifferentiated monocytic leukemia (M5a) and megakaryocytic leukemia (M7) cannot be differentiated from an acute lymphoid leukemia by morphology alone. Immunophenotyping and additional cytochemical stains are required to define the AML subtype. Immunophenotyping is most useful for differentiating a myeloid versus a lymphoid leukemia. Myeloblasts are further characterized by myeloperoxidase (MPO) or Sudan black (SBB) cytochemical staining. The nonspecific esterase reactions are helpful in defining the myeloid leukemias with monocytic features. Ultrastructural analysis and ultrastructural cytochemistry are helpful in defining the M7 and M0 AML subtypes. The M7 subtype is also CD41 positive and stains with Factor VIII ag.

The differentiated myeloid leukemias (M3M6) can usually be defined on the basis of morphology and cytochemistry. The M3 and M3 variant subtype must be confirmed with cytogenetic analysis demonstrating the 15;17 translocation. Sudan black B and myeloperoxidase stains are positive in M2, M6, and M3 subtypes and are differentiated from the M4 and M5b leukemic subtypes by the NSE reaction. The esterase reactions are helpful in defining one of the monocytic subtypes, including M4, M5a, and M5b.

FVIIIag, factor VIII antigen; NSE, nonspecific esterase; PAS, periodic acid-Schiff stain; PPO, platelet peroxidase; CD41, platelet glycoprotein IIb/IIIA.

In the myeloblastic leukemias the specific esterase stain is positive and the nonspecific esterase is negative. Auer rods are positive with the specific esterase. In myelomonocytic leukemia at least 20% of the cells must show monocytic differentiation that is nonspecific esterase-positive and is inhibited by sodium fluoride. In this type of leukemia both activities may be present in the same cell. In the pure monocytic leukemias, 80100% of the blasts are nonspecific esterase-positive and specific esterase-negative. Therefore, the esterase stains are particularly useful in distinguishing an undifferentiated monocytic leukemia (M5b) from undifferentiated myeloblastic (M1,M0) or undifferentiated lymphoid leukemia.

SUBTYPES OF ACUTE MYELOBLASTIC LEUKEMIA

The FAB group has defined eight subtypes of acute nonlymphocytic leukemia (see Tables 53-5 and 53-7 and Plates 53-4 , 53-5 , 53-6 , 53-7 , 53-8 , 53-9 , 53-10 , 53-11 , 53-12 , 53-13 , and 53-14) on the basis of morphologic, immunophenotyping, and cytochemical criteria. The FAB groups purpose was to subdivide the myeloid leukemias according to their predominant cell type and to define the leukemic cells position in the maturation sequence of that specific lineage (Table 53-5). The classification attempts to assign a single lineage to each leukemia, however, cases demonstrate some admixture of cell lines and express features of multiple lineages. Some cases of AML cannot be classified according to the FAB criteria. These unclassifible cases are more frequent among patients with secondary leukemia and represent approximately 25% of all cases. [274] [275] The FAB classification

TABLE 53-7 -- Summary of Diagnostic Features of AMLs

FAB Type	Diagnostic Features
AML-M0	30% blasts; >3% blasts reactive to MPO, SBB, or NSE; immunophenotyping CD33+, CD13+, may be CD34+, TdT+
AML-M1	30% blasts; 3% blasts reactive to MPO or SBB; <10% of marrow nucleated cells are promyelocytes or more mature neutrophils
AML-M2	30% blasts; 3% blasts reactive for MPO or SBB; 10% of marrow nucleated cells are promyelocytes or more mature neutrophils; t(8:21) chromosome abnormality
AML-M3	30% blasts and abnormal promyelocytes; intense MPO and SBB reactivity; promyelocytes and blasts with multiple Auer rods (faggot cells); t(15:17) cytogenetic abnormality
AML-M4	30% myeloblasts, monoblasts, and promonocytes; 20% monocytic cells in marrow; 5×10^9 /L monocytic cells in blood: 20% neutrophils and precursors in marrow; monocytic cells reactive for NSE; abnormal eosinophils in M4 with associated Inv(16) chromosome abnormality
AML-M5a	80% monocytic cells; monoblasts 80% of monocytic cells; monoblasts and promonocytes NSE positive monoblasts usually MPO and SBB negative
AML-M5b	80% monocytic cells; monoblasts 80% of monocytic cells; promonocytes predominate; monoblasts and promonocytes NSE positive; promonocytes may have scattered MPO- and SBB-positive granules
AML-M6	50% erythroid precursors: 30% of nonerythroid precursors are myeloblasts; Auer rods may be present in myeloblasts: dysplastic erythroid precursors frequently PAS positive
AML-M7	30% blasts; 50% cells megakaryoblasts by morphology or electron microscopy; immunophenotyping CD41+, CD61+

CD, cluster designation; MPO, myeloperoxidase; NSE, nonspecific esterase; PAS, periodic acid-Schiff; SBB, sudan black B; TdT, terminal deoxynucleotidyl transferase.

does not include hybrid or biphenotypic leukemias that cannot be classified on the basis of morphology or cytochemistry alone. The FAB classification did not consider clinical characteristics, cytogenetic patterns, response to therapy, or prognosis in its formulation. [276] Other classification systems have been proposed in an attempt to address these issues, but despite its limitations, the FAB classification has been widely adopted and is used almost universally. The classification system does try to take into account the heterogenous nature of AML and recognizes that it is not a single disease but a group of disorders affecting the hematopoietic precursors in the bone marrow.[277]

The FAB group defines five basic classes of AML based on the predominant cell type: (1) myeloid, (2) myeloidmonocytic, (3) monocytic, (4) erythroid, and (5) megakaryocytic (Table 53-5). In each of these classes a number of subtypes are defined that reflect the degree of differentiation or unique morphologic findings. In the myeloid cell type four subsets of myeloblastic leukemia are recognized, based on the percentage of maturing cells beyond the myeloblast stage. These range from the myeloblastic leukemia without morphologic evidence of maturation (M0-AML with minimal differentiation) to the promyelocytic leukemia (M3) where the dominant cell is an abnormal promyelocyte. The division between each of the myeloblast subtypes M0, M1, and M2 is somewhat arbitrary and there is a spectrum of myeloid differentiation. Immunophenotyping and cytogenetics are helpful in defining the subtypes of myeloid leukemia (Table 53-7).

AML of the M0 Subtype (AML Without Differentiation or Maturation)

Myeloblastic leukemia without differentiation (M0) (Plate 53-4) constitutes approximately 3% of all cases of AML. Morphologically, this group is the most difficult to differentiate from the L2 variant of ALL (Plate 57-1). The blasts appear to be very immature and less than 3% of the blast cells are positive with myeloperoxidase or Sudan black B. Lymphoid markers are generally negative except for the enzyme terminal deoxynucleotidyl terminal transferase (TdT) which is expressed in over 60% of the cases.[278] [279] The bone marrow has greater than 30% blasts of all nucleated cells. The blasts are usually large, with fine structured chromatin and distinct, usually multiple nucleoli. The nuclear/cytoplasmic ratio is variable and cells may resemble the L2 lymphoblasts. Some evidence of trilineage dysplasia may be noted but is frequently absent as a result of the high blast count in the bone marrow. Azurophilic granules and Auer rods are absent. The blasts are identified as myeloid either by ultrastructural myeloperoxidase or immunophenotypic markers. [280] [281] The use of monoclonal antibodies to identify the myeloid lineage is essential in this subtype. The lymphoid markers characteristic of B- and T-lineage ALL, including CD10, CD19, CD24, CD3, and CD5, are negative. In about 30% of cases the blasts mark with the T-cell markers CD4 and CD7. CD4 is a marker of mature T cells that is expressed on some myeloid cells. The CD7 antigen is one of the early T-cell antigens and is usually expressed on immature T cells and prothymocytes. This subtype may mark with CD7, usually in association with TdT expression. [282] [283] Myeloid-specific monoclonal antibodies are positive, including CD13 and CD33. Other myeloid antigens may be positive but are less helpful in establishing the diagnosis. The stem cell antigen is strongly associated with AML-M0, with over 90% of M0 cases expressing CD34. [270] M0 blasts may also resemble megakaryoblasts (M7) or undifferentiated monoblasts (M5a). The use of a monoclonal antibody, anti-myeloperoxidase (anti-MPO), is useful in detecting the M0 subtype. [278] The diagnosis of the M0 subtype cannot be made on morphologic criteria alone and requires confirmation with phenotypic markers demonstrating myeloid antigens or ultrastructural cytochemistry.

AML-M0 has a high incidence of complex karyotypes and frequent involvement of chromosomes 5, 7, 8, and 13.[270] The subtype of leukemia expresses the immunophenotypic and karyotypic features of a stem cell leukemia. The M0 subtype is also generally associated with a poor prognosis. [284]

AML of the M1 Subtype (AML Without Maturation)

The M1 subtype accounts for 1520% of AML cases. The bone marrow is infiltrated with poorly differentiated blasts with rare azurophilic granules, Auer rods are rare or absent (Plate 53-5). If granules are absent, the myeloblasts resemble the lymphoblasts of the L2 variant of ALL, and cytochemical stains are necessary to distinguish these two leukemias. The peroxidase reaction is positive in more than 3% of the blast cells, and the PAS stain is negative. The bone marrow contains less than 3% promyelocytes and less than 10% maturing granulocytes. Morphologically the cells may appear pleomorphic, with irregular nuclei with an open chromatin. Some of the cells express CD7, an antigen present on early T cells. [282] [283]

AML of the M2 Subtype (AML with Maturation)

Myeloblastic leukemia with maturation (M2) (Plate 53-6) demonstrates clear evidence of maturation to and beyond the promyelocyte. It occurs in approximately 2530% of all AML patients and represents the most common subtype in most reported series. Morphologically typical promyelocytes account for between 320% of all myeloid cells. There is evidence of maturation in the myeloid series with occasional maturation to eosinophils and basophils. The bone marrow monocytic component represents less than 20% of nonerythroid cells. Auer rods are usually found, and the myeloblasts contain prominent azurophilic granules. The peroxidase and Sudan black stain are both strongly positive; the chloroacetate esterase (specific esterase) stain is positive, reflecting maturation beyond the myeloblast; and the alpha-naphthyl acetate and butyrate esterase (nonspecific esterase) stains are negative. On Wright-Giemsa stain the blasts have a higher nuclear/cytoplasmic ratio than in the M1 variant, and the nuclear chromatin is condensed with less distinct nucleoli. [285]

About half of the patients in this subtype will have a translocation involving chromosomes 8 and 21 [t(8;21)]. [286] [287] The (8;21) (q22;q22) translocation juxtaposes the AML1 gene on chromosome 21 to the ETO (for 8;21) gene on chromosome 8 which results in the production of the AML1ETO fusion protein. [288] [289] In these patients about 25% will present with splenomegaly and 20% will develop extramedullary disease during their course. [290] [291] Morphologically the 8;21 AML cells characteristically contain thin and elongated Auer rods, a basophilic cytoplasm, and indented nuclei. The marrow may have an increased number of eosinophil precursors, some of which may contain Auer rods. In a majority of the patients there is abnormal granulocytic maturation, with dysplastic granulocytes and a pseudo-Pelger-Huet abnormality. There may be dysplastic erythroid precursors but rarely dysplastic megakaryocytes. The dysplastic features are not associated with a poorer response to therapy or a change in the otherwise favorable prognosis of this subtype. [292] [293] Histochemical staining with Sudan black and peroxidase demonstrates localized densely staining clumps, usually on one side of the nucleus or in a cleft of the nucleus, in contrast to the diffuse staining seen in patients without the 8;21 translocation. This variant has a high remission induction rate after standard chemotherapy. However, the remission duration is very variable. Patients with the AMLM2 subtype with a translocation of 8;21 who present with leukocytosis have a higher frequency of extramedullary involvement and a less favorable prognosis than patients who present with this subtype without leukocytosis. [290] [293] The overall survival of patients with the 8;21 translocation, however, is generally better than the other subtypes of AML without this translocation. [287] [292]

AML of the M3 Subtype (Acute Promyelocytic Leukemia)

Acute promyelocytic leukemia (APL-M3) (Plate 53-7) is characterized by the presence of atypical promyelocytes in the bone marrow and peripheral blood. The M3 subtype accounts for 510% of all cases of AML. APL is distinguished from other subtypes of AML by its distinctive morphology, younger patient age at presentation, specific chromosomal abnormality, associated coagulopathy, and unique response to treatment with retinoic acid. There are two morphologic variants of acute promyelocytic leukemia, a hypergranular (M3) and a variant microgranular from (M3v) Plate 53-8 .[294] [295] [296] These two variants differ in their clinical presentation, prognosis, and morphologic appearance. The hypergranular form is the more common of APL, representing 75% of APL cases. In this form the cytoplasm of the promyelocyte typically demonstrates bright pink or dark purplish coarse granules with abundant Auer rods. The promyelocytes are larger than nonmalignant promyelocytes with pleomorphic nucleoli. The Sudan black and peroxidase stains are strongly positive; the PAS stain is usually negative but in some cases may show a diffuse positive tinge with fine cytoplasmic granules; the chloroacetate esterase stain is usually strongly positive. In 1520% of cases some atypical promyelocytes stain weakly for nonspecific esterase. Atypical promyelocytes account for 30% or more of the myeloid cells. Auer rods may be so numerous as to form Auer bundles.

Patients are typically younger, with a median age of 31 years, and present with a lower white blood cell count (WBC) usually in the range of 3,000 to 15,000/mm ^{3} . A majority of the patients present with a WBC less than 5,000/mm ^{3} . Approximately 25% of patients with APL present with the microgranular variant (M3v). The microgranular variant presents with a higher WBC (range 50,000200,000/mm ^{3}) and morphologically atypical promyelocytes. [295] [296] [297] [298]

Cytogenetic studies of the M3 and M3 variant demonstrate the characteristic 15;17 translocation, which is a balanced translocation from the long arm of chromosome 17 to the long arm of chromosome 15 [t(15q+;17q)]. This cytogenetic finding is diagnostic of APL. [299] The chromosome break point on chromosome 17 has been mapped to the site of the retinoic acid alpha receptor (RAR). [300] The retinoic acid receptor is a member of a family of steroid hormone nuclear receptors that are important in the regulation and control of both normal and malignant cellular differentiation and proliferation. [301] In APL the cytogenetic translocation results in a fusion of the retinoic acid receptor alpha gene on chromosome 17 and a region from chromosome 15 referred to as PML (for promyelocytic leukemia). [302] The translocation encodes for a novel DNAbinding protein, which results in the expression of an abnormal mRNA transcript for the RAR and confers a unique therapeutic sensitivity to one of its ligands, all trans-retinoic acid. Myeloid differentiation appears to be blocked by the abnormal PML-RAR fusion protein. This abnormal receptor is the target of all trans-retinoic acid treatment. [303]

Treatment of patients with APL with all trans-retinoic acid, a vitamin A derivative, results in differentiation of the leukemic cells with approximately 7085% of patients attaining a complete remission. [304] Moreover, unlike standard induction therapy, treatment with oral all trans-retinoic acid is not associated with bone marrow hypoplasia and the usual complications of cytotoxic chemotherapy. [305] All trans-retinoic acid induces leukemic cells to replicate and differentiate into cells capable of undergoing normal senescence and cell death.

Patients with APL often present with thrombocytopenia, prolongation of the thromboplastin and thrombin time, increased

levels of fibrin degradation products, and hypofibrinogenemia. The coagulation disorder in APL results from at least three distinct mechanisms: disseminated intravascular coagulation, fibrinolysis, and proteolysis. [304] [306] The disseminated intravascular coagulation (DIC) is attributed to the spontaneous or chemotherapy-associated release of a tissue factor with procoagulant activity present in the granules of the leukemic promyelocytes. [304] [307] [308] The bleeding disorder, however, cannot always be related solely to DIC and in many patients there are signs of primary fibrinolysis. [309] [310] The promyelocytic leukemic cell has both strong procoagulant activity on its cell membrane and proteolytic activity in the cytoplasmic granules, a combination that is unique to the leukemic promyelocyte and may explain the severe coagulopathy seen in some patients. [311] [312] [313] Enhanced fibrinolysis is suggested by the increase in fibrin-fibrinogen degradation products, reduced alpha 2-antiplasmin levels, and normal antithrombin III and protein C levels present in all patients at diagnosis and up to initiation of therapy. [308] [311] Plasma from patients with APL has a plasminogen activator of tissue origin. [311] The proteolysis is due to release from the leukemic cells of lysosomal neutrophilic enzymes, human leukocyte elastase, cathepsin G, and proteinase 3, which are all able to cleave fibrinogen. [295] The mechanism of the coagulopathy therefore remains unclear. [307] The coagulopathy present at diagnosis in 7085% of cases is exacerbated with treatment with cytotoxic chemotherapy. Treatment of the bleeding disorders in patients with acute promyelocytic leukemia following cytotoxic chemotherapy is also controversial with some groups using either heparin, antifibrinolytic therapy, or supportive therapy alone. [307] [308] [309] [314] [315] However, the coagulopathy rapidly improves following treatment with all trans-retinoic acid, and anticoagulation or antifibrinolytic therapy is rarely needed. [302] The prognosis for patients of this subtype is usually favorable. The use of all trans-retinoic acid with or without chemotherapy has changed the prognosis, course, and management of this subtype. The bleeding and clotting problems generally respond promptly to treatment with retinoic acid. The prognosis of patients with APL following treatment with all trans-retinoic acid and chemotherapy is very favorable. The prognostic features associated with treatment with chemotherapy alone include age >50 years, underlying renal function, pretreatment fibrinogen, and presenting WBC. [294] [295]

The microgranular variant typically presents with a very elevated WBC, frequently in excess of 100,000/mm ^{3} , and the cells have minimal rather than excessive cytoplasmic granulation. [316] [317] Auer rods are rare. The nucleus is typically irregular, folded, or bilobed and resembles the nucleus of a monocytic precursor (Plate 53-8). The cells may appear devoid of granules or may contain many or a few fine, dust-like azurophilic granules, often concentrated in one area of the cytoplasm. Cytochemical stains reveal that the cells are intensely peroxidase-positive, Sudan black-Bpositive, and chloroacetate esterasepositive. Ultrastructural examination has demonstrated that the majority of the cells contain numerous microgranules, which are smaller than 250 nm and thus below the limit of resolution of light microscopy. These patients have the typical 15;17 translocation of the standard hypergranular promyelocytic leukemia. The microgranular form can be confused morphologically with a monocytic leukemia. A minority of patients with M3v present with hyperbasophilic cytoplasm and cytoplasmic projections that may resemble megakaryoblasts. [317]

In the microgranular variant the appearance of the blasts in the peripheral blood and bone marrow may be very different. In the bone marrow some of the cells are frequently closer in appearance to those of the typical M3 hypergranular variant. [311] The very high presenting blast count and the coagulopathy associated with this variant affect the outcome of remission induction. Leukostasis and fatal central nervous system and pulmonary hemorrhage are more common in this subtype.

The immunophenotyping of promyelocytic leukemic cells is distinctive as compared to other subtypes of AML. The APL cells are usually CD34, CD14, CD11b, HLA DR, and CD33+.[318]

AML of the M4 Subtype (Acute Myelomonocytic Leukemia)

In the M4 subtype (Plate 53-9), cells have differentiating characteristics of both neutrophilic and monocytes. Patients often present with extramedullary disease, gingival hypertrophy, leukemia cutis, and meningeal leukemia are more common in this subtype than in the myeloid leukemias (M0M3). Morphologically this subtype is similar to AML-M2, but the blast count includes myeloblasts, monoblasts, and promonocytes, which together must exceed 30%. In the marrow, more than 20% of the nonerythroid cells must be of the monocytic lineage at different stages of maturation, as defined by morphological or cytochemical findings. The number of monocytic cells in the blood (including monoblasts, promonocytes, and monocytes) is greater than 5×10^9 /L. This subtype represents 2030% of all AML patients. Cytochemical stains are helpful in identifying the monocytes in the peripheral blood and bone marrow: the bone marrow typically stains with the cytochemical markers for both neutrophilic and monocytic precursors, and the leukemic blasts stain positive with peroxidase, Sudan black, and chloroacetate esterase as well as the nonspecific esterase that is inhibited by addition of sodium fluoride. Serum and urinary lysozyme levels, reflecting the monocytic component, are frequently elevated.

A variant of this subtype, called acute myelomonocytic leukemia with abnormal eosinophils (M4EO) (Plate 53-10), is characterized by the presence of myelomonocytic blasts and 530% of morphologically and cytochemically abnormal eosinophils. [313] This variant represents approximately 510% of all patients with AML or about one-third of all patients with the M4 subtype. Patients with the M4EO subtype often present with a high peripheral WBC (range 30,000100,000/mm^3) and hepatosplenomegaly. The eosinophils have monocytic nuclei with abnormal, often basophilic, granules and lack the typical eosinophil crystals. The eosinophilic granules stain positive with PAS, Sudan black, chloroacetate esterase, and nonspecific esterase, which is typical of granulocytic, but not of eosinophilic, precursors. Presumably the hybrid morphologic and histochemical features of monocytes, eosinophils, and granulocytes in these cells result from abnormal differentiation of a primitive uncommitted leukemic cell before the divergence of the three cell lines. The abnormal eosinophils are part of the leukemic cell population. [314] These cells also express the T-cell antigen, CD2. The myeloblasts are typically negative for other T-cell markers. [315] [316] The peripheral blood typically has myeloblasts and increased monocytes. The abnormal-appearing eosinophils are usually rare in the peripheral blood. Central nervous system involvement is very common in this variant. In one study, 35% of patients relapsed with leptomeningeal disease. [172]

The M4EO variant has a unique karyotypic abnormality involving the long arm of chromosome 16. All patients have an inversion of chromosome 16 between the long and short arm or a balanced translocation between two homologous chromosomes 16. The cytogenetic feature in both of these translocations is the break in the long arm of chromosome 16 at band q22.[319] [320] [321]

The overall complete response rate for patients with myelomonocytic leukemia is between 50 and 65%. However, patients with the M4EO variant have a complete response rate between 70 and 80%, which is significantly higher than the standard M4 subtype. [319] The median duration of the remission and overall survival is also significantly prolonged in the M4EO variant, compared with that in other acute myelomonocytic leukemia

cases.[320] [322] [323] It is therefore important to recognize patients with the M4EO phenotype because they appear to have a very responsive disease and may have a very favorable prognosis with currently available therapies. [322] [324]

AML of the M5 Subtype (Acute Monocytic Leukemia)

The acute monocytic subtype (Plates 53-11 and 53-12) represents 29% of all cases of AML.[325] [326] The monocytic leukemias are divided into two variants, a poorly differentiated monoblastic leukemia (M5a), and a differentiated monocytic leukemia (M5b). The FAB criteria for the diagnosis of M5 (AMoL) requires that 80% or more of the nonerythroid cells in the bone marrow be monoblasts, promonocytes, or monocytes. The blasts in the M5a variant (Plate 53-11) are poorly differentiated monoblasts, with rare granules and occasional cytoplasmic vacuoles. The poorly differentiated monoblasts are large cells with plentiful cytoplasm that may contain vacuoles and are usually basophilic. Auer rods are not usually seen. Morphologically, these cells may resemble lymphoblasts of the L2 variant. The M5a subtype classification requires that greater than 80% of the bone marrow monocytic component are monoblasts. The M5b variant (Plate 53-12) consists of more differentiated monocytes, which have the typical lobulated monocytic nucleus. Nucleoli are not always present. The cytoplasm typically is grayish blue, and Auer rods are rare. Monoblasts comprise less than 80% of the monocytic component. The diagnosis of AMoL is confirmed by the positive alpha naphthyl acetate esterase reaction. The peroxidase, Sudan black, and chloroacetate esterase stains are usually negative in the blasts, but Sudan black can be positive in the more mature monocytic precursors. The PAS reaction is variable: while most of the monocytic leukemias are PAS negative, some will stain with coarse positive granules on a background of diffuse positivity.

There are meaningful clinical differences between the two monocytic leukemias. [327] Patients with the M5a variant are younger, present with a higher blast count in the peripheral blood and bone marrow, and have an overall poorer prognosis. [325] The M5b variant has an increased incidence of gingival hypertrophy and a higher percentage of circulating monocytes. The peripheral blood may show cells of the monocytic lineage which appear to be more mature and differentiated than those found in the bone marrow. The diagnosis of this subtype is determined by the bone marrow findings. Immunocytochemical staining may help in differentiating the two monocytic leukemias. The more immature (M5a) variant is characterized by focal lysozyme staining and a negative CD68 phenotype, whereas the more differentiated monoblastic leukemia (M5b) expresses a diffusely positive lysozyme staining pattern and is positive for CD68. [328]

Extramedullary disease involving the liver, spleen, and lymph nodes is more common in the monocytic than in other AMLs occurring in up to 54% of patients. [327] [328] An elevated white blood count is seen in the majority of cases, up to 30% of patients present with a white blood count higher than 100,000/mm^3 .[328] [329] Laboratory evidence of DIC is common at presentation. Central nervous system involvement occurs in up to 22% of all patients. [329] However, prophylactic central nervous system therapy has not improved survival or prolonged remissions. [328] Gingival hyperplasia and skin involvement are frequent prominent features of the monocytic leukemias and in many patients may be the presenting complaint (Plate 53-3).[330] [331]

The response of patients with the monocytic leukemias is generally poor. The complete remission rate is between 5070%, which is comparable with that in the other types of AML. However, the duration of the complete responses and the overall survival are significantly shorter in this leukemic subtype. [329] [332] [333] This resistance to standard chemotherapy is also reflected in the higher relapse rate for patients with both variants of the monocytic leukemia following autologous and allogeneic bone marrow transplantation.[327] [334]

AML of the M6 Subtype (Acute Erythroleukemia)

Acute erythroleukemia (Plate 53-13) represents between 35% of all cases of AML. This subtype (M6) was initially described by Di Guglielmo and is still often referred to as acute Di Guglielmo syndrome. The FAB defines this subtype differently than other subtypes of AML (Fig. 53-4). The approach to counting blasts depends on the proportion of all nucleated cells that are erythroblasts. The defining criteria for acute leukemia is the same, i.e., greater than 30% blasts. This classification recognizes the continuous spectrum of the mixed proportion of cells in this leukemic subtype and parallel involvement of myeloid and monocytic precursors.

The erythroblasts are morphologically abnormal, with multilobed nuclei, multiple nucleoli, nuclear fragments, and giant pronormoblasts with megaloblastic features. The PAS stain is usually positive, with a granular or diffuse cytoplasmic pattern. The intensity of the stain and the percentage of positive-staining erythroblasts varies considerably in this subtype. Typically the cells with the most abnormal cytologic appearance demonstrate the strongest PAS reaction. However, the PAS reaction is variable, and a negative reaction does not exclude the diagnosis of erythroleukemia if the other morphologic features are present. Erythroblasts are Sudan black Bnegative, peroxidasenegative, and generally esterase-negative. However, considering the usual involvement of the myeloid line, myeloblasts with Auer rods are often present. The granulocytic component demonstrates the typical positive cytochemical staining with Sudan black, peroxidase, and chloroacetate esterase. Iron stains, such as Prussian blue, are useful in this subtype and may reveal prominent ringed sideroblasts. A monoclonal antibody that binds to glycophorin A on the

cytoplasmic membrane appears to be specific for the erythroblast.[335] Trilineage dysplasia is typical in this subtype and differentiating this subtype from an evolving myelodysplastic syndrome can be difficult.[250] In the classic cases of acute erythroleukemia a dominant fraction of erythroblasts is required. Differentiating erythroblasts (proerythroblasts and later) must comprise over 50% of all nucleated cells. Of the nonerythroid cells, 30% must be blasts and typically are myeloblasts frequently containing Auer rods.[249] The erythroid component shows varying degrees of dysplasia, which may be marked in the granulocytes and megakaryocytic lineages. Some cases of erythroleukemia may demonstrate minimal morphological erythroid differentiation and are difficult to differentiate from a undifferentiated leukemia or M0 leukemia or a myelodysplastic syndrome.[336] In these cases the bone marrow has a high fraction of proerythroblasts without a myeloblastic component or dysplastic erythroid hyperplasia. Mature erythroid precursors are absent and a majority of the cells are proerythroblasts, less than 3% of the cells are myeloperoxidase-positive blasts, and Auer rods are usually not present. The proerythroblast cells may be positive for glycophorin A and B, antigens of the AB blood group system, or CD36, which is strongly expressed on erythroid progenitors, erythroblasts, and fetal erythrocytes. In bone marrow biopsy sections immunohistochemical staining for hemoglobin A may be helpful to identify these cells.

In other rare cases dysplastic differentiating erythroblasts may account for more than 90% of the marrow cells without an increase in myeloblasts. This variant has been termed erythremic myelosis but should be considered as an erythroleukemia with a course similar to other cases of M6. [249]

Patients with erythroleukemia tend to be older at the time of diagnosis, with a mean age of over 50 in most studies. [337] [338] The presenting complaints are usually associated with the development

of anemia. The peripheral smear may have only rare circulating blast forms. Hepatomegaly and splenomegaly occur in less that 25% of patients. Some patients present with peculiar rheumatic and immunologic findings, and up to one-third will complain of diffuse joint pain and abdominal, back, and chest pain. [339] Many patients will have a positive rheumatoid factor, increased polyclonal immunoglobulins, a positive antinuclear antibody test, and a positive Coombs test. [339] The erythroleukemias, which are frequently preceded by a myelodysplastic syndrome, represent 1020% of the secondary leukemias and 35% of all de novo AML cases.[340] The preceding myelodysplastic or erythremic myelosis stage is characterized by progressive anemia often associated with intense erythroid hyperplasia in the bone marrow. The peripheral blood may demonstrate prominent basophilic stippling, with abnormal red blood cells with rare circulating blast forms. The bone marrow frequently demonstrates dysplasia of all cell lines. Patients with this subtype generally respond to therapy poorly with a short remission duration. [340] The response to treatment may reflect the increased incidence of secondary leukemias and patients with a prior MDS with this subtype.

AML of the M7 Subtype (Acute Megakaryoblastic Leukemia)

Acute megakaryocytic leukemia (M7) (Plate 53-14) is a recent addition to the FAB classification.[341] However, this is not a new entity; previous cases have been described, and many, if not all, of the previously reported cases of so-called acute myelofibrosis or malignant myelosclerosis probably represented acute megakaryocytic leukemia.[342] Acute megakaryocytic leukemia represents 312% of all cases of AML but its incidence may be higher in patients who transform from a prior myeloproliferative disorder.[343] [344] The incidence of acute megakaryocytic leukemia in patients with a prior myeloproliferative disorder, myelofibrosis, or chronic myelogenous leukemia is between 2451%.[345] [346] Megakaryoblasts are morphologically heterogeneous and vary from small round cells, resembling cells found in the L2 variant of ALL or in an undifferentiated M0 or M1 leukemia, to large atypical megakaryocytes with or without cytoplasmic granules. Binuclear or multinuclear blasts with deeply basophilic cytoplasm, cytoplasmic projections, and vacuoles are common. Undifferentiated blasts may be surrounded by shed platelets and recognizable micromegakaryocytes. In the peripheral blood megakaryocytic fragments are seen, along with large atypical cells with prominent cytoplasmic blebs representing megakaryoblasts. The bone marrow aspirate typically yields a dry tap, and the biopsy shows increased reticulin and fibrosis, the latter a result of the stimulation of the normal fibroblasts in the bone marrow by the local secretion of platelet-derived growth factor by the leukemic cells. [347] [348]

The megakaryoblast is Sudan black-, peroxidase-, and chloroacetate esterase-negative. The nonspecific esterase reaction is difficult to interpret in this leukemic subtype. The alpha-naphthyl acetate esterase reaction may be positive and is inhibited by the addition of fluoride, but the other nonspecific esterase stain, the alpha-naphthyl butyrate esterase, is usually negative. This differential staining distinguishes the megakaryoblast from the monocyte or monoblast. The PAS reaction is often, but not universally, positive. The FAB group recognized the difficulty of using routine morphology and cytochemistry to diagnose this subtype and included ultrastructural analysis and immunologic and cytogenetic criteria. In many cases megakaryocytic features may not be recognized by light or electron microscopy, so that use of monoclonal antibodies to specific platelet glycoproteins is necessary to define this subtype. [349] [350] Immunophenotyping with monoclonal antibodies to platelet glycoproteins 11b/111a, CD42b, CD61, CD41 or to factor VIII-related antigen may be needed to identify the megakaryoblasts. The ultrastructural platelet peroxidase reaction is technically difficult to perform and has been largely replaced by immunologic techniques. When flow cytometric techniques are used to determine surface antigen profile of leukemic cells, platelets adhere to the leukemic cells and may cause a false positive result with antibodies to platelet glycoproteins.[351] Cytospin immunofluorescence techniques are needed to distinguish adherent platelets versus a true positive cytoplasmic and membrane activity.

Cytogenetic abnormalities of chromosomes 3 and 21 have been associated with the M7 subtype.[352] [353] For the diagnosis of the M7 subtype at least 30% of the blast cells must be megakaryoblasts as defined by use of one of the above methods.

The clinical and hematologic features of the M7 subtype are varied and reflect the fact that in many patients the disease evolved from a prior myeloproliferative disorder. These patients frequently present with hepatomegaly and splenomegaly, a finding uncommon in patients with de novo acute megakaryocytic leukemia. [354] The presenting WBC is usually low, less than 5,000/mm ^{3} , and the platelet count is normal or increased in over one-third of cases. Anemia is usually present. The bone marrow aspirate is frequently a dry tap, and the bone marrow biopsy is fibrotic in over 90% of patients. The response to conventional induction chemotherapy is generally poor, with a complete response rate of less than 40%. A complete remission is frequently associated with reversal of the bone marrow fibrosis. [355] The clinical course can be very variable and atypical for an acute leukemia. Some patients whose disease has evolved from a preexisting myeloproliferative disorder may have a slowly progressive indolent disease that extends over a number of months to years. [356]

Patients with Downs syndrome have an increased incidence of acute megakaryoblastic leukemia.[357] In some of these patients the M7 leukemia appears to originate in early progenitor cells and expresses markers of mixed lineages.

Biphenotypic, Hybrid, and Bilineage Leukemias

The classification of AML is based on the predominant cell type and is an arbitrary system that does not attempt to address the biology of the disease or the leukemogenic events. In many cases it is impossible to define morphologically, cytochemically, or with the use of phenotypic markers a single lineage or cell type of a leukemic cell. In an attempt to explain this phenomenon, a number of different terms have been used, including *lineage infidelity, mixed lineage leukemias, biphenotypic or bilineage leukemias, hybrid or biclonal leukemias, and lineage switches*.[358] [359] [360] [361] [362] This confusing and at times arbitrary terminology reflects the heterogeneous nature of these disorders and the lack of specificity of currently available markers. *Lineage infidelity* refers to the expression of markers of more than one cell type by the same leukemic cell.[360] While many of the reported cases reflect the lack of specificity of the phenotypic markers, there are clear examples of blasts that express markers of more than one lineage. The monoclonal antibodies that are used to characterize lymphoid or myeloid leukemias recognize hematopoietic differentiation antigens. These antigens, which are expressed on a number of epithelial cells and overlapping subsets of hematopoietic cells, have important roles in the biology of normal and malignant hematopoiesis.[363] Immunophenotyping is of particular importance in recognizing the major immunologic subclasses of acute lymphoblastic leukemia and identifying the subtypes of AML that cannot be differentiated by morphology and cytochemistry alone, such as subtypes M0 and M7.[364]

Leukemic cells can demonstrate cytochemical and phenotypic markers of both myeloid and lymphoid precursors. [363] [365] [366] This phenomenon may reflect a fundamental abnormality of gene expression that is specific for the malignant clone. [362] [365] The clinical significance of lymphoid antigen expression in myeloid

leukemias is unclear. Lymphoid antigens may be positive in up to 48% of myeloid leukemias.[366] The most common lymphoid antigens expressed in myeloid leukemias are CD2 and CD7, which are expressed in 34% and 42% of patients with AML respectively.[366] The presence of lymphoid-associated antigens does not appear to be associated with a uniformly poorer prognosis. Alternatively, the leukemic cells may express markers of more than one lineage, reflecting the abnormal maturation of an earlier uncommitted stem cell.[367] [365] Many of the widely used monoclonal antibodies are not lineage-specific and are markers of differentiation. While many of the

monoclonal antibodies are considered lineage-nonspecific the two myeloid-associated monoclonals, CD13 and CD33, remain myeloid-specific.

Use of monoclonal antibodies and other molecular probes has shown that leukemic cells can demonstrate characteristics of more than one hematopoietic lineage. [364] [369] These cells may demonstrate Auer rods, stain with peroxidase and/or Sudan black, and react with monoclonal antibodies typical of both myeloid precursors and mature T cells.[370] A number of classification systems have attempted to address the biphenotypic leukemias but none have been widely accepted. [368] [370] Many cases express myeloid and lymphoid antigens and these cases do not represent evidence of biphenotypia, but reflect the inappropriate expression of lymphoid antigens on immature myeloblasts.[282] [366] A minority of acute leukemias have features of both myeloid and lymphoid lineages and are characterized as biphenotypic leukemias. [368] Biphenotypic leukemias can be suspected on morphological grounds when two distinct population of blast cells are noted. The incidence of acute biphenotypic leukemia represents approximately 7% of all adult acute leukemias.[361] In this setting two distinct leukemic cell populations are noted on immunophenotyping. The most common immunophenotype is co-expression of B-lymphoid and myeloid markers and less frequently T-lymphoid and myeloid markers. Biphenotypic leukemias have a high incidence of clonal chromosome abnormalities the most frequent being the t(9;22) (q34;q11), the Philadelphia chromosome, and structural abnormalities involving 11q23. In these cases the malignant transformation presumably occurred in a progenitor cell capable of differentiating into two distinct lines. This is in contrast to mixed lineage or hybrid leukemias, in which the leukemic cell expresses characteristics of more than one lineage. [371]

Lineage switch is the expression of markers of one lineage at diagnosis but markers of a different phenotype or lineage at the time of leukemic relapse. [371] [372] [373] This transformation, which usually occurs following a treatment interval of 1 year or more from the time of initial diagnosis, may reflect the selection of a clone from a bilineage leukemia or modulation of antigens expressed on leukemic cells. This phenomenon has been frequently reported in leukemias of the T-cell subtype in which relapse occurred as acute myeloid or myelomonocytic leukemia.[374] [375]

Hybrid leukemias do not fit into a morphologically or cytochemically defined group. Hybrid leukemias demonstrate malignant transformation of both lymphoid and myeloid cells.[376] The hybrid leukemias are morphologically heterogeneous and can present with undifferentiated or differentiated blasts. The undifferentiated myeloblastic leukemias present with agranular blasts with a high nuclear/cytoplasmic ratio, which are morphologically similar to those found in the lymphocytic leukemias.[377] [378] [379] [380] Some of these undifferentiated leukemias express the CD34 antigen, a marker expressed by hematopoietic stem cells, and early progenitor cells. Some of these disorders may in fact represent true stem cell leukemias and generally have a poor prognosis. [381] More typically the hybrid leukemias demonstrate commitment toward myeloid differentiation with morphologically identifiable myeloblasts. The myeloblasts may contain rare granules but a majority of the blasts do not demonstrate evidence of maturation or reaction with standard histochemical stains that would indicate a myeloid phenotype. The blasts may, however, be peroxidase-positive on electron microscopy or immunocytochemistry.[380] Use of monoclonal antibodies against lymphoid and myeloid surface antigens is necessary to define these hybrid leukemias.

Clinically the biphenotypic and hybrid leukemias present with the usual clinical findings of AML. However, they may present with features of both myeloid and lymphoid leukemias, including prominent diffuse lymphadenopathy and higher circulating blast and platelet counts. [382] [383] Otherwise the clinical presentations are indistinguishable from those of the other forms of AML.

The complete remission rates for the hybrid and biphenotypic leukemias are variable, as are their clinical courses. The undifferentiated and minimally differentiated hybrid leukemias do poorly with standard induction chemotherapy. [381] [384] Myeloid leukemias that are TdT-positive and express T-lymphoid markers are a more heterogeneous population and show variable response to induction therapy, with some patients having a better prognosis than patients with other AMLs. [382] Patients who fail standard AML treatment and demonstrate lymphoid markers may respond to the addition of vincristine, prednisone, and L-asparaginase to their induction regimen.[366] [381] Monoclonal antibodies to cell surface markers are necessary to define these morphologically atypical leukemias, and should be part of the initial evaluation in selected patients who present with an atypical morphological or clinical pattern.

Current models of hematopoietic differentiation are based on the evidence that normal pluripotential precursors give rise to committed precursors of a single-cell lineage and then undergo a series of discrete developmental steps. [377] The acute myeloid leukemias are believed to arise from a single clone that is arrested at a normal stage of committed differentiation. The currently used classification system is based on the premise that leukemic cells adhere morphologically and immunologically to a single lineage. The cases of biphenotypic leukemias, hybrid leukemias, lineage infidelity, mixed lineage, or lineage switch leukemias demonstrate the heterogeneity of these neoplastic disorders and support the concept that in at least some acute leukemias the transforming event occurs at the level of the pluripotential stem cell. Moreover, these data suggest that leukemic cells can differentiate, although aberrantly, and express differentiation markers.

PREDICTORS OF RESPONSE

A number of clinical characteristics have been defined that are important prognostic factors (Table 53-8). Age is the most consistent prognostic variable for induction therapy. While some single-institution studies have treated elderly patients with intensive therapy, most patients over the age of 60 years tolerate intensive treatment poorly.[384] [385] [386] In addition patients over the age of 60 have an increased incidence of unfavorable prognostic variables, such as cytogenetic patterns including abnormalities of chromosomes 5, 7, and 8, and poor-prognosis AML subtypes.[387] [388] [389] [390] Older patients with AML have an increased incidence of multilineage features, suggesting a more primitive stem cell origin. Elderly patients have an increased incidence of dysplastic morphology in the bone marrow and peripheral blood.[388] Moreover, the generally favorable cytogenetic and FAB types are less common in elderly patients. Cytotoxic chemotherapy in elderly patients is associated with a higher morbidity and mortality because of the presence of comorbid diseases, poor tolerance of prolonged pancytopenia, and perhaps impaired drug metabolism and excretion.[391] [392] The use of colony-stimulating factors to improve the neutrophil recovery and outcome of treatment in elderly patients with AML remains controversial. Colony-stimulating factors have been shown to reduce the duration of neutropenia in elderly patients undergoing induction

TABLE 53-8 -- Prognostic Factors in ANLL

Factor	Favorable	Unfavorable
	Clinical	
Age	<50 years	>60 years
Leukemia	De novo	Secondary
WBC	<25,000/mm^3	>100,000/mm^3
FAB type	M3, M4Eo	M0, M5a, M5b, M6, M7
Cytogenetics	t(15;17), inv16 normal cytogenetics	Abnormalities 5, 7, 8
		Philadelphia chromosome
Extramedullary disease	Absent	Present
Auer rods	Present	Absent
Phenotype	CD34+	CD34
	Mdr1	Mdr1+
	In Vitro	
Clonogenic assay	Normal growth	Abnormal growth

chemotherapy but overall effect on the morbidity or mortality is unclear.[391] [392] Less intensive chemotherapy has also been administered to elderly patients in an attempt to decrease the toxicity with variable results.[393] The duration of remission in elderly patients who attain a complete remission is also shorter and the role of post induction chemotherapy in this group is unclear.[387] [389] Patients with secondary AML or a prior myelodysplastic syndrome or myeloproliferative disorder respond poorly to standard chemotherapy regimens.[391] [392] [393] Patients presenting with blast cell counts greater than 100,000/mm^3 and signs of leukostasis also respond poorly to induction therapy. The pretreatment serum albumin, serum lactic dehydrogenase (LDH) level and performance status are important predictors of response.[390] [392] The lower the serum albumin, the less likely the patient will attain a complete remission and the higher the likelihood of having the morbidity and mortality associated with intensive chemotherapy.[394] [395] A poor performance status or elevated serum LDH is also associated with a lower complete response rate and shorter remission duration.[390]

A number of in vitro studies have attempted to correlate leukemic progenitor cell growth characteristics, drug sensitivity, and drug metabolism, retention, and incorporation with outcome of therapy. In vitro growth characteristics may be predictive of the outcome of remission induction therapy and remission duration, but results from such studies remain conflicting.[396] [397] [398] [399] [400] [401] The in vitro growth patterns and the presence of autonomous blast cell colony formation may be predictive of the response to treatment.[397] [402] [403] Additional in vitro studies that correlate with the probability of attaining a complete remission include the proliferative characteristics of leukemic cells, including the percent of cells in S phase, the cell cycle time and the expression of the multidrug resistance gene. [404] [405] [406] [407] Prospective studies are needed before therapy can be altered on the basis of labeling indices or in vitro growth characteristics. The expression of multidrug resistance gene has been implicated as a poor prognostic factor.[407] The best-characterized therapeutic resistance mechanism in AML is that mediated by the multidrug-resistance gene-1 (MDR-1).[406] MDR-1 encodes an ATP-binding transmembrane protein, which extrudes a variety of antineoplastic compounds from the cells including anthracyclines. Twenty percent of de novo AML and 75% of secondary AML cases express MDR-1.[408] MDR-1 expression is linked to the expression of the CD34 antigen.[407] [409] The MDR-1 phenotype is linked to other indicators of adverse outcome in AML including expression of the CD34+ antigen on blast cells, older age, poor prognostic cytogenetics, and immature phenotype and FAB group. The MDR-1 phenotype identifies a group of high-risk, poor-prognosis leukemias, but its role as an independent prognostic indicator remains unclear.[409]

The major determinant of the outcome of remission induction therapy is the capacity of the patient to tolerate intensive therapy. A majority of the patients who fail to

attain a complete remission do so because of the complications of the therapy. Resistant disease accounts for approximately 20% of all induction failures. The majority of patients who die during their initial treatment for AML succumb to complications of treatment including infection or hemorrhage. Therefore, prior medical problems and performance status are important predictors of response. Underlying renal insufficiency and impaired cardiac or hepatic function all limit the amount of chemotherapy that can be administered. Factors that predispose to serious infections decrease the likelihood of a patient attaining complete remission. Patients with concomittant diseases that impair their immune response or who are on medications that predispose them to fungal or other opportunistic infections have increased infectious complications and a higher mortality rate during induction therapy. [410] It remains unclear whether the introduction of hematopoietic growth factors will decrease the incidence of serious infections in patients receiving induction chemotherapy.

In most studies 6070% of patients under the age of 60 will attain a complete remission with induction therapy, and 4070% will relapse in the first 1824 months (Fig. 53-5). Those factors that determine remission duration are still very controversial and dependent in part on the type of post induction chemotherapy employed. [387] [411] [412] Cytogenetic abnormalities are present in the leukemic cells of the majority of patients with AML. [413] Cytogenetics are important prognosticators of response to treatment and remission duration. Cytogenetic abnormalities including t(8;21) and inv(16) are associated with significantly longer remission and survival, while abnormalities of chromosomes 5, 7, and 11q are associated with a poor response to therapy and shorter overall survival. These and other studies have suggested that chromosomal abnormalities constitute an important independent prognostic factor for remission duration but not for remission induction. [414] Other factors that are predictors of remission duration include the previously noted FAB subtypes M0, M4, M5, M6, and M7 having a poorer prognosis, and M2 and M3 and M4E having a better prognosis. The absolute percentage of erythroblasts appears to correlate inversely with remission duration. [415] Auer rods and an increase in the bone marrow eosinophils may also be associated with longer remission and survival. [415] The in vivo sensitivity of the leukemic cell as determined by the number of courses needed to attain a complete remission and the rate of cytoreduction in bone marrow cellularity, appear to be independent predictors of remission duration. [412] Patients who require two courses of induction chemotherapy to attain a complete remission appear to have a shorter remission duration. The morphologic appearance of the bone marrow biopsy at the time of complete remission may also be an important predictor of remission duration. The presence of morphologic dysplasia involving more than one cell line may be associated with a shorter remission duration. [242] [412] However, chemotherapy can induce dysplastic features in the bone marrow, and findings of dysplastic erythroid and myeloid precursors following high-dose induction and consolidation therapy must be interpreted with caution. All these factors, however, are

Figure 53-5 Overall survival for patients with AML (ANLL) can be divided into three phases. Phase 1 is induction therapy. The overall survival during this phase reflects the complete remission rate and the ability of the patient to tolerate chemotherapy and prolonged neutropenia and thrombocytopenia. Most patients who fail to respond die of infections or hemorrhage. True resistant disease accounts for <15% of induction failures. The complete response rate is approximately 6080%. Phase 2 is the first 2 years after attainment of complete remission. Most patients in complete remission will relapse and die of their leukemia in these first 2 years. While much of the attention in therapy for acute leukemia has focused on the first phase surviving induction therapy and attaining complete remissionas this curve suggests, most patients fail after attaining complete remission. This reflects occult disease not recognized at the time of complete remission. In an effort to prolong this phase, multiple studies are addressing the use of post-induction consolidation and maintenance therapy. Treatment of minimal residual disease remains a controversial area of investigation. Phase 3 begins 2 years after complete remission is attained. Patients in remission for >2 years have a markedly increased chance of prolonged survival; 7580% of patients in complete remission at 2 years will have a prolonged disease-free survival. However, the curve of this phase is not flat, and patients continue to relapse 310 years after attaining complete remission. The biologic factors responsible for these late relapses are unknown and may reflect one or more of the etiologic events in the development of AML.

determined from retrospective studies. None of these variables have been critically analyzed in controlled prospective trials.

The clinical events for patients with AML can be divided into three phases (Fig. 53-5). The induction therapy is the first phase. The outcome during this phase reflects the ability of the patient to tolerate chemotherapy and prolonged neutropenia and thrombocytopenia and attain a complete remission. A majority of patients who fail to respond to induction chemotherapy die of infection or bleeding. True resistant leukemia accounts for less than 20% of induction failures. The complete response rate with combination intensive induction chemotherapy is between 60 and 80%. Phase 2 encompasses the first 2 years after attainment of complete remission. The majority of patients in complete remission will relapse and die of their leukemia during the first 2 years. Improvements in supportive therapy have resulted in an increase in the percentage of patients attaining a complete remission as a result of receiving consolidation therapy. However, the majority of patients still relapse after attaining a complete remission. The high relapse rate reflects occult disease not recognized at the time of complete remission. In an effort to prolong this phase, multiple studies are addressing the use of postinduction consolidation and maintenance therapy. The treatment of minimal residual disease remains a controversial area of investigation. Phase 3 begins 2 years after complete remission is attained. Patients in remission for more than 3 years have a markedly increased chance of prolonged survival; 7580% of patients in complete remission at 3 years will have a prolonged disease-free survival. [425] However, patients continue to relapse 310 years after attaining complete remission. The biologic factors responsible for these late relapses are unknown and may reflect one or more of the etiologic events in the development of AML. In large cooperative trials, age < 55 years, a white blood count at presentation of <10,000/mm ^{3} , and favorable cytogenetics were associated with long-term survival. [426] [427] [428] [429]

Chapter 54 - Therapy for Acute Myeloid Leukemia

Elihu H. Estey
Hagop Kantarjian
Michael J. Keating

The goal of the treatment of acute myeloid leukemia (AML) is to produce and maintain a complete remission (CR). Criteria for CR are achievement after chemotherapy of a platelet count >100,000/L, a neutrophil count >1,0001,500/L, and a bone marrow that has <5% blasts. [1] In the 1960s, Freireich et al. demonstrated that patients who achieved a CR, thus defined, lived longer than patients who did not, although the CRs were relatively brief. When not in CR, the two groups had similar survival rates; thus, the difference in survival time was entirely attributable to the duration of time spent in CR, suggesting a correlation between achievement of CR and survival time.[2] These findings have been confirmed for patients treated in the 1980s and 1990s. Patients who achieve a CR on any given day after beginning therapy have longer survival subsequent to that day than patients who are resistant to therapy on the day in question.

Two types of events can interfere with the achievement and maintenance of a CR.[3] First, patients can die as a result of chemotherapy administered to eradicate the AML. This event is classified as a supportive care failure. Second, and more frequent, chemotherapy can be ineffective. Such resistance to therapy is usually manifested when disease recurs after a period in CR, but can also manifest as a failure to enter CR (primary refractory AML). These two types of resistance correspond to the two principal phases of chemotherapy, remission induction and therapy in remission. This chapter considers both phases of treatment, beginning with standard approaches.

STANDARD REMISSION INDUCTION THERAPY

Modern remission induction therapy for AML usually consists of a combination of cytosine arabinoside (ara-C) and an anthracycline. Ara-C, an antimetabolite that is an analogue of the normal nucleoside cytidine, is converted to ara-C triphosphate (ara-CTP). The enzyme deoxycytidine kinase catalyzes the rate-limiting step in the process. Once converted to ara-CTP, ara-C is incorporated into DNA and causes cell death. Mechanisms of cytotoxicity that do not require ara-CTP formation may also exist. When originally used in the 1960s and 1970s, [4] ara-C was administered to patients with leukemia at daily doses of 100200 mg/m ^{2} (standard dose ara-C) either by twice-daily intravenous (IV) infusions or by a continuous IV infusion, the latter because of the drugs very short half-life (15 minutes). When given by continuous infusion, results were schedule dependent: at similar total doses, CR rates were higher when ara-C was given over 5 days rather than 2 days. Given at 200 mg/m^2 daily for 5 days by continuous IV infusion, ara-C produces CR rates of approximately 40% At the standard doses described previously, ara-Cs principal adverse affects are myelosuppression and gastrointestinal toxicities. Anthracyclines such as daunorubicin, doxorubicin, and rubidazone were introduced into the treatment of AML around the same time as ara-C. Daunorubicin, probably the most frequently used anthracycline , when given at 60 mg/m ^{2} daily for 37 days, produces CR rates similar to those seen with ara-C. [5] Anthracyclines and ara-C have similar toxicities, but anthracyclines also cause alopecia and a cardiomyopathy that can be prevented by limiting the total dose administered. Anthracyclines belong to a class of drugs, which also includes etoposide, that are believed to exert cytotoxicity by stabilizing the normally occurring complex between DNA and the enzyme topoisomerase II; stabilization of the complex leads to cell death.

Probably the most commonly used combination therapy for AML is the so-called 3 + 7 regimen, the name reflecting the typical use of 3 days of daunorubicin at 4560 mg/m^2 daily and 7 days of ara-C at 100200 mg/m^2 daily. CR rates are usually approximately 6070% Randomized trials have concluded that daily ara-C doses of 100 and 200 mg/m^2 are therapeutically equivalent in the 3 + 7 regimen. In addition, the 3 + 7 and 3 + 10 (3 days of anthracycline + 10 days of ara-C) regimens give identical CR rates, either regimen producing higher CR rates and quicker remissions, and thus less morbidity, than the less intense 2 + 5 and 1 + 5 regimens. [6] [7] [8] [9] Approximately half the patients who fail to enter CR die during induction, usually of multiorgan, particularly pulmonary, failure with infection, especially fungal infection, often the proximate cause. Hemorrhage, chiefly pulmonary, often contributes, especially in patients with acute promyelocytic leukemia (APL). [3] [10] The other half of the group of patients who fail to enter CR survive induction therapy but nonetheless do not achieve CR. These patients are divided into those in whom marrow hypoplasia is never observed and those in whom hypoplasia develops but is followed by reappearance of AML rather than achievement of CR. In clinical practice, a bone marrow biopsy is usually obtained 23 weeks after beginning therapy. If the marrow continues to show blasts and is cellular, a second course of the same therapy is usually given, sometimes at reduced total dose (e.g., 2 + 5). If the day 14 or 21 marrow is hypoplastic, therapy is usually delayed until it is clear that leukemia has reappeared, at which time the second course begins. A second repeated course of therapy can certainly produce remissions, but these are usually shorter in duration than remissions produced after one course of therapy, [11] illustrating the connection between results of induction therapy and results of postremission therapy. It is important to recognize that the initial marrow aspirate and biopsy obtained after a period of hypoplasia may demonstrate up to 3050% blasts as a reflection of the regeneration of normal, not leukemic, marrow. In the former circumstance, follow-up marrow biopsies show reduction in percentage blasts concomitant with a rise in neutrophils and platelets.

STANDARD POSTREMISSION THERAPY

Three types of postremission therapy can be distinguished. *Maintenance* therapy is usually defined as therapy less myelosuppressive than that used to produce remission. The doses used in *consolidation* therapy usually approach, whereas those in *intensification* therapy may surpass, the doses used during induction. Traditionally, once in remission after treatment with the 3 + 7 regimen, patients receive maintenance therapy with the same drugs given during induction, or only ara-C, administered at approximately monthly intervals for 6 months to 1 year. With this approach, the median remission duration is approximately 11.5 years. [12] One study found that the risk of relapse

begins to decline sharply to a relatively low level once 3 years have been spent in CR. [13] It is thus reasonable to consider patients who are given traditional regimens and who are in CR at this time as potentially cured. Only 1020% of unselected patients fall into this category. [12] [13]

Much attention has been devoted to the need for maintenance therapy. The Eastern Cooperative Oncology Group (ECOG) randomized patients achieving CR either to receive no therapy or to receive a regimen consisting of 4 days of 6-thioguanine (6-TG, probably a minimally active agent, as described later) plus one subcutaneous injection of a relatively low dose of ara-C (60 mg/m^2) weekly for 2 years.[14] Remission duration was superior among patients assigned to receive maintenance. The likelihood of achieving a second remission was the same in both groups, whereas survival was significantly ($P < 0.05$) longer in the maintenance group.

The ECOG study clearly shows that some postremission therapy is needed. Several randomized studies have addressed the issue of how long such therapy should last. As seen in Table 54-1 , 3 studies have found some benefit to maintenance therapy. The Southwestern Oncology Group (SWOG) studied randomized patients who had received 3 + 7 induction therapy followed by two courses of maintenance and three courses of late intensification (consisting of POMP; see later) either with or without additional maintenance.[15] The relative risk of relapse or death was 1.63-fold higher in the no-maintenance arm (95% confidence interval 1.072.56), but there was no difference in survival. The Japanese Acute Leukemia Study Group (JALSG) reported that patients given 12 rather than 4 months of maintenance therapy had superior disease-free survival rates ($P = 0.004$) with probabilities of 3-year disease-free survival (dated from time of CR) of 48% versus 34%. [16] No overall survival data were presented. Büchner et al. reported median remission durations of 13 and 8 months in their maintenance and no-maintenance groups, with probabilities of 3-year disease-free survival of 30% versus 17% dated from time of CR. [17] Again, no survival data were given. In contrast, the Swiss study found no benefit from further maintenance after two courses of consolidation and one maintenance course had been given, [18] and the Southeastern Cancer Study Group found that 3 months of consolidation therapy and 7 months of maintenance therapy gave identical results. [19] In addition, several nonrandomized studies [20] [21] have found no differences between patients given or not given longer durations of consolidation or maintenance therapy.

Why the discrepancies in results illustrated in Table 54-1 ? It might be reasonable to expect that maintenance would primarily benefit patients who had previously received relatively little therapy. Such a hypothesis would explain the German data, because patients in the no-maintenance group were given only one prior course of consolidation. However, it would not explain the positive results in the SWOG and JALSG studies because the therapy given patients before randomization in these studies seemed equally intense as that administered to the patients in the studies finding no effect of maintenance therapy. Another explanation is that the maintenance therapy itself might have been more intense in the positive studies. The JALSG report noted their maintenance therapy was sufficiently myelosuppressive that patients required platelet transfusions after each course. Unfortunately, this type information usually is not available in the other studies. Two of the positive studies (JALSG, German) used drugs (etoposide or cyclophosphamide) that are potentially non-cross-resistant with ara-C or daunorubicin, but the SWOG study did not (Table 54-1). Another possible explanation is that the patients treated in the positive and negative studies differed with respect to variables that predict outcome. Although this does not appear obviously to be the case, information on cytogenetics, perhaps the factor most predictive of length of remission, is included in none of the studies.

Despite the discrepancies in the studies noted in Table 54-1 , it seems clear that any benefit from traditional maintenance after the administration of 34 months of consolidation is relatively small, and perhaps nonexistent with respect to survival. It may well be that this conclusion is not true for all prognostic subgroups of AML. However, it seems realistic to acknowledge that traditional maintenance therapy is on the whole unsatisfactory regardless of the length of maintenance. Therefore, future studies should address more pressing issues.

The poor prognosis of most patients given standard induction and postremission chemotherapy has led to trials investigating modification of such therapy. These have examined choice of anthracycline, use of high-dose ara-C (HDAC), hematopoietic growth factors, drugs other than anthracycline or ara-C, and allogeneic or autologous transplantation.

CHOICE OF ANTHRACYCLINE

Idarubicin has been the most widely investigated alternative anthracycline. Three large U.S. randomized studies [22] [23] [24] compared

TABLE 54-1 -- Randomized Comparisons of Maintenance Versus No Maintenance in Patients in First Remission

Study	No. of Patients	Intensity of Therapy Before Randomization	Months in CR when Randomized	Months of Further Maintenance in Study Groups	Drugs Used in Maintenance	Positive Effect of Maintenance[a]
SWOG (Hewlett et al., 1995)[15]	150	3 + 7 then 2 courses M	23	0 vs. 22	Ara-C, 6-thioguanine, vincristine, prednisone	Yes
JALSG (Ohno et al., 1993)[16]	131	3 + 7 then 3 courses C	34	4 vs. 12	Ara-C, anthracyclines, etoposide, 6-mercaptopurine, prednisone, vindesine	Yes
German (Büchner et al., 1985)[17]	145	3 + 7 then 1 course C	1	0 vs. 36	Ara-C, daunorubicin, 6-thioguanine, cyclophosphamide	Yes
Swiss (Sauter et al., 1985)[18]	74	3 + 7 then 1 course C, 1 course M, 1 course C	34	0 vs. 24	Ara-C, 6-thioguanine, vincristine, prednisone	No
SEG (Vogler et al., 1995)[19]	124	3 + 7	0	3 mo C vs. 7 mo M	Ara-C, daunorubicin	No

SEG, Southern Cancer Group; SWOG, Southwestern Oncology Group; JALSG, Japan Acute Leukemia Study Group; 3 + 7, denotes induction regimen containing 3 days anthracycline + 710 days ara-C; C, consolidation (i.e. therapy equally intensive as 3 + 7); M, maintenance (i.e. therapy less intensive than 3 + 7).

[a] At $P < 0.05$.

standard-dose ara-C plus either daunorubicin (4550 mg/m^2 daily × 3) or idarubicin (1213 mg/m^2 daily × 3) as induction therapy followed in CR by two to three courses of the induction regimen at reduced dose. The studies found CR rates of 5560% with daunorubicin versus 6980% with idarubicin, and the difference was significant ($P < 0.05$) in two of the studies. Median survival ranged from 8.7 to 13.5 months in the daunorubicin groups versus 9.9 to 19.7 months in the idarubicin groups, these differences again being significant in two of the studies. Results seemed similar in both younger and older patients, and extramedullary toxicity was also similar, although duration of myelosuppression was greater in the idarubicin patients in two of the studies. The AML Collaborative Group conducted a meta-analysis of randomized trials comparing idarubicin and daunorubicin. [25] Data came not only from the three U.S. trials but from trials conducted by the Italian national cooperative group (GIMEMA), a French group, and a Mexican group. The meta-analysis indicated that idarubicin was associated with longer survival as well as higher CR rates. In contrast, a similar meta-analysis comparing mitoxantrone and daunorubicin found no differences in disease-free or overall survival rates. [25] These results seem to establish idarubicin, at the doses compared, as the standard anthracycline in newly diagnosed AML. Reasons for idarubicins superiority have focused on the long half-life of its active metabolite, idarubicinol, or the (disputed) possibility that idarubicin is a relatively poor substrate for the multidrug-resistance glycoprotein (MDR1) and hence less subject to efflux from blast cells. The probability of development of idarubicin-related clinical congestive heart failure was found to be 5% in patients receiving cumulative doses of 150290 mg/m[2] . [26] Cumulative doses of at least 150 mg/m^2 can probably be safely given to patients younger than age 70 years with no prior exposure to anthracyclines because the probability of congestive heart failure in these patients was zero, [26] compared with 1020% at the same dose level in patients older than age 70 years, or those with hypertension or prior exposure to anthracyclines.

HIGH-DOSE ARA-C

High-dose ara-C (HDAC) in general denotes daily doses of 212 g/m ^{2} , whereas standard-dose ara-C (SDAC) denotes daily doses of 100 or 200 mg/m ^{2} . Use of HDAC for remission induction in newly diagnosed patients stems from observations that patients who relapse after maintenance with SDAC can again be induced into CR after HDAC.[27] Several toxicities also became apparent only when higher doses were administered. These included cerebellar and cerebral dysfunction, [28] noncardiogenic pulmonary edema,[29] pericardial effusion,[29] and conjunctivitis. The risk of central nervous system toxicity increases sharply with age and decreasing renal function.[28] The effectiveness of HDAC is presumed to be a result of higher intracellular concentrations of ara-CTP. Indeed, correlations exist between the ability of circulating leukemic blasts to form and retain ara-CTP and response of relapsed AML to HDAC. [30] Likewise, the superior outcome of children with Downs syndrome and AML relative to other children with AML may result from the increased ability of myeloblasts from the patients with Downs syndrome to form ara-CTP. [31] At any rate, the studies in relapsed disease led to clinical trials in patients with newly diagnosed disease comparing anthracycline + SDAC with anthracycline + HDAC.

Table 54-2 summarizes randomized trials of HDAC in newly diagnosed AML. The Australian Leukemia Study Group (ALSG) trial of Bishop et al. [32] found that although CR rates were similar in patients given anthracycline + etoposide with either SDAC or HDAC, the latter had longer remissions, with both groups receiving two courses of SDAC + daunorubicin + etoposide in remission. Survival rates were similar, but myelosuppression was greater in the HDAC group not only during induction but during postremission SDAC. This study was limited to patients 1760 years of age. The SWOG trial of Weick et al. [33] entered adults up to age 65 years and randomized patients to receive daunorubicin plus either HDAC or SDAC for induction; in CR, the SDAC induction group was further randomized to receive daunorubicin + SDAC (two courses) or + HDAC (one course). Patients given HDAC for induction received HDAC + daunorubicin (one course) as postremission therapy. Toxicity (neurologic, fatal infection, fatal central nervous system hemorrhage) was significantly more frequent during induction in the HDAC group, and although patients younger than 50 years of age were initially given 3 g/m ^{2} ara-C, this had to be reduced to 2 g/m ^{2} because of toxicity. Nonetheless, CR rates were the same in the SDAC and HDAC groups. Once in CR, disease-free survival was superior in patients given induction with HDAC rather than SDAC (*P* = 0.049, with 4-year estimates of disease-free survival being 21% (SDAC) versus 33% (HDAC) for patients younger than age 50 and 9% (SDAC) versus 21% (HDAC) for patients 5065 years of age. Among patients given SDAC induction, those who received HDAC in CR had similar outcomes, but more neurologic

TABLE 54-2 -- Randomized Comparison of Standard Dose ara-C with High-Dose ara-C in Newly Diagnosed Acute Myeloid Leukemia

Study	HDAC Given During	Patients	CR Rate		Statistically Significant($P < 0.05$) Effect on RD, EFS,EFS in CR, or Survival
			SDAC Regimen	HDAC Regimen	
ALSG (Bishop et al.)[32]	Induction only	279	74%	70%	RD longer with HDAC (median 36.9 vs. 12.7 mo)
SWOG(Weick et al.)[33]	Induction and/or intensification	723	56%	50%	EFS in CR better with HDAC induction, best with HDAC induction and intensification

THERAPY FOR ACUTE MYELOID LEUKEMIA INITIAL ASSESSMENT

INITIAL ASSESSMENT

The diagnosis of AML is made when the bone marrow contains >30% blasts, of which >3% stain positive for myeloperoxidase. Acute monocytic leukemia can be peroxidase negative but will usually show positivity after the performance of butyrate or nonspecific esterase stains. Surface markers and electron microscopy may be useful in diagnosing erythroleukemia and acute megakaryocytic leukemia. When the initial marrow is obtained, specimens are sent for cytogenetics. HLA typing of the patient and family members is also done at diagnosis. Unless symptoms warrant, there is no need to examine the cerebrospinal fluid at this time.

Once the diagnosis of AML is made, the need for emergency treatment should be assessed. Such treatment is required if the circulating blast count is >50,000/mm^3 or if the patient has APL, disseminated intravascular coagulation (DIC), or organ dysfunction attributed to leukemic infiltration. Patients most likely to have leukemic infiltration are those with circulating blast counts of >10,000/mm^3.

SUPPORTIVE CARE

Patients are given bicarbonate-containing IV fluid daily to prevent the development of a tumor lysis syndrome and attendant hyperuricemia. Allopurinol is given if the white blood cell (WBC) count is >10,000/mm^3. If the WBC is >10,00050,000, the patient, particularly if elderly or with a low platelet count, is at risk for development of pulmonary failure in the first week after the start of chemotherapy, characterized by hemorrhagic fluid being recovered after bronchoalveolar lavage. These patients are monitored for this complication in the intensive care unit and the amount of IV fluids is restricted. If the WBC count is >50,000/mm^3, leukapheresis is begun immediately, in conjunction with chemotherapy. By reducing tumor burden, pheresis may prevent the development of the tumor lysis syndrome or pulmonary failure syndrome. If renal function deteriorates or hyperphosphatemia or hyperkalemia develop, continuous hemodialysis is instituted.

Patients who are afebrile (<101°F) at presentation are begun prophylactically on trimethoprim-sulfamethoxazole one double-strength tablet bid, fluconazole 200 mg bid, and itraconazole 200 mg bid. If a temperature >101°F develops unrelated to blood product administration, patients are begun on intravenous imipenem. If pneumonia is documented, amphotericin is begun immediately. Otherwise, amphotericin is begun if the patient remains febrile with negative cultures after 3 days. We routinely use liposomal amphotericin preparations 35 mg/kg/day. Such preparations should certainly be used if the creatinine becomes elevated. If, despite use of amphotericin, there is evidence of progressive infection (development of pneumonia, persistently positive cultures) and persistent neutropenia, we begin administration of GM-CSF and consider granulocyte transfusions from family donors if the donors can be treated with GM-CSF to raise their granulocyte count.

Platelet transfusions are given routinely if the platelet count is <10,000. Exceptions may be made if the count has been below this level for weeks, if the patient is not bleeding, and if the patient does not have mucositis or DIC. If bleeding or DIC is present, platelet transfusions should be given if the platelet count is <50,000. If significant increments in the platelet count are not obtained after the administration of pooled platelet concentrates, family members are used as donors. Transfusions of cryoprecipitate are given to maintain the fibrinogen level at >200 in patients with APL. All blood products are filtered to reduce the possibility of alloimmunization.

REMISSION INDUCTION THERAPY

We treat our patients with APL with all-*trans* retinoic acid (ATRA) 45 mg/m^2/day until CR is achieved. Idarubicin (12 mg/m^2/day × 4 days) is begun 5 days after initiation of ATRA, or sooner if leukocytosis >10,000 develops. If ATRA syndrome develops, we discontinue ATRA and administer dexamethasone (10 mg IV bid) for 3 days, followed by a rapid taper. If the marrow contains persistent excess numbers of blasts, a second course of idarubicin is not begun until 5 weeks have elapsed after initial treatment, unless DIC occurs before then.

Patients with other types of AML are given idarubicin (12 mg/m^2/day on days 13) + ara-C (1.5 g/m^2/day on days 14 by continuous infusion, or 2 g/m^2 over 4 hours once daily on days 14) if they are younger than age 60 years and have a good performance status and no history of abnormal blood counts. If they have any of these features, they are offered investigational therapies. A second course of therapy is not begun before day 21 after the first course, unless the circulating blast count rises before then. Patients not in remission after two courses are first considered for allo-BMT; if this is not feasible, they are offered investigational chemotherapy.

An alternative approach would be to assign patients to treatment on the basis of cytogenetic results, provided these are available within 34 days of presentation. With this approach, patients with abnormalities of chromosome 5 or 7 would be immediately offered investigational therapies based on their low likelihood of achieving CR with conventional therapy or HDAC.

POSTREMISSION THERAPY

By the time remission is achieved, pretreatment cytogenetic information should be available and used to plan therapy. Patients with inv(16) or t(8;21) are given courses of HDAC (1.5 g/m^2/day × 2 days by continuous infusion) + idarubicin (8 mg/m^2/day on days 1 and 2) alternating with fludarabine 30 mg/m^2/day on days 12 + ara-C 1 g/m^2/day on days 12. Patients with APL receive three courses of idarubicin, the first two at 12 mg/m^2/day × 2. If PCR testing is negative, therapy is discontinued. If not, alternative therapies are offered. Patients with other karyotypes and an HLA-compatible donor are offered allo-BMT up to age 50 years and minitransplant up to age 70 years. Otherwise, they are considered for investigational therapy.

BONE MARROW TRANSPLANTATION

Aside from use in poor-prognosis patients in first remission, we recommend allo-BMT transplantation in first relapse if the patient is younger than 70 years of age and has an HLA-matched sibling donor, or is younger than 50 years of age and has an HLA-identical unrelated donor.

toxicity, than patients given SDAC in CR. Postremission outcomes (event-free survival, survival) were best in patients given HDAC for induction and in CR regardless of whether account is made for the more frequent inability of patients given HDAC induction to receive planned post-CR therapy. Both the Cassileth et al. (ECOG) study[34] and the Mayer et al. (Cancer and Acute Leukemia Group B) [CALGB]) study[35] randomized patients once in CR: HDAC versus SDAC (ECOG) or HDAC versus intermediate-dose ara-C (IDAC, 400 mg/m^2 daily × 5) versus SDAC (CALGB). In the ECOG study, one course of postremission therapy was given to the HDAC group (amsacrine + HDAC), whereas the SDAC group received 2 years of postremission therapy. In the CALGB study, patients were to receive four courses of their assigned postremission therapy and then received four courses of SDAC + daunorubicin. Both studies determined outcome to be better with HDAC, but only in patients younger than age 60 years (e.g., actuarial 4-year event-free survival rates of 28% vs. 15%; P= 0.049 [ECOG]; and 44% vs. 29% vs. 24%; P= 0.002 [CALGB], comparing HDAC, IDAC, and SDAC). In patients older than age 60 years, the ECOG noted a mortality rate of 57% (8/14) with a single course of HDAC (3 g/m^2 every 12 hours for 6 days) + amsacrine.

In summary, data from all four studies of HDAC in Table 54-2 note advantages for HDAC given during induction (Bishop et al.,[32] Weick et al.[33]) and/or during post-remission therapy (Weick et al.,[33] Cassileth et al.,[34] Mayer et al.[35]). It must be noted that three of these four studies did not include patients with a history of abnormal blood counts or secondary leukemia (important prognostic factors, as discussed later), that three were limited to patients younger than age 65 years, and that two explicitly noted that outcome was not better and toxicity worse in patients older than age 60 years. Furthermore, it appears that the beneficial effects of HDAC induction and intensification in patients younger than age 6065 years are limited to patients most likely to respond to SDAC, in particular those with favorable leukemia cell karyotypes, as discussed in the Prognostic Factors section.

Mitus et al. combined SDAC and HDAC in a regimen calling for daunorubicin 45 mg/m^2 on days 1, 2, and 3, SDAC 100 mg/m^2 daily on days 17, and HDAC 2 g/m^2 every 12 hours on days 8, 9, and 10.[36] They reported a CR rate of 89% in 94 consecutive patients younger than 65 years of age with de novo AML and no history of abnormal blood counts. Eighty-five percent of the patients with unfavorable cytogenetics achieved CR (95% confidence interval 6297%). Two patients had irreversible

cerebellar toxicity. In CR, patients received an allogeneic or autologous transplant. This so-called Mitus regimen is now being investigated by the SWOG and CALGB.

USE OF COLONY-STIMULATING FACTORS

In principle, administration of colony-stimulating factors (CSFs) in AML can affect either the rate of recovery of normal blood cells after, or the sensitivity of leukemic progenitors to, chemotherapy. The two most widely studied CSFs have been granulocyte-macrophage (GM)-CSF and granulocyte (G)-CSF. In most trials, GM- or G-CSF was begun only after completion of chemotherapy in order to hasten neutrophil recovery, thereby presumably decreasing infection rate; if leukemic cell recovery is not simultaneously enhanced, a higher CR rate should result. Although it was originally believed that sensitization of leukemia to chemotherapy could be achieved only if CSFs were given before or during chemotherapy, some evidence discussed later suggests that CSFs given only after completion of chemotherapy may also affect sensitivity of AML to chemotherapy.

Beginning with the question of neutrophil recovery, most studies have found that use of either GM- or G-CSF speeds this process by 25 days. This result seems to apply regardless of whether CSF is given before as well as during and after induction chemotherapy, or only after such chemotherapy. Less is known about the effects on blood count recovery of CSFs given in CR, although Moore et al. noted that G-CSF given after aziridnyl benzoquinone + mitoxantrone postremission chemotherapy shortened the time to neutrophil recovery compared with a control group of patients given the same chemotherapy. [37]

Accepting that GM- or G-CSF administered after induction or postremission therapy speeds recovery of neutrophils leads of course to the question, does this matter? Table 54-3 summarizes larger trials of GM- or G-CSF in AML according to whether they found significant reduction in morbidity or mortality rates in GM- or G-CSF-treated groups. The differences between G-CSF and placebo in the Godwin et al. [38] and Heil et al.[39] studies applied *only* to days of hospitalization or duration of fever and antibiotic usage, each of which were reduced from 1 to 5 days. The Moore et al. [37] study noted shorter hospitalizations in G-CSF groups receiving postremission therapy (as did the Heil et al. study), but no effect on remission duration or survival. Certainly, the Rowe et al. study [40] (conducted by the ECOG) is the only one in Table 54-3 that found that use of a CSF, GM-CSF, after induction chemotherapy decreased the incidence of *serious* infection and improved *survival*. Its results were directly contradicted by the CALGB study of Stone et al. [41] Possible explanations for the differences between the ECOG and CALGB studies include use of yeast-derived GM-CSF in the ECOG study but *Escherichia coli*-derived GM-CSF in the CALGB study, and the fact that ECOG patients only began GM-CSF or placebo if the marrow was aplastic on day 10, whereas all CALGB patients received GM-CSF or placebo. The most likely explanation, in the authors opinion, is the much smaller size of the ECOG study, making it likely that imbalances in prognostic factors made the placebo group unfavorable relative to the group receiving GM-CSF.

Regarding G-CSF, the SWOG study of Godwin et al. [38] found no difference in CR rate between placebo and G-CSF (49% vs. 42%), whereas the Dombret et al. [42] study found a significant improvement in the G-CSF groups (47% placebo vs. 70% G-CSF). This improvement was unrelated to a reduction in early, or infectious, mortality rates, but purportedly resulted from less resistance to chemotherapy in the G-CSF group. This was particularly noticeable in patients with residual blasts in the marrow on day 8 and in patients with unfavorable cytogenetics. The study is of interest because it is the first to suggest that administration of CSF after chemotherapy can influence sensitivity of leukemia cells to chemotherapy (e.g., by affecting rate of apoptosis). One commonly invoked explanation for the results of Dombret et al. is the possibility that G-CSF promoted differentiation and increased neutrophil numbers, thereby lowering the blast percentage in the marrow, that is, the G-CSF CRs were cosmetic in that only the percentage but not the number of blasts was reduced. Indeed, despite the higher CR rate in the G-CSF group, event-free survival from start of treatment was the same in G-CSF and placebo groups, reflecting short CR durations.

Given all of the aforementioned data, the authors do not favor routine administration of GM- or G-CSF after induction therapy in elderly (or other) patients. They believe that the yeast GM-CSF study (Rowe et al. [40]) should be repeated in a much larger group of patients for the reasons discussed previously. Although it could be argued that there is no harm in routine administration of GM-CSF after chemotherapy, Zittoun et al. [43] found that such use of bacteria-derived GM-CSF, regardless of whether GM-CSF was also given before and during chemotherapy, resulted in lowered CR ($P < 0.01$) and event-free survival ($P = 0.005$) rates compared with patients who received no GM-CSF or GM-CSF only before and during chemotherapy (a four-arm study; see Table 54-3). These results reflected increased resistance to chemotherapy in the GM-CSF after chemotherapy groups. On the other hand, a similar four-arm study by

GM, granulocytemacrophage; G, granulocyte; CSF, colony-stimulating factor; NA, not applicable; D, daunorubicin; A, ara-C; E, etoposide; I, idarubicin.

[a] Numbers are doses in mg/m^2 per day × days administered for chemotherapy, and in g/m^2 (Rowe et al., Godwin et al., Stone et al.,) or g/kg (Heil et al., Löwenberg et al., Witz et al., Zittoun et al., and Dombret et al.) for CSFs.

Löwenberg et al.[44] found no difference between any of the four groups. The Zittoun et al. [43] study documented more fluid retention, weight gain, and hypotension in the GM-CSF postchemotherapy arms, whereas Löwenberg et al.[44] found a higher incidence of fever in these arms. Although the authors are not advocating routine use of GM-CSF after chemotherapy, it does appear reasonable to administer GM- or G-CSF if elderly patients contract fever or infection during remission induction.

As did Löwenberg et al.[44] [45] and Zittoun et al.,[43] others have given GM-CSF before or during chemotherapy in an attempt to sensitize blast cells to chemotherapy. [46] [47] [48] With the exception of a study by Büchner et al. [47] that found longer remission in younger patients given GM-CSF, these studies have either shown no difference in CR rate, remission duration, event-free survival, or survival, [43] [44] [45] [46] or a lower CR rate with no effect on remission duration or survival. [48] Pending results of other studies (e.g., a CALGB study of GM-CSF priming in relapsed AML), GM-CSF should not be used for priming purposes. G-CSF has been used less frequently for this approach, but it was not reported effective in a study at M. D. Anderson. [49] It remains to be seen if specific groups might benefit from this approach or whether pretreatment measurements of various biologic parameters will permit prediction of whether a given patient will benefit from priming. [50] Comprehensive reviews of CSFs in AML are available.[51] [52] [53] [54]

USE OF DRUGS OTHER THAN ANTHRACYCLINE OR ARA-C

Randomized trials (Table 54-4) have addressed the usefulness of the purine analogue 6-TG, the mitotic poison vincristine, the topoisomerase II-reactive agent etoposide, and a four-drug combination (POMP) consisting of the purine analogue 6- mercaptopurine, vincristine, methotrexate, and prednisone when added to or integrated with the basic anthracycline + ara-C regimen. A CALGB study in which 427 patients were randomized to receive daunorubicin + ara-C with or without 6-TG found no difference in CR rate, remission duration, or survival between the regimens. [7] The JALSG reported that addition of vincristine to a daunorubicin, behenoyl ara-C, 6-mercaptopurine regimen produced an inferior CR rate in a 252-patient randomized trial. [16]

Results are more disparate with etoposide. Although this drug, like the anthracyclines, stabilizes the DNA-topoisomerase II complex, anthracyclines and etoposide may have different binding sites on the enzyme. The ALSG randomized 264 patients to receive either the standard 3 + 7 regimen or the same regimen plus etoposide (75 mg/m^2 /d on days 17).[55] In remission, patients received their induction regimen but at reduced dose. Although CR rates were statistically the same in both groups (56%, 59%), remission duration was significantly longer (P = 0.01) in the etoposide-treated patients, with median duration of remission of 12 versus 18 months. This finding reflected results in patients younger than age 55 years who also showed evidence (P = 0.03) of a survival advantage if given etoposide (medians of 9 vs. 17 months). The incidence of diarrhea during induction therapy was greater and the period of myelosuppression was longer in the etoposide-treated patients. At the time of publication in 1990, the median follow-up in the living patients ranged from 18 to 60 months; given that patients can be considered potentially cured once 3 years have elapsed from the CR

TABLE 54-4 -- Effect of Drugs Other than Anthracycline + ara-C When Added to or Integrated with Standard Therapy: Results of Randomized Trials

[a] P < 0.05.

date, it would be of interest to know if the studys results were the same after longer follow-up. In contrast to the ALSG, the Medical Research Council (MRC) in the United Kingdom reported no differences in remission duration or survival rates among 1,874 patients randomized to receive daunorubicin + ara-C + 6-TG or the same therapy but with etoposide (100 mg/m^2 daily × 5) replacing 6-TG.[56] Follow-up time appears longer than in the ALSG study, with 11% of the patients followed for 6 years. Other possible reasons for the discrepancies between the ALSG and MRC studies include different postremission therapies, and inclusion of children but not adults older than age 55 years, and of patients with a history of abnormal blood counts and secondary AML in the MRC but not the ALSG study. However, the MRC noted that results were the same in all age groups, whereas the ALSG noted that etoposides effects were most marked in patients younger than age 55 years; and that if there was any advantage for etoposide in the MRC study, it was in patients with secondary, not de novo AML. Given the much larger size of the MRC study, it is reasonable to conclude that any advantage gained by addition of etoposide to the 3 + 7 regimen is relatively small. Of note, neither the MRC nor ALSG found any benefit for etoposide in patients with French American British classification system (FAB) types M4 and M5, although this was once cited as a possibility. Bow et al. combined mitoxantrone + etoposide as initial induction therapy for patients aged 6080 years. [57] In CR, patients received one course of IDAC. The CR rate was 55% (95% confidence interval 4368%), with median remission duration and survivals of 89 months. It is not clear that these results are better than what could be obtained with 3 + 7 because no comparison group was provided.

The SWOG studied the effect of POMP by randomly assigning 131 patients who had been in CR for 10 months after conventional anthracycline + ara-C treatment to continue to receive ara-C for an additional 3 months or to receive three cycles of POMP. [58] With a median follow-up of 9 years, median survival from time of randomization was 34 months in the POMP-treated group versus 19 months in the ara-C-treated group (P = 0.03). Although trials incorporating amsacrine and 5-azacytidine into postremission therapy have not been successful, [19] [59] the SWOG POMP results suggest that other regimens that contain agents that are noncross-resistant with anthracycline + ara-C might prove effective.

TIMING OF CHEMOTHERAPY

Another way in which therapy can be intensified is by repeating courses at more frequent intervals. Woods et al. treated 589 children and adolescents (up to age 21 years) with a five-drug induction regimen (daunorubicin, SDAC, etoposide, 6-TG, and dexamethasone [DCTER], given over 4 days). [60] Patients were randomized either to receive a second mandatory cycle of DCTER identical to cycle 1 beginning on day 10, or to receive the second course in standard fashionthat is, on day 14 if >40% blasts were present on that day but later if they were not. In CR, patients were allocated to receive an allogeneic transplant if they had a human leukocyte antigen (HLA)-matched family donor and otherwise were randomized between an autologous transplant and continued chemotherapy. Although CR rates were similar in the two arms, patients assigned to receive a second course on day 10 had superior event-free survival ($P < 0.001$), with actuarial rates of 42% versus 27% at 3 years, which corresponded to the median follow-up time. Furthermore, those results applied regardless of the type of postremission induction therapy given, illustrating again the connection between induction therapy and post-CR results. Castaigne et al. [61] examined this approach in adults (1560 years of age with de novo AML), randomizing 307 patients to receive either 3 + 7 standard induction or the same but with an obligatory second course (3 days of mitoxantrone + IDAC) beginning on either day 8 or day 20 (double induction), as in the Woods et al. study. Postremission outcome was better in patients given double induction ($P = 0.05$), but there was no effect on survival. Because the Woods et al. study included only a relatively small number (25%) of patients with unfavorable cytogenetic abnormalities, with no comparison of results by cytogenetic group in the two treatment arms, and because the Castaigne et al. study was limited to patients with de novo AML, it remains to be seen if the results of either study will apply to patients with poor prognostic features.

ALLOGENEIC BONE MARROW TRANSPLANTATION

The use of allogeneic bone marrow transplantation (allo-BMT) was first investigated in patients in chemotherapy-resistant relapse. [62] Sustained remissions were observed in 1020% of patients. This led to trials of allo-BMT in first remission. Trials conducted in the early and late 1980s [63] [64] demonstrated that the relapse rate was invariably lower after allo-BMT than after chemotherapy in patients in first remission. This resulted to some extent from the effects of the high-dose chemotherapy, with or without total-body irradiation, used as the preparative regimen, but perhaps to a larger extent from an immunologic graft-versus-leukemia effect. This effect is presumed to exist because of the inverse relationship between the extent of graft-versus-host disease and relapse rate. [65] Despite the lower relapse rate, differences in survival were generally not observed because of

a higher rate of death in CR in transplanted patients (from graft-versus-host disease, veno-occlusive disease, and infection) and perhaps a shorter survival after relapse in transplanted patients. [63] [64]

Table 54-5 examines studies, reported in the 1990s, comparing chemotherapy with allo-BMT. Chemotherapy consisted of one to two courses of HDAC or IDAC in the studies of Zittoun et al.,[67] Cassileth et al.,[68] Reiffers et al.,[70] Schiller et al.,[74] and Archimbaud et al.,[71] and long-term SDAC ± POMP in the studies of Gale et al.[66] and Hewlett et al.[15] However, in the study by Burnett et al.,[69] patients after completion of three courses of postremission therapy were assigned to allo-BMT or randomized between an autologous transplant or cessation of therapy (i.e., half of the control group received no further therapy). In all the studies, except those by Nesbit et al.[73] and Ravindranath et al.,[72] the chemotherapy and transplant patients were younger than 4155 years of age, whereas the latter studies were performed in children and adolescents (021 years of age). The Gale et al. study [66] compared patients who had been reported to the International Bone Marrow Transplant Registry (IBMTR) as having had an allo-BMT with patients given postremission chemotherapy in a German AML Cooperative Study. Although the Gale et al. study [66] used statistical techniques to adjust for the differences in age and cytogenetics (transplant patients younger and more likely to have the t[15;17] translocation) and for the fact that transplant patients had to remain in remission for a few months before they could be transplanted whereas chemotherapy patients did not, the study does not permit the reader to ascertain the total number of patients from whom the 971 transplanted patients were drawn. This is not a problem with the other studies in Table 54-5 . Each of these studies illustrates that as few as 60% of patients with a suitable match will actually receive a transplant. Because the patients with a match who are actually transplanted are usually presumed to have a better prognosis (e.g., are healthier) than patients who, despite the availability of a match, are not transplanted, the two groups are analyzed together in all the studies in Table 54-5 (except Gale et al.[66]) to avoid the bias that would result if the nontransplanted patients were analyzed with the chemotherapy group. Table 54-5 also illustrates that the percentage of patients younger than 4155 years of age who are actually transplanted in first CR is 1234%, with the latter figure being obtained in a single hospital trial. Further discussion of the relatively small impact that allo-BMT has, even in relatively young patients in CR, can be found in reports by Berman et al., [75] Gamberi et al.,[76] and Proctor et al.[77] Table 54-5 illustrates that an advantage in leukemia-free survival (LFS) was noted in three of the nine studies. Because some of the studies were relatively small and the trend is invariably in favor of improved LFS in the allo-BMT patients, it is possible that statistically significant differences would have been documented in more studies had larger numbers of patients been treated. Furthermore, as discussed by Nesbit et al., [73] the standard statistical comparison of the groups masks the poorer earlier but better later LFS in transplanted

patients. Differences between groups treated with allo-BMT or chemotherapy are least when survival becomes the study end point. Indeed, the study of Cassileth et al.[66] (median follow-up, 3 years) found a small, nonsignificant difference favoring chemotherapy, as did a 1992 study by Schiller et al. [74] Hence, the studies in the 1990s are similar to those in the 1980s in that both find that an advantage in LFS does not translate into an advantage in survival in the allo-BMT group. Furthermore, although approximately 90% of allo-BMT survivors are in good health years after the procedure, [78] they are clearly at increased risk for subsequent development of solid cancers.[79] [80] It is unclear if long-term survivors of chemotherapy have a similar risk for the development of secondary solitary tumors. [13] The authors believe that it might be more appropriate to defer further comparisons of chemotherapy versus allo-BMT in first CR until more time has been allowed for both techniques to improve, because both consistently cure only a minority of even younger patients. Some of these techniques are discussed in the section on Investigational Approaches.

The data in Table 54-5 indicate that either allo-BMT or

continued chemotherapy can currently be recommended for patients achieving CR. Might some patients do better after allo-BMT and others better after continued chemotherapy? Age has been the characteristic that best identifies such patients. It has generally been accepted that the risk of mortality after allo-BMT in patients older than age 5560 years is such that benefitrisk considerations favor chemotherapy in such patients, although, as discussed later, use of less intense preparative regimens may extend the upper age limit beyond that for which allo-BMT remains a realistic possibility. Conversely, it has generally been accepted that in patients younger than age 20 years, the risk of allo-BMT is sufficiently low that allo-BMT rather than continued chemotherapy is warranted. [72] [73] [81] Data indicating that LFS in patients transplanted only in second CR is influenced by length of the first chemotherapy-maintained CR suggest that, aside from the extremes of age noted, similar prognostic factors are operative for allo-BMT and chemotherapy. [82] Of particular interest is the prognostic significance of cytogenetics, which is discussed later in the section on Prognostic Factors.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

AUTOLOGOUS TRANSPLANTATION

Only 3060% of patients have an HLA-matched sibling who can serve as a donor for allo-BMT. The 60% figure comes from data reported from transplantation centers and probably reflects referral of patients already screened before referral. [83] There has been a recent surge of interest in allogeneic transplantation using matched but unrelated donors (discussed later). Still, donors will not be available for many patients (e.g., African Americans or other racial or ethnic groups who are underrepresented in transplantation registries), or the wait to identify and prepare an unrelated donor may be unrealistically long. As a result, interest in autologous bone marrow and blood transplantation (auto-trans) in first CR is likely to continue. In this procedure, high-dose chemotherapy regimens similar to those used in allo-BMT are administered. Hematopoietic rescue from the therapy is accomplished by infusion of the patients own marrow or, more recently, peripheral blood stem cells, collected and stored previously. In auto-trans, relapse can theoretically result not only from an inadequate preparative regimen but from the infusion of leukemia cells in the stored blood or marrow that serves as a graft. This possibility has led to use of techniques to purge such cells of residual leukemia cells. These purging strategies include in vitro treatment of the stored marrow with either chemotherapeutic agents [84] or leukemia cell-specific monoclonal antibodies. [85]

Most favorable reports with auto-trans in first CR with or without purging have been from Europe. [86] [87] [88] [89] [90] Frequently, patients appear to have been referred in CR to the auto-BMT center for the express purpose of undergoing the procedure. This raises the possibility of selection bias; that is, the referring physician may have sent a disproportionate number of patients considered likely to do either particularly well or particularly poorly. Because of these uncertainties, several trials comparing auto-trans in first CR with chemotherapy or, less directly, with allo-BMT have been undertaken. Table 54-6 shows results of the most recent of these. Both in the trials of Cassileth et al. (ECOG) [68] and Zittoun et al. (EORTC, GIMEMA), [67] patients without a suitable donor for an allogeneic transplant were randomized to one course of IDAC or HDAC or an autologous marrow transplant (auto-BMT). The trial reported by Ravindranath et al. (Pediatrics Oncology Group) [72] performed in children and adolescents (ages 021 years) was similar except that more HDAC-based chemotherapy was given than in the ECOG and EORTC/GIMEMA trials. In the trial reported by Burnett et al. (MRC), [69] patients in CR received two to three further courses of consolidation therapy and then, if no donor was available for an allo-BMT, patients were randomized to receive an auto-BMT or to stop therapy. Marrow purging was done in the Cassileth et al. [68] and Ravindranath et al. [72] studies. The data in Table 54-6 indicates that, as with allo-BMT, a significant number of patients did not receive auto-BMT even though randomized to do so. This again indicates the need to include all patients assigned to the treatment in the analysis, as was done in all the studies included in Table 54-6 . Furthermore, the MRC and Pediatrics Oncology Group studies demonstrate that 40% of patients eligible for the randomization do not participate in such a trial because of patient or physician choice. Obviously, such patients are excluded from the results in Table 54-6 . With this consideration in mind, the data in Table 54-6 indicate that only one trial [67] demonstrated a superiority in LFS, and no trial demonstrated a superiority in survival, for auto-BMT compared with chemotherapy (or no further therapy in the MRC study). In summary, there is currently no reason to prefer auto-BMT to chemotherapy in first CR.

AML IN THE ELDERLY

The median age of patients with AML has been estimated to be 64 years.[92] The age-specific incidence rate increases until 75 years of age. [92] The poor prognosis of elderly patients with AML reflects in part the association of advanced age with poor performance status, unfavorable cytogenetics, MDR1 protein expression, and a history of abnormal blood counts. Thus, the management of an older patient cannot be considered independent

of these features, although there is a clear-cut effect of age per se.

Therapeutic approaches in older patients with AML have included (1) no therapy, (2) reduced-dose therapy, and (3) use of GM- or G-CSF. Löwenberg et al. randomly assigned 60 otherwise healthy patients >65 years of age to receive the 3 + 7 regimen or supportive care, the latter continuing until leukocytosis of >50,000, symptomatic thrombocytopenia, organ infiltration, or clinical deterioration occurred, at which time ara-C was commenced. [93] The supportive care-only strategy shortened survival and did not decrease the frequency of hospital admission. These data argue against a supportive care-only approach, unless the patient refuses therapy or is bedridden. In an effort to reduce mortality during induction, investigators have administered attenuated doses of ara-C or daunorubicin, or both. Five randomized[8] [9] [94] [95] [96] and two nonrandomized studies[97] [98] have compared this strategy to administration of usual doses in patients aged >6070 years. The results suggest that although dose reduction may decrease the early death rate, at best it will produce an equivalent CR rate. As noted previously, use of GM- or G-CSF after or concomitant with initial therapy has not in general been successful in improving the outcome in older patients. Most newly diagnosed elderly patients should therefore be considered for investigational approaches in the setting of a formal clinical trial. Exceptions would be patients with favorable cytogenetic abnormalities who are younger than 70 years of age with good performance status and normal organ function. Because the same prognostic factors operate in older as in younger patients,[99] at least some of these patients can expect durable remissions after chemotherapy. The same investigational approaches taken to reduce mortality during induction or decrease resistance in elderly patients could be considered in younger high-risk patients, such as those with poor performance status or unfavorable cytogenetics. These approaches are discussed later.

ACUTE PROMYELOCYTIC LEUKEMIA

Acute promyelocytic leukemia is distinguished morphologically by the presence of abnormal promyelocytes containing coarse, large granules and numerous Auer rods.[100] (See Plate 53-7 .) A microgranular variant exists that is identical clinically to typical APL but in which the granules can be resolved only with electron microscopy.[101] (See Plate 53-8 .) Ninety percent of patients with APL have a translocation between the long arms of chromosomes 15 and 17 (t [15q;17q]) that can be recognized by standard cytogenetic analysis. The t(15;17) is specific for APL. This translocation results from transposition of the gene for retinoic acid receptor (*RAR*) on chromosome 17 to an area adjacent to the promyelocytic leukemia (*PML*) gene on chromosome 15.[100] *PML* is a tumor suppressor gene and disruption of its function by the translocation may contribute to the pathogenesis of APL. Messenger RNA for the PMLRAR fusion protein, or the protein itself, can be recognized using polymerase chain reaction (PCR) technology.[100]

The chief clinical feature of APL is a bleeding diathesis that results both from plasmin-dependent primary fibrinolysis and disseminated intravascular coagulation. Until the early 1970s, most patients with APL died of central nervous system or pulmonary hemorrhage. This picture has changed drastically as a result of use of (1) frequent platelet and cryoprecipitate transfusions to maintain platelet counts above 30,000/L and fibrinogen above 200 mg/dL, and (2) introduction of daunorubicin-based chemotherapy that effectively shuts off the coagulopathy. With use of these measures, there is no need for routine use of heparin. [102] CR rates should be 7085%, with the higher rates obtained in patients presenting with low white blood cell counts and relatively higher platelet counts, both predicting a relatively low likelihood of fatal hemorrhage.[102] [103] The likelihood of primary resistance in APL is much lower than in other types of AML. The chemosensitivity of APL is also apparent from the lengthier remissions (median 2 years) seen in APL treated exclusively with anthracycline + ara-C than in similarly treated non-APL subtypes.[104]

The introduction of all-*trans* retinoic acid (ATRA) has further changed the management of APL. When used alone, ATRA produces CR rates of 6590%, but remissions are transient if chemotherapy is not added. Table 54-7 summarizes trials comparing ATRA + chemotherapy with chemotherapy alone. Comparisons were made with a group not receiving ATRA in the studies of Fenaux et al. [105] and Tallman et al., [106] and to a historical chemotherapy group in the other trials. In the Fenaux et

[b]Not given, but early death rates statistically similar in the two groups.

al.,[105] Tallman et al.,[106] Kanamuro et al.,[107] and Frankel et al.[108] studies, induction therapy was to consist solely of ATRA. However, to prevent the ATRA syndrome (see later), patients received chemotherapy when their white count was elevated. In the Estey et al. [109] study, all patients began idarubicin 15 days after ATRA, again depending on their leukocyte count. In all the studies, patients in CR received chemotherapy regardless of whether they had received ATRA during induction. Patient follow-up appears to be longest in the study of Fenaux et al. This study noted a striking difference in event-free survival rates (and, to a lesser extent, overall survival). This reflected a much lower recurrence rate in the ATRA group. This pattern of improvement in event-free survival in ATRA-treated patients out of proportion to an improvement in CR rate has been noted in four of the five studies listed in Table 54-7 . The results suggest that the major effect of ATRA in APL is to enhance sensitivity to chemotherapy.

Questions regarding ATRA in APL revolve around management of the ATRA syndrome and the optimum timing of ATRA administration. The potentially fatal ATRA syndrome develops in approximately 25% of patients and is characterized by fever, dyspnea, pleural and pericardial effusion, and hypotension. [108] There are two schools of thought regarding management. The first considers the leukocytosis often induced by ATRA a risk factor for development of the ATRA syndrome, and suggests adding chemotherapy whenever leukocytosis develops.[105] The second, popularized by the group at Memorial Sloan-Kettering in New York, does not regard leukocytosis as predictive of the ATRA syndrome,[108] [110] and adds dexamethasone 10 mg IV q6h, but not chemotherapy, at the first clinical sign of potential ATRA syndrome. Other toxicities of ATRA are rash, hearing loss, and headache, the latter perhaps reflecting pseudotumor cerebri possibly caused by ATRA-induced venous thromboses. Regarding timing, the usual approach has been to restrict use of ATRA to induction therapy. The Tallman et al. study [106] randomized patients in CR after two courses of consolidation therapy to receive ATRA or no further therapy. Hence, the study consisted of four groups: (1) ATRA induction, ATRA + chemotherapy post-CR; (2) chemotherapy induction, ATRA + chemotherapy post-CR; (3) ATRA induction, chemotherapy post-CR; and (4) chemotherapy induction, chemotherapy post-CR. Relapse rates were similar in groups 13 and highest in group 4 ($P < 0.00001$). This result clearly demonstrated the beneficial effects of ATRA but showed that it was irrelevant whether ATRA was used during induction or during remission.

The optimal chemotherapy for APL is also under discussion. A SWOG study [104] suggested that long-term outcome was better in patients who received more daunorubicin rather than more ara-C. Estey et al.[109] reported a trial in which ara-C was omitted, permitting use of more anthracycline. Results were better than those reported in historical control subjects, suggesting the feasibility of this approach. It is unclear whether chemotherapy should begin only when the patient is in

ATRA-induced CR, or together with ATRA during initial induction. A randomized study by Fenaux et al. is addressing this issue. To date, CR rates are over 90% in both groups but, as usual, lower in elderly patients. [105]

Use of molecular testing to detect the t(15;17) translocation is important in two phases of the management of APL. First, such testing is mandatory in cases in which a coagulopathy or morphologic appearance suggests APL but in which the t(15;17) cannot be demonstrated on standard analysis. [111] This is particularly important because APL is, together with inv(16) AML and t(8;21) AML, among the curable types of AML, particularly if treated with ATRA + anthracyclines. The second use of molecular testing is in follow-up of patients in remission. After ATRA followed by three courses of chemotherapy, >90% of patients should be PCR negative (i.e., no evidence of the t[15;17] on molecular testing done at a sensitivity of 10^{-4}).[112] [113] If not PCR negative or if a negative PCR becomes persistently positive, therapy should be changed (e.g., an allo-BMT). [112] [113] Likewise, once two negative PCRs are obtained several months apart, therapy can probably be stopped. [113]

Recurrence in APL, although likely to be relatively infrequent, remains difficult to treat. Second CRs after ATRA are common if the last exposure to ATRA occurred greater than 612 months before relapse, but long-term CRs are rare. [115] Three areas of research in this area are of interest. First is the use of new retinoids, particularly 9-*cis*-retinoic acid and liposomal ATRA. The former binds to retinoic acid receptors that remain unbound after standard oral ATRA, [116] whereas use of liposomal ATRA permits maintenance of serum tretinoin concentrations longer than possible with oral ATRA. [117] Second is the use of anti-CD33 monoclonal antibodies bound to toxins, with the antibodies intended selectively to target the APL cells. [118] Third is the use of arsenicals (e.g. arsenic trioxide, As_2O_3). A report from China[119] cited a CR rate of 9 of 10 in patients with relapsed APL refractory to ATRA + chemotherapy, although the definition of refractory is somewhat unclear.

PROGNOSTIC FACTORS WITH STANDARD THERAPY

It is important to note that the results of standard therapy described in earlier sections, namely 6070% CR rates with <20% of all patients achieving long-term disease-free survival, are average results. The study of prognostic factors is important because it may permit recognition of groups of patients with outcomes that differ from the average. If these outcomes are sufficiently favorable, standard therapy might be sufficient. Knowledge of the likely prognosis of patients treated in an experimental study had they received standard therapy is also crucial in interpreting results of such trials.

Prognostic factors (Table 54-8) can be divided into those primarily associated with early death and those primarily associated with resistance to chemotherapy. The principal factors associated with early death are older age, poor pretreatment performance status, and abnormal organ function. [120] The effect of age is also mediated through the association of older age with unfavorable cytogenetics and a history of abnormal blood counts. The characteristic most associated with sensitivity or resistance to standard chemotherapy is pretreatment leukemia cell karyotype (cytogenetics). [121] [122] [123] [124] Excluding the translocation between the long arms of chromosomes 15 and 17 (t[15;17]), which is pathognomonic of APL, three cytogenetic groups can be distinguished. In the first group are patients with either a percentric inversion of chromosome 16 (inv[16] associated with FAB subtype M4EO) or a translocation between chromosomes 8 and 21 (t[8;21] associated with FAB subtype M2). These patients have CR rates of 90% and, more important, 4050% can be cured with standard chemotherapy. [121] [122] [123] [124] Given that these two groups share a better prognosis, the finding that the pathogenesis of these two types of AML likely involves the same core binding transcription factor (AML-1 protein family) is of interest. [125] Patients with a normal karyotype (about one third of patients, making this the most common cytogenetic finding) constitute an intermediate group, with a CR rate of 6070% but a long-term disease free survival rate of only 1025%. [121] [122] [123] [124] Patients with other cytogenetic findings, particularly with complex abnormalities involving chromosomes 5 or 7, have CR rates of 50% and are essentially incurable with standard therapy. [121] [122] [123] [124] The unfavorable prognosis of secondary AML (i.e., developing after chemotherapy for another malignancy) is largely due to its association with unfavorable cytogenetic abnormalities, [126] in particular abnormalities of chromosomes 5 or 7 in patients previously treated with alkylating

TABLE 54-8 -- Established Prognostic Factors for Response to Standard Chemotherapy in Newly Diagnosed Acute Myeloid Leukemia

Factor	Principal Effect on	Favorable if	Complete Remission Rate		Long-term Disease-Free Survival		Reference
			Favorable Group	Unfavorable Group	Favorable Group	Unfavorable Group	
Age	Early death	Younger (e.g., <60 y)	70%	50%	1520%	5%	[120]
Performance status	Early death	Zubrod <3	70%	30%	1520%	<5%	[120]
History of abnormal blood counts	Resistance to therapy	Absent	70%	50%	1520%	5%	[121]
Cytogenetics	Resistance to therapy	inv(16) or t(8;21)	90%	30%	4050%	<5%	[121] [122] [123] [124]
History of chemotherapy for prior malignancy	Resistance to therapy	Absent	6070%	4050%	10%	5%	[126]
MDR expression on blasts	Resistance to therapy	Absent	67%	34%	Same in both groups		[130]

MDR, multidrug resistance.

agents and a deletion of the long arm of chromosome 11 (11q) in patients treated with topoisomerase II-reactive drugs. In contrast, patients with t(15;17) appear to do equally well regardless of whether it develops de novo or as secondary AML. [127] Similarly, the poor prognosis of patients with the rare AML subtypes M6 (erythroleukemia) and M7 (megakaryocytic leukemia) probably largely reflects the association of M6 and M7 with unfavorable cytogenetic abnormalities. [128] [129] The most recently recognized, well established prognostic factor is expression of the multidrug resistance glycoprotein (MDR1) in patients older than age 55 years. [130] This effect is independent of cytogenetics. Although not predictive of survival or relapse-free survival once in CR, MDR1 expression was associated with resistance to, rather than early death after, chemotherapy. During the next few years, increasing numbers of prognostic factors that, like MDR1, are based on laboratory rather than clinical parameters, are likely to be identified. Examples of such prognostic factors awaiting further confirmation include expression of (1) the thrombopoietin receptor (reported unfavorable for CR duration), [131] (2) the immunoglobulin heavy chain gene rearrangement (unfavorable for CR and survival), [132] (3) expression of the transcription factor GATA-1 and the stem cell leukemia gene (unfavorable for CR and survival), [133] and (4) bcl-2 protein and WT-1, a transcription factor regulating bcl-2 (unfavorable for survival). [134] Assays measuring chemotherapy-induced apoptosis (mediated by bcl-2 and other similar proteins) are also likely to be tested for prognostic significance. [135] Finally, low levels of the retinoblastoma gene protein have also been associated with poorer prognosis. [136] It is of course important to consider the effect of prognostic factors when analyzing the therapeutic trials in AML listed in Table 54-2 when taken together. For example, elderly patients (>55 years) with de novo AML, with normal or favorable karyotypes, and whose blasts do not express MDR1, had an 81% CR rate, considerably higher than the average 50% CR rate for patients this age. [130] However, these patients with a favorable prognosis constituted only 25% of all elderly patients with de novo AML and only 20% of all elderly patients. Similarly, <10% of patients will have inv(16) or t(8;21).

The prognostic factors noted previously were largely identified in patients given standard induction and postremission therapy. An important question is whether these same prognostic factors are equally important regardless of which treatment is given. This question has been addressed for HDAC in two studies. [137] [138] Both found that HDACs biggest impact was in patients with t(8;21) or inv(16) in whom cure rates well in excess of 50% can be expected with HDAC-containing regimens. In the CALGB [137] but not the M. D. Anderson study, [138] there was evidence that both IDAC (400 mg/m^2 daily × 5) and HDAC improved outcome in patients with a normal karyotype. In these patients however, even with HDAC, the cure rate was estimated to be considerably less than 50%. Both the CALGB and M. D. Anderson studies found no beneficial effect of HDAC in patients with other karyotypes. Preliminary results from the SWOG [139] suggest that cytogenetics is prognostically significant after allo-BMT. However, data on the effect of cytogenetics on results of allo- or auto-BMT have come primarily from the British MRC. The MRC has reported that cytogenetics and marrow blast percentages after the first course of induction therapy are similarly associated with outcome regardless of whether patients subsequently receive chemotherapy, auto-BMT, or allo-BMT. [140] [141] Specifically, allo-BMT and chemotherapy do equally poorly in patients with unfavorable karyotypes. Any small advantage for allo-BMT is in patients with a normal karyotype, whereas patients with inv(16) or t(8;21) do worse after allo-BMT than after chemotherapy. Trials comparing auto-BMT versus stopping therapy after achievement of CR have indicated no differences in LFS in patients with unfavorable

karyotypes. In patients with favorable karyotypes, the lower relapse rate after auto-BMT was counterbalanced by a higher CR rate after salvage therapy in the stop group, whereas in the standard risk group the lower relapse rate with auto-BMT was counterbalanced by a higher death rate in CR. One can conclude from these studies that new therapies are needed for most patients with AML, except patients with inv(16), t(8;21), or APL. With these considerations in mind, Figure 54-1 illustrates a suggested approach to the management of newly diagnosed AML.

Prognostic factors must also be considered when assessing the results of all clinical trials. Specifically, many trials exclude

Figure 54-1 Suggested management of newly diagnosed acute myeloid leukemia. AHD, antecedent hematologic disorder (i.e., history of abnormal blood counts); AML, acute myeloid leukemia; APL, acute promyelocytic leukemia; ATRA, all- *trans* retinoic acid; BMT, bone marrow transplant; CR, complete remission; HDAC, high-dose ara-C; MDR1, multidrug resistance protein; PCR, polymerase chain reaction; PS, performance status; Rx, treatment; SDAC, standard-dose ara-C.

patients older than age 70 years or with a history of abnormal blood counts, or secondary AML. The patients excluded can constitute up to 50% of patients with newly diagnosed AML. The invariable effect of such exclusions is to make results appear more favorable. [142]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

TREATMENT OF REFRACTORY/ RELAPSED AML

Recurrence of AML occurs in most newly diagnosed patients who attain CR. The most important predictor of outcome after recurrence is length of first CR. [143] At one extreme of the spectrum are patients whose initial CR lasted 2 years; at the other extreme are patients with first CRs lasting <1 year. If the regimen used initially is repeated, 5060% of the former but only 1030% of the latter patients achieve CR. More important, this approach may result in a 3-year disease-free survival rate of 2025% in patients with a long first CR but virtually a zero 3-year survival rate in patients with a short first CR. The prognosis of patients who fail initial induction therapy (with failure usually defined as no CR after two courses) is quantitatively similar to that of the patients with the short first CR. There is no indication that HDAC or the commonly used mitoxantrone + etoposide regimen improves outcome in patients with short or no first CRs, with the latter patients called primary refractory. [143] In contrast, data from the City of Hope[144] and the IBMTR[145] suggest that results are better in primary refractory patients given an allo-BMT. The general consensus is that patients younger than age 55 years whose AML is primary refractory, or recurs after a CR of <12 years after standard or HDAC-containing chemotherapy, should receive an allo-BMT if a suitable donor is available

Figure 54-2 Suggested management of relapsed acute myeloid leukemia. BMT, bone marrow transplant; CR, complete remission; HDAC, high-dose ara-C.

(matched or unmatched). Allo-BMT should not be delayed until second CR. [146] The IBMTR compared chemotherapy with allo-BMT as therapy in second CR. [147] Subject to the criticism that the transplanted patients were referred to IBMTR hospitals because they were thought to be relatively healthy, the results indicate that LFS was superior with transplantation if the patient was younger than 30 years of age with an initial CR 1 year (3-year actuarial LFS rates of 41% vs. 17%), or older than age 30 years with an initial CR <1 year (rates of 18% or 7%). Other patients had similar outcomes with allo-BMT and chemotherapy. Results from the GIMEMA[148] group also suggest a superiority for allo-BMT in second CR. The British MRC investigated the usefulness of auto-BMT in second CR. [149] Patients in first CR after four cycles of chemotherapy had storage of autologous marrow, with half the patients then randomized to receive an auto-BMT and the other half to receive the procedure only in a second CR. Thus, in second CR, patients would either receive or not receive auto-BMT, the latter patients having had an auto-BMT in first CR. There has been no difference in outcome in second CR among patients who did or did not receive an auto-BMT at this time.

Figure 54-2 illustrates an approach to management of refractory or relapsed AML. If an allo-BMT cannot be performed, patients with first CRs of >1 year should receive an induction regimen similar to that used initially. In CR, however, they can be offered investigational therapies. Patients with shorter first CRs or who are refractory to initial therapy should be offered investigational therapies at relapse if allo-BMT is not an option.

As with chemotherapy, the prognosis after relapse following allo-BMT depends heavily on duration of CR. [150] [151] Data suggest that remissions in some patients can be produced by the administration of G-CSF[152] or by donor lymphocyte infusions, [153] which presumably stimulate the graft-versus-leukemia effect. If such therapy is unsuccessful and the patient had a CR of >1 year after the previous allo-BMT, consideration should be given to a second allo-BMT. Otherwise, the patients should be referred for investigational therapy.

INVESTIGATIONAL APPROACHES

The ultimate role, if any, of the approaches described here awaits further patient entry and correlation of results with standard prognostic factors.

Chemotherapy

Topoisomerase I Inhibitors

These represent a new class of agents. Topotecan, the prototype of such agents, has been found to have single-agent activity [154] and is being combined with other active agents.[155] Toxicities of such therapy are myelosuppression and mucositis. Other drugs of this class are under investigation (e.g., 9-aminocamphothecin).

MDR Reversing Agents

Given the association of MDR1 expression with resistance to chemotherapy in elderly patients with AML, there has been interest in overcoming the MDR1-positive phenotype with drugs such as cyclosporine, quinine, and PSC-833.[156] List et al. reported that cyclosporine + daunorubicin + HDAC gave a CR rate of 67% in 15 patients with AML, most of whom had first remissions at <1 year or were primary refractory.[157] It was unclear if the responses reflected reversal of MDR or rather administration of effectively higher doses of daunorubicin consequent to cyclosporines blocking of the hepatic excretion of the drug. In a randomized study, Wattel et al.[158] noted that, provided their blasts expressed MDR, patients had a better CR rate and survival if they were given quinine in addition to mitoxantrone + IDAC. This result suggested a specific effect on MDR-mediated drug resistance. A qualitatively similar result was reported by Solary et al. [159] PSC-833, a cyclosporine analog with high anti-MDR1 and no immunosuppressive effects, was tested with mitoxantrone plus etoposide in a phase I trial. [160] Addition of PSC necessitated a 66% reduction in doses of these drugs. PSC-833 is undergoing phase II and III testing in cooperative group settings.

Toxins Bound to Antibodies

In this approach, a toxin is conjugated with a monoclonal antibody specific for AML blasts to target AML cells selectively. A frequently used antibody is anti-CD33. CD33 is expressed on the surface of most AML blasts, but not on the surface of normal stem cells. Remissions with this approach have been reported in relapsed/refractory cases.[161]

Fludarabine

The purine analog fludarabine can increase formation of ara-CTP by myeloblasts. [162] The combination of fludarabine + ara-C + G-CSF was shown equivalent to idarubicin + ara-C in one study.[133] As with HDAC itself, the fludarabine + ara-C combination may be most useful in patients with ara-Cresponsive disease.

Allogeneic Transplantation

Minitransplant

Giralt et al. demonstrated that engraftment of allogeneic hematopoietic progenitors could be accomplished with purine analog (fludarabine or 2-chlorodeoxyadenosine)-containing chemotherapy without need for the usual myeloablative preparative regimen. [163] The patients treated had a median age of 59 years and ranged up to age 71 years. This approach relies for its efficacy on graft-versus-leukemia effect and is being tested further particularly in older patients or patients with poor performance status, who would not otherwise be eligible for allo-BMT.

Immunologic Approaches

In 1993, Giralt et al.[152] demonstrated that G-CSF could produce remissions in AML that had recurred after allo-BMT. Although the remissions were brief, the results demonstrated the feasibility of manipulation of immune effector cells in the graft. Another approach has involved infusion of allogeneic lymphocytes. [153] Although to date most effective in chronic myeloid leukemia, donor lymphocyte infusions can produce remissions after recurrence of AML following allo-BMT and, more important, will lead to further efforts at stimulating the graft-versus-leukemia effect.

Unrelated Donor Transplants

Although only 3040% of patients have an HLA-compatible sibling, the development of a large computerized registry has increased the likelihood of finding at least an HLA-A, B, DR matched donor from 10% in 1987 to 64% in 1995.[164] The median time from initiation of the unrelated donor search to transplantation is 56 months. [165] The IBMTR[166] reported that compared with a transplant from an HLA-identical sibling donor, the relative risk of treatment failure among patients with acute leukemia in first CR or chronic myeloid leukemia was 2.43 (all *P*-values <.02) with a oneHLA antigen-mismatched related donor, 3.79 with a twoantigen-mismatched related donor, 2.11 with an HLA-matched unrelated donor, and 3.33 with a oneHLA antigen-mismatched unrelated donor. Among patients with more advanced leukemia, relative risks for a oneantigen-mismatched related donor were 1.18 (*P* = NS), and 1.39 (*P*= 0.002) for an HLA-matched unrelated donor, with of course overall results for advanced leukemia being worse than for leukemia in CR. Seattle investigators [165] noted actuarial LFS rates of 12% at 5 years for relapsed AML in patients receiving unrelated donor transplants, ranging from 30% for patients transplanted in relapse but with <30% blasts in marrow and none in blood, to 0% at 2 years for patients with blasts in blood. Patient outcome was improved if the size of the graft was increased.

Timing of Transplantation

Anderson et al.[167] demonstrated the feasibility of allo-BMT as initial therapy in patients with secondary AML with low blast counts. Such patients of course would be expected to have low CR rates with standard remission induction therapy.

Autologous Transplantation

Blood count recovery appears quicker when blood rather than marrow is the source of the stem cells. [168] The relative ease with which peripheral blood stem cells can be collected suggests the possibility of repeated stem cell collections to support multiple cycles of high-dose regimens, particularly in patients with chemotherapy-sensitive disease.

Supportive Care

Because fungal, particularly *Aspergillus*, infections are a leading cause of mortality in AML, [3] [10] it will be important to determine the value of liposomal amphotericin preparations. Finally, the availability of GM- and G-CSF may permit collection of sufficient granulocytes from normal donors [169] [170] to test the utility of prophylactic or therapeutic granulocyte transfusions, particularly in high-risk patients such as the elderly or those with impaired performance status.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

MONITORING OF MINIMAL RESIDUAL DISEASE

Approaches to detect minimal residual disease in patients in CR by more sensitive criteria are in progress. These include fluorescence in situ hybridization (FISH) [171] and PCR.[172] [173] Whereas the usual cytogenetic techniques are logistically limited to analysis of approximately 25 cells, FISH, and especially PCR, permit

examination of a several-log higher number of cells to detect residual cytogenetic abnormalities. Although use of PCR is established in APL, [112] [113] [114] in t(8;21) AML it has been demonstrated that despite positive PCRs patients can remain in CR for years. [174] Hence the value of these techniques may vary depending on the cytogenetic abnormality being monitored.

Chapter 55 - Acute Myeloid Leukemia in Children

Howard J. Weinstein

The acute myeloid leukemias (AML) represent a clinically and biologically heterogeneous group of diseases caused by the malignant transformation of a myeloid stem cell or progenitor cell. [1] The proliferative advantage of the leukemic stem cell coupled with an impairment in differentiation leads to the accumulation of immature or blast cells in the bone marrow. The blasts eventually suppress normal hematopoiesis and infiltrate other organs and tissues. AML has been classified into eight subtypes (M0M7) by a French-American-British (FAB) cooperative group based primarily on blast cell morphology and reactivity with histochemical stains (see Chap. 53).

AML accounts for about 20% of acute leukemias in children and 80% of acute leukemias in adults. The biology of AML, and its response to chemotherapy, is quite similar in children and young adults (age <50 years). One difference is the more frequent extramedullary involvement of AML in infants and young children compared to adults.

In contrast to cure rates for childhood acute lymphoblastic leukemia (ALL), cure rates for AML have improved only modestly over the past two decades. [2] [3] Approximately 40% of children treated with chemotherapy alone appear to be cured of their leukemia. The outcome is somewhat better for children who receive bone marrow transplants from histocompatible sibling donors in first remission. [2] Greater understanding of the biologic and genetic heterogeneity of the acute myeloid leukemias is beginning to lead to better classification schemes and new therapeutic strategies. [4] [5] [6]

EPIDEMIOLOGY

Approximately four hundred new cases of AML are diagnosed in children each year in the United States. [7] In contrast to the early age peak (34 years) in childhood ALL, the annual incidence of AML is quite constant from birth throughout the first 10 years with a slight peak in late adolescence. AML appears to account for the majority of the very rare cases of congenital leukemia. The predominance of AML in this age group may in part be due to the inclusion of infants with the transient myeloproliferative syndrome associated with Down syndrome (see discussion later in this chapter).

The incidence and subtypes of acute leukemia in children do not have significant geographic variation. In Japan and several African countries, however, there are more cases of childhood AML than ALL.[8] [9] Patterns of presentation also vary. For example, an unusually high percentage of children diagnosed with AML in Turkey and several African countries present with myeloblastomas or chloromas involving the orbital area. [10]

ETIOLOGY

As in other forms of leukemia, the etiology of AML is unknown. The vast majority of children with AML have no obvious predisposing factors. Known risk factors include several congenital/genetic disorders, ionizing radiation, and certain drugs or toxic exposures (Table 55-1).[11] [12] [13] [14] [15] [16] [17] [18] [19] [20] [21] [22] [23] [24] For example, occupational exposure to benzene and treatment with alkylating agents or topoisomerase-2-inhibitors (especially the epipodophyllotoxins) for malignant or benign disorders are associated with an excess incidence of AML. [21] [24] In contrast to alkylating agent-induced AML, the secondary leukemias observed after treatment with etoposide or teniposide are usually of the FAB M4 or M5 subtypes, have a shorter latency period (24 years), and usually have chromosomal translocations involving band 11q23(MLL gene rearrangement). MLL gene rearrangements are also present in precursor B cell ALL (especially in infants), [25] [26] [27] and de novo AML of the FAB M4 and M5 subtypes. The likelihood of developing secondary AML from epipodophyllotoxin therapy appears to be schedule- and cumulative-dose-dependent. Increased risk has been noted with twice-weekly or weekly administration of etoposide/teniposide. [24]

TABLE 55-1 -- Congenital Disorders or Acquired Factors Predisposing to AML

Genetic factors
Down syndrome
Fanconi anemia
Blooms syndrome
Neurofibromatosis type I
Klinefelter syndrome
Turner syndrome
Congenital bone marrow failure syndromes
Kostmann syndrome
Diamond-Blackfan anemia
Drugs
Benzene
Alkylating agents
Epipodophyllotoxins
Ionizing radiation
Myelodysplastic syndromes

Children who were exposed to radiation from the atomic bombs in Japan had an increased incidence of leukemia, but no excess of leukemia was noted in Japanese children who were exposed prenatally to the atomic explosions. [20] Several studies have addressed whether exposure to low-frequency, nonionizing radiation (e.g., electromagnetic fields) is leukemogenic. [22] A recently reported study did not find an increased risk of acute lymphoblastic leukemia in children exposed to residential magnetic fields. [23]

Unusual susceptibility to AML has been observed in monozygotic twins and in children with certain genetic disorders. The increased concordance of acute leukemia observed in identical twins (approximately 15%), especially during the first year of life, results from transplacental passage of a single leukemic clone rather than a genetic predisposition in some cases. [11] Patients with diseases associated with chromosome fragility and impaired DNA repair mechanisms (e.g., Fanconis anemia and Blooms syndrome) are predisposed to develop AML. [9] Children with congenital disorders of granulopoiesis and erythropoiesis, such as Kostmanns syndrome and Diamond-Blackfan anemia, are also at increased risk for developing AML. [12] [13]

Children with Down syndrome (trisomy 21) have about a 15-fold increased risk of developing leukemia during the first 10 years of life. [14] From birth through 3 years of age, the incidence of AML (especially FAB M7) is much greater than ALL, and thereafter the ratio of ALL to AML follows the usual childhood distribution. [15]

Some neonates with trisomy 21 may manifest a transient myeloproliferative syndrome (TMS). This intriguing syndrome is diagnosed in neonates with trisomy 21 during the first week of life. [15] [16] [17] In most cases it cannot be readily distinguished from congenital AML. It is nearly always associated with complete clinical and hematologic recovery without therapy within weeks to two months. Infants with TMS may have very elevated white blood cell counts with circulating blasts (megakaryoblasts or erythroblasts), hepatosplenomegaly, and an increased percentage of blasts in the bone marrow. In several cases, the blasts have been shown to be clonal in origin. [15] [16] TMS has also been observed in phenotypically normal newborns who were mosaic for trisomy 21.

Data from retrospective surveys indicate that 2030% of infants who had TMS will eventually develop AML (mostly M7) before 4 years of age. [17] It is not known whether this is a recurrence of the original disease or the appearance of a new disease. Prior to the onset of AML, there is often a several-month prodrome characterized by thrombocytopenia and bone marrow myelofibrosis with dysplastic megakaryocytes. An unexpected finding has been the high cure rate of AML in children with Down syndrome, including those who had TMS as neonates. [28] [29] This may in part be due to an increased in vitro sensitivity of Down syndrome myeloblasts to cytarabine and daunorubicin and the greater generation of ara-C triphosphate (ara-CTP) compared to myeloblasts from children without Down syndrome. [30]

Children with neurofibromatosis (NF 1) are at increased risk for developing acute and chronic myeloid leukemias as well as certain benign and malignant tumors that primarily arise in cells derived from the embryonic neural crest. [18] In patients with NF 1 and leukemia, loss of both NF-1 alleles in bone marrow blasts has been detected in some cases. [19] These data are consistent with a tumor-suppressor function for the NF-1 gene. Inactivation of NF 1 may contribute to leukemogenesis by dysregulating the Ras signaling pathway.

CELL OF ORIGIN AND BIOLOGIC PROPERTIES OF AML

Cytogenetic studies and assays using X-linked polymorphisms have confirmed the clonal nature of AML. [31] [32] [33] The chromosomal changes are varied but predominantly involve balanced translocations, deletions, and inversions. [33] These cytogenetic findings are restricted to the leukemic cells. The bone marrow karyotype returns to normal in complete remission. At relapse the original clone reappears (plus or minus additional genetic changes), suggesting that the leukemic clone was suppressed but not eliminated by treatment. In very rare situations, persistent clonal hematopoiesis has been observed in remission. [31] [34] The significance of a clonal remission is not known but in some cases may be due to skewed lyonization.

The precise target in hematopoiesis for the transforming event in AML has been the subject of investigation and controversy. Theoretically it could occur at any stage from the pluripotent stem cell to a committed precursor such as a myeloblast. [1] [35] Markers of clonality have been useful in addressing this issue. In several adult patients with AML, the clonal marker has been detected in both erythroid and granulocytic cells suggesting transformation of a less-committed progenitor (colony-forming unit granulocyte, erythroid, megakaryocyte, macrophage [CFU-GEMM]). [34] Recent data obtained from inoculating human adult AML cells in NOD/SCID mice suggests that a primitive normal stem cell rather than a committed progenitor is the target for leukemic transformation. [1] In the few studied pediatric cases of AML, the clonal marker has been noted only in cells of the granulocytic or monocytic lineage, suggesting involvement of a more committed progenitor (granulocyte-macrophage colony-forming unit [CFU-GM]). [34]

The principal defect in AML appears to be an arrest in the normal differentiation pathway of myeloid progenitors or precursors rather than abnormal growth kinetics. [4] [36] The molecular mechanism that underlies these blocks in differentiation is largely unknown. Most AML cells maintain their requirement for hematopoietic growth factors for sustained in vitro growth, although a minority exhibit spontaneous growth. [35] In the case of acute promyelocytic leukemia (FAB M3), characterized by the fusion of the PML and RAR alpha genes as a result of the translocation t(15;17), cells are arrested at the promyelocyte stage but the block in differentiation can be overcome (in vitro and in vivo) by pharmacologic doses of all-trans-retinoic acid. [37] Other attempts to treat patients with AML with other differentiating agents (e.g., vitamin D analogues and low-dose cytarabine) have been of limited success. [38]

CLASSIFICATION

Careful examination of the bone marrow aspirate is required to establish the diagnosis of acute leukemia because as many as

TABLE 55-2 -- FAB Subtypes of Recurring Chromosome Abnormalities, and Clinical Features

FAB Subtype	% of Total	Chromosome Abnormality	Clinical or Laboratory Features
M0	2	5 or del (5), 7 or del (7)	Blasts often express CD34 and terminal deoxynucleotidyl transferase (TdT)
M1	1018		
M2	2729	t(8;21) (q22;q22) t(6;9) (p23;q34)	Myeloblastomas (especially orbital)
M3	510	t(15;17) (q22;q21)	Disseminated intravascular coagulation
M4eo		inv(16) (p13;q22) or t(16;16) (p13;q22)	CNS leukemia, eosinophilia
M4	1625	t(9;11) (p22;q23) t(11;19) (q23;p13.1) t(10;11) (p12;q23)	Congenital leukemia and young age (<2 yrs), extramedullary leukemia (especially leukemia cutis), hyperleukocytosis
M5	1322	t(9;11) (p22;q23) t(11;19) (q23;p13.1) t(10;11) (p12;q23)	Congenital leukemia and young age (<2 yrs), extramedullary leukemia (especially leukemia cutis), secondary leukemia after epipodophyllotoxins, hyperleukocytosis
M6	13		
M7	48	t(1;22) (p13;q13)	Infants <1 year with t(1;22), myelofibrosis, Down syndrome
All		+8	Prior myelodysplastic syndrome
All		5 or del (5) (q11-q35)	Older adults, toxic exposure, prior myelodysplastic syndrome
All		7 or del (7) (q22-q36)	Older adults, toxic exposure, prior myelodysplastic syndrome

20% of patients with acute leukemia do not have circulating blasts at diagnosis. Also, the morphology of leukemic cells in the peripheral blood may differ from that of cells in the bone marrow. Various methods are available for characterizing the blast cell population in patients with acute leukemia These include morphologic interpretation of Romanowsky-stained specimens in conjunction with cytochemistry, chromosome analysis, immunophenotype, and molecular genetics. Precise diagnosis and classification are essential to successful treatment and biologic investigation of the childhood leukemias. [3]

AML has been traditionally classified by the pattern of myeloid lineage differentiation noted in the bone marrow (e.g., myeloblastic or granulocytic, monocytic, erythroid, or megakaryocytic lineage). In 1976, the FAB Cooperative group proposed a classification system based primarily on morphologic and cytochemical features of the blast cells with subsequent revisions to include immunophenotypic or electron microscopic confirmation for the M0 and M7 subclasses. [34] [35] [36] [37] [38] [39] [40] [41] The FAB group recognizes eight subgroups of AML and also requires a minimum of 30% bone marrow blasts for the diagnosis of AML. This is an arbitrary cutoff that is sometimes problematic. For example, patients with a t(8;21) may have <30% bone marrow blasts but are as likely to achieve a durable remission as are patients with >30% bone marrow blasts and a t(8;21).[42] For treatment purposes, these patients should be considered to have AML rather than a myelodysplastic syndrome (MDS).

The distribution of FAB subtypes in most children is similar to that seen in young adults with AML (Table 55-2) except for children under 2 years of age, who tend to have M4 or M5.[43] [44] Infants and toddlers with M4 and M5 often present with hyperleukocytosis and extensive extramedullary leukemia, especially leukemia cutis and central nervous system (CNS) disease. Because of the rarity of the M0 subtype in children, no special clinical or biologic associations have been noted thus far. The M7 subtype is most common in children younger than 3 years of age, especially those with Down syndrome.[45]

IMMUNOPHENOTYPE ANALYSIS IN AML

Normal hematopoietic cells undergo changes in expression of cell surface markers as they mature from stem cells into cells of a committed lineage. Monoclonal antibodies have been developed that react with lineage-specific and stage-specific lymphoid and myeloid activation and differentiation antigens. [46] By using a combination of monoclonal antibodies recognizing B-cell, T-cell, and myeloid antigens, it is possible to confirm the diagnosis of AML and differentiate AML from ALL if morphology and histochemistry are inconclusive (<15% of cases). Several classification schemes of AML based on immunophenotype have been proposed, but these do not provide additional prognostic or treatment-related information beyond that of the FAB system. [47] [48]

Several unusual immunophenotypes of AML blasts have been described that are FAB subtype-specific and also associated with unique chromosomal changes. For example, M2 AML with t(8;21) is characterized by expression of the myeloid and stem cell antigens CD13, CD15, CD34, HLA Dr, and expression of the B cell antigen CD19 and the neural adhesion molecule CD56. [49] In a recently published adult AML study, CD56-positive AML with t(8;21) was associated with shorter remissions and overall survival compared to other cases with t(8;21). [49]

It has been estimated from several studies that about 515% of patients with acute leukemia have morphologic, cytochemical, immunophenotypic, or genetic evidence of more than one hematopoietic lineage. Approximately 1025% of AML patients demonstrate lymphoid antigen expression on myeloid blasts and similarly 425% of ALL patients demonstrate expression of at least one myeloid antigen on the blast cell surface. [47] [48] [50] In most of these cases of hybrid or acute mixed-lineage leukemia there is co-expression of lymphoid and myeloid markers on the same blast, but in rare cases there have been two distinct populations of blasts. [50] The pathogenesis of these mixed-lineage leukemias remains poorly understood. They may represent a leukemic transformation in a primitive stem cell or the aberrant expression of a lymphoid gene in a myeloid leukemia.

In a pediatric study, 14 of 16 patients with lymphoid antigen-positive AML expressed a T-cell marker. [50] Interestingly, several of these patients had a poor response to AML induction therapy but subsequently responded to an ALL induction regimen. Mixed-lineage expression in pediatric AML, however, has not been shown to have prognostic significance. [47] [48] Children with AML whose blasts express lymphoid antigens should be treated on AML protocols.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

GENETICS OF AML

The chromosomal abnormalities detected in blasts from the majority of children with AML are important for diagnostic and prognostic purposes, and equally important for cloning genes involved in leukemogenesis. [33] [51] [52] Common repetitive cytogenetic abnormalities observed in cases of AML are listed in Table 55-2 in relation to the FAB classification. Monosomies or deletions of chromosomes 5 and/or 7 and trisomy 8 are not associated with a specific FAB subtype of AML, and are most commonly detected in older adults. In contrast, the balanced translocations and inversions are more frequently observed in children and young adults with AML. [33] Most of the described chromosome changes are not unique to a specific age group, except for the t(l;22)(pl3,ql3) that has only been reported in infants with M7 AML.[53] Newer cytogenetic techniques such as fluorescent in situ hybridization (FISH) can detect cryptic abnormalities that were not evident in banding studies. [54]

Many of the genes at the breakpoints of chromosomal translocations that have been cloned during the past 510 years are proving to be transcription factors. [4] [5] The translocation t(8;21) is the most frequently occurring translocation in AML. Three-way rearrangements may occur and the t(8;21) is frequently associated with loss of a sex chromosome. The t(8;21) produces a fusion protein involving the AML1 gene on chromosome 21 and the ETO gene on chromosome 8. [52] The AML1 gene encodes one of the DNA-binding subunits of the transcription factor complex core-binding factor (CBF). The fusion protein may act as a dominant negative inhibitor of the normal copy of AML1. The AML1/ETO gene has been detected by molecular methods in some patients with t(8;21) in long-term complete remission. [55] The significance of this finding is unknown.

As noted earlier in this chapter, chromosome band 11q23 translocations are commonly seen in infants and toddlers with the M4 and M5 subtypes and secondary leukemias after epipodophyllotoxin therapy. Many partner genes (e.g., t[9;11] and t[10;11]) are involved in this translocation. [25] [26] [27] The 11q23 translocation disrupts the MLL gene (mixed-lineage leukemia) that encodes a large protein with regions of homology to the *Drosophila* protein trithorax, a homeobox protein involved in pattern development in the fly.

The translocation t(15;17) is uniquely associated with both the hypergranular and hypogranular variants of M3 AML. [6] The cloning of the breakpoint revealed rearrangement of a retinoic acid receptor gene (RARalpha), with fusion to the PML gene. [37] The PML-RARalpha gene is expressed in leukemic cells from essentially all patients with the t(15;17) and is felt to be crucially involved in the pathogenesis of this disease. This molecular marker (PML-RARa transcript) provides a convenient assay for diagnosing acute promyelocytic leukemia (APL) and determining the presence of minimal residual disease. [56] Before the RARa gene was shown to be rearranged in t(15;17), observations were made that M3 AML cells differentiated in response to retinoic acid both in vitro and in vivo (see section on acute promyelocytic leukemia).[6]

RT-PCR assays for many of the common gene rearrangements in AML are now available for diagnostic purposes and for following minimal residual leukemia. Prospective studies are underway using these assays to determine the significance of detecting minimal numbers of leukemic cells in patients in hematologic remission.[57]

CLINICAL AND LABORATORY MANIFESTATIONS

The initial signs and symptoms in the majority of children with AML include some degree of pallor, fatigue, skin or mucosal bleeding, or fever/infection that has not responded to appropriate antibiotic therapy (Table 55-3).[58] These signs and symptoms

TABLE 55-3 -- Signs and Symptoms at Presentation in Acute Myeloid Leukemia

Sign or Symptom	Percentage of Patients
Fever	34

[a]Thirty percent of postmenopausal females had menorrhagia.

reflect the anemia, thrombocytopenia, and neutropenia secondary to diminished production of normal blood cells due to bone marrow infiltration with leukemic blasts. AML, in contrast to chronic myelogenous leukemia, is rarely diagnosed as an incidental finding on a routine complete blood count (CBC) in an asymptomatic child. Bone pain and arthralgias are less-common presenting complaints in children with AML compared to those with ALL. Massive hepatosplenomegaly is uncommon except in infants with AML.[44]

Congenital Leukemia

The clinical manifestations of leukemia diagnosed in the first four weeks of life differ in varying degrees from the typical findings in infants over 6 months of age and older children with AML.[44] About one-half of newborns and infants under 2 months of age with AML have leukemia cutis.[59] These babies have been described as looking like a blueberry muffin (Fig. 55-1). The skin lesions are described in the following sections. It is important to note that they may precede bone marrow manifestations of leukemia. Transient spontaneous remissions of leukemia cutis may occur but are usually followed within weeks by their reappearance in association with overt bone marrow involvement.[59] Other signs and symptoms of congenital leukemia include hepatosplenomegaly, lethargy, pallor, and failure to thrive.

Extramedullary Leukemia

The most common sites of extramedullary leukemia in children with AML include skin, gingiva, CNS, and myeloblastomas in the head and neck area (Plate 55-1). [43] Extramedullary involvement with AML is more common in infants than in older children. In a review of 29 infants with AML at St. Jude Childrens Research Hospital, 13 were found to have leukemia cutis, and 11 presented with CNS leukemia.[44] The skin lesions are often widespread, range in size from several millimeters to several

Figure 55-1 Leukemia cutis as commonly seen in congenital leukemia.

centimeters, and are palpated as freely mobile subcutaneous nodules. The color of the overlying skin may be salmon, red-brown, or bluish to slate gray in color. Testicular involvement is extraordinarily rare in children with AML and, like CNS leukemia, is commonly associated with the M4 and M5 FAB subtypes.

The most common pathology of AML in the central nervous system is that of meningeal infiltration by blasts, but epidural or brain parenchymal myeloblastomas have also been described. The incidence of CNS (meningeal) leukemia at diagnosis in children with AML ranges from 515%, [60] [61] but most children are asymptomatic. The diagnosis of CNS leukemia is made by examining a cytocentrifuged specimen of CSF (Plate 55-2). The currently accepted definition of CNS leukemia is CSF with <5 white blood cells (WBCs)/l and definite blasts, or a cranial nerve palsy. The rare symptomatic patient with CNS leukemia may have a headache, vomiting, papilledema, and/or a cranial nerve palsy (VIIth is most common). In contrast, patients with cerebral leukostasis present with seizures, somnolence, and/or stroke

secondary to areas of hemorrhage and infarction in brain tissue.

Fewer than 5% of newly diagnosed patients with AML have myeloblastomas, also known as granulocytic sarcomas or chloromas. [62] These solid tumors of myeloid blasts may occur anywhere but are primarily detected in the bones and soft tissues of the head and neck (often orbits), and in intracranial or epidural locations. [62] [63] Myeloblastomas may herald overt bone marrow involvement with AML by weeks to months and are associated with FAB M2 and t(8;21) and infants with M4 and M5 subtypes.[43] [64]

Laboratory

The initial white blood cell count at presentation in children with AML is variable (1,000/l>500,000/l). About 1520% of children have WBC counts >100,000/l. [58] Marked leukocytosis is associated with the FAB M4 and M5 subtypes and congenital leukemia, whereas lower leukocyte counts are commonly seen in patients with M3 or acute promyelocytic leukemia. The leukocyte differential in most patients includes <1,000 neutrophils/l and a variable percentage of blasts. In about 10% of patients no peripheral blasts are detectable.

Most patients with AML have a normocytic anemia, with occasional teardrop forms and nucleated red blood cells noted on the peripheral smear. Initial hemoglobin levels ranged from 2.714.3 g/dl (median, 7 g/dl) in one large series of children with AML. [58] The rare hemolytic anemia associated with AML is usually a microangiopathic hemolytic anemia secondary to disseminated intravascular coagulation (DIC).

Thrombocytopenia is the usual cause of hemorrhage in patients with AML. Bleeding is usually not observed until the platelet count falls below 20,000/l unless there is an associated coagulopathy. Approximately 50% of children with AML present with platelet counts of <50,000/l. The other major cause of bleeding in children with AML is DIC. Patients with acute promyelocytic leukemia (FAB M3) are most at risk for DIC, but infants with M4 and M5 are also at increased risk. [6] [65] Prior to the use of all-trans-retinoic acid (ATRA) for patients with APL, prophylactic low-dose heparin in addition to transfusion of fresh frozen plasma and platelets was recommended by several groups of investigators. [66] ATRA appears to downregulate tissue factor expression and thereby reduces the severity and duration of DIC in these patients.

The definitive diagnosis of acute leukemia is made by examination of the bone marrow aspirate. [67] The bone marrow is hypercellular in most cases, with 3090% blasts. The bone marrow biopsy may be hypocellular, especially in patients with a history of prior MDS, Fanconis anemia, or paroxysmal nocturnal hemoglobinuria (PNH). Dysplastic changes have recently been reported in patients with de novo AML. The significance of these dysplastic changes remains to be determined.

DIFFERENTIAL DIAGNOSIS

The diagnosis of AML is relatively straightforward after an examination of the peripheral blood and bone marrow. [67] Other diagnoses that can sometimes cause diagnostic difficulty include the myeloproliferative disorders (e.g., juvenile chronic myelogenous leukemia [JCML]), myelodysplastic (preleukemic) syndromes, and overwhelming infections that result in leukemoid reactions or neutropenia secondary to a bone marrow maturation arrest in granulocytic precursors. In the latter situation, the bone marrow may be confused with APL but with resolution of the sepsis, granulocytic maturation ensues.

The differential diagnosis of congenital leukemia is somewhat more challenging, in part because of the leuko-erythroblastic peripheral blood picture noted in neonates with hypoxia or sepsis. Congenital viral infections including cytomegalovirus, herpes simplex, and rubella need to be ruled out as well as the transient myeloproliferative syndrome associated with trisomy 21. [68]

TREATMENT

The long-term survival (>5 years) for children with AML has increased from <10% to approximately 40% during the past 25 years. [69] [70] [71] [72] [73] [74] [75] This improved cure rate has resulted from more effective remission induction chemotherapy and better strategies to prevent relapse. Improvements in supportive care have been equally important, making it safe and feasible to treat patients with myelosuppressive doses of chemotherapy. [76] [77] [78] All children with AML

should be referred to a pediatric oncology center for treatment and are usually enrolled in a cooperative group clinical trial, such as Pediatric Oncology Group (POG), Childrens Cancer Group (CCG), Berlin-Frankfurt-Muenster (BFM) Group, and Medical Research Council (UKAML), or single-institution protocol.

Before chemotherapy is started, the infant or child should be stabilized with regard to renal, metabolic, hematologic (anemia, bleeding, DIC, leukostasis), and infectious disease issues. A double lumen indwelling central venous catheter should be placed early in the treatment course. The metabolic derangements associated with leukemic cell death (tumor lysis syndrome) include hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia. [79] The tumor lysis syndrome is seen more often in children with ALL (especially T cell and mature B cell) than in those with AML. Uric acid nephropathy is avoided by prompt attention to hydration, alkalinization of the urine, and administration of allopurinol. Newer initiatives in supportive care include prophylactic fluconazole during prolonged periods of neutropenia and the use of hematopoietic growth factors (G- or GM-CSF) during induction and after cycles of intensification chemotherapy. Blood products should all be leukopoor and irradiated to prevent graft-vs.-host-disease (GVHD). Platelet transfusions are recommended prophylactically if the platelet count is <10,000/l.

One to two percent of children with AML still die within the first several days to a week after diagnosis. These early deaths usually result from intracranial hemorrhage from either a coagulopathy or CNS leukostasis. [65] [66] [80] [81] If the leukocyte count is >100,000/l, it is important to rapidly initiate measures to prevent leukostasis. Leukostasis refers to plugging of blasts in vessels with invasion of vessel walls leading to hemorrhagic infarction of the brain, lung, or other organs. Children with AML who have leukocyte counts >200,000/l are much more susceptible to leukostasis than patients with ALL and comparable WBC counts. [79] The most clinically relevant target organs for leukostasis are brain and lung with signs and symptoms including somnolence, seizures, stroke, tachypnea, and hypoxemia. Treatment should include immediate measures to lower the WBC, and exchange transfusion or leukapheresis if the patient is symptomatic. Oral hydroxyurea combined with leukapheresis is very effective for rapidly lowering the blast count in patients with AML and preventing the clinical manifestations of leukostasis. [80] [81]

REMISSION INDUCTION

Because of the narrow therapeutic index of the active agents in AML, all induction regimens (except for FAB M3) are designed to achieve rapid bone marrow hypoplasia, an apparent prerequisite for successful remission induction. Children <3 years of age or <0.6 m^2 should have doses of chemotherapy calculated on a per-kilogram rather than per-m^2 basis.[71] The induction of a complete remission is necessary in order to prolong survival for patients with AML. For the past two decades, the gold standard remission induction regimen has included 3 days of an anthracycline, usually daunomycin, and 7 days of cytarabine with or without thioguanine. About 7585% of children with AML achieve a complete remission after this treatment, and about one-third of patients require two such courses to achieve a remission.[2] [71] Lower remission rates are seen in patients with secondary AML, a history of a prior MDS, and certain cytogenetic findings (see section Prognostic Factors). Because of the requisite period of bone marrow hypoplasia and the greater impairment of bone marrow reserve in patients with AML, the remission induction phase of therapy is more toxic than for patients with ALL.

Prospectively controlled pediatric and adult cooperative group studies have shown that daunorubicin is preferable to doxorubicin because it is associated with less oral mucositis and gastrointestinal toxicity.[71] The most disturbing gastrointestinal toxicity during induction is an enterocolitis involving the distal

PATIENT MANAGEMENT: AN APPROACH TO THERAPY FOR AML IN CHILDREN

Remission induction: the combination of cytarabine (seven days) and daunorubicin (three days) remains the cornerstone of induction chemotherapy and results in a complete remission rate of about 80%. Neither the substitution of idarubicin for daunorubicin nor the addition of thioguanine or etoposide to this regimen has been shown to significantly increase the complete remission rate. However, recent adult and pediatric cooperative group studies indicate that intensification of induction chemotherapy significantly prolongs disease-free survival and this is independent of the type of post-remission therapy (allogeneic BMT, autologous BMT, or intensive consolidation chemotherapy). One can intensify induction by either beginning the second cycle of induction on day 10 instead of the usual day 14 from the start of therapy or by using high-dose cytarabine. The author favors the former approach; this strategy also eliminates the need for a day 14 bone marrow exam, which has always been difficult to interpret. For patients with acute promyelocytic leukemia, the combined use of all-trans-retinoic acid and daunorubicin/cytarabine during induction appears to give the best long-term results in this unique subtype of AML.

CENTRAL NERVOUS SYSTEM PROPHYLAXIS

The termination of remission in children with AML by central nervous system relapse occurs in <5% of relapses. Most AML protocols administer periodic doses of intrathecal chemotherapy. No controlled trials support the use of preventive cranial irradiation in AML.

TREATMENT IN REMISSION

Allogeneic BMT early in first remission using an HLA matched family donor results in a significantly better disease-free survival compared with chemotherapy but is limited to about 20% of patients with a suitable donor. The best alternative to an allogeneic bone marrow transplant is 36 months of intensive combination chemotherapy featuring high-dose cytarabine. There is no proven role for maintenance or continuation chemotherapy if it follows several cycles of high-dose cytarabine. Autologous bone marrow transplants performed in first remission do not offer a survival advantage compared to chemotherapy. For those children with AML who have a relatively favorable prognosis after treatment with chemotherapy (e.g., t[8;21], inv 16, Down syndrome), it is reasonable to reserve BMT for early relapse or second remission. Transplants using a matched unrelated bone marrow or cord blood donor remain a high-risk procedure and are usually reserved for patients who have had a relapse.

The prognosis for children who relapse or fail to achieve an initial remission is poor. There is only a small possibility of a long second remission with chemotherapy alone, especially if the duration of the first remission was less than one year. The strategy in the relapsed patient should be to induce a second remission and proceed as rapidly as possible to an allogeneic or autologous bone marrow transplant. Published data is insufficient to recommend one type of transplant over another in this circumstance. The rare patient in relapse with stable clinical and hematologic parameters may be best served by an immediate bone marrow transplant without an attempt at reinduction chemotherapy.

ileum, cecum, and proximal colon. This syndrome is referred to as typhlitis or the right lower quadrant syndrome and is noted in <10% of patients. [82] The signs and symptoms of typhlitis develop about 1014 days after the start of chemotherapy. Treatment recommendations include bowel rest and broad-spectrum antibiotics with double coverage for gram-negative organisms. Surgery is rarely needed and is reserved for intestinal perforation, abdominal wall fasciitis, or massive bleeding.

Several adult and pediatric AML studies have explored the benefits of substituting either mitoxantrone or idarubicin for daunorubicin. [83] [84] Mitoxantrone is at least as effective as daunorubicin and idarubicin may be superior to daunorubicin for remission induction. The addition of thioguanine and/or etoposide to an anthracycline and cytarabine has not been shown to significantly increase the complete remission rate. [73] [74] Several recently completed clinical trials have intensified therapy during induction by using high-dose cytarabine in combination with daunorubicin (Australian Leukemia Study Group) or starting the second induction course at an earlier time (e.g., day 10 in-stead of days 1421) (CCG). [85] [86] Patients receiving intensified induction have had statistically significant increases in disease-free survival compared to those patients randomized to standard induction, but they have not had higher complete remission rates. These data are consistent with the hypothesis that more effective early leukemic cell kill reduces the likelihood of a subsequent relapse in children and adults with AML. [87]

ACUTE PROMYELOCYTIC LEUKEMIA (FAB M3 or APL)

In the past, about 6575% of patients with M3 AML (APL) entered remission after a standard induction with daunorubicin and cytarabine. The remission induction period, however, was associated with significant early mortality secondary to hemorrhagic complications. [88] The use of ATRA alone during induction for patients with acute promyelocytic leukemia (PML/RARa-positive) results in a similar or even higher rate of complete remission with a different toxicity profile. [6] The ATRA-induced remissions are associated with differentiation of the blasts/promyelocytes and a peripheral blood leukocytosis during the first two weeks of therapy.

A significant leukocytosis (>15,000/l) during ATRA requires the addition of chemotherapy. ATRA is also associated with several life-threatening complications including a severe respiratory distress and capillary leak syndrome and pseudotumor cerebri (more common in pediatric patients). The retinoic acid syndrome (respiratory distress) has been successfully managed in most patients with temporary cessation of ATRA and administration of decadron. The symptoms of pseudotumor cerebri disappear within days after withdrawal of ATRA and the drug can usually be safely restarted at a reduced dose. Patients induced into remission with ATRA alone remain PCR-positive for PML/RARa after induction and all eventually relapse if no consolidation chemotherapy is added. The combined use of ATRA and chemotherapy during remission induction results in an improved disease-free survival compared to the sequential use of ATRA followed by chemotherapy.[89]

CENTRAL NERVOUS SYSTEM LEUKEMIA

There is no evidence that CNS-directed therapy with either intrathecal chemotherapy alone or combined with cranial irradiation prolongs disease-free survival in children with AML.[2] [3] [72] Most pediatric AML studies, however, still include intrathecal chemotherapy because isolated CNS relapse occurred in about 20% of children with AML who did not receive any CNS-directed therapy. [60] [61] Using historical controls, the BFM AML group has made a case for using prophylactic cranial irradiation and plan to test their hypothesis in a prospectively controlled clinical trial. [90]

In contrast to ALL, the finding of blasts in the CSF at diagnosis in children with AML does not adversely impact on prognosis. An accepted approach for the treatment of CNS leukemia is weekly intrathecal methotrexate or ara-C until the cerebrospinal fluid (CSF) is clear of blasts. In some protocols this is followed by CNS irradiation at the end of systemic chemotherapy.[2]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

TREATMENT IN REMISSION

Without further treatment after standard induction chemotherapy, more than 90% of patients relapse within one year and the remainder relapse by two years. The intensity and duration of chemotherapy in remission, as well as the role of bone marrow transplantation in first remission, have been areas of active investigation and controversy during the past fifteen years.[74] [91] In the 1970s, pediatric AML studies tested whether modestly myelosuppressive combination chemotherapy given in remission would improve overall survival. These protocols led to a plateau in disease-free survival of 1520% at 5 years. [70] [71] [73] In an effort to improve upon these disappointing results, other approaches were explored, including early intensification or consolidation chemotherapy and bone marrow transplantation (BMT). Allogeneic BMT provided an opportunity for delivering very high doses of chemo-radiation and possibly stimulating a graft-versus-leukemia effect. [91] [92] [93] [94] Although the initial studies were not randomized, the results suggested a benefit for either the intensification of chemotherapy or BMT early in first remission.

Cytarabine, the single most active agent in AML, was the prototype drug for intensification because laboratory and clinical studies indicated that at least a log increase in its dose could overcome certain mechanisms of resistance.[95] [96] About 40% of patients with AML who are refractory to standard doses of cytarabine achieve a complete remission rate with high-dose cytarabine.[95] The superiority of high-dose compared to standard-dose cytarabine has also been confirmed in a prospective randomized clinical trial in adults with AML.[96] Most pediatric AML studies that were initiated in the late 1980s included several consolidation cycles of high-dose cytarabine. These protocols resulted in 5-year leukemia-free survival plateaus of 3560%. [74] [75] [94] Maintenance chemotherapy with oral thioguanine and standard doses of cytarabine given after consolidation chemotherapy has not been shown to further increase the proportion of patients in long-term remission. The optimal number of consolidation chemotherapy cycles has not been determined.

A recently completed multi-institutional trial has shown that ATRA, when combined with daunorubicin and ara-C for patients with M3 AML, significantly improves leukemia-free survival compared with chemotherapy alone.[97] Therefore, ATRA should be included in the induction regimens for all patients with acute promyelocytic leukemia. The role of maintenance ATRA is under active investigation.

BONE MARROW TRANSPLANTATION IN FIRST REMISSION

Allogeneic BMT from a histocompatible family donor was first evaluated in children and young adults with AML in first remission in the mid-1970s. [91] [92] [93] It is an effective therapy, albeit with substantial up-front risks, that results in lower relapse rates compared to chemotherapy alone. Published data from many pediatric AML bone marrow transplant series show 5-year leukemia survival rates ranging from 5575%. [2] [93] [94]

Many of the early transplant studies, however, were not prospectively designed and therefore were biased in their selection criteria, not controlled for the timing of BMT in first remission, and excluded patients who were eligible for a transplant but who relapsed before the procedure. In an effort to avoid these biases, it was suggested that outcomes of studies comparing BMT to chemotherapy be analyzed according to the intention-to-treat

TABLE 55-4 -- Prospective Comparative Studies of BMT and Postremission Chemotherapy for Childhood AML

Study	Number of Patients	DFS or EFS from Remission or Randomization

		chemo

analysis, which includes all eligible patients (i.e., those having a matched family donor) and not just individuals who actually received the transplant. [94] [98] When the data are analyzed in this way, there is still a statistically significant survival advantage for allogeneic BMT compared to chemotherapy in most studies. [86] [98]

A limited donor pool of histocompatible related individuals, and the late effects of BMT including chronic GVHD, continue to be major limitations in the more widespread application of this procedure in patients with AML. [99] [100] The late effects of BMT in young children may include growth problems, gonadal toxicity, secondary malignancy, and chronic GVHD.[100] [101] Because of these issues, some pediatric oncologists are beginning to recommend chemotherapy alone, especially for children with a relatively favorable prognosis, and reserving BMT for subsequent relapse. Thirty to forty percent of patients with AML transplanted (allogeneic or autologous) in early relapse or second remission appear to be long-term leukemia-free survivors. [102] [103] [104]

For patients who lack suitable donors (5 or 6 antigen-matched family member), autologous BMT became an attractive option in first remission after it was reported to be effective in some patients with AML in second remission (5-year survival rates of 3040%). [104] The results of three randomized trials in pediatric AML have concluded that autologous BMT is not superior to intensive chemotherapy in first remission [95] [105] [106] (Table 55-4). A fourth study indicated that the addition of autologous BMT to four courses of intensive chemotherapy substantially reduces the risk of relapse in patients with AML leading to an improvement in long-term survival.[107] Because of the good chance of salvage for children who relapse from chemotherapy and the morbidity, mortality, and late effects of autologous BMT, the authors suggest that delay of the autograft until second remission may be appropriate.

PROGNOSTIC FACTORS

The prognostic significance of several clinical and biologic features in children with AML is summarized in Table 55-5 . In contrast to childhood ALL, very few clinical, laboratory, or treatment

TABLE 55-5 -- Patient Characteristics Relating to Duration of Remission

Characteristics	Favorable Value
Cytogenetics	t(15;17), t(8;21), inv 16
Leukocyte count	<100,000/l
Secondary AML	Not present
FAB subtype	M1 or M2 with Auer rods, M3 and M4eo
Courses to CR	1

associated factors have been consistently related to prognosis [2] [108] (Table 55-3). A white blood cell count >100,000/l at diagnosis, monosomy 7, and secondary AML are associated with lower remission rates. [109] [110] Favorable factors for predicting complete remission include FAB M1 with Auer rods, chromosome findings of inv 16 or t(8;21), and the combined use of ATRA and chemotherapy for acute promyelocytic leukemia(FAB M3). [89] [110] [111] [112]

In some studies, the M4 and M5 FAB subtypes, high initial leukocyte count, age under 2 years, extramedullary leukemia (other than CNS) at diagnosis, and longer time to enter remission (more than one induction cycle) were found to have an adverse impact on remission duration. [108] In the German BFM studies, two risk groups were identified. [110] The BFM favorable risk group includes children with FAB M1 or M2 with Auer rods, M3 and M4eo, rapid response to induction chemotherapy, and Down syndrome. Included in this favorable group are patients with t(8;21) and inv 16. Several groups of investigators have reported that children with AML and Down syndrome have a very good outcome after treatment with chemotherapy alone. [28] [29] The presence of acute mixed-lineage or biphenotypic leukemia (AML with lymphoid-associated antigen[s] does not influence prognosis. [48] [113]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

MANAGEMENT OF RELAPSE

The prognosis for children who relapse or fail to enter remission with front-line chemotherapy is very poor. [114] [115] Many different chemotherapy regimens have been evaluated in children and adults with refractory or relapsed AML. Relapse regimens that have been investigated include high-dose cytarabine with L-asparaginase or mitoxantrone, etoposide (VP-16) and amsacrine with or without azacytidine, fludarabine and cytarabine, and 2-chlorodeoxyadenosine (2-CDA). [116] The best predictor of response to chemotherapy after relapse is the duration of the first remission. Children who relapse within 1 year after achieving remission have a substantially lower likelihood of achieving a second remission compared to those patients who relapse later. [115] The complete remission rate for the former group is 3040% and 6070% for the latter group. Less than 20% of the complete responders are projected to remain in remission for more than two years unless they receive a bone marrow transplant.[102]

The projected 5 year survival rate after an allogeneic or autologous BMT in second remission is 3050%. [103] Because of the higher rate of relapse after an autologous compared to an allogeneic bone marrow transplant, there is a growing experience with matched unrelated transplants using bone marrow or cord blood. [117] [118] In selected patients (short duration of first remission or early relapse), it is reasonable to undertake a bone marrow transplant without an attempt at inducing a second remission. This is only feasible if a transplant option is immediately available and the patient is clinically stable. [102]

FUTURE DIRECTIONS

The major challenge for the future is to develop more effective therapies because the majority of children with AML continue to relapse and ultimately die from their disease.[2] [111] The primary cause of relapse is the development of drug resistance. Newer insights into the multiple mechanisms of drug resistance are beginning to be elucidated. For example, increased expression of the multidrug resistance gene (mdr 1) or its protein product P-glycoprotein has been demonstrated in blasts from 2040% of newly diagnosed patients with AML and increases approximately two-fold at the time of relapse. [119] [120] High in vitro expression of mdr is associated with resistance to natural product drugs such as etoposide, anthracyclines, and vincristine, by promoting their cellular efflux. A number of compounds including verapamil and cyclosporine are capable of reversing the mdr

phenotype in vitro via a direct interaction with P-glycoprotein. [120] Clinical trials are ongoing to determine whether such compounds can reverse drug resistance in vivo.

The increasing availability of alternative sources of hematopoietic stem cells from unrelated bone marrow or cord blood donors will greatly expand the use of BMT in all phases of therapy.[117] [118] Strategies based on preclinical models are also being developed that will hopefully achieve a more favorable balance of the graft-versus-host and graft-versus-leukemia reactions. Biologic response modifiers such as IL-2 and genetically engineered tumor vaccines are under study for their potential to enhance the patients immune response against the leukemia. [122] Eventually, it may be possible to target the genetic lesions of leukemic cells as exemplified by the use of all-trans-retinoic acid in acute promyelocytic leukemia. Finally, the increasingly sophisticated methods available for measuring minimal residual numbers of leukemic cells will allow us to better tailor our therapies.

Chapter 56 - Pathobiology of Acute Lymphoblastic Leukemia

Jeffrey E. Rubnitz
A. Thomas Look

INTRODUCTION

Normal lymphoid cell populations undergo diverse clonal rearrangements of their immunoglobulin or T-cell receptor (TCR) genes, followed by highly regulated proliferation of the cells that successfully complete these genetic changes. This developmental process generates B cells and T cells with the specificities needed to support a fully competent immune system. When a lymphoid progenitor cell becomes genetically altered through somatic changes, the result can be dysregulated proliferation and clonal expansion, eventually leading to acute lymphoblastic leukemia (ALL). In most cases, the pathobiology of transformed lymphoid cells reflects the altered expression of genes whose products contribute to the normal phenotypes of B- and T-cell progenitors, but it may also involve the aberrant expression of otherwise quiescent genes.

Because leukemic blasts represent the clonal expansion of hematopoietic progenitors that are blocked in differentiation at discrete stages of development, they provide large uniform populations for molecular and functional analyses. Leukemic cells duplicate most of the features of normal lymphoid progenitors and provide models for elucidating the regulatory cascades disrupted by specific genetic changes. For instance, molecular studies of chromosomal breakpoint regions in ALL cells have identified genes whose protein products are transcription factors that presumably control the expression of developmentally important genes. [1] [2] [3] [4] Indeed, most of the recent progress in understanding ALL pathobiology has come from the study of rearranged or mutated genes and their associated proteins.

CLONAL ORIGIN OF LEUKEMIC LYMPHOID CELLS

Human ALL arises from a single progenitor cell that has undergone genetic damage leading to dysregulated growth and arrested differentiation. Evidence that each leukemic cell has descended from a single transformed progenitor comes from cytogenetic studies showing common numerical and structural chromosomal abnormalities within discrete leukemic cell populations. The clonal development of leukemic cell populations is further demonstrated by uniform rearrangements of immunoglobulin or TCR genes, as compared with the heterogeneous pattern of rearrangements observed in populations of normal T and B lymphocytes. [5] [6]

Perhaps the best evidence of clonality is provided by X chromosome-linked genes that are inactivated during embryogenesis. This process occurs before somatically acquired transformation events and thus is independent of changes induced by differentiation and stem line evolution. In accord with the Lyon principle, one or the other of the X chromosomes is randomly inactivated early in the embryogenesis of females, in large part through DNA methylation, leading to a heterozygous pattern of inactivation of either the paternally or maternally derived X chromosome in all tissues, including the hematopoietic system. By contrast, in clonally derived cell populations, as found in the leukemias and other malignancies, every cell is characterized by inactivation of the same X chromosome. Thus, the unicellular development of a leukemic cell population can be demonstrated by detecting a single type of glucose-6-phosphate dehydrogenasean enzyme encoded by a gene on the X chromosomein the neoplastic cells of heterozygous female patients who express a double-enzyme pattern in their normal tissues. [7] [8] In addition, the methylation patterns of restriction fragment length polymorphisms (RFLPs) in X-linked genes, detected by Southern blot analysis, have been used to show that even rare ALL cases with two completely different cytogenetic stem lines probably arise by clonal evolution from a single transformed progenitor. [9]

LINEAGE-SPECIFIC FEATURES OF LEUKEMIC LYMPHOBLASTS

An important advance in the understanding and treatment of ALL was the realization that malignant lymphoblasts share many of the features of normal lymphoid progenitors.[10] [11] Thus, ALL cells rearrange their immunoglobulin and TCR genes and express components of antigen receptor molecules and other differentiation-linked cell-surface glycoproteins in ways that correspond to developing normal B and T lymphocytes. In many cases, leukemic cells appear to represent the clonal expansion of a lymphoid progenitor that is blocked or frozen in an early stage of B- or T-cell differentiation. [12] With better understanding of the normal patterns of antigen-independent lymphoid cell development, however, it has become clear that leukemic lymphoblasts can show asynchronous gene expression with subtle variations in phenotype.[13] Hence, it should not be surprising that in some cases of ALL, the blast cell phenotypes differ from those of normal lymphocyte progenitors, presumably because of aberrant regulation of gene expression. Still, the general concept that leukemic cells should be classified according to their normal developmental stage remains an important one, providing a basis for the study of immunophenotype-specific genetic changes and for the assignment of patients to phenotype-directed therapy.

B-Cell ALL

The diagnosis of B-cell leukemia depends on the detection of surface immunoglobulin on leukemic blasts. This rare phenotype accounts for only 23% of ALL cases, and the lymphoblasts generally have a distinctive morphology, with deeply basophilic cytoplasm containing prominent vacuoles; this morphologic pattern is designated L3 in the French-American-British (FAB) system. [14] [15] [16] Prominent clinical features include concomitant extramedullary lymphomatous masses in the abdomen or head and neck, frequent involvement of the central nervous system (CNS) and cranial nerves, and hyperuricemia with acute renal failure due to uric acid nephropathy. Most investigators believe that acute B-cell leukemia is a disseminated form of Burkitt lymphoma, as these conditions share common cytogenetic, molecular genetic, immunologic, cytologic, and clinical features. [17]

Acute B-cell leukemia does not respond well to chemotherapy traditionally used for childhood ALL. However, outstanding results, with event-free survival (EFS) rates of nearly 90%,

have been obtained with treatments designed for Burkitt lymphoma, which emphasize cyclophosphamide and the rapid rotation of antimetabolites in high dosages. [18] [19] [20] [21] [22] Thus, B-cell leukemia is the first form of ALL to be recognized as a distinct clinical entity based on immunophenotypic and cytogenetic features and the first to be treated by separate protocols designed specifically for the leukemias unique features.

Pre-B and Early Pre-B ALL

Approximately 80% of ALL patients have lymphoblasts with phenotypes corresponding to those of B-cell progenitors. [16] [23] These cases can be identified on the basis of cell-surface expression of CD19 and at least one other recognized B-lineage-associated antigen: CD20, CD24, CD22, CD21, or CD79. [16] [23] [24] [25] [26] Some 9095% of B-lineage ALL cases also express CD10 (CALLA, or common ALL antigen). The lymphoblasts may also express nuclear terminal deoxynucleotidyl transferase (TdT),[27] or CD34, an antigen of unknown function whose normal expression in hematopoiesis is restricted to lymphoid and hematopoietic precursors. [28] [29] About one-fourth of B-progenitor ALL cases express cytoplasmic immunoglobulin heavy chain proteins and are designated pre-B-cell ALL. Early pre-B ALL lacks the cytoplasmic heavy chain but express HLA-DR, TdT, and CD19 and have rearranged immunoglobulin genes. [30] [31] Pre-B cases were originally shown to have a worse long-term response to therapy than early pre-B cases, an observation that was later attributed to the presence of a specific t(1;19) in about one-fourth of the pre-B cases.[32] The adverse effect of this cytogenetic feature appears to have been nullified by the development of effective chemotherapy. [33] [34]

DNA rearrangement of immunoglobulin genes occurs before heavy chain gene expression in B-cell development, providing a genetic marker of B-lymphocyte ontogeny.[35] [36] The variable region of immunoglobulin heavy-chain genes is assembled from three classes of DNA segments on human chromosome 14, termed V_H (variable), D_H (diversity), and J_H (joining), which must recombine correctly during cell development to produce a functional protein. The initial attempt at rearrangement may be productive, resulting in immunoglobulin heavy chain synthesis, or it may be aberrant, with no production of heavy chain molecules, in which case rearrangement of the other heavy chain allele is attempted. Similar rearrangements occur between the V and J regions of the and light chain genes on chromosomes 2 and 22, with attempts to rearrange the alleles occurring first, followed by recombination of alleles if these attempts are nonproductive. Rearrangement of each of these genes results in deletion of introns containing restriction endonuclease cleavage sites. This in turn causes changes in the sizes of restriction fragments bearing the rearranged gene under study, which can be detected by Southern blot analysis. Because lymphocytic leukemias are clonal, the DNA from each cell contains identical rearrangements apparent as discrete bands that differ from germline bands.

Korsmeyer and co-workers pioneered the use of heavy and light chain gene rearrangements to support an early B-lineage origin of most ALL blasts. [35] [36] This work was extended to establish synchrony between immunoglobulin gene rearrangements and the expression of B-lineage-restricted cell-surface antigens. Immunoglobulin heavy chain gene rearrangements have also been documented in about 15% of T-cell ALL cases and a similar percentage of AML cases. [37] [38] [39] Thus, caution must be exercised when assigning cell lineage on the basis of studies of immunoglobulin gene rearrangement.

T-Cell ALL

Leukemias of T-cell precursors are identified and classified according to the sequence of expression of T-cell-associated surface antigens during normal thymocyte ontogeny.[40] [41] Thymocyte differentiation begins with the prothymocyte, which expresses CD7, TdT, and cytoplasmic T3 antigen. Next is the early thymocyte, which retains these markers and acquires CD5 and CD2, the receptor for sheep erythrocytes. Intermediate thymocytes co-express CD4 and CD8 as well as CD1. Mature thymocytes lose CD1 expression and produce functional TCRs, leading to expression of CD3 on the cell surface. Using a battery of monoclonal antibodies specific for these cell-surface glycoproteins, one can identify patterns of expression that correspond to equivalent stages of normal thymocyte development. [42] [43] [44] [45] The clinical features most closely associated with T-cell ALL are high blood leukocyte counts, CNS involvement, and radiographic evidence of a thymic mass in about one-half of cases at presentation. Historically, patients with T-cell ALL have had an adverse prognosis in comparison with patients with B-lineage ALL. With the wider use of intensive chemotherapy, however, the outlook for patients with T-cell leukemia appears improved. [46] In addition, expression of specific antigens, including CD2, CD5, and CD10, may identify subgroups of T-cell ALL with better responses to therapy. [46] [47] [48]

The human antigen-specific TCR molecule is a heterodimer composed of disulfide-linked - and -polypeptide subunits, each encoded by gene families containing variable, joining, and constant sequence elements that rearrange at the DNA level to generate diversity, in a manner analogous to the immunoglobulin genes. Hence, rearrangement of the TCR- chain genes can be used to establish clonality and lineage derivation within leukemias of T-cell progenitors. Although TCR- chain genes

are generally in a germline configuration in B-lineage leukemic cells, about 10% of cases possess aberrant rearrangements. [49] [50] Clonal rearrangements of the TCR- and chain genes are even less restricted to the T-cell lineage, being observed in a significant number of B-lineage ALL cases. [51] [52]

Mixed-lineage Leukemia

Acute mixed-lineage leukemias are defined by blast cells that co-express markers of both the lymphoid and myeloid lineages. Two distinct forms of these leukemias are recognized: those with lymphoid morphology, which co-express myeloid-associated antigen, [53] [54] [55] [56] and those with myeloid morphology and reactivity to myeloperoxidase staining, which co-express cell-surface antigens normally restricted to lymphoid cells. [57] [58] The origin of mixed-lineage leukemias has not been established. One possibility is malignant transformation of pluripotent progenitor cells that retain the ability to differentiate into both the myeloid and lymphoid lineages; another is immortalization of rare progenitor cells that normally co-express features of both lineages; and a third is aberrant gene expression due to specific genetic alterations. [59]

Controversy exists over whether cases of lymphoid leukemia with expression of one or more myeloid cell-surface antigens (e.g., CD13, CD33, or CD14) have an adverse prognosis. However, Pui et al. [56] found that in the 16% of childhood ALL cases with expression of myeloid antigens, the prognosis was no worse than in cases without this feature. This finding has recently been supported by Uckun et al., [60] who also found that myeloid expression in ALL was not an adverse prognostic feature. The expression of T-lymphoid properties, such as cytoplasmic T3 and cell-surface CD2 and CD7, by predominantly myeloid leukemias appears to identify patients with a lower likelihood of complete remission with standard AML therapy but who respond well to induction agents commonly used in ALL therapy. [58]

GENETIC BASIS OF LYMPHOID LEUKEMIA

Multiple somatically acquired genetic abnormalities are responsible for the malignant transformation and disordered cell

growth and differentiation seen in ALL. These abnormalities include microscopically evident chromosomal rearrangements as well as lesions detectable only by molecular analysis of lymphoblast DNA. The ability to identify these changes in a precise, consistent manner and to relate them to the clinical course of the disease has led to risk-specific therapy for ALL. It is worth noting that most children with leukemia have normal constitutional karyotypes, indicating that the genetic abnormalities in their leukemic cells are acquired somatically and thus are restricted to the malignant clone.

Chromosomal translocations are found in 75% of ALL cases (Fig. 56-1). [61] [62] [63] They can be broadly classified as recurring lineage-restricted abnormalities, accounting for approximately two-thirds of the translocations in ALL, and as so-called random translocations, which have been identified in single cases only. Molecular characterization of the breakpoints of recurring translocation led to the cloning of genes intimately involved in leukemogenesis. [1] [2] [3] [4]

Transcriptional Control Genes

Molecular studies of the breakpoints of specific chromosomal translocations of human leukemic cells have focused on transcription factor genes (Table 56-1), whose alteration leads to the differentiation arrest and aberrant growth of leukemic lymphoid and myeloid progenitors. [1] [2] Conserved amino acid sequence motifs within the sequence-specific DNA-binding domains of these nuclear trans-activating proteins allow them to be grouped into families, which in many cases appear to be involved in similar regulatory processes. Thus, the transcription factor genes in Table 56-1 are grouped according to shared structural features of their DNA-binding domains: basic region helix-loop-helix (bHLH), cysteine-rich (LIM), homeodomain (HOX), basic regionleucine zipper (bZIP), zinc finger, AT hook minor groove, ETS-like, or runt homology. Another important association is the lineage restriction of transcription factor genes affected by specific chromosomal translocations, suggesting that the proteins they encode may disrupt the differentiation programs of specific lymphoid progenitors. This interpretation implicates transcription factors as preferred targets in leukemia induction. It also suggests that the normal developmental programs of progenitor cells of different lineages are controlled by different regulatory programs.

Rabbitts [64] has aptly described a key group of regulatory transcription factors as the products of master genes. In his model, the nuclear proteins encoded by these genes act positively to up-regulate critical target genes or negatively to interfere with normal regulatory pathways. The net effect is disruption of gene regulatory cascades that control and coordinate the expression of large numbers of proteins required for completion of lymphoid cell differentiation programs. Disruption of transcription factors in leukemic blasts occurs by at least two distinct mechanisms: the dysregulated expression of intact genes and the creation of chimeric transcription factors.

Dysregulated Expression of Structurally Intact Genes

Activation of *MYC* in B-Cell ALL

In B-cell acute leukemia and Burkitt lymphoma, translocation of one allele of the prototypic bHLH gene, *myc*, on chromosome 8 into the vicinity of an immunoglobulin gene, either the heavy chain gene on chromosome 14q32 or the or light chain genes on chromosomes 2 and 22, leads to dysregulation of that allele. [65] [66] [67] [68] [69] [70] [71] [72] [73] In the predominant t(8;14) translocation, the involved *myc* locus is translocated into the heavy chain gene on chromosome 14, adjacent to the coding sequences of the immunoglobulin constant region. [65] [66] [67] The coding sequences of the immunoglobulin variable region generally are reciprocally translocated to the distal tip of chromosome 8. In variant translocations, the *myc* gene remains on chromosome 8, and portions of the respective light chain genes are translocated to that chromosome downstream of the *myc* locus. [68] [69] [70] [71] [72] [73]

Dysregulation of *myc* appears to transform lymphocytes by altering the interactions of the myc protein with several other transcription factors. Normally, myc dimerizes with the MAX transcription factor, which also can heterodimerize with MAD and Mxil. [74] [75] [76] [77] Myc/MAX dimers activate gene expression, [74] [75] whereas MAD/MAX dimers interact with the SIN3 protein to repress transcription. [78] [79] Overexpression of *myc* as a result of t(8;14) or related translocations leads to increased levels of myc/MAX heterodimers relative to MAD/MAX, ultimately causing transformation by the activation of unknown target genes. [80] This model has been supported by the experimental overexpression of myc in transgenic mice and in B lymphoblasts in culture. [81] [82] [83] Although the oncogenic targets of myc/MAX have not yet been identified, the *cdc25* cell cycle phosphatase gene has been implicated. [84]

[b] Partial list of MLL fusions.
[c] Lacks a DNA-binding domain, but forms a complex with AML1.

Activation of *bHLH, LIM*, and *HOX11* Genes in T-Cell ALL

In leukemias with a T-cell phenotype, chromosomal breakpoints consistently involve the TCR- chain enhancer (7q34) or the enhancer (14q11). These enhancers, which are highly active in committed T-cell progenitors, cause dysregulated expression of transcription factors located at the breakpoint on the reciprocal chromosome involved in these phenotype-specific rearrangements (Table 56-1). Within the bHLH class of transcriptional regulators, translocations in T-cell ALL affect the *myc*,[85] [86] [87] *TAL1/SCL*, [88] [89] [90] *TAL2/SCL2*, [91] and *LYL1* [92] genes. Presumably, dysregulated expression of these bHLH proteins in T lymphoblasts, like *myc* in B cells, causes transformation via altered expression of unknown target genes.

The best characterized of these genes is *TAL1*, which is altered by t(1;14) or by site-specific deletions in approximately one-fourth of childhood T-ALL cases. [93] [94] [95] [96] [97] [98] *TAL1* is expressed in a lineage-specific fashion and heterodimerizes with E2A. [99] Although not expressed in T cells, TAL1 is required for the generation of all hematopoietic lineages, which suggests that it is an essential regulator of early hematopoietic development. [100] [101] [102]

Another gene family whose expression can be altered by translocation into the proximity of the T-cell receptor loci is the LIM domain genes, *LMO1/RBTN1/TTG1* and *LMO2/RBTN2/TTG2*.[103] [104] [105] Both of these genes encode proteins that possess duplicated cysteine-rich LIM domains but lack homeobox DNA-binding domains as found in other transcription factors in this family, suggesting that the LIM domain may function in protein-protein rather than protein-DNA interactions. In support of this model, LMO2 interacts with TAL1 in erythroid cells and in T-cell leukemias. [106] [107] [108] Moreover, homozygous disruption of *LMO2* in mice causes the same phenotype as described previously for *TAL1* knockouts, indicating that a multiprotein complex involving LMO2, TAL1, and potentially other proteins is required for normal hematopoietic development.[102] [109] In addition, overexpression of *LMO1* or *LMO2* in thymocytes of transgenic mice leads to T-cell lymphomas, recapitulating human T-cell tumors.[110] [111] [112] [113] [114]

The homeodomain gene *HOX11*, located on chromosome 10, band 24, is one of the more interesting proteins activated by translocation into the vicinity of the TCR loci.[115] [116] [117] [118] [119] Within the homeodomain transcription factor superfamily, *HOX11* is most closely related to *HLX*, a recently described murine gene homeobox gene expressed in specific hematopoietic cell lineages and during embryogenesis. [120] *HOX11* is normally expressed during embryogenesis in specific regions of the branchial arches and ectoderm of the pharyngeal pouches of the developing hindbrain in the mouse, but not by developing thymocytes or resting or activated T cells.[121] Homozygous disruption of *HOX11* in the mouse results in asplenia in otherwise normal mice.[121] Although essential for the genesis of the spleen, the role

of HOX11 in the development of the branchial arch and hindbrain structures is apparently compensated for by other proteins, as the nervous system develops normally in these mice. When expressed in transgenic mice, HOX11 interferes with the G_2/M cell cycle checkpoint by interacting with specific phosphatases, demonstrating a mechanism by which HOX11 alters the cell cycle.[122] In contrast to loss of *LMO1* and *TAL1*, the development of the hematopoietic system is not affected by loss of *HOX11*. However, overexpression of Tal1 in T lymphocytes of transgenic mice results in T-cell lymphomas and leukemias similar to those caused by t(10;14) and t(7;10) in humans.

Other Genes Activated by Translocation

Transcription factors are not the only genes activated by translocation to the sites of the immunoglobulin or TCR genes. In cases of B-precursor ALL carrying t(5;14), the *IL-3* gene is activated by juxtaposition with the immunoglobulin heavy chain locus. [123] [124] In T-cell ALL, the *TAN1* gene, which shares homology with the *Drosophila notch* gene, undergoes dysregulated expression following its relocation to the TCR- locus as a result of t(7;9). [125] Similarly, relocation to the TCR- locus activates expression of the LCK tyrosine kinase genes in T-cell ALL cases with t(1;7). [126] [127] [128]

Chimeric Transcription Factor Genes

Formation of chimeric proteins whose functional domains come from two normally separate genes represents a second, more prevalent mechanism of aberrant transcription factor activation. Thus, chromosomal translocations may produce a chimeric protein by fusing the DNA-binding, dimerization, and trans-activation regions

of discrete genes, a process facilitated by the molecular structure of transcription factors.

E2A-PBX1 Fusion Genes in Pre-B ALL

A well-known example of a chimeric transcription factor with oncogenic potential is the *E2A-PBX1* rearrangement, which results from a t(1;19)(q23;p13) chromosomal translocation in human pre-B-cell ALL. This translocation fuses the *E2A* gene on chromosome 19, which encodes a bHLH transcription factor, to a homeobox gene (*PBX1*) on chromosome 1, leading to the expression of several forms of hybrid E2A-PBX1 oncoproteins (Fig. 56-2).[129] [130] [131] *PBX1* is related to the *Drosophila exd*, a homeotic gene that plays a role in segmental development through its ability to heterodimerize with and alter the downstream regulatory programs of the products of the HOM-C major homeobox genes.[4] [132] [133] [134] [135] [136] The hybrid proteins resulting from t(1;19) retain the amino-terminal trans-activation domains of E2A (AD1 and AD2), but not the bHLH DNA-binding/protein interaction domain. [130] [131] [137] The bHLH domain is replaced by the homeobox DNA-binding domain of PBX1, enabling the fusion protein to function as a chimeric transcription factor. [138] [139] [140]

The transforming potential of *E2A-PBX1* was first demonstrated by the rapid induction of AML in lethally irradiated mice repopulated with bone marrow stem cells that had been infected with recombinant retroviruses containing *E2A-PBX1* genes.[141] The fusion has also been shown to transform NIH-3T3 fibroblasts and induce T-cell lymphomas in transgenic mice.[142] [143] The transgenic mouse model also demonstrated lymphopenia in both B cells and T cells, suggesting induction of apoptotic cell death that preceded malignant transformation in T cells expressing E2A-PBX1 proteins. [142] Additional studies of

Figure 56-2 Proposed role of the E2A-PBX1 chimeric protein in ALL. Joining of the chromosome fragments produced by the t(1;19) translocation creates a fusion gene consisting of *E2A* and *PBX1* coding segments. The resulting protein binds to the DNA sequences normally recognized by the homeobox PBX1 protein; however, its effector (or trans-activator) region may interact with the transcription machinery in a manner analogous to that of the normal E2A protein. Consequently, transcription may be dysregulated and contribute to the development of ALL.

the fusion have shown that deletion of one of the E2A activation domains diminishes its transforming activity, but deletion of the PBX1 homeodomain has no effect. [143] [144] However, the homeodomain and flanking sequences are required for interactions with other HOX proteins and for optimal binding of E2A-PBX1 to specific DNA sequences.[145] [146] [147] [148] [149] It thus appears that complex interactions between E2A-PBX1 and other HOX proteins target the fusion protein to specific target genes whose activation is critical to lymphoid cell transformation.

Chimeric *E2A-PBX1* transcripts can be readily detected by using the reverse polymerase chain reaction (PCR) to amplify junctional sequences from leukemic cell RNA.[150] [151] In our analysis of 17 cases with t(1;19),[150] 10 of 11 pre-B cell cases expressing cytoplasmic immunoglobulin (cIg) heavy chains had typical *E2A-PBX1* chimeric transcripts with identical junctions. By contrast, none of the six cases of t(1;19)-positive, cIg ALL had evidence of detectable *E2A-PBX1* chimeric transcripts, suggesting that t(1;19) in these cases affects entirely different loci on chromosomes 1 and 19. Patients whose leukemic blasts express *E2A-PBX1* have a poor prognosis when treated with conventional antimetabolite-based therapy. [32] However, the poor prognosis of these patients can be overcome by the use of more intensive therapy, demonstrating the importance of detecting the *E2A-PBX1* fusion at diagnosis.

E2A-HLF Fusion Genes in Early Pre-B ALL

We and others have identified a second fusion gene, created by t(17;19), that combines *E2A* elements with those of a previously unidentified hepatic leukemia factor gene (*HLF*),[152] [153] which belongs to the PAR subfamily of bZIP transcription factors (Fig. 56-3).[154] [155] [156] [157] Although little is known about the normal function of PAR proteins, their similarity to the *C. elegans* CES-2 protein, which regulates the death of specific nerve cells in the developing worm, suggests a role in cell survival.[158] [159] [160]

The hybrid E2A-HLF protein expressed by leukemic cells contains the two E2A trans-activation domains linked to the DNA-binding/protein-protein interaction domain of HLF.[152] [153] As predicted by the absence of other PAR proteins in hematopoietic cells, the E2A-HLF fusion binds DNA as a homodimer. [161] Like E2A-PBX1, E2A-HLF can transform NIH-3T3 fibroblasts, a process that requires the HLF leucine zipper domain and the E2A trans-activation domains. [162] E2A-HLF can also induce lymphoid tumors in transgenic mice.[163]

Recent work from our laboratory has indicated that E2A-HLF functions in leukemogenesis by inhibiting apoptosis. Expression of a dominant-negative form of E2A-HLF in t(17;19)-carrying cell lines blocked E2A-HLF function and resulted in apoptosis. [158] In normal pro-B lymphocytes, expression of E2A-HLF reversed IL-3-dependent and p53-induced apoptosis. These results suggest that a normal apoptotic pathway in B lymphoblasts, perhaps regulated by a CES-2-like protein, is interrupted by E2A-HLF in t(17;19) leukemias.[158] [160] In these cases, E2A-HLF may activate target genes normally repressed by CES-2-like proteins, causing abnormal cell survival and leukemic transformation.

Because t(17;19) is seen in less than 1% of ALL cases, its clinical significance is unclear. [164] However, of seven patients whose blasts expressed *E2A-HLF*, each died of disease despite aggressive therapy.[161] [165] [166] [167] It seems likely that resistance to chemotherapy in these cases is mediated by the role of E2A-HLF in inhibiting apoptosis.

MLL Fusion Genes

Translocations involving chromosome 11 band q23 occur in approximately 80% of infant ALL cases, 5% of AML cases, and 85% of secondary AML cases that occur in patients treated with topoisomerase II inhibitors. [63] [168] [169] [170] [171] [172] [173] [174] [175] [176] [177] The gene that is bisected by 11q23 translocations is designated *MLL* and encodes a 431-kd protein that shares sequence homology with the *Drosophila trithorax* protein, a regulator of homeotic gene function during embryogenesis. [178] [179] [180] [181] *Trithorax* regulates homeotic genes in the *Antennapedia* and *Bithorax* complexes of the fly and is required for normal head, thorax, and abdomen development.[182] *MLL* shares three regions of homology with *trithorax*, including two central zinc finger domains and a 210-amino acid C-terminal segment. [178] [179] [180] [181]

Figure 56-3 Schematic diagram of the recently discovered E2A-HLF hybrid transcription factor. This protein, a result of the t(17;19) translocation in pro-B lymphoblasts, combines the trans-activation domain of the E2A protein with the bZIP DNA-binding and dimerization domain of HLF, a protein of the bZIP family that appears to regulate gene expression in hepatocytes and renal cells. Because HLF is not usually expressed in hematopoietic cells, its unscheduled presence in lymphoid progenitors may serve as an oncogenic stimulus. *(From Inaba et al.,[161] with permission.)*

This C-terminal region also shares homology with the *Drosophila enhancer of zeste*, which, like *trithorax*, regulates genes in the *Antennapedia* and *Bithorax* complexes.[183] Other structural features of MLL include three AT hook domains near the N-terminus, which are thought to bind the minor groove of DNA in AT-rich regions, and a 47-amino acid region of homology with the noncatalytic domains of human DNA methyltransferase. [184] [185]

Translocation breakpoints cluster in an 8.5-kb region of *MLL* between exons 5 and 11 and fuse the N-terminal region of MLL, containing the AT hook and methyltransferase domains, to a variety of partner proteins. [177] [179] [180] [186] [187] [188] [189] [190] [191] [192] [193] Although the role of the partner protein in leukemogenesis has not been determined, it appears that at least some of the partners may contribute functional domains to the fusion. For example, t(4;11), t(9;11) and t(11;19)(q23;p13.3) fuse MLL to AF-4, AF-9, and ENL, respectively. [179] [180] [186] [187] [191] [194] All three of these partners are small serine- and proline-rich proteins with nuclear localization signals, suggesting that they may function as transcriptional transactivators. An unrelated gene, *ELL*, is fused to *MLL* by t(11;19)(q23;p13.1).[188] [189] ELL was also independently isolated as an RNA polymerase II elongation factor. [195] Still other partners, however, may simply act to truncate MLL and interfere with its normal function.[193]

Homologous recombination techniques have been used to create mice lacking one or both copies of *Mll*, the murine homologue of *MLL*.[196] *Mll* heterozygous mice

demonstrated the effects of haploinsufficiency, including anemia, thrombocytopenia, and reduced numbers of B lymphocytes. In addition, these mice had homeotic transformations of the cervical, thoracic, and lumbar regions that were the result of shifts in the pattern of *Hox* gene expression, establishing a crucial role for *Mll* in *Hox* gene regulation. These results are also consistent with other data suggesting a role for *Hox* genes in normal hematopoiesis.[197] [198] Mice with *Mll* homozygously inactivated died in utero and demonstrated no *Hox* gene expression, further supporting a key role for *Mll* in *Hox* regulation.

Corral et al.[199] used similar recombination techniques to generate an *Mll-AF9* fusion gene in embryonic stem cells and then introduced these cells into blastocysts to create chimeric mice. Although cells of various tissues expressed *Mll-AF9* under the control of the normal *Mll* promoter, transformation occurred only in myeloid cells, consistent with the association of *MLL-AF9* with AML in humans. However, the chimeric mice developed AML after a latency period of 412 months, suggesting that additional mutations may be required for the fully transformed phenotype. Chimeric mice that expressed a truncated *Mll*, rather than *Mll-AF9*, did not develop malignancy, indicating that the fusion is essential for transformation.

Molecular techniques to detect *MLL* fusions in ALL include Southern blot analysis and RT-PCR. Southern blots can detect essentially all *MLL* rearrangements regardless of the partner gene involved, and this technology has proved to be more sensitive and specific than standard cytogenetics.[172] [174] [200] RT-PCR assays are even more sensitive than Southern blotting and have the advantage of detecting specific fusion transcripts.[201] [202] [203] [204] However, RT-PCR is limited to detection of fusions for which the partner gene has been cloned and sequenced. Clinically, it is important to identify all patients with *MLL* gene rearrangements, as these rearrangements are associated with dismal outcomes despite aggressive chemotherapy.[172] [174] [205] [206] [207] [208] [209] Thus, patients with *MLL* rearrangements are candidates for bone marrow transplantation in first remission, or for other highly intensive therapies.

TEL-AML1 Fusion Gene in Early Pre-B ALL

Although t(12;21) is detected by cytogenetics in less than 1 in 1,000 ALL cases, the *TEL-AML1* fusion gene it creates is actually the most common genetic lesion in pediatric ALL, occurring in one-fourth of B-lineage cases.[210] [211] [212] [213] [214] The chimeric protein contains the HLH domain of TEL fused to nearly all of AML1, including both the trans-activation domain and the DNA- and protein-binding runt homology domain. Although the role of *TEL-AML1* in lymphoid transformation has not yet been elucidated, it is interesting that both genes are involved in a variety of hematopoietic malignancies. *TEL* was first identified in a fusion with the platelet-derived growth factor receptor- gene (*PDGFR*) created by t(5;12) in chronic myelomonocytic leukemia[215] and is also fused to *abl* and *MN1* by t(9;12) and t(12;22), respectively.[216] [217] AML1 is the DNA-binding component of the AML1-CBF- transcription factor complex that is targeted by t(8;21), t(3;21), and inv(16) in AML.[218] This complex is thus the most common target of chromosomal translocations in leukemia (Fig. 56-4).

It seems likely that a lack of expression of genes normally turned on by *AML1* plays a role in *TEL-AML1*-induced transformation. Evidence in support of this model includes the interference of AML1-dependent transcriptional trans-activation by TEL-AML1 in vitro.[219] In addition, homozygous disruption of the murine *AML1* gene or *CBF* gene results in a lack of definitive hematopoiesis, indicating that genes regulated by AML1 are essential for normal hematopoietic development.[220] [221] [222] [223] [224]

We and others have recently demonstrated that *TEL-AML1* expression is associated with an excellent prognosis, with event-free survivals of approximately 90% (Fig. 56-5).[225] [226] [227] [228] In addition, the prognostic impact of *TEL-AML1* was independent of age and leukocyte count and remained favorable across several different protocols.[226] [227] Thus, *TEL-AML1* expression identifies a large but previously unrecognized subset of B-precursor ALL patients who may be candidates for less intensive therapy.

Figure 56-4 The transcription factor complex AML1/CBF is the target of a variety of translocations, including t(3;21), t(8;21), t(12;21), and inv(16). TA and DBD represent the transactivation and DNA-binding domains of AML1. In AML, the t(8;21) fuses the DNA-binding domain of AML1 to ETO, whereas the t(3;21) fuses the same portion of AML1 to either EAP or EVI1. In other cases of AML, the inv(16) fuses CBF to MYH11. In ALL, the t(12;21) creates a chimeric protein consisting of the helix-loop-helix portion of TEL fused to nearly all of AML1. *(Adapted from Shurtleff SA, Buijs A, Behm FG et al: TEL/AML1 fusion resulting from a cryptic t(12;21) is the most common genetic lesion in pediatric ALL and defines a subset of patients with an excellent prognosis. Leukemia 9:1985, 1995, with permission.)*

Developmental Biology of Oncogenic Transcription Factors

A surprising connection has emerged from studies of oncogenic transcription factors and the developmental proteins regulating segmentation in *Drosophila*. The DNA-binding domains of these proteins often show striking homology (Table 56-2), an observation that carries important implications for the types of DNA sequence elements recognized by many transcription factors.

The classes of *Drosophila* segmentation genes shown in the first column of Table 56-2 reflect findings made over the last decade on the molecular control of pattern formation during *Drosophila* embryogenesis.[229] [230] According to this model, gap proteins are expressed in broad domains, approximately three segments wide, in response to gradients of maternal cytoplasmic polarity proteins. *Gap* genes are among the first to be transcribed in the embryo and earned their name from the characteristic spaces produced in segmentation patterns by mutations of these genes. Gap proteins act in concert to regulate the expression of pair-rule genes, which are transcribed in the primordia of every other segment and form repetitive segmental divisions in the embryo, and are expressed in a pattern of seven stripes along an anterior-to-posterior axis. Mutations of pair-rule genes generally cause the deletion of portions of every other segment. Pair-rule proteins regulate the expression of segment polarity genes, which are responsible for the formation of certain repeated structures, such as the boundary regions, common to each segment. Mutations of these genes cause the deletion of a portion of each segment, which is repetitively replaced by a mirror-image structure from the same segment. Pair-rule proteins interact with gap proteins and other regulators to control the expression of homeotic genes, which encode proteins that determine the unique structures (e.g., antennae, wings, legs) expressed by each segment. Thus, each of these classes of genes encodes transcriptional regulatory proteins whose expression is determined as a hierarchical cascade in the developing embryo.[231] Ultimately, these transcription factor genes regulate the developmental programs of structural genes that define the three-dimensional form of the unfolding embryo.

The structural similarities shown in Table 56-2 among the proteins regulating segmentation pattern in *Drosophila* and the oncogenic transcription factors activated by chromosomal translocation in acute leukemia suggest that these two classes of proteins may share functional properties as well. An obvious difference, however, is that the *Drosophila* proteins have been identified by the morphologic effects of recessive mutations that cause loss of function, whereas in ALL the proteins arise from dominant lesions that activate expression from one copy of the affected gene or genes, most of which are normally quiescent in lymphoid cells. The suggestion from this body of research is that the morphologic changes associated with lymphoid and

TABLE 56-2 -- Oncogenic Transcription Factors in Human Leukemia: Convergence with Proteins Regulating Segmentation Pattern in *Drosophila*

Drosophila Protein	Morphogenetic Role	Common DNA-Binding Domain	Leukemia Protein	Activating Translocation

myeloid cell differentiation are regulated by proteins analogous to those regulating the segmentation pattern during *Drosophila* embryogenesis. Hence, the proteins participating in leukemogenesis apparently interfere with a network of hematopoietic transcription factors leading to arrested cell development at stages corresponding to those of early lymphoid or myeloid progenitors. Recent evidence implicating the major *HOX* genes in the control of hematopoiesis as well as embryogenesis, together with the established roles of *Drosophila* segmentation genes in controlling *HOM-C* gene expression, suggests that the *HOX* loci may serve as proximal targets of a wide spectrum of hybrid and dysregulated transcription factors in the acute leukemias. [4] In this model, the oncogenic transcription factors inappropriately activate or suppress the expression of *HOX* genes, which in turn regulate gene programs with pleiotropic effects on normal hematopoietic cell development.

Tyrosine Kinase Genes: *bcr-abl*

The 22q chromosomal marker, which arises from the t(9;22)(q34;q11), was originally identified in patients with chronic myelogenous leukemia (CML), but is also found in about 4% of childhood cases and 25% of adult cases of ALL. [16] [232] [233] [234] The t(9;22) breakpoints on the distal tip of the long arm of chromosome 9 are variable in CML and may occur over a distance of more than 100 kb within the *abl* proto-oncogene, upstream of the tyrosine kinase domain. [235] [236] [237] By contrast, the CML breakpoints on chromosome 22 are confined to a 5.8-kb region of DNA known as the major breakpoint cluster region (M-bcr). [238] This region of chromosome 22 is within a gene called *bcr* [238] [239] that encodes a 160-kd phosphoprotein with undetermined function. As a result of the translocation, a *bcr-abl* fusion gene is produced, consisting of 5 (upstream) sequences from *bcr* and 3 (downstream) sequences of *abl*. The 8.5-kb fusion transcript found in CML encodes a 210-kd hybrid protein (p210) that is activated as a tyrosine-specific protein kinase similar to the v-abl protein. [240] [241] [242] [243]

Although t(9;22) is identical by karyotyping in CML and ALL, molecular studies of the *bcr* and *abl* proto-oncogenes, which are rearranged in both diseases, have revealed potentially important differences. [244] [245] [246] In ALL, the rearrangement produces a 6.5- to 7.0-kb fusion transcript and a 185- to 190-kd hybrid protein (p190), which are distinct from the products of the rearranged *bcr-abl* fusion gene in CML. [244] [245] [246] The breakpoints on chromosome 22 in ALL cases are not within the 5.8-kb region of *bcr* that contains the breakpoints in CML, but lie further upstream within the *bcr* gene, in a minor breakpoint cluster region (m-bcr). [247] [248] [249] The ALL fusion protein includes N-terminal bcr amino acids but lacks the internal residues found in the CML fusion proteins near the *bcr-abl* junction.

N-terminal sequences of *abl* are replaced in activated forms of the gene, with the Moloney virus *gag* gene in the case of v-*abl* [250] [251] [252] and with *bcr* in the 9;22 translocation of CML. [240] [241] [242] [243] Both the v-*abl* and the *bcr-abl* fusion genes can transform pre-B cells, but the *bcr-abl* fusion gene is unable to transform fibroblasts unless it is also fused to the *gag* gene. [253] Thus, N-terminal alterations influence not only the ability of *abl* to function as a lineage-specific transforming gene but also the tyrosine kinase activity of its protein product.

When expressed in murine hematopoietic precursors, both p190 and p210 induce a syndrome similar to CML. [254] [255] [256] [257] Ras signaling is required for transformation, and activated abl is coupled to ras by the GRB2, SHC, and CRKL adapters, resulting in activation of Jun kinase. [258] [259] [260] Transformation by bcr-abl also involves myc, cyclin D1, and the signal transducer STAT5. [261] [262] [263] Hence, multiple signaling pathways and cell-cycle-regulated genes are involved in transformation of hematopoietic cells by bcr-abl.

Expression of *bcr-abl* is associated with an extremely poor prognosis in ALL patients despite treatment on contemporary protocols. [233] [264] [265] Until recently, it was believed that the only curative treatment for Philadelphia chromosome-positive ALL was bone marrow transplantation in first remission. However, results from St. Jude indicate that a subset of these patients, primarily those with low leukocyte counts at diagnosis, are, in fact, cured with intensive chemotherapy. [266] [267]

Tumor Suppressor Genes

Much attention has been focused on recessively acting oncogenes whose products normally suppress tumor formation in differentiating cells of a particular lineage. Loss of function of a tumor suppressor protein, occurring through deletion or mutational inactivation of both chromosomal loci of the gene that encodes it, leads to malignant transformation. Knudson first proposed that inactivation of both alleles of a single locus is needed to initiate the development of retinoblastoma, basing his ideas on the observed frequencies of hereditary and sporadic forms of this disease. [268] Allelic loss of defined regions of many different chromosomes has been linked to specific types of human tumors. [269] [270] By analogy with the findings in retinoblastoma, a reasonable hypothesis is that each of these regions harbors a tumor suppressor gene whose product is uniquely involved in the inhibition of cell cycle progression and promotion of terminal differentiation of the normal cells that give rise to these different types of tumors. Tumor suppressor genes that play an important role in ALL include *p53* [271] [272] [273] [274] [275] [276] and the *p16* locus. [277] [278]

p53, which is located on chromosome 17, band p13, is mutated or lost through chromosomal deletion in a wide variety of human tumors, [274] including colon cancer, [275] [276] lung cancer, [279] breast cancer, [280] and osteosarcoma. [281] Heritable cancer associated changes of the *p53* tumor suppressor gene occur in families with Li-Fraumeni syndromean unusual aggregation of sarcomas, brain tumors, leukemias, adrenocortical carcinomas, and premenopausal breast cancers. [282] [283] [284] [285] *p53* encodes a 53-kd transcription factor that functions as a cell cycle checkpoint. [271] [272] [273] [274] [275] [276] [282] [283] [284] [285] *p53* expression is increased by DNA damage, blocks cell division at G_1 to allow DNA repair, and activates apoptosis in cells that have suffered DNA damage. [271] [286] [287] [288] [289] [290] [291]

p53 is also inactivated in a variety of hematopoietic malignancies, including B-cell ALL and Burkitt lymphoma, but is mutated or deleted in less than 3% of pediatric B-precursor or T-cell ALL cases at diagnosis. [292] [293] [294] It thus appears to play a limited role in the etiology of pediatric leukemia. *p53* mutations, however, are seen in approximately 25% of relapsed T-cell ALL cases, suggesting a role for *p53* inactivation in the development of resistant disease. [292] [293] In addition, *p53* mutations were detected in three of ten ALL patients in whom induction therapy failed or who sustained early relapse, further supporting a role for *p53* inactivation in disease progression. [295] [296]

The cyclin-dependent kinase inhibitors (CDKIs), which include p15 (INK4B/MTS2), p16 (INK4A/MTS1/CDKN2), p18 (INK4C), p19 (INK4D), p21 (WAF1/CIP1/SDI1/CAP20), p27 (KIP1), and p57 (KIP2), compose a family of tumor suppressors that negatively regulate the cell cycle by inhibiting cyclin-dependent kinase (CDK) phosphorylation of pRB. [297] For example, *p15* and *p16* encode highly homologous proteins that function as specific cell cycle inhibitors by inhibiting activated cyclin D-cdk4/6 complexes. These complexes control the cell cycle by phosphorylating and inactivating pRB, leading to release of transcription factors necessary for entry into S phase. Thus, inactivation of *p16* is predicted to increase the proportion of cells entering S phase and hence increase cell proliferation. In fact, while the roles for *p15, p18, p19, p21, p27*, and *p57* in malignancy appear to be limited, *p16* is among the most commonly mutated genes in human cancer. [277] [278]

Deletions of *p16* were initially detected in nearly one-half of

tumor-derived cell lines, suggesting that *p16* is a tumor suppressor gene. [277] [278] Subsequent analysis of primary tumor samples, however, revealed a much lower frequency of *p16* deletions (1020%) and very few point mutations, suggesting that inactivation in some cases occurs during the establishment of permanent cell lines in vitro. Homozygous deletion of *p16* has been detected in approximately one-fourth of pediatric B-precursor ALL cases and three-fourths of T-cell cases. [298] [299] [300] [301] [302] [303] [304] [305] [306] [307] [308] [309] In addition, *p16* deletions are associated with higher leukocyte counts at diagnosis and may represent an independent prognostic factor in pediatric ALL. [301] [303] [309]

Direct evidence for the role of the *INK4a* locus in tumorigenesis was recently provided by the targeted disruption of exon 2 of *p16* in mice. [310] *p16*-deficient mice developed tumors (primarily lymphomas and fibrosarcomas) that were enhanced by the topical application of carcinogens and ultraviolet light. [310] A major breakthrough, however, has shed new light on the role of *INK4a* as a tumor suppressor locus. [311] [312] This locus, which encodes the p16 protein, also encodes a protein from an alternative reading frame, designated $p19^{ARF}$. [311] Interpretation of *p16* knockout experiments was uncertain because targeted disruption of exon 2 of *p16* also disrupted $p19^{ARF}$. Further genetic analysis showed that selective disruption of $p19^{ARF}$ reproduced the phenotype described for *p16*-null mice, indicating that $p19^{ARF}$ is a bona fide tumor suppressor. [311] In addition, embryonic fibroblasts from $p19^{ARF}$-null mice did not senesce and were efficiently transformed by Ha-*ras*, indicating a crucial role for $p19^{ARF}$ in cell cycle control and immortalization. It is likely that both *p16* and $p19^{ARF}$ are tumor suppressors, acting through either the pRB

or p53 pathways in different tumor subsets.[312]

Identification of recurring chromosome deletion syndromes in human ALL indicates that other tumor suppressor loci may be involved in this disease. These syndromes, which affect the long arm of chromosome 6, the short arm of chromosome 9, or the short arm of chromosome 12, can be found in leukemic cells from approximately 10% of patients with ALL, making them among the most frequent cytogenetic abnormalities in this disease. Functional deletion can result either from interstitial deletion of the involved chromosome arm or from derivative chromosomes that result from unbalanced chromosomal translocations. For each chromosome, the deleted regions overlap a single target region, which may contain key genes of the tumor suppressor type, whose loss could be an important step in leukemic transformation.

Deletions of the long arm of chromosome 6 are consistently found in about 10% of cases of ALL. [63] Interstitial deletions affecting bands 6q15q24 have been reported most frequently; translocations with breakpoints within this region are also common. Band q21 of chromosome 6 seems to be involved in each of the abnormalities, suggesting that the target gene(s) resides in this region. Deletions of chromosome 6q occur with equal frequency in pro-B, pre-B, and T-cell cases.

Deletions or translocations involving the short arm of chromosome 12 are also found in about 10% of ALL cases, with most clustered around band 12p13. [63] These cases generally have a B-precursor phenotype, and blast cells usually express CD10 and HLA-DR on the cell surface. Abnormalities of the short arm of chromosome 12 are rarely found in T-cell cases. Translocations involving chromosome 12p13 may be balanced or unbalanced and can involve multiple different donor chromosomes. Molecular studies, however, have revealed that the majority of translocations involving 12p13 are cryptic 12;21 translocations, resulting in the *TEL-AML1* fusion.[210] [211] [212] [213] [214] In the cases with unbalanced translocations, DNA sequences distal to the breakpoint are lost from the affected homolog and subsequently from the leukemia cell genome, so the result is similar to interstitial deletion. The frequency of deletions involving the 12p13 region suggests that these lesions primarily inactivate one allele of a tumor suppressor gene in this chromosomal region. Although the *TEL* gene is a common target of deletion in these cases, there is also evidence for a second tumor suppressor gene in the 12p13 region. [313] [314] [315] [316] [317] [318]

Deletions affecting the short arm of chromosome 9 are associated with T-cell disease, bulky lymphadenopathy, splenomegaly, hyperleukocytosis, and a high risk of treatment failure, but they may also occur in patients with standard-risk early pre-B ALL. [319] [320] The critical region of deletion appears to be the 9p2122 region, suggesting the presence of a potential tumor suppressor gene.

Mutated *ras* Genes

Activation of cellular proto-oncogenes by point mutation is difficult to detect, because such lesions lack the cytogenetic abnormalities that signal other forms of transforming alterations. Genes of this type must be identified in experimental systems, so that investigators know in advance the type of activating point mutations that are likely to occur in human tumors. The prototypic genes of this class are genes of the *ras* family, with mutations affecting defined amino acids of the corresponding proteins. Human tumor DNAs were initially found to contain activated homologs of either the H- *ras* or K-*ras* genes,[321] [322] [323] proto-oncogenes that had already been identified on the basis of their homology with viral oncogenes. Gene transfer methods identified an additional member of the *ras* gene family, called N-*ras*, [324] [325] that had not been previously observed as a component of a transforming retrovirus.

Proto-oncogenes of the *ras* familyH-*ras*, K-*ras*, and N-*ras*encode 21-kd proteins that are associated with the inner surface of the cytoplasmic membrane.[326] These proteins bind guanidine nucleotides and function as intermediates in signal transduction pathways that regulate the growth of cells. The *ras* proto-oncogenes are activated to transforming oncogenes by somatic mutations that alter the amino acids specified by codons 12, 13, or 61. [327] Mutated *ras* genes also bind guanine nucleotides, but have diminished capacity to hydrolyze GTP to GDP. [328] [329] [330] Transforming properties of activated ras proteins may result from their inability to hydrolyze GTP, which could play an important role in modulating signal transduction.

The transforming potential of human *ras* genes activated by point mutation has been documented in experimental systems. The *ras* oncogenes will transform NIH-3T3 murine fibroblasts in vitro, and will collaborate with other oncogenes to transform primary cultures of embryonic fibroblasts. [331] [332] [333] [334] In addition, their role in mammalian tumorigenesis has been documented in carcinogen-induced animal tumor model systems.[335] [336] [337]

Activated N-*ras* genes appear to be preferentially involved in hematopoietic malignancies. They were detected in the myeloid cell lines HL-60, KG1, and Rc2A, [338] [339] in fresh leukemic cell samples from patients with AML and CML,[340] [341] [342] and in lymphoblastic leukemias with a T-cell immunophenotype.[343] In AML, N-*ras* gene mutations involving codon 13 or 61 were found in approximately 20% of cases, regardless of morphologic subtype. [340] [344] Mutation of codon 12 of the K-*ras* gene was also observed in two of 37 cases studied.[344] In a study of lymphoblasts from children with ALL, 2 of 19 patients showed mutated N-*ras* genes, both involving codon 12.[345] Mutated *ras* genes have also been documented in patients with preleukemic syndromes, indicating the potential involvement of activation of these genes in an early stage in the biogenesis of some leukemias.[346]

Gene Amplification

Gene amplification at the DNA level provides the cell a means to increase expression of critical genes whose products are ordinarily tightly controlled. Clinically important examples of

proto-oncogene amplification have been documented in solid tumors of adults and children. For example, the N- *myc* gene is amplified 10- to 300-fold in tumor cells in about one-third of cases of childhood neuroblastoma; such amplification has been linked to an advanced stage of disease and a poor prognosis. [347] However, the cytogenetic hallmarks of gene amplificationdouble-minute chromatin bodies and homogeneously staining regionsare rarely found in karyotypes of human leukemia cells, making it unlikely that consistently amplified cellular proto-oncogenes will be identified in this disease.

Abnormalities of Leukemia Cell Ploidy

Abnormalities of chromosome number, which generally occur in the absence of specific chromosomal translocations, have important prognostic implications in childhood ALL.[348] [349] [350] In an analysis of patients treated in the St. Jude Total Therapy studies IX and X, chromosome number as determined by karyotyping was the strongest single predictor of outcome: patients with hyperdiploid >50 chromosomes had the best response to therapy. [350] Hyperdiploid ALL patients can also be identified rapidly by flow cytometric measurement of the DNA of leukemic blast cells, in which nuclei stained with a DNA-specific dye are analyzed for the amount of DNA per cell.[351] This DNA measurement (DNA index, or DI) is expressed as the ratio of the cellular DNA content of G_1 /G_0 -phase leukemic cells compared with that of normal diploid cells. Using this technique, we showed that among patients treated on our Study X protocol, DI 1.16, corresponding to 53 chromosomes, was the most favorable prognostic factor.[351] More recently, the favorable impact of hyperdiploidy has been confirmed for patients treated on the Pediatric Oncology Group AlinC 14 protocol[352] and St. Jude studies XI[34] and XII.[353] The improved outcome for hyperdiploid patients may be due, at least in part, to increased sensitivity of hyperdiploid blasts to antimetabolites and to increased accumulation of methotrexate polyglutamates. [354] [355]

Specific subsets of the hyperdiploid group of patients may have even better outcomes than the group as a whole. For example, Harris et al. [356] have demonstrated that among patients with DI 1.16, those with trisomies of both chromosomes 4 and 10 had a better outcome than those without these trisomies. Similarly, we have shown that patients with 5667 chromosomes fare better than those with 5155 chromosomes.[357] In contrast to the hyperdiploid group, patients with a near-haploid or hypodiploid <45 line appear to have a poor prognosis and may require alternative therapies. [358]

IMPLICATIONS OF GENETIC FINDINGS FOR LEUKEMIA THERAPY

Childhood ALL: A Model for Gene-based Risk Assessment

Chromosomal and molecular genetic abnormalities in the leukemic blasts of children with ALL are among the best predictors of response to currently available chemotherapy. Initially performed by time-consuming and labor-intensive cytogenetic methods, the classification of chromosomal abnormalities in leukemic lymphoblasts has been aided by flow cytometric techniques (to detect hyperdiploidy) and by clinically applicable molecular techniques. [355] Thus, at St. Jude Childrens Research Hospital, leukemic blast cells from each new case of childhood ALL are examined for the ploidy of leukemic stem lines, *MLL* and *TEL* gene rearrangements, and expression of the *MLL-AF4, TEL-AML1, E2A-PBX1*, and *bcr-abl* fusion transcripts. With the availability of these tests, uniform treatment of pediatric ALL patients is no longer optimal. Rather, modern trials emphasize risk-based therapy to reduce toxicity in good-risk patients and to ensure appropriate therapy for patients at a high risk of relapse.

Currently, we propose a risk classification scheme for childhood ALL based largely on genetic features of leukemic blasts (Table 56-3).[353] [360] According to this scheme, patients with hyperdiploidy or *TEL-AML1* are in a low-risk group and are candidates for antimetabolite-based therapy. The intermediate-risk group includes patients with standard-risk age and leukocyte count as defined by the NCI criteria, [361] if they have no prognostically important genetic features. The high-risk group includes patients with high-risk age and leukocyte count, [361] T-cell phenotype, *E2A-PBX1*, or a slow, early response to therapy. Patients in the very high-risk groupthose with *MLL* gene rearrangements or expression of *bcr-abl*are eligible for bone marrow transplantation in first remission. This risk classification scheme provides a means to incorporate the molecular genetic findings of the past decade into therapy trials that seek to define optimal treatment intensity.

Therapy Targeted to Oncogenic Transcription Factors

Improved understanding of the leukemia-inducing pathways mediated by aberrantly controlled transcription factors has provided a mechanistic underpinning for the positive responses of acute promyelocytic leukemia (APL) patients to therapy with all-trans-retinoic acid (ATRA) and arsenic trioxide

TABLE 56-3 -- Clinical Risk Assignment in Childhood ALL by Genetic Characterization of Leukemic Lymphoblasts

Risk Group	Features	Patients Affected (%)	Recommended Therapy
Low risk	Hyperdiploid (DI >1.16)	20	Conventional anti-metabolite-based
	TEL-AML1 fusion	20	
Intermediate risk	Standard-risk age/leukocyte count,[a] without clinically significant genetic risk features	15	Intensified anti-metabolite based
High risk	*E2A-PBX1* fusion	6	Intensive multi-agent chemotherapy
	T-cell ALL	15	
	High-risk age/leukocyte count,[a] without clinically significant genetic risk features	15	
Very high risk	*bcr-abl* fusion	3	Allogeneic bone marrow transplantation in first remission
	MLL rearrangement	4	
	Induction failures	2	

[a] Standard- and high-risk refer to NCI criteria.[361]

Figure 56-6 (Figure Not Available) The effects of all- *trans*-retinoic acid (ATRA) and arsenic trioxide ($As_2 O_3$) on the blast cells of acute promyelocytic leukemia. ATRA interaction with PML-RAR causes degradation of the fusion protein and reassembly of PML into nuclear structures called PODs. $As_2 O_3$ induces even more rapid degradation of PML-RAR and eliminates native PML. ATRA leads to promyelocyte differentiation, while $As_2 O_3$ induces programmed cell death. *(Adapted from Look AT: Arsenic and apoptosis in the treatment of acute promyelocytic leukemia. J Natl Cancer Inst 90:86, 1998, with permission.)*

($As_2 O_3$).[362] [363] [364] [365] [366] [367] [368] The vast majority of APL patients have a t(15;17) that produces PML-RAR fusion proteins, whose DNA and ligand-binding domains, encoded by the *RAR* gene on chromosome 17, are linked to amino acids encoded by the *PML* gene on chromosome 15.[369] [370] [371] [372] [373] PML-RAR fusion proteins appear to interfere with normal myeloid cell development, leading to arrested differentiation in the promyelocyte stage and promoting the survival of the leukemic cells.[374] In response to pharmacologic doses of ATRA, the fusion proteins are degraded and the leukemic cells differentiate into mature myeloid cells with a limited life span (Fig. 56-6 (Figure Not Available)). [363] [364] [365] This therapy is specific for APL blasts that express PML-RAR fusion proteins; it is ineffective for other types of myeloid leukemia. Although resistance to ATRA develops quickly, within 34 months on the average, this specific modulator of PML-RAR chimeric receptors has proved a useful adjunct to cytotoxic chemotherapy for inducing remissions and improving disease-free survival in APL patients. [375]

Recently, $As_2 O_3$ was shown to be effective in patients with APL that was resistant to ATRA.[367] [368] In contrast to ATRA, which causes terminal differentiation of leukemic promyelocytes, $As_2 O_3$ rapidly induces apoptosis (Fig. 56-6 (Figure Not Available)). [376] [377] Because the apoptotic effects of $As_2 O_3$ occur in cells sensitive or resistant to ATRA, the incorporation of this agent into front-line protocols may improve the outcome of APL patients. In addition, it may be especially useful in the treatment of relapsed patients.

Whether better understanding of the mechanisms of action of other chimeric or dysregulated leukemogenic transcriptional control proteins will lead to improved therapy is difficult to answer. Unfortunately, most transcription factors do not contain convenient ligand-binding domains, so the model provided by chimeric PML-RAR proteins in APL will be difficult to reproduce in leukemias with the activated transcription factor genes listed in Table 56-1 . Nonetheless, new drugs may be found that

interfere with the modulation of gene expression by specific transcription factors and lack many of the side effects of available cytotoxic agents. Other approaches, such as antisense strategies to block chimeric transcripts and gene therapy to introduce dominant negative inhibitors of protein-protein or protein-DNA interactions essential for transcription factor function, could yield novel therapies. [4]

AML DEVELOPING AFTER THERAPY FOR ALL

With the wide use of genotoxic drugs, including the epipodophyllotoxins, in recent clinical trials, an apparent increase has been observed in the incidence of secondary AML developing in patients treated for ALL. [378] [379] [380] [381] Epipodophyllotoxin-induced secondary AML is characterized by rearrangements of the *MLL* gene, a short incubation period without a myelodysplastic phase, and a monoblastic morphology. [200] [378] [380] [382] [383] [384] [385] In addition, the risk of secondary AML is influenced by the schedule of epipodophyllotoxin administration and the concomitant use of other agents. [379] [380] [381] Unfortunately, secondary AML induced by epipodophyllotoxins is generally not responsive to chemotherapy, suggesting that allogeneic bone marrow transplantation is warranted for this group of patients.

FUTURE DIRECTIONS

The immediate applications of the emerging molecular information include a redefinition of risk classification schemes to emphasize the roles of somatically acquired genetic abnormalities that carry a defined prognosis and likelihood of therapeutic failure. Patients are assigned to treatment according to their initial clinical features and, increasingly, the genetic and biologic properties of their leukemic cells. We are now in a position to view ALL as a group of heterogeneous diseases defined by discrete molecular lesions. As these lesions have been systematically analyzed in larger numbers of patients, it has been possible to devise new classification schemes for ALL that reflect prognosis with exquisite precision. The opportunity is now at hand to improve therapy through randomized trials coordinated on a nationwide or even worldwide scale that focus on key subsets of acute leukemia patients whose lymphoblasts harbor specific chimeric fusion genes. The development of new drugs based on the molecular biology of ALL is clearly a priority for the future, and will likely take the form of compounds developed to specifically interfere with oncoproteins expressed by each patients leukemic blasts.

Chapter 57 - Clinical Manifestations of Acute Lymphoblastic Leukemia

Stacey L. Berg
C. Philip Steuber
David G. Poplack

Before the institution of modern chemotherapy, acute lymphoblastic leukemia (ALL) was a uniformly fatal disease, most patients surviving only 23 months. With current chemotherapy, most children with ALL have prolonged disease-free survival and up to approximately 70% are considered cured. Although most adults also attain complete remission with chemotherapy, 3- to 5-year actuarial survival rates range from only 2035%. [1] [2] [3]

EPIDEMIOLOGY

Acute lymphoblastic leukemia is the most common malignancy of childhood. In the pediatric population, ALL is five times more frequent than acute nonlymphoblastic leukemia (ANLL). In contrast, ALL accounts for less than 1% of all adult malignancies, and for less than 20% of the acute leukemias in this population. [4] [5] [6] In children, the peak incidence of ALL occurs at approximately 2 to 3 years of age. [7] In adults, the greatest number of cases occur in those older than 65 years.

Some children are at particular risk for development of ALL. Children with certain chromosomal abnormalities, including Downs syndrome, [8] Blooms syndrome,[9] Fanconis anemia, [10] and ataxiatelangiectasia,[11] are all at higher risk than the general population for development of leukemia. In addition, siblings, especially twins, of children with leukemia are at greater risk for development of leukemia, although this risk may be only approximately twice that of the general population. [12] [13] Some cases of childhood ALL may be related to hereditary or acquired mutations in the *p53* gene.[14]

CLINICAL MANIFESTATIONS

Patients with ALL present most frequently with signs and symptoms of the uncontrolled growth of leukemic cells in bone marrow, lymphoid organs, and other sites of extramedullary spread. Bone marrow involvement results in varying degrees of anemia, thrombocytopenia, and granulocytopenia that may be manifested by pallor and fatigue, petechiae, purpura or bleeding, and fever. Liver, spleen, and nodal enlargement is present in most patients and are the most common sites of extramedullary disease spread. Both hepatosplenomegaly, which occurs in approximately two thirds of patients, and lymphadenopathy, clinically detectable in over half of presenting cases, are usually asymptomatic. Bone pain, however, is a common presenting feature, particularly in the young child with ALL whose first symptom may be the onset of a limp or refusal to walk. [15]

Symptoms may be present from a few days to several weeks before the diagnosis of ALL is made, although in some cases a relevant clinical history may precede diagnosis by several months. The nonspecific nature of the signs and symptoms of ALL occasionally leads to delay in diagnosis. In addition, because ALL may imitate a variety of disorders, there may be diagnostic confusion. For example, arthralgias arising from leukemic infiltration of the joints may be confused with juvenile rheumatoid arthritis or osteomyelitis. In rare cases, ALL has presented with unusual manifestations such as aplastic anemia or hypereosinophilia (Table 57-1 (Table Not Available)). [16] [17]

Extramedullary Spread

Acute lymphoblastic leukemia frequently involves organs other than bone marrow. Most patients have some extramedullary disease at diagnosis and extramedullary relapse is a known complication of the disease. The incidence of occult extramedullary involvement in patients presumed to be in clinical remission is difficult to ascertain, but has been estimated to be as high as 50%. [18] [19] [20] Actual organ dysfunction secondary to leukemic involvement is rare and usually is seen in patients with progressive, end-stage disease. The occurrence of an extramedullary relapse is significant because it frequently heralds the development of bone marrow relapse. The most commonly affected extramedullary sites of disease include the central nervous system, testes, lymph nodes, liver, spleen, and kidney. Of these sites, the central nervous system (CNS) and the testes have the greatest clinical significance.

Central Nervous System

Central nervous system leukemia is presumed to develop either from hematogenous spread, through seeding of the meninges by circulating leukemic cells, or by direct extension from involved cranial bone marrow. [21] [22] [23] The meninges are the primary site of disease, but, particularly in advanced disease, other sites within the brain parenchyma and spinal cord may be involved. [24] In patients with clinically overt CNS leukemia, signs and symptoms are usually caused by increased intracranial pressure and include headache, nausea and vomiting, lethargy or irritability, papilledema, and nuchal rigidity. Cranial nerves, most commonly the seventh, third, fourth, and sixth, may be involved and may on rare occasions be an isolated site of CNS relapse. The hypothalamicobesity syndrome, in which infiltration of the hypothalamus produces hyperphagia and pathologic weight gain, is a rare complication of CNS leukemia. Because of its varied symptomatology, CNS leukemia must be

TABLE 57-1 -- Some Unusual Clinical Presentations of Acute Lymphoblastic Leukemia

(Not Available)

Adapted from Nesbit,[116] with permission.

considered as a possible diagnosis in any patient with ALL in whom neurologic signs and symptoms develop.

The diagnosis of CNS leukemia is made by evaluation of cerebrospinal fluid (CSF) obtained by lumbar puncture. CNS leukemia is often classified into three groups: CNS 0, in which there are <5 WBC/l of CSF and no blasts are seen; CNS 2, in which there are <5 WBC/l of CSF, but blasts are present; and CNS 3, in which there are 5 WBC/l of CSF and blasts are present, or cranial nerve palsies are noted. [21] In symptomatic patients, the opening CSF pressure is usually increased, the CSF cell count is usually elevated, the CSF protein is frequently elevated, and the CSF glucose may or may not be decreased. CSF examination after concentration of cells by cytocentrifugation reveals the presence of leukemic lymphoblasts. The heightened awareness of CNS leukemia has led to routine lumbar puncture surveillance of patients undergoing treatment. As a consequence, in many patients, the diagnosis of CNS leukemia is being made earlier in the course of CNS disease. In such cases, the CSF opening pressure, cell count, protein, and glucose may all be normal and only careful examination of a cytocentrifuged CSF specimen may help identify leukemic lymphoblasts. Other techniques have been explored in an attempt to improve the ability to diagnose CNS leukemia in equivocal cases, including terminal deoxynucleotidyl transferase (TdT) determination and the use of monoclonal antibodies and flow cytometry. Contrast-enhanced magnetic resonance imaging or computed tomography scanning may also be useful.

Central nervous system involvement is relatively uncommon at diagnosis. Less than 5% of children and up to 15% of adults have evidence of CNS disease on initial evaluation. [24] Unless adequate CNS preventive therapy is administered, however, CNS disease eventually develops in most patients. This is presumed to be related, in part, to the bloodbrain barrier, which effectively makes the CNS a pharmacologic sanctuary and prevents many systemically administered antileukemic agents from penetrating adequately into the CNS. For this reason, specific CNS treatment, in the form of intrathecal chemotherapy or cranial radiation, is required to prevent the development of CNS leukemia. Once present, CNS leukemia, although usually controllable in the short term, frequently recurs. The most important consequence of CNS leukemia is that it places patients at a high risk of subsequent bone marrow relapse. Therefore, the development of effective means of preventing CNS disease has become an important focus of clinical investigation, particularly (but not solely) in childhood ALL, where the incidence of CNS disease historically has been higher than in adults.

Testicular Leukemia

As the survival of patients with ALL has increased, so has the incidence of testicular involvement, particularly in children, where testicular leukemia has become a major site of disease recurrence. This complication occurs in approximately 1015% of boys undergoing chemotherapy. The testes are also a site of late relapse in a substantial proportion of boys who had previously successfully completed a full chemotherapy regimen. [25] [26] Although clinically evident testicular involvement is rare at initial diagnosis, occult testicular disease has been reported in up to 25% of newly diagnosed boys. [27] When clinically overt, testicular leukemia presents as a painless testicular enlargement that is usually unilateral. Diagnosis of testicular involvement is made by wedge biopsies, which should be done bilaterally because of the high incidence of contralateral testicular involvement. [28] Testicular leukemia is characterized by infiltration of leukemic cells into the interstitium; involvement of the seminiferous tubules occurs in more advanced disease. [29] Although it had been believed that the testes are a leukemic sanctuary site, protected from systemic

chemotherapy by a bloodtestes barrier, animal studies suggest this is not the case. [30]

Testicular disease frequently occurs as an isolated clinical relapse in patients in bone marrow remission. The actual incidence of true isolated testicular disease, however, may be less than previously believed. In one study, a high percentage of patients with testicular relapse who were presumed to be in bone marrow remission were found to have occult leukemia in other abdominal sites, including lymph nodes, liver, and spleen, when evaluated by exploratory laparotomy. [31] Thus, the frequent diagnosis of testicular involvement may simply reflect the relative ease with which recurrence can be detected clinically at this anatomic site. This point is underscored by the observation that the most successful treatment regimens for testicular recurrence use both bilateral testicular radiation (usually 2,400 cGy) and intensive systemic reinduction and retreatment. [31] [32] [33] [34]

As in the case of CNS leukemia, testicular recurrence frequently is followed by systemic relapse. This fact, and the observation that occult disease can be detected in up to 15% of boys who have successfully completed a full treatment course, led to the practice of performing routine testicular biopsies during maintenance treatment or immediately before its completion. Histopathologically, however, testicular biopsies are notoriously difficult to assess and are associated with a relatively high false-negative rate. This has caused investigators to question the wisdom of performing surveillance testicular biopsies, in view of their relative inability to predict eventual testicular relapse. [34] [35] [36] [37]

Lymph Nodes

Nodal involvement is a characteristic feature of ALL and is often responsible for bringing the patient to medical attention. Leukemic involvement usually results in obliteration of the normal microscopic structure of the node. Typically, the lymphadenopathy is generalized and enlarged nodes are painless and freely moveable. Nodal enlargement is an indirect measure of tumor burden and has been associated with prognosis. The presence of massive lymphadenopathy or a large mediastinal mass, a particular feature of patients with T-cell disease, has been associated with a poor prognosis. [38] [39] [40]

Liver and Spleen

Hepatosplenomegaly is common in newly diagnosed patients with ALL. As in the case of nodal enlargement, there is a correlation between the extent of hepatic and splenic enlargement and prognosis, significant enlargement being linked to a poor outcome. [40] [41] Pathologically, these organs show diffuse enlargement secondary to infiltration by leukemic lymphoblasts. In the spleen, the normal distinction between red and white pulp is lost. In the liver, leukemic infiltration of the portal areas is common. Even in cases associated with marked hepatomegaly, liver function abnormalities, if present, are usually mild.

Kidneys

Renal enlargement at diagnosis is common and represents diffuse infiltration by leukemic blast cells. [42] [43] Preferential involvement of the cortex occurs. Renal dysfunction, in the absence of the development of uric acid nephropathy, is a rare phenomenon.

Differential Diagnosis

In the differential diagnosis of ALL, the clinician must include a variety of malignant and nonmalignant disorders, some of

TABLE 57-2 -- Differential Diagnosis of ALL

Nonmalignant disorders
Aplastic anemia
Myelodysplastic syndrome (a)
Myelofibrosis (a)
Autoimmune diseases (e.g., systemic lupus erythematosus) (a)
Infectious mononucleosis
Juvenile rheumatoid arthritis (c)
Idiopathic thrombocytopenic purpura (c)
Leukemic reactions secondary to infection
Malignant disorders
Other leukemias
Hodgkins and non-Hodgkins lymphoma
Bone marrow metastases from solid tumors (e.g., neuroblastoma) (c)
Multiple myeloma (a)

Where indicated, symbols denote disorders that are to be particularly considered in the differential diagnosis of children (c) or of adults (a).

which are listed in Table 57-2 . ALL must be distinguished from other malignancies, including both Hodgkins and non-Hodgkins lymphomas, and those solid tumors that may exhibit metastatic spread to bone marrow. For example, the morphologic appearance of neuroblastoma in the bone marrow may be difficult to differentiate from that of ALL, especially if pseudorosettes are not present. Infectious mononucleosis, immune thrombocytopenic purpura, aplastic anemia, and infectious causes of lymphocytosis (e.g., pertussis) are other conditions that may mimic ALL. Careful evaluation of a bone marrow aspirate using special stains as well as a panel of monoclonal antibodies usually permits the clinician to make the definitive diagnosis of ALL (see later).

LABORATORY EVALUATION

Hematologic Findings

Over 90% of patients with ALL have clinically evident hematologic abnormalities at diagnosis. These usually reflect the degree to which normal marrow is replaced with leukemic cells. Anemia, usually normochromic and normocytic and characteristically accompanied by a low reticulocyte count, is present in approximately 80% of cases. In approximately 50% of patients, the initial leukocyte count is elevated; in up to 25% it is >50,000/ml at presentation. Patients with a profoundly elevated leukocyte count at diagnosis (>50,000/ml) have a particularly poor prognosis. Despite the elevation in leukocyte count at diagnosis, however, many patients present with severe neutropenia (<500 granulocytes/mm^3) and are at significant risk of serious infection. [44] Thrombocytopenia is extremely common; over three fourths of patients present with platelet counts <100,000/ml. Only approximately one third of patients have a platelet count <50,000/ml at diagnosis. Although petechiae and purpura are present in many patients, severe bleeding is unusual at initial presentation, even when the platelet count is <20,000/ml, unless fever, infection, or an accompanying coagulopathy, such as disseminated intravascular coagulation, are also present.

Examination of the peripheral blood smear reveals the presence of leukemic lymphoblasts in most patients at diagnosis. Definitive diagnosis (see panel) usually requires examination of the bone marrow, which is usually hypercellular and infiltrated with leukemic lymphoblasts. Technically the presence of greater than 5% leukemic blasts cells confirms the diagnosis. Most institutions, however, require at least 25% blast cells before definitive diagnosis is rendered. More than three fourths of patients have greater than 50% lymphoblasts in their bone marrow at initial presentation.

Morphologic Classification

Acute lymphoblastic leukemia cells manifest significant heterogeneity and have been subclassified on the basis of differences in their appearance under the light microscope. The most widely used system, developed by the FrenchAmericanBritish (FAB) Cooperative Working Group (Table 57-3) divides lymphoblasts into three categories. L1 lymphoblasts are small, with scanty cytoplasm and inconspicuous nucleoli (Plate 57-1A). L2 lymphoblasts in general are larger, although they may demonstrate considerable variation in size, and have more prominent nucleoli and abundant cytoplasm (Plate 57-1B). Lymphoblasts of the L3 type are large, manifest deep cytoplasmic basophilia and prominent cytoplasmic vacuolation, and are identical cytomorphologically to Burkitts lymphoma cells (Plate 57-1C). The L1 morphology is predominant in childhood ALL, occurring in approximately 85% of childhood cases. The L2 subtype is more common in adults. [45] Lymphoblasts of the L3 are characteristic of only 12% of ALL cases. Although there is no apparent correlation between the FAB L1 and L2 morphologic types and immunologic cell surface markers, cells of the L3 variety possess cell surface immunoglobulin and other characteristic B-cell markers. [46] [47] [48] The association between FAB classification and prognosis is discussed later.

Immunophenotyping

Immunophenotyping now plays a major role in the diagnosis of the acute leukemias. The use of monoclonal antibodies specific for various stages of B-cell, T-cell, and myeloid differentiation enables the clinician to determine more definitively whether a leukemia is lymphoid or myeloid in origin. In most

TABLE 57-3 -- FAB Classification of Lymphocytic Leukemia

Cytologic Features	L1	L2	L3
Cell size	Small cells predominate	Large, heterogeneous in size	Large and homogeneous
Nuclear chromatin	Homogeneous in any one case	Variable; heterogeneous in any one case	Finely stippled and homogeneous
Nuclear shape	Regular; occasional clefting or indentation	Irregular; clefting and indentation common	Regular, oval to round
Nucleoli	Not visible, or small and inconspicuous	One or more present, often large	Prominent; one or more
Amount of cytoplasm	Scanty	Variable, often moderately abundant	Moderately abundant
Basophilia of cytoplasm	Slight or moderate, rarely intense	Variable, deep in some	Very deep
Cytoplasmic vacuolation	Variable	Variable	Often prominent

Box 57-1. DIAGNOSTIC EVALUATION OF THE PATIENT WITH ACUTE LEUKEMIA

The diagnostic evaluation of a patient with acute leukemia is a comprehensive process which includes a detailed history and complete physical examination, morphologic and laboratory assessment of peripheral blood and bone marrow, blood chemistries, comprehensive clotting studies (prothrombin time, partial thromboplastin time, thrombin time, and fibrinogen), a lumbar puncture and CSF examination, and other studies necessary to ensure that the newly diagnosed patient will receive optimal supportive care.

HISTORY AND PHYSICAL EXAMINATION

A detailed history is obtained to determine the nature of presenting symptoms and their duration. Specific attention is paid to signs and symptoms of anemia, thrombocytopenia, and neutropenia. Information is garnered regarding possible adverse environmental exposures (e.g., chemicals, radiation) and a detailed family history that includes the occurrence and nature of any malignancies among family members is obtained. On physical examination, signs that reflect leukemic marrow involvement and its sequelae are sought. The degree of pallor, evidence of bleeding (e.g., petechiae or purpura), and the presence of any signs of infection are noted. The degree of lymphadenopathy and hepatosplenomegaly is carefully assessed and documented. The pattern of lymph node enlargement provides helpful information. Generalized lymphadenopathy is more common than regional enlargement. In children, palpable, small axillary, cervical, and inguinal nodes are common, but enlargement of posterior auricular, epitrochlear, or supraclavicular nodes is abnormal. Careful examination of the optic fundi to rule out evidence of retinal hemorrhages secondary to thrombocytopenia or leukemic infiltration is important. The oropharynx is evaluated, including the gingivae, a common site of hypertrophy in patients with acute myelomonocytic or monocytic leukemia.

HEMATOLOGIC EVALUATION

A blood count usually reveals evidence of varying degrees of anemia, thrombocytopenia, and anemia. These changes are also detectable on peripheral blood smear, which, in most patients, reveals the presence of leukemic cells. In most cases, bone marrow aspirate should be obtained before the start of therapy. The posterior iliac crest is the preferred site for marrow aspiration. In cases where aspiration does not yield sufficient material for evaluation, bone marrow biopsy is performed. Bone marrow biopsy also is helpful in assessment of the degree of marrow cellularity. Sternal marrows are rarely required and, because of the risk of retrosternal bleeding, the sternum is not an appropriate site for marrow biopsy. Once the diagnosis of leukemia is confirmed, definitive assignment of the type of leukemia is crucial if appropriate treatment is to be delivered. In the past, the distinction between ALL and ANLL was based solely on the morphologic assessment of a bone marrow specimen. Although this is the appropriate initial step in evaluating a bone marrow specimen, additional diagnostic techniques must always be used. These include histopathologic evaluation with special cytochemical stains, biochemical assessment (i.e., TdT determination), comprehensive immunophenotyping, and cytogenetic analysis.

Special histochemical stains may be particularly helpful in delineating ALL from acute myeloid leukemia (see table) and should be performed routinely in the diagnostic evaluation of bone marrow aspirate specimens.[106] The myeloperoxidase

Morphologic, Cytochemical, and Biochemical Characteristics Helpful in Distinguishing ALL from Acute Myeloid Leukemia (AML)

Table provides information on characteristics that may be useful in differentiating ALL from AML (see text for details). Wide variation in morphology is encountered in both disease categories. Diagnostic evaluation should include more refined classification of disease according to FAB subtype.

[a] Tdt is usually negative in typical FAB L3 ALL.

stain detects myeloperoxidase in primary granules and is considered specific for cells of the myeloid lineage. Classically, an acute leukemia in which 3% of cells in the bone marrow are myeloperoxidase positive has been considered to be myeloid, although this definition is arbitrary and may cause confusion in cases of mixed lineage leukemia. The Sudan black stain sometimes has been used as a substitute for myeloperoxidase, but because rare cases of ALL demonstrate Sudan black positivity, the myeloperoxidase stain is preferred. The periodic acid-Schiff (PAS) stain is positive in approximately 50% of cases of ALL and often shows a characteristic pattern of block positivity. The PAS reaction may be negative in ALL, however, and has been positive in rare cases of acute myeloid leukemia, limiting its diagnostic utility. Naphthyl AS-D chloroacetate esterase is an enzyme found in cells of neutrophilic lineage that may help define myeloid disease but is generally considered less sensitive than the myeloperoxidase stain. The -naphthyl acetate esterase and -naphthyl butyrate esterase stains are helpful particularly in defining monocytic lineage.

Analysis of TdT present in lymphoblasts of T- and B-cell precursor lineage, but not usually found in mature B-cell ALL or in ANLL, is also a helpful diagnostic procedure. Detailed immunophenotyping using a panel of monoclonal antibodies is undertaken in all newly diagnosed cases of acute leukemia. Use of a sufficiently comprehensive monoclonal antibody panel capable of detecting the major lymphoid (both B- and T-cell), myeloid, and platelet-related antigens enables a definitive lineage assignment to be made in most cases of acute leukemia. Molecular phenotyping provides useful information regarding the status of the immunoglobulin or T-cell receptor gene rearrangement in lymphoid leukemic cells. However, because immunoglobulin gene rearrangement has been observed in T-cell ALL and T-cell receptor gene rearrangement in B-cell precursor ALL, molecular phenotyping cannot be used to distinguish definitively between immunologic subtypes of ALL. Cytogenetic analysis, *Box continued on following page*

including evaluation of both chromosomal number and structure, is routinely performed and may reveal characteristic chromosomal abnormalities.

When this overall diagnostic strategy is used, it is rare to encounter a leukemia that defies classification.

LUMBAR PUNCTURE

Lumbar puncture should be performed in all newly diagnosed patients to rule out CNS leukemia. In patients with marked thrombocytopenia, platelet transfusions are

When this overall diagnostic strategy is used, it is rare to encounter a leukemia that defies classification.

LUMBAR PUNCTURE

Lumbar puncture should be performed in all newly diagnosed patients to rule out CNS leukemia. In patients with marked thrombocytopenia, platelet transfusions are given to ensure that the platelet count is optimal (>40,000/mm^3) before performing the lumbar puncture. In addition to measurement of CSF opening pressure, the CSF cell count, protein, and glucose are determined. Examination of a cytocentrifuged specimen of CSF is always performed because this technique increases diagnostic sensitivity (see text).

OTHER DIAGNOSTIC AND LABORATORY STUDIES

A chest radiograph is routinely obtained in newly diagnosed patients. When significant mediastinal enlargement is detected, computed tomography can help to define its extent more accurately. Patients presenting with significant bone pain undergo radiologic examination of the involved site. All newly diagnosed patients have a comprehensive battery of blood chemistries performed, including uric acid, electrolytes, calcium, phosphorus, blood urea nitrogen, serum creatinine, and liver function tests (including lactate dehydrogenase). In addition, magnetic resonance imaging or computed tomographic imaging of the brain at diagnosis may be useful, particularly as a baseline for comparison in the event of CNS relapse or toxicity.

SUPPORTIVE CARE

The blood type of all patients is determined and appropriate cross-matching instituted if transfusion is required. Packed red cell transfusions are used to maintain an adequate hemoglobin. Platelets are usually administered prophylactically to maintain the platelet count >20,000/mm^3. If the patient becomes refractory to random donor platelets, single-donor or human leukocyte antigen-matched platelets may be useful.

All newly diagnosed patients receive allopurinol and vigorous hydration to prevent uric acid nephropathy and complications from tumor lysis. In patients with extremely high initial white blood cell counts (e.g., >100,000/ml), leukapheresis or, in very young patients, exchange transfusion is sometimes helpful, although its role is controversial, especially in ALL. [107] [108]

Newly diagnosed patients who are febrile receive an extensive evaluation to rule out infection. The febrile neutropenic patient is placed on broad-spectrum antibiotic coverage.

The diagnosis of leukemia places extraordinary stress on patient and family alike. Starting at the time of initial diagnosis, careful attention is given to evaluating the psychosocial profile of patient and family so that appropriate psychosocial support for both can be instituted. Optimal psychosocial support requires a concerted, coordinated effort of physician, nurses, social workers, clergy, and other skilled health care personnel.

cases, immunophenotyping also permits assignment of the relative stage in the process of B- or T-cell differentiation from which the leukemic clone is believed to have arisen. An example of the type of monoclonal antibody panel used in the immunophenotypic diagnosis of the acute leukemias is shown in Table 57-4 . Approximately 8085% of childhood ALL is believed to develop from the monoclonal proliferation of B-cell precursors. In contrast, only approximately 12% of cases manifest surface immunoglobulin and are classified as mature B-cell ALL. The remainder of cases are of T-cell origin. A variety of classification schemes have been developed that define both B-cell precursor ALL and T-cell ALL according to their degree of differentiation or maturation. One prognostically useful system, devised by the Pediatric Oncology Group, separates childhood ALL into T-cell, B-cell, and B-cell precursor disease. [49] Approximately one third of patients with B-cell precursor ALL have demonstrable cytoplasmic immunoglobulin (preB-cell ALL) and, in the past, were considered to have a worse prognosis. However, current data suggest that the poor outcome noted in these patients is associated with a high incidence of the t(1;19) translocation (see later). [50]

The development of recombinant DNA technology permits identification of immunoglobulin gene and T-cell receptor gene rearrangement in leukemic cells. Although it is possible to relate the patterns of immunoglobulin gene rearrangement and T-cell receptor gene rearrangement to the stages of development of B-cell precursor and T-cell ALL, respectively, the occurrence of immunoglobulin gene rearrangement in some cases of T-cell ALL and the presence of T-cell receptor gene rearrangement in cases of B-cell precursor ALL undermine the value of molecular phenotyping to assign B- or T-cell lineage. [51] [52] [53]

Most cases of ALL express surface antigens and molecular markers that help to identify them as derived from a specific lineage. However, cases of lineage infidelity, or biphenotypic leukemias, exist in which leukemia cells exhibit markers of more than one cell type on the same leukemic cell. Simultaneous expression of lymphoid and myeloid markers also occurs both in childhood and adult ALL and may be associated with a poor prognosis, although this issue remains unsettled (see later). [47] [54] [55] [56] [57]

Other Laboratory Studies

At the time of diagnosis, many patients with ALL have elevated serum uric acid levels, a by-product of the increased purine metabolism of leukemic cells. The degree of uric acid elevation reflects the extent of tumor burden, higher levels occurring in patients with high initial leukocyte counts and pronounced lymphadenopathy and hepatosplenomegaly. Hyperuricemia must be corrected by vigorous use of hydration and administration of the xanthine oxidase inhibitor allopurinol to prevent uric acid nephropathy and renal failure. Administration of urate oxidase, an enzyme that catalyzes the oxidation of uric acid to allantion, has been investigated as another means of rapidly reducing uric acid concentrations. [58]

Abnormalities in a number of lysosomal enzymes are also evident at diagnosis. Serum lactate dehydrogenase (LDH) is frequently elevated. The degree of elevation appears to correlate with tumor burden and also with prognosis. [35] [59] In addition, isoenzyme I, an acid hydrolase hexosaminidase, is frequently elevated in B-cell precursor ALL.[60]

A variety of metabolic abnormalities, including elevated serum levels of calcium, potassium, and phosphorus, may be observed in the newly diagnosed patient with ALL. These are more frequently encountered in those patients with a high leukocyte

count and extensive tumor burden. Hypercalcemia may be due either to extensive infiltration of bone or to the ectopic release of a parathormone-like substance by leukemic lymphoblasts.[42] Hyperphosphatemia may accompany the extensive destruction of tumor cells. It may occur either as a result of ineffective leukopoiesis or as a consequence of chemotherapy induced tumor lysis.[61] Hyperkalemia also can occur as a result of extensive leukemic cell lysis. Spurious hyperkalemia, the result of the release of potassium from leukemic cells during the process of clotting in vitro, must be ruled out as a cause of high potassium levels.[62] Lactic acidosis may also be present at diagnosis or relapse.[63]

Other laboratory abnormalities are also occasionally present at diagnosis. Low serum immunoglobulin levels at diagnosis have been reported in up to 30% of children with ALL and have been associated with a poor prognosis.[64] [65] Significant coagulation abnormalities are not a typical feature of ALL at diagnosis. Although disseminated intravascular coagulation may occur, it is infrequent. Clotting abnormalities are observed, however, in many patients under active treatment with L-asparaginase.[66]

PROGNOSTIC FACTORS

A number of clinical and laboratory features evident at diagnosis have prognostic value for predicting the remission duration of patients treated for ALL (Table 57-5). The identification of these prognostic factors has provided a means of stratifying patients into different risk groups and tailoring treatment accordingly. This approach has become an important feature of many current treatment protocols, particularly in children. In assessing the relative prognostic value of any feature, it is important to determine whether it functions as an independent prognostic determinant rather than a dependent. Multivariate analysis is helpful in this regard. Advances in technology, especially in molecular genetics, have led to more precise definitions of some risk factors. In addition, changes in treatment strategies may result in previously significant risk factors losing their prognostic value.

The initial leukocyte count at diagnosis has proven to be an important prognostic factor in virtually all ALL studies. In general, the prognosis is inversely related to the leukocyte count. Those patients with initial leukocyte counts greater than 50,000/ml have a particularly poor prognosis. [67] [68] [69] The relationship between white count and prognosis appears to be linear and continuous.

Age at diagnosis also has prognostic importance. Patients who are very young (<2 years) and older patients (>10 years) tend to have a worse prognosis. [70] [71] [72] [73] Among children, infants younger than 12 months of age have the poorest prognosis; their disease has a number of unique biologic features that in part may explain their relative resistance to therapy. [74] In adults, progressively older age is associated with lower rates of remission induction and shorter remission duration. [2] [75]

Cytogenetic analysis also provides important prognostic information. [76] [77] [78] [79] [80] [81] [82] The association between chromosomal number and prognosis is well characterized. Patients with hyperdiploidy (>50 chromosomes [79] or DNA index >1.16 [80]) have a favorable prognosis. Investigators in the Pediatric Oncology Group found that the combined trisomy of chromosomes 4 and 10 independently predicts favorable outcome in B-cell precursor ALL. [81] In contrast, patients with hypoploidy and pseudodiploidy fare less well. [79] Near-tetraploidy also appears to be associated with a poor prognosis, although this may not be an independent factor because many patients with this abnormality also have T-cell disease. [82]

In addition to chromosome number, abnormalities in chromosome structures also convey important prognostic information. A number of chromosomal translocations are associated with both a high rate of induction failure and early relapse, including the t(8;14) translocation associated with B-cell ALL, the t(9;22) found in Philadelphia chromosome-positive ALL, the t(1;19) occurring in B-cell precursor ALL, and the t(4:11) translocation occurring most frequently in infants. Furthermore, technical advances have led to the identification of previously unappreciated, prognostically significant gene rearrangements. For example, the t(12;21) translocation, which results in rearrangement of the *tel* gene, is present in approximately 25% of

cases of B-cell precursor ALL and is associated with improved outcome. [84]

Immunophenotype also correlates with prognosis. [85] [86] [87] ALL patients with either mature B- or T-cell immunophenotypes have a worse prognosis than patients with B-cell precursor ALL. The prognostic influence of T-cell phenotype is less striking after adjustment for its association with high initial leukocyte count. The intensity of treatment appears to influence the degree to which T-cell phenotype influences prognosis. In intensive treatment protocols, the prognostic influence of T-cell phenotype has not been evident. [38] [41] [88] [89] [90] Highly aggressive treatment also improves the outcome of patients with B-cell ALL. [91]

The expression of myeloid markers on ALL cells may be associated with a poor prognosis in children with ALL, although this is controversial. [47] [55] [56] There is also a relationship between morphologic subtype and prognosis. The FAB L3 subtype is associated with B-cell ALL and thus conveys a poor prognosis. In many studies of childhood ALL, the L2 subtype has also been associated with a poor prognosis, [38] [48] [92] [93] whereas the L1 subtype is associated with a more favorable outcome. This finding has not been universal, however, and may not be a helpful distinction in adult ALL. [1] [94] [95] [96]

Race and gender may also influence outcome. Female patients have a more favorable prognosis. This appears to be related to the impact of testicular relapse and to the higher incidence of T-cell disease in male patients. [68] [72] [97] Ethnicity appears to be an important prognostic determinant. African American and Hispanic patients have a lower remission induction rate and a higher likelihood of experiencing bone marrow relapse. [94] [98] [99] The reasons for this poor outcome are related in part to the more frequent recurrence of very elevated initial leukocyte counts, mediastinal masses, and L2 morphology in this population. [88] [94] [100] However, even when adjusted for age, initial white blood cell count, and so forth, there still appears to be an increased risk of treatment failure for nonwhite patients. [101]

Tumor burden can be assessed indirectly by evaluating the degree of hepatosplenomegaly and lymphadenopathy. In numerous studies, hepatomegaly,

splenomegaly, and mediastinal mass have been demonstrated to have prognostic importance, although on multivariate analysis they are found to be closely dependent on the initial leukocyte count. Despite this, hepatomegaly and splenomegaly have been useful to some investigators in the prospective definition of risk groups. For example, the German BFM study group uses a risk factor index, computed on the basis of initial leukocyte count and measurement of hepatosplenomegaly, to define different treatment groups for childhood ALL. [102]

In addition to the features already noted, a variety of other characteristics have been found to have prognostic value. In children, low serum immunoglobulins, particularly low IgM levels, are associated with poor event-free survival. [64] [65] [103]

Perhaps one of the most significant prognostic factors is the response to initial treatment, although, strictly speaking, it is not a presenting clinical or laboratory feature of patients with ALL. Nonetheless, patients who fail to achieve complete remission after completing an initial course of induction therapy have markedly reduced remission duration and survival. The rapidity of initial cytoreduction appears to be extremely important. For example, the presence of residual leukemia on day 7 or 14 of induction therapy has been associated with shorter event-free survival compared with patients whose marrow shows no evidence of residual disease at that time. [38] [69] [88] [104]

As noted earlier, current treatment regimens for childhood ALL use prognostic factors to define different risk groups that are subsequently treated according to their relative risk of failure. In turn, improved treatment strategies may reduce the impact on survival of a given prognostic factor. In most centers, patients with poor risk features receive more intensive treatment, whereas those with good risk features receive treatment

TABLE 57-6 -- Uniform Assessment of Risk Factors in Childhood ALL

Risk Factor	Associated with Better Outcome	Associated with Worse Outcome
Age	1.09.99 years	<1 or 10 years
White blood cell count	<50,000/l	50,000/l
DNA index	>1.16	1.16
Trisomy 4 and 10	Present	Absent
M1 marrow day 7 or 14	Yes	No
Peripheral blasts at day 8	Absent	Present[a]
Cytogenetics		t(1;19)
		t(9;22)
		t(4;11)
Immunophenotype	B-cell precursor	T cell[a]
Central nervous system leukemia	CNS 0	CNS 2[a] CNS 3

CNS, central nervous system; CNS 0, no blasts in CSF; CNS 1, <5 WBC/l with blasts; CNS 3, 5 WBC/l with blasts or cranial nerve palsy.

[a]In some studies.

designed to be effective yet minimize treatment-related adverse sequelae. The use of different prognostic factors for stratification of risk groups may lead to difficulty in comparing the results of different approaches to therapy. A workshop at the National Cancer Institute has proposed a uniform approach to risk factor assessment based on a combination of clinical and laboratory criteria (Table 57-6). [105] The success of this risk-based strategy and the general principles of treatment for the patient with ALL are detailed in Chapter 58 .

Chapter 58 - Treatment of Childhood Acute Lymphoblastic Leukemia

Lewis B. Silverman
Stephen E. Sallan
Harvey J. Cohen

INTRODUCTION

Advances in the treatment of childhood acute lymphoblastic leukemia (ALL) have been the product of clinical trials and the prospective evaluation thereof (Fig. 58-1). Further advances in the treatment of this disease and attempts to limit therapy-related toxicity require ongoing prospective studies. Thus, in the 1990s, no child with newly diagnosed ALL should receive individualized treatment; rather every child with this diagnosis should be enrolled in a trial to ensure optimal treatment and subsequent advances for future generations of children with leukemia.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

HISTORY AND PHILOSOPHY OF TREATMENT

Prior to 1947, when the first complete remission in childhood ALL was attained by Farber and coworkers, [1] the median duration of survival from the time of diagnosis was 2 months.[2] The development of a model for the scientific methodology of clinical therapeutic research in childhood ALL has been elegantly summarized in detail by Frei.[2] During the 1950s drugs such as 6-mercaptopurine, methotrexate, and corticosteroids were found to be active in leukemia-bearing mice [3] and subsequently in human leukemias.[4] The first controlled clinical trials were conducted by Frei and associates, [5] who ushered in the era of single-agent (and soon thereafter combination-agent) antileukemic chemotherapy trials (Table 58-1).[6]

Active drugs introduced in the 1960s and 1970s, such as the anthracyclines (doxorubicin and daunorubicin), asparaginase, and the epipodophyllotoxins (VP-16 and VM-26), usually underwent initial evaluation in patients whose leukemia had become resistant to the drugs in Table 58-1 . Complete remission rates of 2448% with doxorubicin [7] and 5060% with asparaginase [8] [9]

Figure 58-1 Event-free survival of children with ALL treated between 1973 and 1991 on Dana-Farber Cancer Institute/The Childrens Hospital-based protocols. Abbreviations: CCR, complete continuous remission; F/U, follow-up. *(Adapted from Sallan et al,[15] with permission.)*

TABLE 58-1 -- Chemotherapy of Childhood ALL: Historical Perspective

	Frequency of Complete Remission (%)
Single agents	
Prednisone	57
Vincristine	55
6-Mercaptopurine	27
Methotrexate	21
Cyclophosphamide	18
Combination agents	
Prednisone + vincristine	85
Prednisone + 6-mercaptopurine	81
Methotrexate + 6-mercaptopurine	45
Vincristine + prednisone + methotrexate + 6-mercaptopurine	94

From Freireich and Frei,[6] with permission.

were achieved. The efficacy of these agents, as measured by the frequency of complete remissions, may have been underestimated because they were tested in patients with previously treated and potentially drug-resistant disease. To evaluate antileukemia agents in newly diagnosed rather than in relapsed patients, the concept of an investigational window was developed in the early 1980s. Patients treated with an investigational window receive a single agent 35 days before the onset of multiagent chemotherapy. Using this approach, the Dana-Farber Cancer Institute (DFCI) group evaluated the pharmacokinetics of different preparations of asparaginase in previously untreated patients, [10] and also demonstrated that high-dose methotrexate was more effective than conventional-dose methotrexate.[11]

Critical to the pioneering efforts of early clinical trials was an understanding of the principles of the first-order cytokinetic effect of chemotherapeutic agents and the need for clonal eradication. In the early 1960s, Skipper and associates initiated a series of studies that addressed the quantitative biology of leukemia in mice and its perturbation by chemotherapy.[12] The first-order cytokinetic effect of chemotherapy on tumor (leukemia) cells means that for a given treatment there is a constant fractional reduction of leukemia cells that is independent of the total leukemia burden. The cytokinetic model for antileukemia therapy is depicted in Figure 58-2 .

Figure 58-2 A cytokinetic model for antileukemia therapy relating to hypothetical cell kill with components of treatment.

Using the mouse leukemia models of Skipper and colleagues, it was shown that the time of death following treatment was a precise measure of the number of leukemia cells persisting at the end of treatment.[12] [13] They further demonstrated that having only one L1210 leukemic cell present was enough to cause the death of the animal. This observation led to the understanding of the need for clonal eradication. Moreover, their models provided important observations with respect to drug resistance, combination chemotherapy, and the cycling of chemotherapeutic agents. By the 1960s, effective systemic chemotherapy and the development of improved supportive care with blood products and antibiotics resulted in an increased percentage of complete remissions and an increase in the duration of remissions. The ability to support a patient through prolonged myelosuppression has permitted clinical investigations that have demonstrated the importance of using maximal tolerable doses of drugs.[14] [15]

Box 58-1. THE THERAPEUTIC APPROACH TO CHILDHOOD ALL

The proper treatment of all children with newly diagnosed ALL must begin in a specialized pediatric hematology/oncology center and must subsequently be continued or closely supervised by experienced specialists. As soon as the diagnosis is confirmed and the patient stabilized with appropriate supportive care (hydration, blood products, antibiotics, etc.), chemotherapy should be instituted. Such treatment should be part of a prospective clinical protocol to ensure that each of the children with this disease ultimately contributes to the development of more effective and less morbid treatment regimens.

Conceptually, early treatment should be with high doses of multiple drugs to ensure maximal leukemic cell kill and to address the issues of drug resistance. Although it is impossible to assess the importance of early intensive treatment on the basis of only the percentage of complete remissions or the time to induce a complete remission, long-term results support the use of intensive induction therapy. We use vincristine, prednisone, doxorubicin, methotrexate, asparaginase, and intrathecal cytosine arabinoside. Each agent is individually cytotoxic to leukemic cells and, in combination, the agents presumably are maximally cytotoxic. The dose-limiting aspect of induction therapy is the potentially additive side effects of the drugs; for example, doxorubicin and methotrexate both can result in damage to the gastrointestinal mucosa, and therefore the doses of each must be modified.

After obtaining a complete remission, attention is focused on CNS treatment and further reduction of the total (currently immeasurable) residual leukemic cells (the *minimal residual leukemia*). The treatment of the CNS should be maximally effective and minimally harmful, a balance that is difficult to attain (and controversial among clinical investigators). We treat all children with intensive systemic chemotherapy, including repeated doses of prednisone and high-dose asparaginase, which are also effective for CNS leukemia. Patients at higher risk of CNS relapse (white blood cell count >50,000/mm^3, age <1 or >10 years, and T-cell ALL), who comprise 40% of all patients, are treated with cranial radiation (18 Gy) and concurrently two-drug (methotrexate and cytosine arabinoside) intrathecal therapy. For standard-risk patients, we are currently conducting a randomized trial comparing cranial radiation and concurrent intrathecal drugs with intensive intrathecal therapy (without radiation). For all patients, intrathecal therapy is continued intermittently for 2 years.

Intensive systemic therapy with multiple drugs (including vincristine, prednisone, asparaginase, 6-mercaptopurine, and methotrexate or doxorubicin, depending on the risk group of the patient) is administered after CNS treatment for approximately 6 months. Thereafter continuation therapy (with vincristine, prednisone, 6-mercaptopurine, and methotrexate) is administered to complete a total of 2 years of treatment. Bone marrow transplantation in initial complete remission is recommended for children with ALL who have lymphoblasts that express the Philadelphia chromosome [t(9;22)] (34% of patients) and for those whose leukemia is refractory to initial induction chemotherapy (12% of patients). Infants are treated as high-risk patients, but their therapy includes an extra month of intensification with high-dose cytosine arabinoside and high-dose methotrexate. Children with mature B-cell ALL (SIg+) are treated on a separate protocol that features B-cell-specific drugs.

All current antileukemia therapy is leukemia nonspecific, which means that all the drugs have acute toxicities and many of them also have long-term adverse effects. Thus, treatment programs must be balanced with regard to the risk/benefit ratio. The first goal must be eradication of the leukemic clone. When identical treatment is used, patients characterized as being at standard risk of relapse have a higher likelihood of successful outcome (cure) than those characterized as high-risk patients. Therefore, it is our practice to gradually diminish the potential toxicity in new therapy programs for the standard-risk group, while always being mindful of the risk of more treatment failures. On the other hand, as long as the high-risk group is inadequately treated (too many relapses), we believe that treatment of these patients, albeit associated with known acute and late toxicity, should be intensified. Despite that, efforts need to be made to modify both short- and long-term devastating toxicities (stroke, congestive heart failure, learning disorders, second malignant neoplasms) even in these high-risk patients while at the same time attempting to increase their overall survival. Thus, we are searching for less toxic forms of asparaginase and less cardiotoxic ways of administering anthracyclines, and altering methods for the delivery of cranial radiation. Hopefully, in the near future we will be able to use more specific antileukemia therapy, measure the number of residual leukemic cells, and base the intensity and duration of therapy on individual needs.

In the 1960s, the incidence of central nervous system (CNS) leukemia as an initial site of relapse became progressively more common, [16] [17] and the concept of the CNS as a pharmacologic sanctuary (i.e., an anatomic space that is poorly penetrated by systemically administered chemotherapeutic agents) emerged. Several avenues of approach to the problem of CNS leukemia and its treatment and prevention have been explored. These include intrathecal administration of drugs, [18] craniospinal radiation,[19] cranial radiation plus intrathecal drugs, [20] and high doses of systemically administered drugs that result in therapeutic concentrations in the cerebrospinal fluid (CSF). [21] [22] The optimal delivery of CNS treatment remains controversial.

Current regimens for the treatment of ALL result in high proportions (>95%) of children achieving complete remission and favorable long-term outcome for the majority of patients. This is true despite the fact that, with few exceptions, the drugs used for the treatment of ALL in the 1990s were all available by the late 1960s. Philosophically, treatment should be with curative (not palliative) intentwhich means that all complications of the disease and its therapy need be vigorously treated, but that the major effort should be directed at eradication of disease rather than relief of symptoms (see box on therapeutic approach).

SUPPORTIVE CARE

Supportive care is an important determinant of outcome in children with ALL. Before instituting chemotherapy, patients must be assessed and treated for any metabolic disturbances, hematologic abnormalities, and presumed or documented infections.

Rapid turnover of leukemia cells before and immediately after the initiation of chemotherapy leads to the release of intracellular contents, which can overwhelm the bodys normal excretory mechanisms. The resultant metabolic disturbances include hyperkalemia, hyperuricemia, hyperphosphatemia, and hypocalcemia. Patients with high levels of uric acid are at risk for the development of acute renal failure secondary to uric acid deposition in the kidney. [23] To ensure that uric acid remains in solution within the renal tubule for optimal excretion, intravenous hydration (usually with twice the maintenance volumes of fluids) and urinary alkalinization (pH 78) (usually with 0.25 N $NaHCO_3$) should be instituted immediately after diagnosis. If urinary alkalinization is difficult, $NaHCO_3$ -containing solutions can be increased to 0.5 N strength. In addition, administration of a xanthine oxidase inhibitor such as allopurinol should be started prior to institution of antileukemia drugs. Allopurinol prevents the formation of uric acid during cell lysis. For patients with white blood cell counts >200,000/mm^3 , leukapheresis has been advocated to prevent hyperviscosity and lysis-related problems. [24]

Thrombocytopenia, in association with neutropenia and anemia, is a common presenting feature of ALL; [25] however, active bleeding is a relatively unusual feature at the time of diagnosis. Despite this fact, most investigators recommend prophylactic platelet transfusions for patients with thrombocytopenia, as opposed to transfusions only for active bleeding. Prophylactic transfusions have frequently been given when platelet counts fall below 15,00020,000/mm^3 . A recent study in adults with acute myeloid leukemia (AML) has demonstrated the safety of decreasing the prophylactic platelet transfusion threshold to a platelet count of 10,000/mm^3 in clinically stable patients. [26] Any active hemorrhage associated with a platelet count of <100,000/mm^3 should be treated with platelet transfusions. Similarly, symptomatic anemia should be treated by transfusion of packed red blood cells. Most investigators recommend prophylactic red cell transfusions for a hematocrit below 2025 volume percent. Stabilization of these two hematologic parameters should take no longer than 1224 hours and therefore should not delay the start of antileukemic therapy.

Patients should also be treated intensively for any documented or presumed infection before beginning chemotherapy. [27] For a temperature above 38.5°C, broad-spectrum intravenous antibiotic coverage should be administered immediately after obtaining cultures, while awaiting laboratory confirmation of an infectious etiology. Chemotherapy should be started as soon as possible after diagnosis despite the need for antibiotics. Although newly diagnosed patients might not have severe neutropenia (granulocyte counts <500/mm^3), the usual state of marrow replacement with lymphoblasts and the anticipated marrow hypocellularity associated with antileukemia treatment make such antibiotic recommendations prudent. One series documented bacteremia in 21% of episodes of fever and neutropenia in children receiving chemotherapy. [28]

Various approaches have been used to prevent or reduce infections in patients once they have started treatment. Prophylaxis with trimethoprim-sulfamethoxazole, usually from the time of complete remission, successfully prevents *Pneumocystis carinii* pneumonia. [29] The optimal use of hematologic growth factors, such as granulocyte colony-stimulating factor (G-CSF), remains a matter of controversy. In prospective randomized studies, the use of G-CSF in children [30] [31] and adults [32] [33] receiving intensive therapy for ALL was associated with a shorter duration of neutropenia and a tighter adherence to the planned treatment schedule. However, although some investigators reported a significantly decreased incidence of severe infections in patients treated with G-CSF during ALL therapy, [30] [33] others have not confirmed this finding. [31] [32] Moreover, a recent study found that G-CSF treatment did not prolong survival or reduce the cost of supportive care for children with ALL. [31]

CONCEPTS OF THERAPY

Therapy for children with newly diagnosed ALL usually includes four componentsremission induction, intensification, continuation, and CNS treatment. The *remission induction* component of therapy is designed to rapidly destroy measurable leukemia cells and minimize residual leukemia burden (i.e., the total number of leukemia cells in the body). The *intensification* component (also called *consolidation* therapy) is designed to further reduce the total body leukemia cell burden and address issues of antileukemic drug resistance. Such treatment usually consists of higher doses of the same drugs used during remission induction, or of high doses of different drugs. When induction drugs are used again in the same doses, the treatment is known as *re-induction* therapy. The *continuation* component is designed to eradicate the residual leukemia cell burden. In the past, this part of treatment was referred to as maintenance therapy. However, because the current concept is to eradicate all remaining leukemia cells, as opposed to maintaining a low tumor burden, the newer terminology is preferred. The CNS treatment component is used to address the issue of *pharmacologic sanctuary sites* (i.e., areas of the body, such as the brain and spinal cord, that are not well penetrated by conventional doses of most antileukemia drugs).

An important concept in the treatment of ALL in children is risk-directed therapy. Clinical trials conducted during the 1970s and early 1980s established groups of patients whose risk of subsequent relapse varied according to different characteristics. Current clinical trials use these outcome predictors to stratify therapy. For example, children with the least likelihood of relapse can be treated on protocols that modify or eliminate certain intensive components of therapy in order to decrease morbidity. In contrast, individuals at a greater risk of relapse can be more intensively treated, thus limiting the potential higher risks of such intensified therapy to only these patients.

For many years, pediatric cooperative groups and institutions have applied prognostic factors differently when defining risk categories. A more uniform approach to risk classification

---

was proposed and agreed on at a National Cancer Institute sponsored workshop held in 1993. [34] For patients with B-precursor ALL, the standard or better risk category was defined as age between 1 and 9 years and initial leukocyte count <50,000/mm ^{3} , as this population has a predicted 4-year event-free survival of approximately 80%. Presenting features used by some investigators to further identify patients with standard-risk" disease includes a hyperdiploidy (DNA index >1.16) and trisomy of chromosomes 4 and 10. The remaining patients, with a predicted 4-year event-free survival rate of approximately 65%, were considered to have high-risk ALL. Other characteristics used by the various cooperative groups to classify patients as high risk include T-cell phenotype, adverse cytogenetic translocations, such as t(9;22),t(4;11) and t(1;19), overt CNS leukemia at diagnosis, and slow early response to induction chemotherapy. [34]

One must be mindful of the potential misuse of pejorative terms such as good-risk, standard-risk, or high-risk patient groups. Philosophically, ALL is a high-risk disease inasmuch as 2030% of affected children are unsuccessfully treated and die as a result of their disease. [35] [36] [37] Ultimately, treatment is the most important prognostic factor, and the importance of a particular presenting feature in predicting outcome depends on the therapy delivered to that patient.

Remission Induction

As soon as the patient has been stabilized by the supportive measures discussed above, antileukemia chemotherapy is begun. The goal of induction therapy is to rapidly induce a complete remission. *Hematologic remission* is defined as attainment of a normocellular bone marrow with 5% or fewer blasts and peripheral blood without lymphoblasts and with a granulocyte count exceeding 500/mm ^{3} and a platelet count exceeding 100,000/mm ^{3} . *Complete remission* is defined as achievement of the above criteria plus the absence of any signs and symptoms of extramedullary leukemia. The duration of most induction regimens is 34 weeks.

A complete remission must be induced before the next component of therapy is begun and is therefore essential in prolonging survival. Using a two-drug regimen of weekly vincristine and daily prednisone, 8090% of children with ALL will achieve remission at the end of 1 month of therapy (see Table 58-1).[38] [39] With the addition of a third agent, such as asparaginase or an anthracycline, the remission rate increases to approximately 95%. [40] [41] In addition to improving remission rates, intensified three-drug induction regimens also prolong remission duration. The importance of induction intensity in determining overall survival was demonstrated in a study in which children were randomly assigned to receive identical therapy except for induction drugs; one group received vincristine and prednisone and the other received those two drugs plus an anthracycline. Although the complete remission rates for both groups exceeded 90%, there was long-term benefit for the more intensively treated group (event-free survival for the two groups at 16 years was 37% and 63%, respectively). [41] [42] In theory, the more intensive induction regimen may prevent the emergence of drug-resistant leukemia clones by an initial leukemia cell lysis of greater rapidity and magnitude. [43] Thus, most investigative trials currently use at least three drugs (e.g., vincristine, prednisone, and asparaginase). [40] The benefit in terms of long-term survival of using four or more drugs during induction is widely accepted in higher risk patients, [44] but less clear in lower risk patients. [45] Even with very intensive induction regimens, very few toxic deaths are reported. [35] [36]

Pharmacologic sanctuary sites, such as the CNS, should be treated during induction. Some commonly used systemic drugs such as glucocorticoids, asparaginase, and high-dose methotrexate affect CNS leukemia cells, but intrathecal agents such as cytosine arabinoside and methotrexate are also recommended. Intrathecal cytosine arabinoside has the advantage of having no additive myelosuppression because it is immediately inactivated by deaminases when it enters the blood.

Failure to achieve remission after 1 month of therapy (induction failure) is uncommon, occurring in fewer than 5% of patients. Successful treatment of refractory ALL has been reported with the use of drugs such as cytosine arabinoside, teniposide, daunomycin, and idarubicin. [46] [47] [48] [49] However, even after achieving remission, overall survival for patients with a history of initial induction failure is very poor, [50] and these patients should be considered candidates for allogeneic bone marrow transplantation (BMT) or other intensive therapies.

Even for patients who achieve remission within 1 month, the rapidity of response to induction chemotherapy, as measured by clearance of peripheral and bone marrow lymphoblasts, is an important predictor of outcome. In an era of relatively less intensive induction therapy it was shown that the time required to enter complete remission had prognostic significance; shorter times of induction were associated with more favorable outcomes. [51] In more recent studies, investigators have reported that response to a short course of corticosteroids, as measured by the absolute peripheral blast count after 1 week of prednisone (plus intrathecal methotrexate), is one of the most sensitive predictors of subsequent event-free survival. [36] [52] Others have demonstrated that the rapidity with which a patient clears peripheral blasts after multiagent induction chemotherapy also has important prognostic significance, with slow responders having a significantly worse outcome. [53] [54] The Childrens Cancer Group (CCG) has reported that the presence of leukemia in bone marrow specimens obtained 7 or 14 days after beginning multiagent chemotherapy strongly correlates with poor outcome,[55] [56] although the adverse prognosis of slow early responders can be improved with intensification of postinduction therapy for these patients. [57]

Although clinical complete remission is the goal of multidrug induction therapy, it must be recognized that clinical remissions are not *biologic* cures. Even after the induction of complete remission, leukemia cells remain in the marrow, undetected by light microscopy. Indirect evidence for this observation was derived from early clinical trials in which chemotherapy was stopped after induction of a clinical complete remission; all patients relapsed within 6 months. [58] According to the principle of first-order cytokinetic killing of leukemia cells, a fixed proportion (99%, 99.9%, 99.99% or more) of cells are destroyed with any given dose of drugs and a fixed proportion (1%, 0.1%, 0.01% or fewer) of leukemia cells remains after each dose of therapy. It is the remaining tumor burden that necessitates postinduction treatment. The use of molecular biology techniques, such as the polymerase chain reaction, may aid in assessing whether the rate or degree of initial cell kill will be a predictive factor for long-term survival. Some recent studies suggest that high levels of molecularly detectable residual disease in patients in clinical remission at the end of induction predicts poor outcome, [59] [60] although this result has not been confirmed by others. [61] [62]

Intensification Chemotherapy

Postinduction intensification is a common component of most pediatric protocols. The goals of intensification therapy are to further reduce the disease burden and to adjust the intensity of treatment based on the risk of subsequent relapse (i.e., to formulate risk group-specific therapy). Further reduction of the disease burden necessitates intensive cytoreductive treatment, which can be given at the time of complete remission because the bone marrow is relatively normocellular at the beginning of this phase of treatment.

A wide variety of agents and schedules have been used during

the intensification phase of treatment in pediatric trials. The Pediatric Oncology Group has reported a significant improvement in the outcome of patients treated with an early intensification phase consisting of intermediate-dose or high-dose antimetabolite therapy, [63] [64] [65] an observation confirmed by others.[37] [66] The DFCI group has shown that early intensification with weekly high-dose asparaginase improves survival for all patients, [67] and that the use of doxorubicin during intensification with asparaginase favorably influences the outcome of high-risk patients, particularly those with T-cell disease. [35] [68] The Berlin-Frankfurt-Munster (BFM) group and CCG have demonstrated that patients benefit from a delayed intensification, consisting of an intensive re-induction cycle after a period of an interim maintenance regimen.[36] [44] [45] [69] The United Kingdom ALL group reported that patients treated with both an early and delayed intensification cycle had a superior outcome when compared with patients who received only one of these cycles.[70] Thus, although most clinical trials demonstrate the importance of intensification therapy, the optimal treatment schedule remains under investigation.

Continuation Therapy

Nearly all current treatment regimens for ALL use a phase of continuation therapy, in which patients are treated with less intensive chemotherapy to complete at least 2 years of therapy.[35] [36] [37] [44] [45] [64] [65] [70] Most continuation regimens consist of weekly low-dose methotrexate and daily oral 6-mercaptopurine. Some groups add regular pulses of vincristine and corticosteroid to this regimen, [35] [44] [45] although the benefit of these pulses remains controversial. [69] [71] Researchers at the St. Judes Childrens Research Hospital have reported that higher risk patients benefit from an intensified continuation therapy consisting of rotating pairs of non-cross-resistant drugs.[37]

The optimal duration of therapy remains unknown. Most investigators continue to treat patients for a total of 23 years, based on results of older studies, in which patients received therapy that was less intensive than current regimens. [72] One recent attempt to shorten therapy duration to 18 months from 24 months resulted in a significant increase in relapses. [69] Ongoing studies of minimal residual disease may help to clarify the optimal therapy duration for patients in the era of intensive, multiagent chemotherapy. Leukemia cells from the majority of patients display clonal abnormalities not found in their normal hematopoietic cells. Current efforts to evaluate minimal residual disease have focused on the identification of these clones at diagnosis by probing for chromosomal translocations or patient-specific immunoglobulin or T-cell antigen receptor gene rearrangements. [73] Once patient-specific clones are identified, molecular techniques, such as polymerase chain reaction, can be used to detect extremely small numbers of residual leukemia cells in subsequent samples.

Initial clinical studies of minimal residual disease in childhood ALL have yielded conflicting results. Many studies suggest that the presence of detectable residual disease late in treatment or at the completion of therapy is predictive of subsequent relapse, [62] [74] [75] although others have reported that molecularly detectable leukemia can persist even after the completion of therapy in patients who remain in clinical remission. [61] [76] Additionally, the absence of detectable residual leukemia at the end of chemotherapy is insufficient to ensure that the patient is cured. [77] Investigation of more sensitive quantification techniques in larger, prospective trials is necessary before the prognostic significance of minimal residual disease testing can be established.

In addition to quantitative levels of residual disease, differences in the proliferative and growth potentials of the remaining leukemia cells are also important considerations in determining optimal duration of therapy. For example, clinical trials of rapidly proliferating, mature B-cell ALL have shown that short, intensive regimens (lasting only 23 months) have been quite effective. [78] [79] On the other hand, disease with cells that have a lower proliferative activity might benefit from a longer course of therapy.

Treatment of the CNS

Treatment of the CNS is usually initiated during induction therapy, and definitive CNS treatment is usually begun immediately after achieving complete remission (to prevent seeding from the CNS to the periphery). This concept is based on data from the 1960s that demonstrated most children who developed CNS leukemia did so during the first year of therapy. However, some clinical trials have delayed definitive CNS treatment for several months to permit more intensive systemic therapy. [37] [80] In these studies, there was no increase in CNS relapse, except in patients who had presented with leukemia blasts in their CSF at diagnosis. [81] There is also variability among investigators regarding the duration of CNS treatment. It remains uncertain whether treatment only during induction and after induction sanctuary therapy is adequate or whether prolonged intermittent CNS treatment is more effective. However, trials with the lowest reported incidence of CNS relapse used prolonged CNS treatment.[82]

Optimal CNS treatment should provide maximum antileukemia efficacy with minimum morbidity. Current CNS treatment strategies include intrathecal chemotherapy, high-dose systemic chemotherapy, or cranial radiation. Much of the controversy surrounding the use of cranial radiation originated from studies of previously irradiated survivors of childhood ALL, who have been noted to have learning disabilities, neuroendocrinologic abnormalities, and an increased incidence of second malignant neoplasms.[83] [84] Based on these concerns, some investigators have replaced cranial radiation with extended intrathecal therapy and have found that it provides adequate CNS prophylaxis when delivered in the context of effective systemic therapy, especially in lower risk patients. [85] [86] [87] However, the neurocognitive sequelae of patients treated in this manner has not been well delineated. Uncertainties about the relative efficacy and morbidity of CNS treatment options have resulted in a wide range of treatment philosophies. For example, by the middle 1980s, the proportion of children receiving cranial irradiation as a component of primary treatment varied from 0%[88] to 100% [70] among different national and international trials. Based on our own experience [82] and that of others,[85] [89] we recommend cranial radiation and intrathecal drugs (methotrexate and cytosine arabinoside) for the 40% of children whom we classify as high-risk patients.

For patients who are treated with cranial radiation, the optimal dosage and schedule of radiation also remain under investigation. Although early studies used a dose of 2,400 cGy, subsequent trials demonstrated that 1,800 cGy is as effective in preventing relapse [90] and may be associated with fewer neurocognitive sequelae.[91] The BFM group has successfully used a radiation dose of 1,200 cGy in the treatment of intermediate-risk patients. [36] [69] The DFCI group is testing whether 1,800 cGy delivered in hyperfractionated (twice daily) rather than conventional (daily) doses maintains efficacy while reducing late toxicity.

Systemic therapy plays an important role in the prevention of CNS leukemia. Penetration of the CSF by drugs has been clearly demonstrated with the use of glucocorticoids[92] and very high doses of methotrexate and cytosine arabinoside. [21] [22] It has also been shown that systemically administered asparaginase, whose efficacy is a function of asparagine depletion, effectively lowers CSF asparagine levels, [93] and lowers the number of lymphoblasts in the CSF of children with CNS disease.

Approximately 1520% of patients will present with detectable CNS leukemia (defined as the presence of any blast on a

cytospin preparation, regardless of CSF white blood cell count). [81] These patients are at increased risk for CNS relapse. [81] For these children, we recommend treatment with twice weekly intrathecal cytosine arabinoside until the CSF no longer has detectable blasts. Thereafter, at the time of complete remission, the CNS is treated with cranial radiation and intrathecal drugs (usually methotrexate and cytosine arabinoside).

SPECIAL TREATMENT CONSIDERATIONS

Subgroups of patients have been identified who have an extremely poor prognosis, even when they are treated with current, intensive regimens. These patients are often considered candidates for alternative treatments, including allogeneic BMT. For instance, the Philadelphia chromosome, t(9;22)(q34;q11), detectable in approximately 5% of children with ALL,[94] portends a dismal prognosis, with long-term event-free survival rates of 040%. [94] [95] [96] [97] Although some preliminary studies suggest patients with Philadelphia chromosome-positive ALL and low presenting leukocyte counts may be successfully treated with intensive chemotherapy, [98] most investigators recommend allogeneic BMT in first remission for all patients with this chromosomal translocation. [99] [100]

Patients diagnosed with ALL during infancy (<1 year of age) also represent a special patient population because of their poor prognosis, as well as their increased vulnerability to the toxic effects of therapy. Infants appear to have a biologically different form of the disease, characterized by molecularly detectable rearrangements of the *MLL* gene on chromosome 11q23.[101] [102] [103] [104] [105] Their overall outcome is significantly worse than that for older children with ALL, with reported long-term event-free survival rates <20%.[106] [107] [108] Some investigators currently recommend allogeneic BMT in first remission for infants with ALL, especially those with detectable *MLL* gene rearrangements.[105] [108] The DFCI group has observed an improvement in the event-free survival infants treated with a regimen including early intensification with high-dose methotrexate and cytosine arabinoside and delayed cranial radiation (delivered at age 1 year). [109]

One to two percent of children with ALL present with mature B-cell phenotype, characterized by surface immunoglobulin, L3 morphology, and a cytogenetically detectable translocation of the *myc* photo-oncogene on chromosome 8, usually t(8;14)(q24;32), but sometimes t(2;8)(p11-p12;q24) or t(8;22)(q24;q11). Such patients fair poorly and should be treated with regimens used for advanced stage Burkitts lymphoma. [78] [79]

LATE EFFECTS OF TREATMENT

The treatment of children with ALL has resulted in prolonged, event-free survival for 7080% of patients. [35] [36] [37] However, even for these successfully treated children, long-term effects of the disease and its treatment often result in organ toxicity of varying but clinically significant magnitude. Detailed analyses of the long-term complications of therapy have been thoroughly summarized by Green.[110] The consequences of treatment to the normal tissue are a function of the organ system involved and the type of therapy. The most common, and often most problematic, late effects involve the CNS, [83] but other problems include cataracts,[111] cardiac abnormalities,[112] hepatic toxicity,[113] short stature,[114] obesity,[115] abnormalities of gonadal function and reproduction, [116] and second malignant neoplasms.[117] [118]

Low and low average intelligence quotients (IQs) have been frequent findings in survivors of ALL. [119] [120] [121] [122] More detailed neuropsychological studies have demonstrated that learning disabilities are related to a slow speed of processing information, distractibility, and difficulty in dealing with complex or conceptually demanding material.[123] [124] The severity of neuropsychological sequelae varies, depending on both treatment and patient characteristics. For example, younger children (<5 years old) are more vulnerable than older children, [119] [120] [122] and in some studies, girls are more vulnerable than boys. [123] [125] [126]

Most CNS toxicity has been attributed to cranial radiation. [119] [120] [121] [124] The most severely impaired long-term survivors are those who received cranial radiation doses (2,4002,800 cGy) that are higher than doses used in current treatment regimens (1,2001,800 cGy). [91] [127] Microcephaly has also been reported as a late effect of CNS treatment and was found to depend upon the radiation dose.[128]

The contribution of systemic and intrathecal chemotherapy to the development of neurocognitive toxicities has not been fully assessed. It has been demonstrated that systemic chemotherapy affects the severity of radiation-associated neuropsychological sequelae. In one study, escalating doses of systemic methotrexate in children who had received cranial radiation were associated with development of leukoencephalopathy. [129] In another series, IQ decline was associated with combined therapy of high-dose systemic methotrexate and 1,800 cGy cranial radiation, but not with either therapy alone. [130] Moreover, evidence suggests that cognitive deficits are present in long-term survivors treated without cranial radiation, [131] and in one study, there were no significant differences in the severity and range of deficits between irradiated and nonirradiated patients. [126]

Neuroendocrine abnormalities are also frequently observed in survivors of childhood ALL. In some studies, survivors are shorter than expected for their age. [114] [132] [133] The greatest impact in final height has been noted in patients treated with 2,400 cGy cranial radiation, with less severe growth failure noted in patients whose CNS prophylaxis treatment included 1,800 cGy or no cranial radiation. [132] One study showed normal linear growth in children treated without cranial radiation. [134] Young age and female sex are associated with greater growth failure. [114] [132] In girls, puberty may occur early, and in both sexes, normal pubertal growth spurts may be blunted.[133] [135] In some studies, short stature in survivors of childhood ALL has been associated with growth hormone deficiency, [136] [137] suggesting that growth hormone replacement may have a potential therapeutic role. Others have failed to show impaired growth hormone secretion in similar survivor populations. [138] Moreover, controversy surrounding possible additive cardiac toxicity (especially in patients with anthracycline-induced cardiomyopathy), [139] as well as the possible risk of secondary leukemias in patients previously treated with chemotherapy and radiation, [140] necessitates that growth hormone be prescribed with great care.

Small, nonprogressive posterior subcapsular cataracts, which do not impair vision or require surgical treatment, have been reported in over 50% of children treated for ALL.[111] Although the cataracts were thought to be related to the administration of corticosteroids, the patients described had also received cranial radiation (which included treatment of the posterior half of the globes and the optic nerves).

Echocardiographic abnormalities, particularly increased afterload and decreased contractility, are common late effects of anthracycline therapy. [112] [141] The mechanism of this toxicity is impairment of myocardial growth. The severity of cardiac dysfunction is correlated with higher cumulative doses of anthracycline and higher dose rates.[112] [141] [142] [143] Patients treated at a young age, females, and those with Down syndrome appear to be more vulnerable to anthracycline-associated cardiac toxicity.[142] [143] Despite these echocardiographic abnormalities, most long-term survivors treated with anthracycline do not develop overt congestive heart failure,[141] [143] although longer follow-up is needed to fully assess the risk of late symptomatic cardiac disease.

Late occurring hepatotoxicity is a relatively uncommon effect of ALL therapy. [113] [144] Despite the large number of patients treated with regular doses of methotrexate and 6-mercaptopurine,

---

there have been few reports of fibrosis or other abnormalities. [113]

Ovarian and testicular function are relatively unaffected by most antileukemia therapy, [133] [135] [145] with the possible exception of programs that use alkylating agents (such as cyclophosphamide),[146] [147] high doses of cytosine arabinoside,[146] or prophylactic gonadal irradiation. [147] Several normal children have been born of patients successfully treated for childhood ALL. [148]

Second malignant neoplasms, including malignant gliomas,[84] [117] [118] treatment-related AML,[118] [149] [150] and carcinomas of the parotid and thyroid glands, [117] [118] have been reported in survivors of ALL. Patients treated on regimens that include epipodophyllotoxins [149] [150] or alkylating agents (such as cyclophosphamide) [151] have a much higher risk of secondary AML than do patients who were treated without these agents. [152] Although cranial or craniospinal radiation has been associated with the development of solid tumors within the radiation field, the risk of secondary malignancies, including brain tumors, from radiation for ALL appears to be relatively low. For instance, fewer than 1% of patients treated on DFCI protocols with cranial radiation (none of whom received alkylating agents or epipodophyllotoxins) developed a second malignancy. [153]

TREATMENT OF RELAPSED ALL

The recurrence of ALL is a life-threatening event. Factors that influence subsequent treatment include whether the recurrence is: (1) in the bone marrow or at an extramedullary site, such as the CNS, testis, ovary, eye, or a combination of sites;[154] and (2) after a relatively short initial remission (<1824 months), or after a longer first remission.[154] [155] [156] [157] [158] [159] The latter factor is sometimes thought of as the distinction between recurrence during therapy and recurrence after cessation of therapy;[154] [157] however, variable lengths of treatment programs make this criterion a less sensitive determinant of the outcome of subsequent therapy. Our observation has been that the time to relapse was more important than whether the relapse occurred while the patient was on or off therapy. [160] The presence of circulating blasts at the time of the relapse has been shown to be a significant predictor of adverse outcome. [161]

Depending on the intensity of initial therapy, induction of second complete remissions can be expected in 7090% of children, with conflicting data pertaining to whether some patients who were initially more intensively treated have a lower likelihood of second remission. [155] [156] [162] [163] [164] [165] Second induction treatment usually consists of multiple drugs, most often combinations of vincristine, prednisone, asparaginase, and an anthracycline (with or without methotrexate, an epipodophyllotoxin, and cytosine arabinoside). [155] [162] [164] [165] If the CNS has been involved as a site of relapse, intrathecal therapy with one or more drugs (methotrexate, cytosine arabinoside, hydrocortisone, thiotepa) is usually recommended on a weekly or twice weekly basis until the CSF is clear. Thereafter, when the patient is in complete remission, subsequent CNS treatment ("reprophylaxis") is indicated. [166] Local therapeutic approaches for isolated CNS relapses include intrathecal chemotherapy,[167] [168] craniospinal radiation,[168] [169] cranial radiation with intrathecal drugs,[167] and systemically administered high doses of methotrexate or cytosine arabinoside. [170] [171] Testicular relapses are usually treated with bilateral gonadal irradiation as well as with systemic chemotherapy. [172] [173] [174] [175]

After a second complete remission has been attained, the options for subsequent treatment include BMT and chemotherapy. Many trials of the latter have been unsuccessful at producing long-term survival,[163] [176] [177] especially in patients who relapse within 18 months of diagnosis and those with T-cell disease. [156] [164] The most successful chemotherapy trial results have been achieved with patients whose initial complete remissions exceeded 1830 months. The reported event-free survival of this subset of patients after treatment with intensive chemotherapy in second remission ranges from 36% to 65%. [156] [178] [179]

Sibling-matched allogeneic BMT for relapsed ALL has resulted in long-term survival in 2560% of patients. [157] [158] [180] [181] [182] [183] [184] [185] Transplantation in second remission has generally been more favorable than in third or subsequent remission. [181] In many published reports, the most common cause of failure after allogeneic BMT is recurrence of leukemia.[157] [182] [183] [184] Therapy-related toxicity, including infections and severe graft-versus-host disease, is also a major cause of death, occurring in 1530% of patients.[158] [183] [184] [185] [186] In recent years, the incidence of treatment-related complications appears to be decreasing with improvements in supportive care.[183] In some trials, duration of initial remission is an important predictor of outcome after allogenic BMT, with improved survival observed in patients with longer initial remissions.[157] [185] Other investigators report that patients with short initial remissions fare as well as those with longer initial remissions. [156] [183]

Because there are no randomized trials comparing chemotherapy and allogeneic BMT in relapsed ALL, published comparisons of the two modalities have generally been complicated by variability of patient selection and treatment. A retrospective, matched-pair analysis comparing outcome after sibling-matched allogeneic BMT with that achieved after chemotherapy demonstrated that BMT was associated with improved leukemia-free survival. [185] Others have also observed that sibling-matched allogeneic BMT confers a survival advantage, especially in patients with short initial remissions. [156] [176] [183]

For patients without matched sibling donors, alternative transplant options include autologous and matched-unrelated donor BMT. Autologous BMT is an attractive alternative because of the absence of graft-versus-host disease or need for long-term immunosuppression. Several investigators have studied autologous BMT, often in conjunction with ex vivo purging of residual leukemia in harvested marrow via immunologic or pharmacologic techniques. [159] [160] [187] [188] [189] For patients with long initial remissions, results achieved after autologous transplantation are comparable to those observed after allogeneic BMT, with event-free survival ranging from 40% to 50%.[160] [186] [188] [190] Patients with short initial remissions fare less well. [190] Relapse is the most common cause of treatment failure after autologous BMT, with a lower incidence of toxicity-related deaths than is observed after allogeneic BMT. [186]

Transplants from human leukocyte antigen-matched unrelated donors have been successful for some children with recurrent leukemia. [189] [191] [192] In studies that include patients treated after multiple relapses, event-free survival ranges from 20% to 30%. [189] [191] [192] The risk of treatment-related morbidity and mortality is substantial, often secondary to graft-versus-host disease.

Isolated extramedullary relapses, usually CNS or testicular, are manifestations of systemic disease. Therefore, in addition to therapy directed to the local site of disease (i.e., twice weekly intrathecal drugs for CNS or bilateral testicular irradiation for testicular relapse), intensive systemic therapy is also indicated. Given the high propensity for hematologic relapse after an isolated CNS relapse, [193] [194] we recommend BMT as postremission therapy for these patients. Emerging evidence suggests that intensive chemotherapy regimens may also provide adequate postremission therapy for patients with an isolated CNS relapse, especially those with late-occurring relapses. Recent studies report long-term event-free survival of 4570% for patients treated in this manner. [167] [168] [175] For patients with isolated testicular relapses, systemic chemotherapy and testicular irradiation have resulted in prolonged second remissions in >80% of patients with late-occurring relapses. [172] [173] This approach has been less successful in patients whose testicular relapses occur during or soon after cessation of initial therapy, with long-term

event-free survival ranging from 20% to 43%.[172] [174] Therefore, we recommend BMT for this subset of patients.

FUTURE DIRECTIONS

Future approaches to the treatment of childhood ALL include redefinition of prognostic factors, so that more intensive regimens are reserved for children at high risk of relapse and attempts to diminish long-term toxicity are addressed in patients who are successfully treated with current therapies. The use of molecular techniques may identify biologically distinct leukemia subtypes that may supplement or replace the epidemiologic factors currently used to determine risk-based therapy. Areas of investigation include the evaluation of more specific treatments (e.g., monoclonal antibodies linked to toxins), [195] the stimulation of leukemia-specific immunity,[196] the use of antiangiogenesis factors,[197] and the documentation of minimal residual disease.[73] The possibility of developing patient-specific treatment regimens based on in vitro cytotoxicity assays also is a promising new approach to the improved treatment of this disease. Chapter 59 - Acute Lymphocytic Leukemia in Adults

Dieter Hoelzer

Acute lymphocytic leukemia (ALL) is a malignant disease characterized by the accumulation of lymphoblasts. Two thirds of children and approximately one third of adults with the disorder can be cured with therapy currently available. Prognostic factors for leukemia-free survival (LFS) allow adult ALL patients at presentation to be stratified into low- and high-risk groups. This stratification is necessary for the recognition of patients who require more intensive chemotherapy or bone marrow transplantation (BMT) as curative therapy during first remission.

The difference in outcome of treatment between children and adults is probably not due to the presence of a different disease, but rather is a result of the higher frequency in adults of ALL subtypes associated with adverse prognoses, such as

Philadelphia (Ph) chromosome-positive ALL.[1] [2] Furthermore, a different pharmacology of cytostatic drugs and the higher rates of hematologic and nonhematologic toxicity contributes to their poorer outcome, particularly in ALL patients older than 50 years of age.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

EPIDEMIOLOGY

According to a report from the National Cancer Institute, the age-adjusted overall incidence of ALL in the United States was 1.5/100,000 in whites and 0.8/100,000 in blacks. The male-to-female ratio was 1.4:1.0. After a first peak in children younger than 5 years of age (5.3/100,000), the incidence decreases continuously. There is a slight increase after the age of 35 years and a second minor peak is reached in the age group of 8084 years (2.3/100,000). In the subsequent reporting periods from 1973 to 1987, there was a slight increase of age-adjusted incidence rates from 1.2 to 1.4. [3]

BIOLOGIC AND MOLECULAR ASPECTS

Preferred Approach to Diagnosis

Classification of the phenotype of the blast cells in acute leukemia requires morphologic and cytochemical evaluation, immunophenotyping, cytogenetic analysis, and molecular genetic analysis. Morphology remains the means by which acute leukemia is initially detected and together with cytochemical reactions is the major aid in distinguishing between ALL and acute myeloid leukemia (AML). For more precise subclassification of ALL into B or T lineages, immunologic techniques must be used to detect lineage-specific antigens as well as surface or intracytoplasmic molecules. The presence of terminal deoxynucleotidyl transferase (TdT) activity in leukemic blasts can facilitate the diagnosis of ALL. Cytogenetic analysis is a prerequisite for diagnosis of ALL because it has strong prognostic value. Molecular genetic techniques for confirmation of diagnosis in particular subsets of ALL (e.g., *bcr-abl*-positive ALL), as well as to evaluate therapeutic efficacy by detection of minimal residual disease (MRD), are of increasing importance.

Morphology

The cytologic features of leukemic blast cells in ALL and their division into L1 to L3 according to the French-American-British (FAB) classification are discussed in Chapter 57 . The distribution of L1 and L2 subtypes is of minor relevance for prediction of outcome. The subtype L3, observed in up to 5% of adult patients, should be distinguished because it is indicative for B-cell ALL, with different treatment option, but should be confirmed by surface marker analysis.

Cell Surface Marker Analysis

Acute lymphoblastic leukemia is divided into subtypes by immunologic criteria based on the presence of specific receptors or antigens on the cell surface of leukemic blast cells. Within the B or T lineage ALLs, the subtypes are defined according to their stage of differentiation. [4] For more details on the immunologic classification of ALL, see Chapters 56 and 57 .

The frequency of and definition of ALL subtypes in adult and childhood ALL are compared in Table 59-1 . In the German multicenter trials for childhood ALL (BFM) and adult ALL (GMALL), the phenotypic characteristics of 1,756 children and 946 adults with ALL were analyzed prospectively. B-precursor ALL is more frequently found in children, whereas T-lineage ALL has a higher incidence in adults. Within the B and T lineages, the more immature subtypes, early pre-B ALL and pre-T ALL, occur more frequently in adults. [4]

B-Lineage ALL

Early pre-B ALL, also termed *pre-pre-B ALL* or pro B, lacks B-, T-, and pre-B-cell markers but expresses human leukocyte antigen (HLA)-DR, TdT, and CD19, and has rearranged immunoglobulin genes. It occurs in approximately 10% of adult and 5% of childhood ALL. *Common ALL* is the major immunologic subtype in childhood as well as in adult ALL. It comprises >50% of cases of adult ALL. Common ALL is characterized by the presence of CD10 (formerly, CALLA) and a glycoprotein (gp100/CD10). Common ALL blast cells do not express markers that characterize relatively mature B cells such as cytoplasmic immunoglobulins or surface membrane immunoglobulins. The blast cells are positive for CD19 and TdT.

Pre-B ALL is characterized by the expression of cytoplasmic immunoglobulin, which is absent in common ALL, but is identical to common ALL with respect to the expression of all other cell markers (Table 59-1). Only very rarely may CD10 be absent in this subtype. Pre-B ALL comprises nearly 10% and 15% of adult and childhood ALL, respectively.

Mature B-cell ALL is found in approximately 4% of adult and 3% of childhood ALL patients. The blast cells express surface antigens of mature B cells, including surface membrane immunoglobulin. CD10 may be present, as well as occasionally cytoplasmic immunoglobulin.

T-Lineage ALL

Approximately 25% of adult ALL cases have blast cells with a T-cell phenotype. All cases express the T-cell antigen gp40 (CD7), and they may, according to their degree of T-cell differentiation, express other T-cell antigens (e.g., the E rosette receptor [CD2] or the cortical thymocyte antigen T6 [CD1]). A minority

TABLE 59-1 -- Immunologic Classification of Childhood and Adult Acute Lymphocytic Leukemia (ALL)

	Children (%; N = 1,756[4])	Adults (%; N = 946[4])	Surface Marker
B-lineage			
Early pre-B ALL	5	11	HLA-DR+, TdT+, CD19+
Common ALL	65	51	HLA-DR+, TdT+, CD10+, CD19+
Pre-B ALL	15	10	HLA-DR+, TdT+, CD10±, cytoplasmic immunoglobulin+
B-cell ALL	3	4	HLA-DR+, CD10±, CD19+, immunoglobulin+
T-lineage			
Pre-T ALL	1	7	TdT+, cytoplasmic CD3+, CD7+
T-cell ALL	11	17	TdT+, cytoplasmic CD3+, CD1a/2/3+

+, positive; ±, positive or negative; HLA, human leukocyte antigen; TdT, terminal deoxynucleotidyl transferase.

of T-cell ALL blast cells may also express CD10 together with T-cell antigens. In most cases of T-cell ALL, one or more of the T-cell receptor genes is rearranged.

These properties make it possible to classify T-cell ALLs according to their stage of differentiation into early T-precursor ALL (or pre-T ALL), 7% and 1% of adult and childhood ALL, respectively, and more mature T-cell ALL, 17% and 11% of adult and childhood ALL, respectively. [5]

Cytogenetic Analysis

Cytogenetic abnormalities are the most important independent prognostic variables for predicting the outcome of adult ALL. In two recent studies, clonal chromosomal aberrations could be detected in approximately 6285% of adult ALL patients; [6] [7] 1538% of the cases had normal metaphases. With careful attention to collection of the bone marrow cells and their rapid transport and preservation, the success rate in analysis of ALL marrow can be increased, and the identification of clonal abnormalities can be achieved in >90% of cases.

The major cytogenetic abnormalities in ALL are clonal translocations (t[9;22], t[4;11], t[8;14], t[1;19] or t[10;14]), and other structural abnormalities (9p, 6q, or 12p abnormalities). If none of the structural aberrations is present, the abnormalities can be classified according to the modal chromosomal number (<46, 46 with other structural abnormalities, 4750, >50; Table 59-2).

The demonstration of chromosomal abnormalities in ALL is relevant for several reasons: the presence of such defects may confirm the diagnosis if a karyotype specific for ALL is found; and chromosomal abnormalities are closely correlated with clinical features and immunologic subtypes and are independent prognostic variables for predicting LFS.

Molecular Genetic Analysis

Molecular analyses, detecting gene rearrangements in ALL by the polymerase chain reaction (PCR), Southern blot analysis, or fluorescent in situ hybridization with chromosome-specific DNA probes, are useful approaches in establishing a more precise diagnosis and defining the quality of remission, and may also give insights into the pathophysiology of the leukemic process (e.g., the mechanisms of leukemic cell stimulation by bcr-abl fusion proteins).

The most frequent molecular markers in ALL are bcr-abl and

ALL1-AF4. The Ph chromosome t(9;22)(q34q11) results from a translocation involving the breakpoint cluster region of the *bcr* gene on chromosome 22 and the *abl* gene on chromosome 9. The *bcr-abl* gene rearrangement can be demonstrated by molecular techniques. PCR analyses revealed an incidence of 2026% *bcr-abl*+ ALL in adult [8] [9] [10] compared with 3% in childhood ALL patients. One third of adult ALL patients with a Ph chromosome show M-*bcr* rearrangements (resulting in a 210-kd protein), similar to patients with chronic myeloid leukemia (CML), whereas two thirds have m-*bcr* rearrangements (resulting in a 190-kd protein). It is noteworthy that *bcr-abl* is more frequently detected than the corresponding chromosome abnormality (t[9;22]) because of occasional difficulties in obtaining sufficient material for cytogenetic analysis.

The most frequent form of 11q23 abnormality in ALL is t(4;11)(q21;q23). The involved gene on chromosome 11 is named *MLL* for mixed lineage leukemia. Synonyms are *ALL-1*, *HRX*, and *HTRX1*. The *MLL* gene is fused to a gene located on chromosome 4 that is named *AF-4* (also referred to as *FEL*). The translocation is frequently detected in infant leukemia and in patients with the early pre-B subtype (CD10 negative). The overall incidence in adults is approximately 6%. [11]

ETIOLOGY

The cause of ALL remains unknown. However, certain factors are related to its development. [12]

Genetic Predisposition

In epidemiologic studies, patients with some rare congenital chromosomal abnormalities showed an increased risk for development of acute leukemias, including ALL. In children with leukemia (predominantly AML), there is a 20-fold higher incidence of Downs syndrome than would be expected. There is also an increased risk of ALL associated with inherited disorders such as Klinefelters syndrome, Fanconis anemia, Blooms syndrome, ataxia-telangiectasia, and neurofibromatosis. The impact of genetic predisposition on the pathobiology of ALL may also be inferred from reports of the simultaneous development of ALL in identical twins. Such observations may also indicate that the disease is caused by an intrauterine event affecting both twins. [13]

Irradiation

The incidence of acute leukemias, mainly AML, but also ALL, was increased almost 20-fold in survivors of the atomic bomb explosions (>1 Gy exposure) in Japan, [14] with a peak incidence occurring 67 years after the radiation exposure. Induction of leukemia by emissions from nuclear power stations has also been raised as a possible environmental leukemogenic risk. An increased incidence of leukemia in children living in the vicinity has been observed, but it could not be directly related to radioactive emissions. [15]

Whether radiation exposure after the Chernobyl accident led to an increased incidence of leukemia is still controversial. So far, there is no evidence for a major increase in the Chernobyl region or in countries with high levels of contamination. [16] [17]

Chemical

The risk for development of ALL may also be increased after exposure to chemical agents such as benzene or other agents capable of producing bone marrow aplasia, including chemotherapeutic drugs. Secondary, therapy-related AMLs can occur after exposure to alkylating agents such as cyclophosphamide, epipodophyllotoxins, topoisomerase II inhibitors, and, rarely, anthracyclines [18] when used extensively in the treatment of ALL. Rarely, secondary ALL occurs in people with a history of chemotherapy

or irradiation as a second neoplasm. [19] Future treatment strategies might involve reduction of exposure of the patient to these drugs.

Viral

There is no direct evidence that a virus causes human ALL. Indirect findings, however, suggest involvement of a virus in the pathogenesis of two lymphoid neoplasias. [20] In the endemic African type of Burkitts lymphoma, the Epstein-Barr virus, a DNA virus of the herpes family, has been implicated as a potential causative agent. [21] The endemic infection with human T-cell leukemia virus I (HTLV-I) in Japan and the Caribbean has been shown to be an etiologic agent for adult T-cell leukemia/lymphoma. [22]

CLINICAL MANIFESTATIONS

Most adult patients initially present with clinical symptoms resulting from bone marrow failure. Physical findings such as pallor, tachycardia, weakness, and fatigue are due to anemia; petechiae or other hemorrhagic manifestations are attributable to thrombocytopenia; infectious complications are due to neutropenia. Clinical signs of leukemia related directly to infiltration of organs with leukemic blasts, such as lymphadenopathy, splenomegaly, and hepatomegaly, are present in most patients but are infrequently the problems for which the patient first seeks medical advice.

Symptoms and clinical manifestations of 938 adult ALL patients, 1565 years of age, entering two consecutive German multicenter trials, are given in Table 59-3 . One third had infection or fever at presentation, and one third presented with hemorrhagic episodes. Weight loss was observed only occasionally. Approximately one half of the patients presented at diagnosis with lymphadenopathy, splenomegaly, and hepatomegaly, and hilar lymph node enlargement or a thymic mass (detected on chest radiographs or computed tomography scans in approximately 14% of patients). Most (85%) patients with mediastinal masses had T-cell ALL. Massive thymic enlargement can cause dyspnea, especially when associated with pleural effusions. Although 7% of ALL patients at presentation had central nervous system (CNS) involvement (as demonstrated by leukemic blast cells in the cerebrospinal fluid), only 4% of these initially had CNS symptoms such as headache, vomiting, lethargy, nuchal rigidity, and cranial nerve or peripheral nerve dysfunction.

Virtually any organ can be infiltrated by ALL blast cells, and approximately one tenth of the patients had such organ involvement (Table 59-3). Most often a pleural effusion was observed, and this occurred almost exclusively in those patients with mediastinal enlargement and T-cell ALL. Some of those patients also had a pericardial effusion. Bone or joint pain was rarely observed compared with childhood ALL; bone lesions could be found in only 1.2% of cases. Initial involvement of the testis was very rare (<1%). Lymphoblastic infiltration of retina, skin, tonsils, lung, or kidney was observed only occasionally, particularly in mature B-cell ALL and to a lesser extent in T-cell ALL. Such organ infiltration can result in the typical clinical pattern associated with high-grade non-Hodgkins lymphoma (NHL).

LABORATORY EVALUATION

The peripheral blood cell values at diagnosis of the same cohort of patients are shown in Tables 59-459-6.

The leukocyte count (Table 59-4) was elevated in 59%, 14% had normal counts, and 27% had leukopenia. In 92% of the patients, leukemic blast cells were seen in the blood smear. Thus, aleukemic leukemias account for only a small proportion of

cases of adult ALL. With automated blood counting, the diagnosis may be missed in patients with normal or decreased white blood cell (WBC) counts and with low blast cell contents. For this reason, the need for microscopic examination of blood smears in people suspected of having acute leukemia should be stressed. An elevated blood count >100,000 × 10^6 /L was observed in 16% of the patients, and occasionally WBC counts >500,000 × 10^6 /L have been observed. In general, a high WBC count is found more frequently in T-cell ALL patients compared with B-lineage ALL.

Neutrophils (Table 59-5) <500 × 10^6 /L were seen in 23% of the patients and thrombocytopenia <25,000 × 10^6 /L in only 30% of patients, corresponding roughly with

the symptoms of infection and bleeding present at diagnosis. Anemia at diagnosis is observed in most adult ALL patients.

Bone marrow aspiration or biopsy is mandatory for diagnosis of ALL. In <15% of patients, the bone marrow cannot be aspirated and a biopsy must be performed. Dry taps are due to densely packed blast cells, fibrosis, or inadequate technique; the first two resolve after therapy. Most patients have >50%, or even >90% of blast cells in the bone marrow (Table 59-4). In <3% of cases, the blast cells constitute <50% of the nucleated marrow cells.

An initial lumbar puncture should be done to determine whether the CNS is involved. However, if there is a risk of bleeding due to a very low platelet count or of blast cell contamination due to a high leukemic blast content in the peripheral blood, lumbar puncture should not be performed. When the leukocyte count in the spinal fluid is low, or the morphologic detection of blasts is inconclusive, demonstration of an immunologically defined blast cell population can confirm a diagnosis of CNS involvement.

The most frequent metabolic abnormality is an increased serum uric acid level in approximately one half the patients; hypercalcemia was rare. Serum lactate dehydrogenase may be elevated as a result of cell destruction in patients with a large tumor mass, particularly in B-cell ALL. In a small proportion of patients (Table 59-6), the initial fibrinogen level was <100 mg/dl. Disseminated intravascular coagulation in ALL was rarely observed at diagnosis.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

DIFFERENTIAL DIAGNOSIS

Difficulty is rarely experienced in establishing the diagnosis of ALL. The differentiation from lymphocytosis, lymphadenopathy, and hepatosplenomegaly in viral infections and other acute or chronic leukemias can usually be done by lymphocyte surface markers.

Aleukemic pancytopenic ALL patients without blast cells in peripheral blood (<10%) have to be distinguished from those with aplastic anemia, which may also be a preleukemic syndrome. In contrast to ALL, in aplastic anemia the bone marrow is hypocellular.

In rare cases with low bone marrow infiltration, an arbitrary distinction between ALL and NHL is usually chosen according to the degree of infiltration, above or below 25%.

Mixed or hybrid leukemias are those in which blast cells express lymphoid as well as myeloid antigens; they may also be termed biphenotypic or bilineage leukemias. Biphenotypic leukemias are defined as those in which markers of lymphoid and myeloid lineages are coexpressed on the same leukemic cells. Bilineage leukemias are those with two populations of blast cells that have either lymphoid or myeloid antigens and might be allocated to a treatment strategy either for ALL or for AML.

Occasionally difficulties can occur in distinguishing Ph/bcr-abl-positive ALL from primary lymphatic blast crisis of CML. Sometimes final diagnosis can be done only after treatment initiation. In ALL patients achieving complete clinical remission (CR), the peripheral blood count shows normal values, whereas CML cases revert to a chronic phase with pathologic left shift.

THERAPY

Initial Evaluation and Supportive Therapy

At diagnosis, the evaluation of an adult with ALL should include a history and a careful physical examination. Speed in clinical evaluation and diagnosis is important in order to initiate supportive measures and to decide on appropriate therapy. Only in a few cases is the leukemic process so far advanced that immediate treatment of leukemia is necessary (e.g., in patients with symptoms due to a large mediastinal mass and pleural effusions or to a rapidly progressing B-cell ALL).

A few general measures should be initiated at once. Sufficient fluid intake to guarantee urine production of 100 ml/hour throughout induction therapy should be maintained to reduce the danger of uric acid formation. Parenteral fluid administration may be required when the patients oral intake is inadequate because of nausea or difficulty in swallowing. Placement of an implantable port system is advantageous when anticipating a long period of induction therapy or when part of the therapy will be carried out on an outpatient basis.

Patients should receive allopurinol to reduce the formation of uric acid and avoid the danger of urate nephropathy. Allopurinol should be given at a dose of 300 mg/day, which may be increased to 600 mg/day if high leukocyte counts or organomegaly persist. The dose of allopurinol has to be reduced when 6-mercaptopurine is given because it potentiates the action of 6-mercaptopurine.

Approximately one third of adult patients present with infection and bleeding. They are at high risk of infectious and hemorrhagic complications during the induction period because thrombocytopenia and granulocytopenia are aggravated by chemotherapy.

In general, platelet transfusions should be given in response to bleeding episodes and to prevent bleeding when platelet counts fall to <20,000 (10^6/L), especially during febrile periods. Most often 48 U/day of platelets are given until bleeding ceases. HLA-matched platelets are given to patients who become refractory to random donor platelets. The incidence of fatal hemorrhage during induction therapy has been significantly lowered by these measures.

Infection Prophylaxis

The use of more intense cytostatic regimens has resulted not only in improved response rates of malignancies but in higher morbidity and mortality rates due to infections.[23] Long-term

neutropenia is the most important risk factor, but CD4 lymphopenia, antibody deficiency, and multiple immunosuppression in allogeneic transplantation also lead to severe and lethal infections. Whereas formerly gram-negative microorganisms were the leading cause of febrile neutropenia, in the last decade gram-positive bacterial infections have increased, especially those due to more frequent use of indwelling catheters. Fungal infections also occurred more frequently. [24] The successful management of febrile neutropenia is based on hygienic procedures including general body hygiene, low-germ food, reverse isolation or high-efficiency particulate air filtration, antibiotic prophylaxis, sufficient diagnostics, and consequent empirical infection prophylaxis.

For antibacterial prophylaxis, cotrimoxazole or fluorochinolones, both mainly directed against gram-negative organisms, have mostly been used. [25] Cotrimoxazole also reduces the incidence of *Pneumocystis carinii* pneumonia, which occurs in approximately 20% of patients without prophylaxis. [26] Although antifungal prophylaxis with oral amphotericin B solution or triazoles may successfully reduce candidal colonization and prevent local candidal infections, the prophylactic procedures for reducing systemic mycoses are disappointing. Fluconazole has been reported to reduce only systemic *Candida albicans* infections in BMT patients, but increased non-*albicans* infections, especially *Candida krusei*, have been found. Because of its high lethality, *Aspergillus* infection is particularly feared. Attempts to prevent aspergilloses have included prophylaxis with itraconazole, intravenous low-dose amphotericin B, liposomal amphotericin B, and inhalation of aerosolized amphotericin B, but in randomized studies no benefit could be shown.[27]

The diagnostic procedures in febrile neutropenia include physical examination, cultures of blood, urine, sputum, and other sites of suspected infection, and imaging procedures such as chest radiography or abdominal ultrasound. High-resolution computed tomography of the lungs is especially important for the early diagnosis of *Aspergillus* pneumonia. Fungal pneumonias also may be microbiologically proven with bronchoalveolar lavage. More recently, PCR has been studied for use in the early detection of fungal infections.

The standard treatment of febrile neutropenia is the empiric administration of broad-spectrum antibiotics without waiting for microbiologic results. As initial therapy, combinations such as -lactam antibiotics plus aminoglycosides have been the gold standard, but monotherapy (e.g., with carbapenems or cephalosporins of class 3 and 3a) has been suggested to be equally effective. [28] Considering the increasing problems due to systemic fungal infections, empiric antimycotic treatment for persisting fever despite adequate antibacterial therapy in patients with pulmonary infiltration has been introduced. [29] Standard antifungal therapy is conventional amphotericin B, which may be combined with 5-flucytosine. Other formulations of amphotericin B, such as liposomal amphotericin B, the colloidal dispersion or the lipid complex, have been introduced to reduce amphotericin B toxicity. [30]

Hematopoietic Growth Factors

The use of hematopoietic growth factors such as granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) is a valuable component of supportive therapy during the treatment of ALL (Table 59-7). There is no indication that these CSFs stimulate leukemic cell growth in a clinically significant manner.

Most clinical trials demonstrate that the prophylactic administration of G-CSF significantly accelerates neutrophil recovery, [31] [32] [33] [34] [35] and several prospective, randomized studies also show that this is associated with a substantially reduced incidence and duration of febrile neutropenia and of severe infections. [32] [34] [35] The enhanced marrow recovery allows closer adherence to the dose and schedule of chemotherapeutic regimens. However, it still remains open whether the increased dose intensity translates into an improved LFS.

The advantage of G-CSF administration is particularly evident in selected high-risk patients receiving multiple treatment cycles, [32] whereas clinical effects appear to be negligible in patients at low risk of infectious complications. [36] Conversely, the results of the St. Jude trial show that even in cases of acute leukemia with a >40% probability of severe neutropenia, not all patients benefit from G-CSF treatment. [37] A comparison of this study[37] with other trials [34] [35] highlights the great importance

of CSF scheduling. When CSFs are first given at the end of a 4-week chemotherapy regimen, potential benefits are limited. Therefore, it is noteworthy that G-CSF may even be given in parallel with chemotherapy without aggravating the myelotoxicity of these specific regimens, [33] [34] [35] [38] and that this scheduling is an important determinant of the clinical efficacy.

An accelerated neutrophil recovery time, decreased rate of documented infection, and a shortened duration of intravenous antibiotic use and hospital stay could reduce costs of treatment. This has to be weighed against the expense of the hematopoietic growth factors. So far, the limited number of trials that have performed a cost-benefit analysis of G-CSF administration have demonstrated slightly decreased [39] or unchanged[37] overall treatment costs. On the other hand, the authors believed that

the CSF administration contributed substantially to quality of life. [39]

Chemotherapy

Chemotherapy of ALL is usually divided into several phases, beginning with remission induction. The objective of induction chemotherapy is to achieve CR, that is, eradication of leukemia as determined by morphologic criteria and, more recently, also by molecular markers. Although the induction phase is usually well defined, postremission therapy can be subdivided into intensification and maintenance phases. Usually prophylactic CNS treatment is added (Table 59-8).

Remission Induction Therapy

Exact diagnosis and management of initial complications are the prerequisites for successful induction therapy. A cautious cell reduction phase is recommended for patients with a large leukemic cell burden or a high leukocyte count (>25,000 × 10^6 /L). Patients with extreme leukocytosis (>100,000 × 10^6 /L) have been treated initially with leukapheresis. However, these patients

can also be managed with vincristine and prednisone (Table 59-9) in nearly all cases without complications. Thus, leukapheresis in adult ALL is not recommended except in rare instances, such as when leukemia occurs during pregnancy. For mature B-cell ALL, initial treatment with cyclophosphamide and prednisone for 1 week usually results in lysis of large tumor masses.[40]

Standard induction therapy for ALL in most studies consists of vincristine, prednisone, asparaginase, and an anthracycline. The combination of vincristine and prednisone alone produces CR rates of approximately 3667%, but a median remission duration of only 37 months. Prednisone and prednisolone have been most frequently administered, although dexamethasone shows a higher antileukemic activity in vitro and a better penetration to the cerebrospinal fluid. [41] The addition of anthracyclines, daunorubicin, or doxorubicin (Adriamycin) increases the CR rate to 7085%. [42] Asparaginase does not affect the CR rate but probably improves LFS, and if not used during induction therapy, it is often included as part of the consolidation treatment. Evidence comes from pediatric studies where the addition of asparaginase to vincristine and prednisone led to improved CR rates in relapsed ALL patients. [43] LFS also was improved by the administration of postinduction doses of asparaginase.[44] [45] The addition of asparaginase to conventional induction therapy did not improve the CR rate in one trial in adult ALL. There was, however, a trend toward a higher LFS in patients treated with asparaginase. [46]

The next step in improving induction therapy was the addition of cyclophosphamide and cytosine arabinoside (AC; Table 59-8). This does not raise the overall CR rate but possibly improves the quality of remission. Cyclophosphamide and AC therapy is particularly useful as initial treatment for special ALL subgroups such as T-cell ALL.

High-dose Treatment

A more recent strategy is to add high-dose AC (HDAC; 13 g/m^2 , usually for 12 doses) after the standard induction therapy. This approach has resulted in a median CR rate of 79% (Table 59-10), which is not superior to that obtained with conventional treatment, and it remains uncertain whether and for which subgroups it may be beneficial for LFS. The initial, relatively high early mortality rate is now decreasing with better handling and improved supportive care.

A new approach is the up-front administration of HDAC before conventional induction treatment, which in two preliminary reports yielded high remission rates of 8494% (Table 59-10). [47] [48] The aim of high-dose treatment, however, is not only to improve the CR rate but, even more, to increase the quality of remission. This means that a lower tumor load should lead to a better LFS.

Failure During Induction Therapy or Refractory ALL

Fifteen to 20% of adult ALL patients do not achieve CR after induction therapy, in contrast to <5% of children with ALL. Less than 10% of adult ALL patients die during the induction period. Mortality during induction is age dependent, increasing

ED, early death; BM, betamethasone; see Table 59-8 for other abbreviations.

with age from <3% in adolescents to 2030% in patients >60 years of age. The main cause of death in approximately two thirds of the patients is infection, in part fungal infection. The remaining nonresponders may achieve a partial remission or may be refractory to standard treatment. The number of patients (approximately 10%) who are refractory to chemotherapy is steadily decreasing with the use of more intensive induction regimens. These, however, lead more frequently to aplasia or toxic death, which stresses the need for implementation of optimal supportive treatment to overcome hematologic and nonhematologic toxicity in older patients.

Intensification Therapy

Consolidation therapy refers either to high-dose chemotherapy, to the use of multiple new agents, or to readministration of the induction regimen. These measures are aimed at eliminating clinically undetectable residual leukemia after induction chemotherapy and thereby preventing relapse as well as emergence of drug-resistant cells.

In adult ALL, intensification therapy can prolong LFS (see Table 59-8). Intensification schedules include teniposide, etoposide, m-amsacrine, mitoxantrone, idarubicin, and HDAC, or intermediate- or high-dose methotrexate (HDMTX). Allogeneic or autologous BMT should also be considered as a form of intensive postinduction therapy.

It is generally assumed that early intensification therapy is effective in prolonging remission and preventing relapse in ALL. [49] Evidence comes from nonrandomized trials. In earlier studies, the results of treatment of patients who did not receive consolidation therapy were reported to be poor. [50] [51] Historical comparisons confirmed this observation. Thus, the addition of a six-drug consolidation cycle led to a significantly improved LFS compared with a previous trial without consolidation. [52]

More recent randomized trials failed to demonstrate a clear advantage of different consolidation regimens. The difficulty in assessing the efficacy of certain consolidation schemes is evident from a recent Cancer and Leukemia Group B study. Therapy consisting of two consolidation courses with DA 7+3 (daunorubicin × 7 days + AC × 3 days) and DA 5+2, in addition to 6-mercaptopurine and methotrexate, was not superior to conventional maintenance alone. [53]

In two studies of the Gruppo Italiano Malattie Ematologiche Maligne dellAdulto (GIMEMA) focusing on the impact of intensified versus conventional maintenance treatment, no advantage could be demonstrated for the intensified regimen. [54] [55] In a randomized trial of the Medical Research Council (MRC), however, there was a reduction of relapse risk in patients receiving early or late intensification. [56] Despite these uncertainties, consolidation is now part of almost all adult ALL studies.

High-dose Chemotherapy

High-dose chemotherapy has been used mainly to overcome drug resistance or to achieve therapeutic drug levels in the cerebrospinal fluid.

HDAC.

Although there is considerable experience with HDAC for the treatment of ALL [42] [57] it still remains uncertain what dose is optimal. HDAC has been included in several trials in adult de novo ALL as part of consolidation therapy [58] [59] [60] [61] or during induction and consolidation treatment. [62] With a weighted mean for the LFS of 30% (2650%), the results are not superior to trials without HDAC.

It is unknown whether specific subgroups of ALL profit from a HDAC treatment; thus, excellent results are achieved for pediatric B-cell ALL, with LFS of >80% [63] and apparently for adult pre pre-B ALL, with LFS of 5060%. [64] For other adult poor-risk groups such as late responders, Ph+ ALL, or pre-T ALL, the value of HDAC remains to be determined.

An additional argument for the use of HDAC might be its effectiveness in treating CNS leukemia. There is evidence that in ALL and NHL, higher levels of AC triphosphate can be reached with 3 g/m^2 compared with the lower dose of 1 g/m^2 AC; in addition, with the higher dose, the cerebrospinal fluid can be cleared of blast cells. [65] Thus, for high-risk adult ALL patients, HDAC (3 g/m^2) still seems to be justified despite a higher associated morbidity.

High-dose Methotrexate.

The use of HDMTX has been extensively studied for the treatment of childhood ALL and, to a lesser extent, adult ALL. [66] Intermediate doses (0.5 g/m^2), high doses of 18 g/m^2 , and even doses of 33 g/m^2 have been used. HDMTX appears to be effective in preventing systemic and testicular relapses. [67]

The effect of HDMTX on CNS leukemia may contribute to the favorable results reported with its use. HDMTX at a dose of 6 g/m^2 resulted in an 80% CR rate in children with CNS relapse, [68] indicating that systemic application yields cytotoxic levels in the cerebrospinal fluid.

Several studies have investigated the efficacy of HDMTX as consolidation [69] [70] [71] [72] or during consolidation and induction treatment [73] [74] in combination with other chemotherapeutic agents in adult ALL. The weighted mean for LFS of six studies is 41%, with a wide range (3156%). Most favorable results have been achieved in small trials with HDMTX as part of intensive multidrug consolidation regimens.

The combination of cycles having HDAC with cycles having HDMTX during consolidation was reported from six trials with a weighted mean for LFS of 32% (1748%). [54] [55] [75] [76] [77] Thus, there is some evidence that the inclusion of HDAC and HDMTX as part of multidrug consolidation treatment may improve overall results.

Maintenance Therapy

The optimal duration and form of maintenance therapy in adult ALL is unknown. Because the aim of maintenance or continuation therapy is to eliminate minimal

residual disease (MRD), the optimal form of maintenance therapy will not be identified until reliable methods for detection of MRD are available. Standard maintenance is based on combination treatment with 6-mercaptopurine and methotrexate. The potential effect of further intensification cycles for specific subgroups of ALL remains open. In a large, multicenter Italian study (GIMEMA 0183), after intensive consolidation treatment patients were randomly assigned to postconsolidation therapy with conventional maintenance therapy or to additional alternating treatment courses of different intensity. [54] In this report, there was no difference in the survival rate at 10 years between the treatment groups, which may suggest that after adequate early consolidation therapy the intensity of the maintenance therapy has no influence on survival. However, attempts to omit maintenance altogether after induction and consolidation therapy have resulted in inferior results. [60] [73] [78] [79] Prospective trials with maintenance schedules adapted to immunologic subtypes of ALL (e.g., longer for common ALL, shorter for T-cell ALL, and none for B-cell ALL) or to cytogenetic subgroups (e.g., Ph*/bcr-abl*-positive ALL chemotherapy maintenance vs. interferon-/interleukin-2) are needed.

Prophylaxis of CNS Leukemia

Central nervous system leukemia occurs in 6% (110%) of patients with adult ALL at diagnosis, with a higher incidence in T-cell ALL (8%) and mature B-cell ALL (13%).[80] Treatment and prophylaxis of CNS leukemia may consist of intrathecal methotrexate alone or in combination with AC or prednisone, similar intraventricular therapy administered by an Ommaya reservoir, cranial irradiation, or systemic treatment with HDAC or HDMTX.

Adult ALL patients who do not receive specific prophylactic CNS treatment have a CNS relapse rate of 30% (2932%), [80] similar to that observed in children without CNS prophylaxis.[81]

With intrathecal chemotherapy alone, the rate of isolated and combined CNS relapses could be reduced to 13% (819%). Intermittent application during maintenance therapy improves the efficacy compared with application of only a few doses during induction treatment. [82] In most adult ALL trials, additional prophylactic CNS irradiation (24 Gy) has been included. This combined approach further reduces the CNS relapse rate to 9% (319%). There is some evidence that early irradiation after remission induction is superior to delayed irradiation during consolidation treatment. [80] It is questionable whether systemic high-dose treatment alone provides sufficient CNS prophylaxis because the CNS relapse rate is approximately 14% (1016%).

In many recent trials, combined treatment approaches have shown high efficacy. For high-dose chemotherapy together with intrathecal therapy, the rate of CNS relapses was 7% (216%); with additional CNS irradiation, the relapse rate was 6% (113%). The efficacy of intensified CNS prophylaxis was also demonstrated in a retrospective analysis from the M.D. Anderson Cancer Center, where the lowest CNS relapse rate (2%) was achieved in a trial with early high-dose chemotherapy and intrathecal therapy for all patients. [75]

Because the risk for CNS relapse is associated with other prognostic factors such as T-cell ALL, B-cell ALL, extreme leukocytosis, high leukemia cell proliferation rate, high serum lactate dehydrogenase levels, and extramedullary organ involvement, a risk-adapted CNS prophylaxis has been suggested. [75] This approach, however, in contrast to childhood ALL, is not widely used in adults.

Prophylactic treatment of the CNS may result in acute or chronic neurotoxicity. Adverse effects include febrile reactions, arachnoiditis, leukoencephalopathy, and subclinical dysfunctions, including learning disabilities. These adverse reactions occur primarily in children and are only subclinical in adults. [83]

Therapy for Relapsed and Resistant Leukemia

Patients who fail to achieve CR or those who relapse subsequently have been treated with a variety of protocols (summarized in Welborn [84] and Bassan et al.[85]). The repetition of regimens including vincristine, anthracyclines, and steroids, similar to standard induction treatment in earlier studies, led to CR rates of 61%. [84] [85] Use of single-agent HDMTX, HDAC, and probably the anthracycline derivatives mitoxantrone and rubidazone resulted in a second remission in 30% of patients, whereas other agents such as amsacrine, teniposide, and etoposide are effective in 1015%. [49]

High-dose AC has been extensively studied in relapsed adult ALL. From several small pilot studies comprising 90 patients in total, the weighted mean remission rate was 37%.[86] Higher CR rates (5060%) were achieved with combination regimens that included HDAC and mitoxantrone, amsacrine, or vincristine plus steroids, again with a wide variation that may be attributed to patient selection and nonuniform intensity of pretreatment. Because HDAC is increasingly administered during front-line treatment, its efficacy during relapse treatment may be impaired. Therefore, new combinations with idarubicin (4664% CR rate) [87] [88] [89] [90] or fludarabine (6783% CR rate)[91] [92] have been evaluated. Median remission duration or survival was reported by only a few groups, but did not exceed 5 months and 16%, respectively. The combination of moderate- to high-dose methotrexate with asparaginase and folinic acid rescue produced CR rates of 51%, and was well tolerated. [84]

The most significant predictive factor for treatment response in relapsed patients is the duration of first remission. Patients with longer previous remission (>18 months) have a higher CR rate and longer remission duration compared with those with a short previous remission (<18 months). [93] [94]

For all chemotherapy regimens, the duration of second remission is usually short (<6 months), and the long-term survival rate with chemotherapy alone is <5%. Thus, the only curative chance for adult patients with relapsed or resistant ALL is BMT, and the major aim of relapse treatment is the induction of a second remission with sufficient duration to prepare BMT.

BMT in Adult ALL

Bone marrow transplantation is one of the postremission strategies for eradication of residual disease in ALL. Prognostic factors for remission duration after chemotherapy (i.e., age, WBC count, immunophenotype) are also predictive for the outcome after BMT. [95] Ph-positive ALL seems to be an exception, in which results with chemotherapy alone are very poor, but results with allogeneic BMT are much more favorable, with an LFS rate of 3040%. [96] [97] [98] [99]

Allogeneic BMT from Sibling Donors

The outcome of allogeneic BMT for ALL depends on the age and remission status of the patient. [100] The best results have been obtained with patients transplanted during the first remission. In a total of 875 patients, the LFS rate was 45%, albeit with wide variations (2166%). The relapse probability (RP) was 29% and the treatment-related mortality rate (TRM) 33% (Table 59-11). In more recent studies, results are apparently improving, most probably because of a reduction in TRM. [101] There is evidence that graft-versus-leukemia effects are also present in ALL because several studies have shown that the RP is lower in patients with limited graft-versus-host-disease (reviewed in Appelbaum [102]).

TABLE 59-11 -- Recent Results of Bone Marrow Transplantation in Adult Acute Lymphocytic Leukemia

BMT	Disease Stage	N	Leukemia-Free Survival[a]	Relapse Probability[a]
Allogeneic	CR1	875	45% (2161%)	29% (1050%)
	CR2	104	26% (1541%)	64% (6271%)
	Rel/refr	231	18% (1232%)	71% (5778%)
Autologous	CR1	759	43% (1575%)	57% (2767%)
	CR2	465	28% (1031%)	74% (6988%)
	Rel/refr	27	8%	90%
MUD (mostly children)		65	39% (2353%)	16%
	Rel/refr	25	20%	52%

MUD, matched unrelated donor; Rel, relapsed; refr, refractory; CR1, first remission; CR2 second remission.

[a]Pooled data from literature.

After allogeneic BMT in second remission, the LFS rate is 26% (1541%). The RP of 64% is still high. Improvements may be achieved by increasing remission quality, such as with intensified conditioning regimens or transplantation of peripheral blood stem cells (PBSC) to induce a graft-versus-leukemia reaction. In advanced ALL (refractory or in relapse), allogeneic BMT results in an 18% (1232%) long-term survival rate.

Mismatched Related or Unrelated BMT

Only one third of potential BMT candidates with ALL have an HLA-identical sibling donor. To extend the possibilities of allogeneic BMT by enlarging the number of bone marrow donors available, mismatched BMT from related donors or matched BMT from unrelated donors has been increasingly used. With BMT from partially mismatched family donors, two groups have reported quite favorable results (LFS 3853%) in pediatric and adult patients with relapsed ALL, although the TRM and the rate of graft failure were significantly higher compared with fully matched allogeneic BMT. [103] [104]

Bone marrow transplantation from matched unrelated donors can also result in long-term survival. In a recent report from the Seattle group, including children, the LFS was 39% for ALL in second remission and 10% for ALL transplanted in relapse. The cumulative TRM for all leukemias was 39%, whereas the RP was 41%. [105]

In ALL as a whole, the results of matched unrelated BMT seem encouraging, particularly when it is considered that these are often patients with advanced stages of disease. However, the median age in these series is low, and all studies include children. It remains to be shown in larger studies what the results are for adult patients only.

Autologous BMT

Another attempt to overcome the limited availability of bone marrow donors is autologous BMT. [100] This form of BMT is associated with a risk of reinfusing residual leukemic cells and also of a higher relapse rate owing to the lack of a graft-versus-leukemia effect. Purging of the marrow graft is of interest because it may reduce the leukemia cell burden. Several methods are in use, such as monoclonal antibodies reactive to surface markers on leukemic cells with or without complement, chemotherapeutic drugs such as 4-hydroperoxycyclophosphamide and mafosfamide, or immunomagnetic beads. Purging with immunomagnetic beads can reduce tumor load by 2 log for either bone marrow or PBSC grafts in ALL. [106] [107]

The results for autologous BMT in first remission are surprisingly good, with an LFS of 42% (1575%) and a low TRM (<20%) in a literature survey of 906 patients (Table 59-11). Similar results with an LFS rate of 42% in standard-risk ALL (N = 280) and 40% in high-risk ALL (N = 174) have been reported from the European Bone Marrow Transplant Group (EBMT).[108] There is still a high RP of 50%. In addition to purging, the administration of maintenance treatment after autologous BMT may contribute to a reduction of RP. Favorable results therefore have been achieved in a trial with autologous BMT or PBSC transplantation in adult ALL patients in first CR followed by a 2-year maintenance treatment with 6-mercaptopurine and methotrexate.[109]

For patients with autologous BMT in second CR, the LFS in a large cohort of 513 patients was 22%, which is clearly superior to chemotherapy, but the RP of 71% is still high (Table 59-11).

PBSC Transplantation

2A recent strategy for the treatment of adult ALL is to transplant autologous or allogeneic PBSCs. [110] Several studies have shown that neutrophil and platelet recovery is faster after PBSC transplantation compared with autologous or allogeneic BMT, and that transfusion dependence is reduced. In Ph+ ALL, PBSC transplantation provides the particular advantage that Ph-negative stem cells can be collected in some patients, [111] whereas autologous bone marrow grafts are almost always Ph positive.[107] [112] Whether these advantages will result in a higher LFS remains open. Furthermore, in heavily pretreated patients, the collection of a sufficient number of stem cells from the peripheral blood may be difficult. In a preliminary report from the EBMT in ALL patients in first remission, the LFS rate was 41% after PBSC transplantation, compared with 35% after autologous BMT, with a similar RP of 60%. [113]

Comparison of Different Transplantation Procedures and Chemotherapy

When comparing these results with those achieved by chemotherapy, it is obvious that all patients in second remission should receive transplants, because the outcome after BMT is clearly superior to the 5% cure rate achieved with chemotherapy alone.

The use of BMT during first remission of ALL remains more controversial. The LFS rate of 45% after BMT is superior to that obtained with chemotherapy alone; however, when these results were adjusted for age, risk factors, and time to BMT (thereby excluding early relapses), the differences between BMT and chemotherapy were no longer significant in a comparative analysis of BMT patients from the International Bone Marrow Transplant Registry and chemotherapy patients treated according to the GMALL protocol (34% vs. 32%). This was predominantly due to a higher TRM in the transplant group (53% vs. 5%), whereas the RP was higher in the chemotherapy group (30% vs. 66%).[114]

The French study group conducted a randomized trial with autologous BMT versus chemotherapy in patients without sibling donor and allogeneic BMT for all patients with sibling donor. The LFS rate in patients treated with allogeneic BMT (44%) was not significantly superior to that in those treated with chemotherapy (32%) or autologous BMT (39%). [115] In high-risk patients, however, there was a significantly better outcome for patients treated with allogeneic BMT (39%) compared with those in the control group (14%).[116]

Preferred Approach to BMT

Taking all results together, it appears advisable that low-risk groups having an LFS of approximately 50% after chemotherapy should receive BMT only after relapse and second remission. For high-risk adult ALL patients, allogeneic BMT in first remission results in a survival advantage compared with chemotherapy alone. For veryhigh-risk patients (such as Ph+ ALL) without a compatible donor, BMT from a matched unrelated donor is recommended in younger patients, whereas older patients should receive autologous BMT. With improving strategies for supportive care and prophylaxis of graft-versus-host disease, the TRM after matched unrelated BMT might be reduced without losing the advantage in terms of relapse probability.

PROGNOSIS

The major risk factors in attaining a CR are advanced age and Ph+ ALL. Prognostic factors are of greater importance for duration of remission and survival (Table 59-12). Appreciation of the impact of such risk factors (Table 59-13) can result in the generation of risk-adapted treatment protocols for adult ALL, a strategy already well established for childhood ALL (Table 59-14).

TABLE 59-12 -- Outcome of Adult Acute Lymphocytic Leukemia According to Subgroups

[a] *Pooled data from published studies.*
[b] Results from pediatric studies.

Age

There is a continuous decline in the CR rate from 95% in children to 4060% in patients >5060 years of age. [1] [117] Most trials demonstrate that increasing age is also associated with shorter remission duration and survival. [53] [118] [119] [120] [121]

It is difficult to define an age limit where a change in prognosis occurs, but in almost all studies LFS is inferior in patients older than 5060 years of age. This age limit seems to be practical because patients younger than 50 years of age are candidates for intensified treatment approaches such as BMT, whereas for the older group, new strategies need to be explored, carefully weighing the gain in survival against quality of life. Thus, elderly patients >5055 years of age who have achieved a CR and are in good clinical condition are potential candidates for autologous BMT. PBSC transplantation is even applied in patients older than 60 years of age if in a biologic good condition.

Immunophenotype

The immunophenotype is an independent prognostic variable in ALL, despite the fact that with modern treatment strategies the previously poor prognosis of phenotypes such as T-cell ALL and mature B-cell ALL has been changed. In ongoing recent

[a] *Analysis and cut-off varies by study.*

trials, there is a tendency to use the immunophenotype to adjust treatment regimens accordingly (e.g., for B-cell ALL).

T-Lineage ALL

Results for T-cell ALL have improved to CR rates of >80% and an LFS of 46%, compared with earlier results with remission duration of <10 months and survival rates <10%. In vivo and in vitro evidence has accumulated to suggest that AC and cyclophosphamide, in addition to the usual cytostatic drugs for ALL, are mainly responsible for this improvement. The inclusion of AC and cyclophosphamide pulses during continuation therapy was beneficial in childhood T-cell ALL. In adult T-cell ALL as well, the combination of AC and cyclophosphamide added to the conventional drugs improved the CR and LFS rates. [122] [123] Increased CR and LFS rates for T-cell ALL were also observed in a Cancer and Leukemia Group B (CALGB) study using the addition of cyclophosphamide to the conventional induction regimen of vincristine, prednisone, daunorubicin, and L-asparaginase (VPDA).[124] HDMTX contributes to the improvement of survival in children, [125] [126] as does HDAC.[127] HDAC improved the prognosis for adult ALL patients with high WBC counts and T-cell ALL. [128] For adults, the benefit of HDAC and HDMTX in T-cell ALL has to be confirmed in larger trials.

B-Lineage ALL

In common ALL, CR rates in adult trials have improved to 80% or more, but patients still relapse in most studies over a period of up to 56 years, and only one third survive. This may in part be explained by the fact that approximately 30% of adult patients with common ALL are Ph/ *bcr-abl* positive and their prognosis remains poor. The results, however, also are not encouraging for adult patients with Ph-negative common ALL. Higher doses of anthracyclines given in induction and reaching a certain cumulative amount may be beneficial.[129] The outcome of patients with pre-B ALL seems to be similar to that of common ALL.

Adults with the subtype pre-pre-B ALL or the t(4;11) translocation have a poor prognosis, similar to childhood ALL patients. [130]

TABLE 59-14 -- Preferred Approach to the Risk-adapted Treatment of Adult Acute Lymphocytic Leukemia

	Low-risk ALL	High-risk ALL	Very-High-risk ALL	Mature B-Cell ALL

WBC, white blood cell count; CNS, central nervous system; BMT, bone marrow transplant. See Table 59-8 for other abbreviations.

[a] For patients with a large leukemic mass or a high leukocyte count.

[b] C 200 mg/m^2 × 5, P 60 mg/m^2 × 5.

With intensive regimens including HDAC and mitoxantrone as consolidation therapy, the results for adults seem to improve. [11]

Complete remission rates for adults with B-cell ALL a decade ago were low, and remission duration and survival was short. In nine studies with a total of 63 patients, the weighted mean CR rate was 44%, and most patients relapsed rapidly, reflected by a median remission duration of 11 months and a very low survival rate. [131] A change was brought about by innovative childhood B-cell ALL studies that significantly improved outcome, with CR rates of 8094% and an LFS rate of 63% (weighted mean).[40] The drugs responsible for the improvement were high doses of fractionated cyclophosphamide, HDMTX (0.58 g/m ^{2}), and HDAC in conjunction with the conventional drugs for remission induction in ALL, given in short cycles at frequent intervals over 6 months.

The application of these childhood B-cell ALL protocols in original or modified form also brought a substantial improvement for adult patients with B-cell ALL. CR rates now range from 60100% and LFS rates from 2065%.[40] Adverse prognostic factors are late CR (more than two cycles of chemotherapy), high WBC (>50 × 10 ^{9} /L), and age >50 years. Patients with these high-risk features are candidates for BMT. B-cell ALL has a higher incidence of CNS involvement at diagnosis and of CNS relapse. Therefore, effective measures against CNS disease, such as HDMTX and HDAC as well as intrathecal therapy, are important components of treatment regimens. Maintenance treatment has been omitted. Because relapses occur almost exclusively within the first year in childhood as well as in adult B-cell ALL studies, patients thereafter can be considered to be cured.

Myeloid Antigen-Positive ALL

Whether myeloid antigen expression in ALL has an adverse impact on outcome is not established. In childhood ALL, myeloid coexpression has apparently no prognostic relevance (reviewed by Drexler and Ludwig [132]). Some adult studies indicated an inferior outcome for myeloid antigen-positive ALL patients both for CR rate and LFS, but more recent studies do not confirm this.

Cytogenetics

Chromosomal abnormalities markedly correlate with outcome in ALL independent of other features. [6] [7] [133] Hypodiploidy and translocations, particularly the t(9;22) Philadelphia chromosome, are unfavorable findings in adults.

Philadelphia chromosome/*bcr-abl*-positive ALL has the worst prognosis in children as well as in adults. In 13 studies with a total of 384 patients, the weighted mean CR rate is 67% (4476%). The median remission duration in all series is short (511 months) and the survival rate, from 016% at 35 years, is extremely poor in all reports.

Treatment options for Ph/*bcr-abl*-positive ALL in adults include HDMTX or HDAC; so far, no convincing progress for this subgroup of patients has been reported. The use of biologic response modifiers found successful in CML, such as

-interferon, was initially encouraging but has not fulfilled its promise. In a study using a combination of -interferon and interleukin-2 after autologous BMT, although there was a two- to threefold increase in T-cell subsets and a five- to sevenfold increase in natural killer cell activity, this did not result in an apparent clinical benefit.[134] The only curative chance for adult Ph/*bcr-abl*-positive ALL patients is therefore BMT.

The adverse impact of the translocation t(4;11) seems to have changed with new treatment modalities (see pre-pre-B ALL in section on B-lineage ALL).

The translocations t(8;14), t(8;2), and t(8;22) are present in most cases of mature B-cell ALL [135] and in Burkitts lymphoma.[136] [137] These translocations have lost their poor prognostic impact because of the improved treatment for patients with B-cell ALL or Burkitts lymphoma. Patient numbers are too small to evaluate whether there is any difference in prognosis for these three translocations.

Other Prognostic Factors

With regard to gender, several studies have observed a higher remission rate in female patients, but these results have not reached statistical significance in most adult ALL reports. When sex-related differences were reported, they were in favor of female patients (e.g., in long-term outcome). Extensive organ involvement at presentation (e.g., hepatomegaly, splenomegaly, CNS leukemia, and mediastinal involvement) has been found in some studies to have an adverse influence on remission duration. CNS leukemia is considered an adverse prognostic factor [138] [139] in some reports. However, in other studies, [140] [141] the LFS for patients with initial CNS involvement was not inferior. Mediastinal mass, although indicative of a large tumor burden, had no adverse influence on either CR rate or remission duration in several adult ALL series. Most ALL patients with mediastinal tumor have the T-cell ALL subtype, so that any adverse influence of mediastinal mass is probably outweighed by the recent improvement in treatment for T-cell ALL.[123] The rare cases with mature B-cell ALL and mediastinal mass, which have to be distinguished from a mediastinal large B-cell lymphoma with sclerosis but no bone marrow involvement, have an apparently poor outcome. [40] Splenomegaly, hepatomegaly, or hepatosplenomegaly at the time of diagnosis had an adverse impact only in single studies. An adverse influence of organ enlargement on CR rate [118] was not correlated with an adverse effect on remission duration, [142] [143] although overall survival might be shortened.

FUTURE DIRECTIONS

Multidrug Resistance

Circumvention of multidrug resistance (MDR) is an alternative treatment strategy. The *MDR* gene encodes for a membrane glycoprotein, p170, which is thought to function as an efflux pump.[144] The expression of this gene confers resistance to some chemotherapeutic agents, including vinca alkaloids, toxoids, anthracyclines, and epipodophyllotoxins. [145] Ten to 50% of patients with ALL at diagnosis and 1560% at relapse express *MDR*.[146] In adults, the incidence of MDR positivity increases markedly after relapse (10% at diagnosis, 50% after relapse). [147] The expression of MDR is associated with a lower CR rate (56% for MDR-positive vs. 93% for MDR-negative; $P = 0.05$) and a higher relapse rate (100% vs. 46% respectively; $P = 0.05$). This results in a survival advantage for MDR-negative patients. [147] Pharmacologic inactivation of a 190-kd P-glycoprotein, which is coded for on chromosome 16p13, may be more clinically relevant than MDR. [148]

Minimal Residual Disease

Recent advances in molecular and immunologic techniques have allowed the detection of MRD, defined as leukemic cells undetectable by morphologic examination. Methods to detect MRD include cytogenetics, cell culture techniques, flow cytometric sorting and immunophenotyping, and detection of leukemia-specific DNA or RNA frequencies by Southern blot tests or PCR (the reader is referred to summaries [149] [150] [151] [152]). Rearrangements of the immunoglobulin (Ig) heavy chain gene or T-cell receptor genes are one target for MRD detection. The clonal nature of ALL is manifested by a specific and unique rearrangement of these genes in all malignant cells, whereas normal cells have a germ-line configuration. Amplification of such leukemia-specific markers by PCR can identify one leukemic cell among 10^5 normal cells. The major limitation with this technique is that because the rearrangement is unique for each clone, specific probes must be generated for each patient. Recent attempts to detect antigen receptor gene rearrangements by monitoring two or more functional regions of multiple genes found that PCR detection of MRD is possible in approximately 90% of ALL patients and that false-negative results due to clonal evolution may be reduced to 10% or less. [153] [154]

The detection of a leukemia-specific chromosomal translocation by PCR is a tool for MRD with a high sensitivity (10^6). More than 50% of adult ALLs have identifiable chromosomal translocations (e.g., *bcr-abl*, *E2A-PBX1*, *MLL-AF4*, and *TEL-AML1*), which can be detected by PCR analysis.

Detection of MRD by immunologic methods, such as multiparameter flow cytometric analysis measuring characteristic constellations of two or more cell surface antigens, has also been proposed (sensitivity of 10^4). [155]

Clinical studies evaluating MRD by PCR analysis have shown a widespread pattern. After induction chemotherapy with a 3- to 4-log reduction in the number of leukemic cells, even when morphologic (clinical) CR is achieved, some residual disease can be documented. In *bcr-abl*-positive ALL, most patients in clinical CR still have MRD at a molecular level, [112] [156] and most of them relapse.

Persistence of MRD or repeated positive results indicates a high likelihood of subsequent relapse. An increase in leukemic cells can also be detected by PCR before a relapse becomes clinically evident. However, the absence of MRD during or after treatment does not guarantee continuous remission. [157]

Interpretation of MRD is complicated even further by the fact that PCR studies have shown the presence of the *bcr-abl* fusion gene or the *bcl*-2 gene in apparently healthy people at a very low level. [158] [159] This indicates that the expression of a fusion transcript is not necessarily identical with malignant proliferation.

Thus, for practical clinical reasons, it is not only whether MRD is present, but the kinetics of disappearance after treatment, and the subsequent confirmation of negative results, that might be of greater clinical relevance. In most studies of patients with continuous CR, a successive decline of patients with positive MRD has been shown. A substantial number of patients, however, may remain MRD positive even at the end of therapy without subsequent relapse. [160] The kinetics of MRD in the first weeks of induction therapy appear to be very predictive. A level above one target cell in 10^3 normal cells after the end of induction treatment is associated with a high risk of relapse. [161] [162] Apart from possible technical reasons for error in the detection of MRD, there is a need for larger, prospective studies to evaluate the potential of MRD determination.

Detection of MRD could have several consequences for ALL, such as the redefinition of CR in patients who are in morphologic CR but with detectable MRD, or the evaluation of the effectiveness of specific treatment elements, such as consolidation, maintenance, or bone marrow purging. Furthermore, if

there is no MRD, treatment could be stopped, or alternative treatment approaches such as BMT could be considered in patients with positive MRD and therefore a high likelihood of relapse. Evaluation of MRD in ALL therefore may eventually lead to an individualization of therapy.

Chapter 60 - Myelodysplastic Syndrome

Peter L. Greenberg

INTRODUCTION

Terminology describing the indolent myeloid clonal hemopathies has been refined since it was initially published in 1953. [1] Numerous terms, including preleukemia (or hemopoietic dysplasia), refractory anemia with excess of blasts, subacute or smoldering myeloid leukemia, oligoleukemia, and myelodysplastic and dysmyelopoietic syndromes,[2] [3] [4] [5] [6] [7] [8] [9] have been used to describe patients with refractory cytopenias whose marrows showed morphologic evidence of dysplastic changes in at least two of the three hemopoietic cell lines and in whom the disease showed a propensity to undergo transformation into acute myeloid leukemia (AML). The term myelodysplastic syndrome (MDS) is currently accepted as describing this clinical entity. It should be recognized, however, that although the leukemic transition in these patients morphologically resembles de novo AML, the AML transformation developing from MDS is generally more resistant to standard induction chemotherapy. The poor prognosis of patients with this leukemic transformation is similar to the poor prognosis of patients with chronic myeloproliferative disorders and leukemic transformation (Fig. 60-1).

In these MDS patients, variations in marrow morphology and in the potential for survival and transformation into AML have been recognized. To aid in categorizing patients, the disease was subclassified by the French-American-British (FAB) Cooperative Group, which formulated a set of criteria based on marrow morphology, including the proportion of myeloblasts and the degree of derangement of the hemopoietic cell lines. [10] This morphologic classification scheme subdivides the disease into five subgroups: refractory anemia (RA), refractory anemia with ringed sideroblasts (RARS), refractory anemia with excess blasts (RAEB), refractory anemia with excess blasts in transformation (RAEB-T), and chronic myelomonocytic leukemia (CMML) (Table 60-1). The first four entities are characterized by abnormal marrow myeloid cell differentiation patterns (dysplasia) with RA or RARS patients having <5% blasts, associated with dysplasia of the three hemopoietic cell lines, RAEB patients having between 5% and 20% blasts, and RAEB-T patients having 2130% blasts. In contrast, AML is considered to be present if the patients marrow contains >30% blasts. This morphologic characterization has been helpful for assessing the prognosis of patients. However, because these entities evolve into aggressive disease, an additional criterion necessary for categorization is the *pace* of such progression. This characteristic helps distinguish relatively indolent MDS from the disease that evolves rapidly to frank AML. Therefore, stability of the peripheral blood cell counts and marrow morphology for at least 26 weeks aids in categorizing the condition as MDS. The inclusion of CMML in MDS is problematic, as CMML is predominantly a myeloproliferative rather than a myelodysplastic disorder and may (depending on marrow and blood findings) be more like either chronic myeloid leukemia with an excess of monocytes or RAEB with monocytosis (see later).

In most patients with primary MDS the disease develops de novo. However, an increasing number of patients who had previously been treated with chemotherapy or chemotherapy plus radiation therapy for other malignancies, or who had been extensively exposed to a variety of marrow toxins, are developing

Figure 60-1 Evolutionary transitions occurring in clonal myeloid hemopathies. Ess., essential.

a secondary form of MDS.[11] This secondary MDS generally has a more aggressive course than primary MDS.

PATHOGENESIS

MDS provides a clinical model for evaluating the evolution of a relatively benign clonal myeloid hemopathy into a frankly malignant neoplasm, a form of AML. Biologic data, particularly marrow cytogenetics, in vitro myeloid progenitor cell proliferation characteristics, and clonal analysis utilizing restriction fragment length polymorphisms (RFLPs), indicate that biologically the marrow stem cells of MDS patients are derived from a myeloid malignant clone. [12] [13] [14] These laboratory approaches have been used to attempt to improve our understanding of the mechanisms underlying MDS.

Cells derived from hemopoietic stem cellsneutrophils, monocytes, erythrocytes, and plateletsare clonally derived in MDS. Evidence for this breadth of hemopoietic lineage involvement has been obtained using karyotypic markers [15] [16] [17] [18] [19] [20] [21] or by RFLP analysis using X-linked inactivation assays. [15] [18] [19] [20] [22] [23] [24] [25] In some studies, combined cytogenetic and X-linked inactivation studies have been performed, [19] [20] and results have been concordant in identifying clonal derivation of the hemopoietic cells. With these techniques, data have also been reported concerning the origin of lymphoid cells in MDS patients. Lymphoid cells appear to be part of the abnormal clone in some but not all cases, as clonal T cells [16] [18] [21] [22] [25] and both clonal[21] and polyclonal B cells[23] have been demonstrated in MDS.

Cytogenetic Abnormalities

Cytogenetic abnormalities in the marrow cells of patients with de novo MDS are found in
4060% at diagnosis, whereas >80% of patients with secondary MDS have abnormal karyotypes.[26] Single or complex chromosomal abnormalities may be present initially and evolutionary changes may occur during the course of the disorder. These genetic derangements reflect the multistep process believed to underlie the evolution of MDS. Generally, the more aggressive the stage of the disorder, in terms of rapidity of clinical course and high number of marrow blasts, the more complex is the abnormal karyotype. Major

TABLE 60-1 -- Myelodysplastic Syndrome Subtypes: FAB Cooperative Group Criteria

FAB Subtype	Bone Marrow Blasts (%)	Peripheral Blood Blasts (%)	Auer Rods	Monocytes >1 × 109/L	Ring Sideroblasts > 15% of Nucleated Erythroid Cells
RA	< 5	1			
RARS	< 5	1			+
RAEB	520	< 5			±
CMML	20	< 5		+	±
RAEB-T	21 30 or	5 or	±	±	±

karyotypic aberrations, including many structural changes, rings, and dicentrics, are commonly seen in RAEB and RAEB-T, but only sporadically in RA.

Both structural and numerical chromosomal changes may be found in MDS.[27] [28] [29] Compared with AML, MDS is often associated with chromosome deletions as a primary karyotypic anomaly. Deletions leading to gene loss suggest that a recessive mechanism plays a role in the origin of leukemic transformation. [30] With regard to specific associations between chromosome markers and the FAB morphologic subgroups, apart from the 5q chromosome as sole karyotypic anomaly that is often present in RA, most other aberrations are distributed throughout all MDS subgroups. Chromosome 5q with other abnormalities, however, is unusual in CMML. Monosomy 7 is rarely observed in RA patients. The most frequently occurring clonal chromosomal abnormalities in MDS involve chromosomes 5, 7, 8, 11, 12 and 20.[26] [31] [32] The prevalence of chromosomal anomalies in secondary MDS is higher and the abnormalities are more complex, the most common single abnormality being monosomy 7, followed by 5q, trisomy 8, monosomy 5, and 20q.

Chromosomal abnormalities identify areas of the genome that are susceptible to damage or that may be important in the pathogenesis of disease. The frequent occurrence of the 5q chromosomal abnormality implicates one or more genes residing on chromosome 5q in the development and maintenance of abnormal hemopoiesis. Within the critical regions involved in the deleted region in the 5q abnormality cluster several genes coding for hemopoietic growth factors (HGFs) (Table 60-2). In addition, other genes, such as EGR1, which encodes the GTPase-activating protein for p21 ras, are present in this chromosome region. [33] The interferon regulatory factor-1 (IRF-1) gene was found to be deleted in the 5q syndrome. [34] Since activated forms of this gene decrease cell proliferation, its loss as well as the loss of those for the HGFs may result in the abnormal cell proliferation occurring in this syndrome. Other as yet unidentified tumor suppressor genes may also be deleted in 5q chromosomes.

A detailed analysis of chromosomal aberrations shows similarities between those present in MDS and in other myeloid clonal hemopathies, such as AML and myeloproliferative disorders (MPDs).[26] These observations suggest that a continuum exists between differing FAB subgroups of MDS and also that similar genetic events of the same stem cell may result in a variety of clinical conditions, such as MDS, AML, and MPD.

Secondary MDS is associated with an abnormal karyotype in >80% of cases. As in primary MDS, recurrent aberrations significantly involve chromosomes 5 and 7 with partial or total monosomy, although with a differing prevalence (Table 60-3).[12] [26] [35] Loss of material from the long arm of chromosomes 5 and 7 may also be due to unbalanced translocations typically observed in secondary MDS/AML. [12] [26] [35] [36] [37] [38] [39] MDS or AML may arise as a secondary disorder, suggesting biologic relatedness between secondary MDS and AML. Accordingly, both are characterized by the same chromosomal aberrations and a very short survival. Regions commonly involved in secondary MDS and AML have been delineated, in addition to deletions of chromosomes 5 and 7. Regions on chromosomes 3p1421, 6p23, 12p11p12, 17p11p12, 19q13, and 21q2122 frequently undergo structural rearrangements such as deletions and translocations. [26] [35] The pathogenetic implications of these abnormalities have not been established.

Hematopoietic Regulatory Interactions

MDS marrow hemopoietic precursors demonstrate uncoupling between their proliferative and differentiative abilities, leading

to ineffective hematopoiesis due to defective differentiation. The lesion underlying this defect resides predominantly at the level of the hemopoietic stem cell, and phenotypic expression of such aberrant cells is clonal in nature. In vitro hemopoietic progenitor cell assays have allowed analysis of the hemopoietic stem cell/progenitor cell compartments and the humoral HGFs that regulate hemopoietic cell proliferation and differentiation.

The biochemical and functional nature of HGFs and their receptors have been characterized and assessment of HGF-receptor interactions have allowed the start of analysis of their mechanisms of action (see Chap. 14). Chromosomes coding for HGFs and their receptors (Table 60-2) are often deranged in MDS, suggesting possible pathogenetic relevance of these findings. [40] [41] [42] [43] [44] [45] [46]

Hematopoiesis

Despite the more indolent nature of MDS relative to AML, many in vitro myeloid progenitor cell abnormalities evident in AML are also present in MDS. These biologic parameters have been useful for evaluating pathogenetic mechanisms and prognosis in MDS patients. [40] [47] The colony-forming capacities of all of the marrow hemopoietic precursor cells (colony-forming unit-granulocyte/erythroid/macrophage/megakaryocyte [CFU-GEMM], burst forming unit-erythroid [BFU-E], CFU-E, CFU-granulocyte/macrophage [CFU-GM], CFU-megakaryocyte [CFU-Mk]) are quite low or absent in most MDS patients, [40] [47] [48] [49] [50] [51] as well as in most AML patients. Also as found in leukemic patients, an increased proportion of CFU-GMs are of light buoyant density, and abortive myeloid cluster formation and defective cellular maturation occur within the colonies. [40]

In MDS, in vitro hemopoietic regulatory derangements have been shown in progenitor cell assays, which demonstrate decreased responsiveness of hemopoietic precursors to proliferative and differentiative stimuli as well as diminished production of certain HGFs (Table 60-4). [40] These findings suggest that the ineffective hemopoiesis existing in MDS may be related to such biologic abnormalities. In MDS, granulocyte-macrophage colony-stimulating factor (GM-CSF) and interleukin-3 (IL-3) have greater myeloid proliferative effects in vitro than G-CSF, whereas G-CSF has greater myeloid differentiative effects. [52] This is particularly evident in patients with RAEB or RAEB-T and those with normal cytogenetics. These in vitro studies have provided a biologic rationale for the differentiation induction therapy used to potentially counter the relative uncoupling between proliferative and differentiative signals existing in MDS. Such marrow myeloid progenitor cell assays also provide prognostic information and therefore complement evaluation of marrow morphology and cytogenetics in the analysis of disease progression in these patients.

In vitro studies and preclinical data indicate that a critical lesion underlying leukemia and MDS relates to an uncoupling of proliferation and differentiation at the level of the hemopoietic stem cell. [53] Induction of differentiation in culture diminishes the ability of leukemic stem cells to self-generate in vitro and reduces in vivo leukemogenicity in murine models. [54] [55] [56] Studies with these murine models have demonstrated increased survival of animals with leukemia after in vivo treatment with inducers of myeloid differentiation such as G-CSF, MGI-2, or vitamin D. [53] [54] [55] [56] [57] [58] Other studies have also demonstrated differentiation of colonies assayed from human normal and leukemic and MDS marrow after in vitro exposure to retinoids and vitamin D. [51] [56] [59] [60] The in vitro myeloid differentiative and proliferative responses of normal and MDS cells to pharmacologic levels of G-CSF and GM-CSF [52] are consistent with the high proportion of in vivo neutrophil responses following the therapeutic use of these agents in MDS. Increased numbers of marrow CFU-GM post treatment have also been demonstrated in patients who experience such neutrophil responses. [61]

In vitro erythroid progenitor cells in MDS have suboptimal responses to EPO. [51] [62] [63] Analysis of the relationship between EPO levels in MDS and the patients erythroid progenitors indicates that the anemia in MDS is not attributable to an abnormality in the capacity of EPO to induce the generation of CFU-E but is influenced by the size of the BFU-E population: a severe deficiency in the BFU-E population results in insufficient influx of EPO-responsive cells. [62] G-CSF markedly augments the in vitro EPO responsiveness of BFU-E in normal and MDS marrow. [63]

Hemopoietic growth factor production has also been analyzed in MDS. Marrow cells and peripheral blood T cells from MDS patients provide decreased amounts of GM-CSF, IL-3, M-CSF, and IL-6.[64] Blood cell production of G-CSF is predominantly generated by microbe-stimulated monocytes. [65] Decreased levels of monocyte-derived G-CSF have been demonstrated in MDS patients but (as most of these patients are elderly) also from elderly control subjects. [65] Thus, the defective production of a variety of HGFs, in addition to decreased precursor cell responsiveness to some of these factors, may contribute to the ineffective granulopoiesis in MDS patients. The effects of IL-1 and IL-6 in combination with GM-CSF on the in vitro colony formation of myeloid progenitors from patients with

MDS indicate that neither IL-1 nor IL-6 alone has colony-stimulating activity, and in normal bone marrow cultures these factors did not alter the stimulatory effects of GM-CSF.[66] However, in the majority of the MDS cases, an enhancing effect of IL-6 or IL-1 in combination with GM-CSF was observed. Other studies indicate that the actions of IL-1 and IL-6 on hematopoiesis are mainly indirect and are mediated by enhanced production of GM-CSF, G-CSF, or IL-3 by accessory cells. [67]

Tissue growth factor- (TGF-) inhibits early normal and leukemic progenitor cell proliferation in vitro. [40] [68] [69] [70] [71] Interferon- (IFN-) IFN-, and IFN- are also inhibitory against both normal and leukemic hemopoietic progenitors. [72] [73] By contrast, prostaglandin E has been shown to have less inhibitory activity for MDS and AML hemopoietic precursors than for normal cells. [74] [75] Similarly, MIP1a and other regulators inhibit normal early stem cells [76] [77] [78] [79] [80] but have a lesser effect on leukemic precursors. Thus, the selective functional nature of these inhibitors may permit a growth advantage of leukemic over normal cells. Further, tumor necrosis factor- (TNF-) generation is increased in MDS and AML and, in addition to its ability to increase CSF production, may inhibit hemopoietic precursor development. [81] [82] These findings suggest that in addition to defective responsiveness of hemopoietic precursors to stimulatory cytokines, enhanced levels of inhibitory cytokines may play a role in the abnormal hemopoiesis in MDS.

Immunologic cell dysfunction has also been demonstrated in MDS patients. In these individuals, T cells, natural killer (NK) cells, and B cells all appear to be defective in proportion and function. Deficiencies have been documented in T-helper cell populations and in the mitogenic response of T cells. [83] [84] [85] These abnormalities also appear to contribute to the decreased HGF production in MDS.

Molecular AbnormalitiesApoptosis

Altered regulation of marrow cell survival has been proposed as a mechanism to explain the ineffective hematopoiesis with associated cytopenia that is characteristic of MDS, as well as the frequent subsequent evolution to AML that occurs in many of these patients. Apoptosis (programmed cell death) is an active cellular process that regulates cell population size by decreasing cell survival and that differs from necrosis both morphologically and biochemically. [86] [87] [88] [89] [90] [91] Apoptosis is characterized by low molecular weight oligomeric DNA fragmentation patterns and specific cellular morphologic changes. Morphologic evidence of increased apoptosis has been demonstrated in MDS, particularly in the early subtypes. [92] Recent studies from a number of laboratories have demonstrated increased levels of apoptosis in MDS marrow cells.[93] [94] [95] [96] [97] Some investigators have found this process most evident within the CD34+ hemopoietic precursor cell population, [94] whereas others have found it predominantly within more differentiated cells and in stromal cells. [93] Flow cytometric data indicate that marrow CD34+ cells (containing the hematopoietic progenitor cells) from early MDS (e.g., refractory anemia) have an increased proportion of fragmented (apoptotic) DNA compared with cells from patients with more advanced stages of MDS or AML.[94] Treatment of MDS patients with the cytokines G-CSF and EPO, alone or in combination, enhanced effective hematopoiesis in vivo and was associated with decreased levels of apoptosis. [94] [97] Increased endogenous marrow levels of the inhibitory cytokine TNF- have been reported in MDS, which appears to enhance the level of apoptosis in these patients. [95]

Several of the genes responsible for the regulation of apoptosis have been identified. They include the proto-oncogenes *bcl*-2 and c-*myc*.[98] [99] [100] [101] [102] [103] *bcl*-2 and certain members of the *bcl*-2 gene family (*bcl*-2, *bcl*-X_L and *Mcl*-1) are anti-apoptotic.[98] [99] [100] [101] In contrast, other members of the *bcl*-2 family (*bax*, *bcl*-X_S , *bad*), c-*myc*, and *p53* act as potent inducers of apoptosis for hemopoietic cells. [102] [103] [104] The intracellular ratio of c-*myc* to *bcl*-2 oncoproteins is increased in MDS CD34+ cells compared to those from normal and AML CD34+ cells.[94] On in situ immunohistochemical staining, *bcl*-2 expression within early myeloid precursors in MDS marrow correlated, in both proportion and absolute number, with initial MDS stage (i.e., higher levels in later-stage disease), progressed over time, and was associated with evolution to AML.[105] These findings are consistent with the hypothesis that an altered balance between cell death and cell survival programs is associated with the increased degrees of apoptosis present in MDS hematopoietic precursors and may contribute to the ineffective hemopoiesis in this disorder. In contrast, decreased apoptosis is associated with enhanced leukemic cell survival as MDS progresses toward AML.

Oncogenes

Conversion of normal cells into those that have preleukemic and ultimately leukemic characteristics is a multistep process requiring the accumulation of genetic lesions. Additional oncogenes to those involved in apoptosis are abnormally expressed in many MDS patients. The *fms* gene encodes the CSF-1 receptor (M-CSF receptor). Mutations of *fms* have been observed in 1218% of MDS patients,[30] with the highest prevalence in the CMML subgroup, consistent with the observation that M-CSF is a monocytic growth factor. The *ras* family of proto-oncogenes encodes a GTP-binding protein. [106] [107] The importance of these genes lies in their role in mitogenic and differentiation-related signal transduction. [136] Mutations of *ras* may give rise to abnormal protein products that have the capacity to transform cells into a malignant phenotype. Mutational activation of *ras* occurs at codons 12, 13, and 61, which correspond to the GTP-binding sites. [108] [109] [110] Mutations of *ras* have been detected in MDS patients, with a wide range of frequencies (333%) reported. [108] [109] [110] [111] These mutations are somatically acquired, and mutant-bearing cells may be present as minor populations that may be lost on progression to AML, indicating that they are unlikely to be initiating events in transformation. The incidence of *ras* mutations varies between FAB types, with the highest occurrence in CMML. In some studies, *ras* mutations may be associated with a poor prognosis in terms of survival or progression to AML.[111] Mutations of the *p53* tumor suppressor gene (anti-oncogene) have been detected at a low frequency in MDS. [29] [30] [112] Thus,

although mutations of these cell growth regulatory genes have been described in MDS, their role in disease progression is currently unclear.

CLINICAL MANIFESTATIONS

MDS generally presents as a refractory cytopenia, predominantly in the elderly, with >80% of the patients being older than 60 years of age. [113] [114] After 70 years of age, the prevalence of MDS is approximately 2245 per 10^5 population,[113] [114] [115] indicating that MDS is as prevalent as the other most common hematologic malignancies of the aged, chronic lymphocytic leukemia (CLL) and multiple myeloma (Fig. 60-2).[113] [114] [115]

Blood and Bone Marrow

Anemia/Fatigue

Nearly all MDS patients are anemic, and many have associated fatigue. The anemia is usually macrocytic with a low reticulocyte response. In this elderly patient population, it is necessary to exclude vitamin B_{12} or folate deficiency as a cause of the macrocytic anemia. The anemia of MDS is usually due to ineffective erythropoiesis. In addition, patients may have abnormal iron metabolism, [116] disordered globin chain synthesis, [117] decreased levels of red cell enzymes, [118] increased levels of hemoglobin

Figure 60-2 Age-specific incidence of myelodysplastic syndrome in comparison with acute and chronic leukemias. (Data extrapolated from references [113] [114] [115] .)

(Hb) F,[119] Hb H inclusions,[120] [121] abnormal red cell antigens,[122] or a positive Ham test.[123] Low levels of pyruvate kinase may occur,[118] with associated hemolysis. Together with the requirement for long-term red cell transfusions, the abnormalities in iron metabolism may lead to hemochromatosis with subsequent organ (hepatic, pancreatic islet cell, testicular, cardiac) dysfunction.

Morphologic evidence of dyserythropoiesis in MDS includes ringed sideroblasts, multinuclear fragments, bizarre nuclear shapes, internuclear bridging, mitosis, abnormal dense chromatin or fine chromatin with asynchronous cytoplasm, and abnormal cytoplasmic features (intense basophilia, Howell-Jolly bodies). The red cells may demonstrate anisocytosis, poikilocytosis, nucleated forms, and acanthocytes (Fig. 60-3). Erythroid precursors show megaloblastoid changes (Figs. 60-4A and 60-5A). Because of the macrocytosis in these patients, vitamin B_{12} and folic acid deficiency need to be excluded. The occurrence of five or more siderotic granules is considered pathologic, and when these granules constitute more than one-third of the nuclear rim, the term ringed sideroblast has been used (Fig. 60-4B).[124] The disruption of mitochondria by these siderotic granules and the observed changes in heme synthesis relate to the ineffective

erythropoiesis, premature erythroid destruction, and RA in this disorder. Very rarely, sideroblastic anemia will respond to pyridoxine. RA is differentiated from RARS by the presence of >15% ringed sideroblasts. If erythroid precursors account for >50% of bone marrow cells, with >30% of the myeloid cells being blasts, the diagnosis of erythroleukemia is made (M6 variant of AML) (see Chap. 53).

Neutropenia/Infections

A substantial proportion (
60%) of MDS patients are neutropenic and are also often unable to mount an appropriate inflammatory response to infection. This likely is due to the poor myeloid marrow responsiveness to and decreased production of HGFs. Qualitative abnormalities occur in MDS neutrophils. [125] [126] [127] [128] [129] [130] In addition, because HGFs play important roles in mature neutrophil and monocyte cell functions, a decreased production of HGFs contributes to the phagocyte abnormalities noted in these patients.[40]

Morphologic abnormalities of granulocytes are common in MDS and are present in both the peripheral blood and bone marrow. The most common abnormalities are hypogranulation (which may be associated with a negative peroxidase reaction), low levels of leukocyte alkaline phosphatase, and hyposegmentation of the polymorphonuclear leukocytes with abnormal chromatin condensation (Pelger-Huët-like anomaly) (Figs. 60-3C and 60-4C). Occasionally the chromatin appears excessively clumped, leading to an appearance of nuclear fragmentation associated with a loss of segmentation. A critical finding of dysplasia within the marrow is nucleocytoplasmic asynchrony in abnormal early myeloid cells (type III blasts or abnormal promyelocytes), with granular cytoplasm, a reticulated nucleus possessing a nucleolus, and a prominent perinuclear Golgi zone. The proportion of type I marrow myeloblasts determines the subtype of MDS (Table 60-1) and is a major reflection of the differentiative abnormality present.

Infections are common in MDS. Approximately 10% of patients present with evidence of infection, and in 21% it is the cause of death. [131] [132] Most infections in MDS are bacterial, usually involving host organisms, and are associated with neutropenia. Defective adhesion, phagocytosis, and bacterial killing are commonly found. [125] [126] [127] [128] The migration of qualitatively abnormal granulocytes into sites of infection often leads to poorly resolving abscesses, which may be occult. [129] In MDS, blood monocytes are derived from the abnormal clone, and in CMML they proliferate in a poorly controlled manner. Certain monocyte functions are impaired, including

phagocytosis, which is decreased.[130] Further altering inflammatory responses, NK cells in MDS are reduced in number and are functionally immature, with impaired ability to produce interferon. [133] [134] [135]

Thrombocytopenia/Bleeding

Thrombocytopenia is common (
60% of cases) in MDS and occasionally becomes severe. In
5% of cases it is the only cytopenia observed. [113] Giant and agranular platelets are often seen, and platelet function may be abnormal, as reflected in prolonged

Figure 60-5 Myelodysplastic syndrome morphology: bone marrow biopsies and aspirates. **(A)** Dyserythropoiesis in RA. **(B)** Dysmegakaryopoiesis in RAEB. **(C)** RARS with erythroid hyperplasia (hematoxylin-eosin, ×200 [orig. mag.]). **(D)** Myeloid hyperplasia with increased immature forms and abnormal megakaryocytes in RAEB (×400 [orig. mag.]). **(E)** Atypical localization of immature myeloid precursors. *(Courtesy of Dr. James W. Vardiman, University of Chicago Hospitals.)*

bleeding times (even without thrombocytopenia) and reduced platelet aggregation. [136] Progressive thrombocytopenia is often a marker of disease evolution. The risk of hemorrhage during surgery or after trauma is increased because of the defective platelet function. Thus, bleeding in these circumstances may occur at relatively normal platelet counts, and platelet transfusions should be administered under these conditions. Splenomegaly occurs in
10% of MDS patients and may contribute, by sequestration of platelets, to the thrombocytopenia.

Common morphologic abnormalities of megakaryocytes in MDS occur and include micromegakaryocytes, mononuclear megakaryocytes, multiple small nuclei separated by strands of nuclear material, dysmorphic nuclear features, and hypogranularity (Figs. 60-4C and 60-5B and D). The 5q syndrome is frequently associated with morphologic abnormalities of megakaryocytes, which are usually small with single eccentric round nuclei.

Clinical Variants

Rheumatic and immunologic processes occur uncommonly in association with MDS. Their features include cutaneous vasculitis, peripheral neuropathy, and lupus-like syndromes.[137] A subgroup of MDS patients have acute seronegative inflammatory arthritis temporally related to the discovery of cytopenia. [138] Episodes of oligoarthritis or polyarthritis may occur, along with such systemic features as fever, pleuritis, pericarditis, and hemolytic anemia. The arthritis and systemic features often respond to corticosteroid therapy.

The association of MDS and lymphoid malignancies, particularly

B-cell neoplasias, has been reported. Chronic lymphocytic leukemia, hairy cell leukemia, lymphocytic lymphoma, multiple myeloma, large granular lymphocytic leukemia, and T-helper cell lymphoma all have been diagnosed simultaneously with MDS. [139] The mechanism whereby such associations occur is unknown but suggests involvement of a common hematolymphoid stem cell in the inciting transformation. After chemotherapy with alkylating agents, secondary MDS may develop in some patients and contribute to problematic cytopenias.

The 5q syndrome is an MDS variant, usually seen in RA, that exhibits not only characteristic morphologic featuresmacrocytic anemia, normal or high platelet counts, nonlobulated micromegakaryocytes, and hypoplastic erythroid cellsbut also results in a clinical course in which, when it is the sole karyotypic abnormality, evolution to acute leukemia is uncommon.[33] [37] [38] [39] Superimposed cytogenetic lesions, however, are associated with a poorer prognosis.

Overlap SyndromesHypocellular MDS

Although most patients with MDS have hypercellular or normocellular bone marrows, a small subgroup of MDS patients (<15%) have marrow hypoplasia at the time of diagnosis.[140] [141] Differentiation of this syndrome from either aplastic anemia or hypoplastic AML may be difficult. When marrow cellularity is low, recognizing hemopoietic dysplasia from either the aspirate or the biopsy specimen may be problematic. Most hypocellular MDS cases fit into the categories of RA and RAEB. [140] [141] [142] CMML, which classically is characterized by a hypercellular bone marrow, has not been reported to have a hypocellular variant. A potentially useful means of identifying hypocellular MDS is the finding of an associated clonal cytogenetic abnormality characteristic of MDS (e.g., 5, 7, 5q, 7q, +8). [143] [144] [145] In a recent large series of patients with aplastic anemia, clonal chromosomal abnormalities were present in only 4% of individuals but were those frequently seen in MDS or AML. [143]

MDS with Fibrosis

Myelofibrosis refers to a generalized increase in the number and thickness of reticulin fibers that is detected with a silver stain of the bone marrow biopsy specimen.[146] Mild to moderate myelofibrosis has been reported in up to 50% of MDS cases, with marked fibrosis occurring in <15% of cases. [146] [147] [148] Myelofibrosis occurs in all FAB subclassifications of MDS. [149] [150] The incidence of myelofibrosis in therapy-related MDS is greater than in primary MDS. [185] [186] Marked fibrosis has been reported to occur in up to 50% of cases of therapy-related MDS, with mild fibrosis occurring in up to 85% of such cases. [149] [150]

The syndrome of MDS with myelofibrosis is characterized by the abrupt onset of pancytopenia without organomegaly but with substantial red cell anisopoikilocytosis, a hypercellular bone marrow with myelofibrosis, trilineage dysplasia, atypical megakaryocyte proliferation with hypolobated forms, and increased numbers of marrow blasts.[148] [149] [150] Occasionally a leukoerythroblastic peripheral blood picture is evident. The patients usually experience a rapidly progressive clinical course. [151]

The distinction between this entity and MPDs may not be clear-cut. Other diagnostic entities that should be excluded before making a diagnosis of MDS with myelofibrosis are primary myelofibrosis, the accelerated phase of CML, post-polycythemia vera myelofibrosis with myeloid metaplasia, AML (especially acute megakaryoblastic leukemia; AML-M7), AML with trilineage dysplasia, and acute myelofibrosis. [152] A period of myelodysplasia may herald a leukemic transformation in up to 50% of patients who develop acute leukemia as a terminal event of polycythemia vera. [153] [154] In most cases this event is related to previous cytotoxic therapy and therefore resembles other therapy-related myelodysplastic disorders, although a myelodysplastic phase has also been reported in polycythemia vera patients treated by phlebotomy alone.[153] [154]

Chronic Myelomonocytic Leukemia

Some patients have disorders with features of both MDS and chronic MPD from the outset. Included in this group are those with leukocytosis, hypercellular bone marrows with variable amounts of dysplasia, and splenomegaly. Some of these patients (i.e., those with monocytosis) may have CMML. Although CMML is defined as an MPD by the FAB group, it also serves as a prototype of those disorders that straddle MDS and chronic MPD. The FAB criteria for CMML include a peripheral monocytosis exceeding 1×10^3 /mm^3 , increased numbers of monocytic cells in the bone marrow (Figs. 60-3D and 60-4D), dysplasia in either the erythroid, megakaryocytic, or granulocytic series, <5% circulating blasts, and <30% marrow blasts (Table 60-1).[10] [155] Pericardial, pleural, synovial, and ascitic effusions have been reported in CMML.[156] These serous effusions appear to be associated with high peripheral monocyte counts.

CMML was categorized as an MDS primarily because of the dysplasia that occurs in some patients and because cytopenias of one or more peripheral blood elements are not uncommon.[155] However, the nosologic position of CMML as a subtype of MDS is not accepted by all investigators, because myeloproliferative features predominate in a substantial portion of the patients. [157] [158] Because of these disparate findings, the disorder has been subdivided into two forms, a proliferative and a nonproliferative form. The proliferative form of CMML (with WBCs >12,000/mm^3 , hepatosplenomegaly, constitutional symptoms) is more akin to an MPD than to MDS.[158] This disorder differs in its major clinical features from the nonproliferative subtype of CMML (i.e., in MDS patients who have monocytosis but relatively low WBC counts and who previously were likely considered to have RAEB or RA with monocytosis). Clinical outcomes in patients with CMML are more closely related to

the proportion of marrow blasts than to peripheral monocyte numbers. These latter features include marked monocytosis or neutrophilic leukocytosis (in nearly 50% of patients), tissue infiltration by monocytes, splenomegaly (50%), and hepatomegaly (up to 20%). [105] [157] [158] [159] In addition, the behavior in vitro of marrow progenitor cells in CMML resembles that of chronic MPD, with increased numbers of colonies and clusters, rather than the pattern of MDS, in which progenitor cells proliferate poorly in short-term cultures.[40] Therefore, CMML may be considered a disorder that encompasses features of both chronic MPD and MDS.

Atypical Chronic Myeloid Leukemia

Another disorder, Ph^1 chromosome-negative CML, in some cases, has features of MDS as well as those of an MPD.[155] [160] [161] These features include dysplastic granulocytes, a low percentage of basophils, a sum of promyelocytes, myelocytes, and metamyelocytes that is >10%, and, often, monocytosis and thrombocytopenia. In a retrospective study of cases previously diagnosed as Ph^1 chromosome-negative CML, 60% of the patients had significant dysplasia, and 3040% of the cases met the criteria for CMML. Subsequent studies, however, demonstrated that, in some cases of Ph^1 chromosome-negative CML, the breakpoint cluster gene (*BCR*) on chromosome 22 was rearranged as in Ph^1 -positive CML, despite the absence of a cytogenetically detectable Ph^1 chromosome.[162] Patients lacking the Ph^1 chromosome t(9;22) but possessing the *BCR* rearrangement have morphologic and clinical features indistinguishable from those of Ph^1 chromosome-positive CML. The remaining patientsthose exhibiting some features of CML but lacking the Ph^1 chromosome and *BCR* rearrangementform a heterogeneous population that includes patients with features of both MDS and chronic MPD. Some, but not all, of these patients have

findings that meet the criteria for CMML. Thus, many of these patients defy placement into current classification schemas and have been designated as having atypical CML.

Secondary Myelodysplastic Syndrome

Secondary (i.e., therapy-related and toxic chemical-related) MDS is emerging as a significant clinical problem and may cause morbidity and mortality with or without progression to AML.[162] [163] [164] [165] [166] [167] [168] [169] The increasing incidence of secondary MDS and AML reflects a number of factors, including a longer period of risk after the successful treatment of solid tumors, more intensive treatment regimens combining high-dose chemotherapy and irradiation, broader utilization of adjuvant chemotherapy and irradiation for the treatment of solid tumors, and environmental pollution and exposure to chemicals and carcinogens (particularly organic solvents)[163] [164] [165] [166] [167] [168] [169] in industrialized nations. Generally these patients have a poorer prognosis than those with primary MDS. The major organic solvent implicated in leukemogenesis is benzene, and its association with disease pathogenesis is related to the intensity and duration of exposure to the carcinogens. Recent studies have indicated that mutations in enzymes that detoxify benzene, with a concomitant increase in toxic metabolites capable of damaging DNA, are associated with enhanced susceptibility to benzene poisoning and the development of leukemia. [170] [171] [172] [173]

In secondary MDS, abnormal karyotypes are evident in almost all patients. Multiple chromosomal aberrations are the rule, and chromosomes 5 and 7 are most frequently (85%) involved (Table 60-3). Accumulating experience in therapy-related leukemia suggests that chemotherapeutic agents may have different leukemogenic potential, associated with differing pathophysiologic processes. The classic therapy-related leukemia involving chromosome 5 and 7 abnormalities, and implicating alkylating agents and irradiation, remains the most common form. The benzene-induced cytogenetic abnormality is frequently trisomy 9. [12] [164] [172] Two additional forms of therapy-related leukemia have recently been described, one attributed to exposure to topoisomerase II-active chemotherapeutic agents and involving the chromosome 11q23 locus and the other involving the chromosome 21q22 locus. [167] [169]

THERAPY

A variety of treatment approaches have been used in MDS, with supportive care generally the mainstay of therapy in the community. Patients should be treated as needed with antibiotics for infection and with red cell and platelet transfusions for symptomatic anemia and thrombocytopenic bleeding. Long-term red cell transfusion support may lead to iron overload and secondary hemochromatosis. Adverse effects from the needed transfusion support include hepatic pancreatic, gonadal, and cardiac complications. When patients have had, or are anticipated to have, prolonged red cell transfusion requirements, prophylactic or therapeutic desferrioxamine chelation treatment should be considered. Such treatment may delay or occasionally reverse iron-related organ damage. [174]

As MDS is relatively indolent and occurs predominantly in the elderly, the development of treatment modalities for the cytopenia that would not cause excessive toxicity remains a therapeutic challenge. Elderly patients frequently have concomitant medical illnesses that markedly limit therapeutic options. Patients with abnormal cytogenetics, abnormal in vitro marrow myeloid colony growth patterns, and deranged clinical and marrow morphologic features have worse prognoses. These abnormalities generally correlate with the more advanced FAB classifications. Because of this variability in prognosis in subgroups of patients with MDS, stratification by risk factors is necessary in order to determine the efficacy of various treatment options.

Chemotherapy

Chemotherapeutic options for this disease have ranged from intensive cytotoxic therapy to low-dose therapy with DNA synthesis inhibitors such as cytosine arabinoside (Ara-C) or hydroxyurea. Intensive chemotherapy in these generally elderly individuals is often poorly tolerated. In addition, a high proportion of these patients have marrow cells that express the P-glycoprotein, which confers multi-drug resistance (MDR). [175] [176] Thus, in addition to MDS patients having poor marrow recovery after marrow hypoplasia induced by intensive therapy, difficulty often exists in eradicating their abnormal clonal cells. In secondary MDS, the increased frequency of MDR positivity, unfavorable cytogenetics, and treatment-related stromal damage contributes to the relatively poor therapeutic responses, compared with responses in patients with de novo AML. [206] [207] In an attempt to improve therapeutic responses in high-risk MDS patients or those with AML after MDS (i.e., those with an increased degree of MDR expression), several multicenter trials using MDR-modulating agents (e.g., cyclosporine, PSC833, quinine) plus chemotherapy have demonstrated encouraging results. [177] [178] The French Cooperative Leukemia Groups Phase III randomized study with quinine plus chemotherapy indicated improved responses in the MDR-positive patients when compared with responses in patients who received chemotherapy alone. [179]

In studies evaluating the use of standard intensive induction chemotherapy in MDS, variable complete remission rates of 1351% have been reported, but with significant morbidity and a high number of toxic deaths. [180] [181] [182] [183] [184] Better results have been achieved in younger patients and in those with favorable karyotypes. In addition to the severe toxicity of this treatment the remission rates and durations of the responses are generally less than in patients with de novo AML.

Numerous studies have evaluated the use of low-dose Ara-C to treat these patients, generally with 1020% of these individuals achieving a complete remission. [185] [186] However, the durability of these responses is usually short, and in a randomized trial evaluating low-dose Ara-C versus supportive care alone, the complete remission rate was only 8%, and no improvement in survival was noted. [187] In addition, marrow toxicity, particularly thrombocytopenia, has resulted in significant difficulties in the management of these patients. Organomegaly, skin lesions, and serous effusions in CMML may respond to low-dose oral chemotherapy.

Early results of clinical trials using the relatively low-intensity chemotherapeutic agents 5-azacytidine, [188] decitabine,[189] and topotecan[190] have shown responses in 3040% of MDS patients. However, the initial trials with topotecan used relatively high doses of the drug, which were associated with significant toxicity. Recently, improved responses have been reported with lower topotecan doses in combination with cytarabine. [191] A report of a randomized, controlled CALGB Phase III trial of 5-azacytidine versus observation in MDS showed increased responses and decreased AML evolution in the azacytidine arm, whereas survival did not differ in the two groups.[192] Clinical trials are ongoing to assess the relative efficacy of these agents.

Bone Marrow Transplantation

Several investigators have reported the use of allogeneic bone marrow or peripheral blood stem cell (PBSC) transplantation for MDS patients. [193] [194] [195] [196] [197] Because of restrictions based on patient age, performance status, and donor availability, only a small

proportion of this patient population is currently eligible for this procedure. The median age of individuals (generally 2939 years) in these protocols is much lower than that of most MDS patients (>65 years). In a recent large study, the probabilities of disease-free survival, relapse, and non-relapse-related mortality at 4 years were 41%, 28%, and 43%, respectively.[193] Multivariate analysis indicated that younger patients (<40 years old) and patients with low marrow blast counts (<5%) had better prognoses (62% disease-free survival). However, for older patients (>40 years old) and those with >5% blasts (i.e., patients with RAEB or RAEB-T), the disease-free survival rate was only 17% and 32%, respectively; 51% of patients with >5% blasts experienced disease relapse. For patients in this study with secondary MDS, only two of eight individuals remain alive and disease free. In seven MDS patients with associated myelofibrosis, none survived after bone marrow transplantation.

In a study by the European Bone Marrow Transplantation Group, the disease-free survival after bone marrow transplantation in patients with RAEB and RAEB-T was somewhat better, approximately 5074%.[194] The report did not give the ages of individuals who responded to therapy. In another study, a disease-free survival rate of 40% was reported for 15 MDS patients who underwent bone marrow transplantation.[195] Nine (60%) of these patients died of transplant-related complications in the first 100 days. Three of nine RAEB or RAEB-T patients experienced relapse. An increased percentage of marrow blasts had a negative impact on outcome, as only two of ten patients in this group survived, compared to six of ten patients with a lower percentage of blasts before transplantation. In recent reviews of the experience at the Fred Hutchinson Cancer Center and the International Bone Marrow Transplant Registry, patients with complex cytogenetic abnormalities had significantly higher relapse rates and a shorter disease-free survival, whereas those with normal cytogenetics had a better outcome. [196] [197] Taken together, these data suggest that matched sibling allogeneic marrow transplantation may be useful for a portion of relatively young patients with low-risk MDS. However, other forms of therapy should be considered in patients with more advanced forms of MDS (RAEB, RAEB-T) and complex cytogenetics, particularly if they are elderly.

HLA-matched unrelated donor marrow or PBSC transplants have been performed in an increasing number of MDS patients. Recent data from Seattle show 2-year disease-free survival, risk of relapse, and risk of nonrelapse transplant-related mortality rates of 38%, 28%, and 48%, respectively. [198] Relapse rates were significantly higher in patients with RAEB-T or MDS-related AML. Mortality not associated with relapse was higher in older patients. Further studies using newer preparative regimens are ongoing to determine the possible improved tolerance of allogenic stem cell transplantation for high-risk MDS patients.

Hormonal Therapy

Corticosteroids have been used in a small number of MDS patients, with 10% exhibiting transient responses.[199] In individuals who responded there has often been a correlation with in vitro marrow culture studies demonstrating T-cell-mediated inhibition of hemopoiesis. Androgens have also been used to treat MDS patients. However, survival data indicate that patients who received the androgens did no better than those treated by observation and supportive care.[200] A randomized trial of androgens versus low-dose Ara-C or observation indicated similar survival in these groups.[201] Treatment with danazol has been used in some individuals with MDS who were believed to have immune-associated thrombocytopenia.[202] The platelet counts in some patients improved; however, the rate of such responses was generally quite low, and clinically useful responses were rare.

Nonspecific Differentiation-Inducing Agents/Hematopoietic Stimulants

The use of differentiation-inducing agents for treating myeloid malignancies is based on a large body of in vitro marrow culture studies and preclinical data indicating that such drugs may diminish self-replication of abnormal cell clones concomitant with enhancing their differentiation.[53] [54] [55] [56] [57] [58] [59] [60] [203] A variety of differentiation-inducing agents have been used for treating MDS, including retinoic acid [204] [205] [206] and vitamin D,[207] as well as some HGFs (discussed later). Although trials of 13-cis-retinoic acid showed an increase in neutrophils in 3050% of MDS patients, a randomized trial demonstrated that survival was not improved.[205] Similar results, indicating a low response rate, were reported in a trial that used all-trans-retinoic acid.[206] The use of 1,25-dihydroxyvitamin D_3 to treat MDS was found not to be beneficial.[207]

Recent studies with a small number of MDS patients who received phosphothiol amifostine demonstrated hematopoietic responses in 3050% of treated patients.[208] [209] Although the mechanisms whereby this agent improves hematopoiesis are not clear, the drug is well tolerated and may be useful as a low-intensity treatment option. Clinical trials with this agent are ongoing.

Interferons

Because of its effect on enhancing monocytic differentiation of myeloid cells, IFN- has been used to treat MDS patients. In a study using high and low doses of IFN-, 30 MDS patients (18 with RAEB, 10 with RAEB-T) were treated.[210] The median survival of these patients was 12 months. Two patients had partial responses, and in 12 individuals transformation to AML occurred. No clear differences were demonstrated between patients receiving the high- and low-dose therapy. Clinical benefit with regard to number of infectious episodes or improvement in blood cell counts was not demonstrated, and no complete responses were noted. In another study, none of 25 MDS patients had complete responses to IFN-, although three patients had good responses.[211]

IFN- has also been used to treat patients with MDS. In one study of 14 patients (three with RA, nine with RAEB, two with CMML), myelosuppression was noted in 11 individuals, and in five of them the disease evolved to AML.[212] No sustained improvement in blood cell counts occurred in these patients. In other studies, three of ten low-risk MDS patients[213] and two of eight high-risk patients[214] had transient responses. These data do not support using IFN- or IFN- in treating MDS.

Hemopoietic Growth Factors

The HGF have critical physiologic roles in controlling hemopoiesis in vivo.[40] [215] [216] Several of these growth factors, including IL-3 and GM-CSF, have predominantly proliferative effects on early hemopoietic cell compartments, whereas others, such as G-CSF and M-CSF, have major differentiative as well as proliferative effects on later, more lineage-restricted precursor cells (i.e., granulocytes and monocytes, respectively). Each hemopoietic cell lineage appears to be regulated by both proliferative and differentiative stimuli. These factors have been used to attempt to improve the cytopenias and natural history of MDS.

Colony-Stimulating Factor-Granulocyte/Macrophage

The results of five Phase I/II therapeutic trials that used recombinant human GM-CSF short term to treat primary MDS have been reported.[217] [218] [219] [220] [221] [222] Generally treatment was administered for 714 days, with one to five courses of therapy. In combined

data from these studies, neutrophil counts improved in 38 of 45 patients treated with GM-CSF, associated increases in marrow myeloid maturation occurred in nine, 14 had increased reticulocyte counts (with three of these individuals having decreased RBC transfusion requirements), and eight had transient increases in platelets (Table 60-4). In 12 patients an increase in the percentage of marrow blasts or peripheral blood blasts (or both) was noted. In seven patients progression to AML occurred; particularly affected were individuals with >15% marrow blasts (i.e., those with RAEB or RAEB-T).

A trial that used GM-CSF to treat patients with secondary MDS (i.e., MDS developing after prior cytotoxic chemotherapy for other malignancies) demonstrated neutrophil responses in eight of ten evaluable patients.[223] Several patients enjoyed a transient improvement in platelet numbers, and in three active infections resolved. Transformation to AML occurred in four patients after 511 months of therapy, and three other patients died of the underlying malignancy. The median survival of these patients, 11 months, reflected the poor prognosis in this group of patients.

A multicenter study[224] provided information regarding the use of GM-CSF in relatively low-risk MDS patients (RA, RAEB patients with <10% marrow blasts) for longer periods (up to 2 months). Eighty-two patients (50 with RA, 32 with RAEB) received either of two different fixed daily dose levels of GM-CSF. These untreated low-risk MDS patients would have been expected to have relatively good prognoses, with median survivals of several years and a low incidence of evolution to AML. Nearly all of the MDS patients treated with GM-CSF responded with increased neutrophil counts. However, only 35% of the patients completed 8 weeks of treatment, and the drug was discontinued in the others because of progression of disease and the development of local pulmonary infiltrates, flu-like syndromes, hyperleukocytosis, or bone pain. In 25% of patients platelet counts decreased during GM-CSF administration to <50% of baseline values, whereas two patients had increases in platelet counts. Six patients had progressive disease, in two of whom with RAEB acute leukemia developed; erythroid responses did not occur. No differences in responses were noted between the two dose levels of GM-CSF used. The impact of GM-CSF on progression of disease could not be addressed because of the small number of patients and the short duration of treatment. Similar results were noted in a preliminary report of another multi-institutional randomized trial of GM-CSF treatment for periods of up to 6 months versus observation in 21 patients with MDS, with crossover occurring in patients with infections.[225] A decrease in infections in the GM-CSF group was reported. Severe toxic effects requiring a reduction in or discontinuation of the GM-CSF dose occurred in a substantial proportion of the patients. No improvements in platelet counts or hemoglobin levels were noted. Additional patient accrual and longer follow-up will help to determine the impact of this therapy on transformation to AML. These studies demonstrated some of the potential difficulties and benefits of chronic administration of a predominantly proliferative myeloid growth factor, such as GM-CSF, to patients with MDS.

The effects of GM-CSF plus low-dose Ara-C were evaluated in small Phase II studies.[226] The MDS patients were randomly assigned to receive either GM-CSF alone or GM-CSF plus low-dose Ara-C for 2 weeks, repeated monthly for three cycles. Patients receiving GM-CSF alone generally had increases in leukocyte and neutrophil counts, with only one patient having an improvement of platelets. In the group receiving both GM-CSF and low-dose Ara-C, the leukocyte count also increased during administration of the combined treatment, whereas the platelet count declined significantly. In patients who received three courses of marrow combined treatment, partial short-term responses occurred, with a somewhat decreased percentage of blasts. In a Phase III trial, the EORTC leukemia group compared these two drugs given sequentially or simultaneously.[227] Limited responses and no differences in duration of responses were seen in the two arms of the study, and the treatment-related mortality was 16%. These partial transient improvements with combined GM-CSF and low-dose Ara-C suggest that further studies using myeloid growth factors combined with low-dose cytotoxic chemotherapy are needed to validate this approach in this clinical setting. It will be important to analyze long-term as well as short-term outcomes in these individuals, to determine which subtypes of patients may respond and the degree of supportive care needed during such therapy.

Granulocyte-Colony Stimulating Factor

Treatment of 18 MDS patients (two with RA, nine with RAEB, seven with RAEB-T) has been reported. Subcutaneous injections of G-CSF, were administered daily,

with escalating dosage levels every 2 weeks, from 0.1 to 3.0 mg/kg/day, for a 2-month period. [228] [229] Sixteen patients, including those with severe neutropenia, had significant elevations into the normal range of both WBC counts and absolute neutrophil counts. In five patients a greater than twofold increase in reticulocyte counts occurred, and three of 12 red cell transfusion-dependent patients had decreases in transfusion requirements. Improved marrow myeloid maturation was noted in 16 of 18 patients. No significant changes in other blood cell counts were found during treatment in 17 of 18 patients (Table 60-4). After G-CSF treatment was discontinued, peripheral blood WBC counts returned to baseline levels over 24 weeks.

The results of a short-term trial of G-CSF in 40 MDS patients (20 with RA, 20 with RAEB/RAEB-T) have been reported. [230] Twenty of 22 patients (7-day treatment) and 16 of 18 patients (14-day treatment) had substantial improvement in neutrophil levels, which was associated with decrements in percentage of marrow blasts in eight of 13 evaluated patients. In seven of 11 patients with infections prior to G-CSF therapy, the infections resolved after treatment with G-CSF and antibiotics.

As a result of the clinical response and the tolerance of MDS patients for short-term G-CSF treatment, prolonged maintenance therapy was administered, and 10 of the 11 patients studied had persisting improvements in neutrophil counts for 628 months. [229] Marrow granulocytic maturation improved in seven of nine patients. Two of four red cell transfusion-dependent patients had reductions in their transfusion requirements. Platelet counts were generally not altered by this therapy. Neutrophil function (in vitro chemotaxis and phagocytosis), which was maintained or improved after 2 months of treatment, was further augmented in five patients after an additional 6 months of G-CSF therapy. A significant reduction in infection risk was retrospectively demonstrated in responding patients who achieved an absolute neutrophil count of >1,500/mm^3 after G-CSF treatment, compared to the number of pretreatment episodes. Toxic responses to G-CSF were minimal. In five of 18 patients treated long term, four initially with RAEB-T, the disease converted to AML after 616 months of the study. In this study, chronic G-CSF administration was well tolerated and effective in eliciting persistent improvement in neutrophil counts, in vitro function, and marrow myeloid maturation, and possibly in decreasing bacterial infections and red cell transfusion requirements in MDS patients. A Phase III multi-institutional randomized trial evaluating 102 patients with high-risk MDS (RAEB/RAEB-T) compared long-term G-CSF administration with observation in an attempt to determine the impact of G-CSF on the natural history of the disease. [231] Preliminary data from this study showed no difference in the frequency of evolution to AML between the two arms. However, a decreased survival was observed in the RAEB patients receiving G-CSF. No change in the incidence of infections was noted in the two arms.

[b]Unsustained.

These data demonstrate the lack of impact of G-CSF on the natural history of MDS.

Evidence of Clonal Responses

Cytogenetic evaluations and investigations analyzing RFLP were performed in several studies. [24] [229] [231] to determine whether selective responses to HGFs of normal versus abnormal clones occurred in MDS. The persistence of cytogenetic abnormalities and clonal hematopoiesis after treatment with GM-CSF and G-CSF indicated that these cytokines induced differentiation of the abnormal clone. With one exception in which polyclonal hemopoiesis developed after GM-CSF treatment, [231A] most evidence has indicated that GM-CSF or G-CSF does not preferentially stimulate normal marrow stem cells to proliferate and does not have the ability to eradicate the cytogenetically abnormal clone by inducing terminal differentiation.

Interleukin-3

Two short-term studies have reported the effects of IL-3 therapy in 22 MDS patients. [232] [233] These studies indicated modest improvements in neutrophil counts; however, the improvements were not as great as those demonstrated with G-CSF or GM-CSF (Table 60-5). Further, only limited responses occurred in the other cell lines. Similar results were found in a longer-term study that treated low-risk (RA/RARS) MDS patients for 3 months with IL-3. [234] Transient improvement in platelet counts occurred in two of five patients who initially had counts of <50,000 platelets/mm^3 . These data indicate that IL-3 will need to be combined with other HGFs in order to substantially mitigate the cytopenia of MDS.

Interleukin-6

Fifteen low-risk MDS patients and one with CMML were treated with IL-6 in an attempt to improve their platelet counts. [235] Preliminary information indicated that platelet responses occurred in five of 16 patients, including two patients with platelet counts of <50,000/mm^3 . Moderate to severe toxicity with constitutional symptoms occurred, without an improvement in leukocyte number, and anemia worsened in a substantial proportion of these patients. The durability of these platelet responses and the long-term tolerance for this agent remain to be determined.

Erythropoietin

Serum EPO levels may be suboptimally elevated in MDS patients relative to the degree of anemia. [236] Thus, recombinant human EPO therapy has been instituted in an attempt to correct the hypoproductive anemias associated with MDS. A number of published reports have detailed the erythroid responses of MDS patients to this form of treatment. Results of the initial seven studies utilizing EPO in MDS [237] [238] [239] [240] [241] [242] [243] indicated that 14 (19%) of 75 patients responded to EPO (Table 60-6). A relatively higher response rate was found in patients with endogenous serum EPO levels of <100 mU/ml. [241] Extremely poor responses

occurred in patients with the RARS subtype of MDS.[241] Generally, the patients needed relatively high doses of EPO (>200 U/kg/day) to achieve responses. This limited in vivo responsiveness of MDS marrow cells to EPO is not totally unexpected, as the defective erythroid precursors in MDS have demonstrated suboptimal in vitro responses to EPO alone.[40] [62]

HGFs such as G-CSF are synergistic with EPO in vitro, enhancing normal and MDS marrow BFU-E numbers or responsiveness to EPO, [244] suggesting their potential to provide more prominent in vivo erythroid responses in combination than can be achieved with either agent alone. EPO is a relatively late-acting factor that acts predominantly on CFU-E and on a portion of the earlier BFU-E that generate CFU-E. Two clinical studies describing the effects of combination therapy with G-CSF plus EPO to treat the anemia of MDS[245] [246] have shown an enhanced proportion of responses. Therapy was initiated with G-CSF at 1 g/kg (0.33 g/kg) administered by daily subcutaneous injection and adjusted to either normalize or double the neutrophil count. EPO was then administered by daily subcutaneous injection of 100 U/kg and dose-escalated to 150300 U/kg every 4 weeks in one study, or kept at 120 U/kg/day in the other study, while G-CSF was continued. Ten (42%) of 24 patients in one study[245] and 8 (38%) of 21 in the second study[246] demonstrated substantial erythroid responses, including patients with prior RBC transfusion requirements. Responses were more frequent in patients with less advanced pancytopenia, lower endogenous EPO levels, [245] [246] or responsive marrow BFU-E.[244] Patients with ringed sideroblasts, who generally respond poorly to EPO alone, had an increased response rate (60% in this study). These findings suggest synergistic in vivo effects of G-CSF and EPO for the anemia of patients with MDS.

To determine which pretreatment variables predicted erythroid responses to EPO plus G-CSF combination therapy, 98 patients in a multi-institutional trial were evaluated.[247] Overall, 36% of patients showed responses to treatment, particularly those with the RARS subtype of MDS (Table 60-7). In multivariate analysis, the major clinical variables predicting responses to the combination therapy were baseline serum EPO levels and initial red cell transfusion requirement. With pretreatment serum

[a]Multivariate logistic regression analysis: weighted logistic coefficients.

EPO levels used as a ternary variable (<100, 100500, or >500 U/L) and red cell transfusion requirement as a binary variable (<2 or 2 units per month), a statistically weighted analysis provided a predictive score for erythroid response. Based on this score (Table 60-8), patients were separated into three groups: one group with a high probability of erythroid responses (74% of responders), one group with an intermediate probability (23%), and one group with a low probability (7%). This predictive scoring system appears helpful for decision making regarding the use of these cytokines for treating the anemia of MDS. A recent extension of this trial indicated good durability of the responses (median, 24 months) for patients receiving maintenance therapy with these drugs. [248]

PROGNOSIS

Marrow Histologic Features

The FAB morphologic classification, developed in 1982, has been useful for helping to determine prognosis in MDS. Although MDS is a heterogeneous disorder with an incidence evolution to AML varying between 10% and 50%, [10] there has been a moderate degree of consistency in prognostic findings in relation to survival and evolution to AML in a number of major large studies when FAB subgroup morphologic criteria were used (Table 60-9 , Fig. 60-6).[249] [250] [251] [252] [253] [254] [255] [256] Patients with RAEB and RAEB-T have had relatively poor prognoses, with median survivals generally ranging from 5 to 12 months, in contrast to RA or RARS patients, who have had median survivals of about 36 years. The proportion of individuals in whom disease transformed to AML varied similarly: in the high-risk RAEB and RAEB-T patients this incidence was 4050%, whereas in the low-risk group it was 515%. In a study evaluating time to disease evolution, 25% and 55% of patients with RAEB and RAEB-T, respectively, experienced transformation to AML at 1 year, and 35% and 65% at 2 years. In contrast, for patients with RA the incidence was 5% and 10% at 1 and 2 years. None of the

patients with RARS experienced leukemic transformation within 2 years.

According to studies using the FAB classification, the major prognostic feature for survival of CMML patients (as for the other MDS subgroups) is the percentage of marrow blasts.[253] [255] [257] The median survival of CMML patients with <5% marrow blasts was 53 months, whereas for those with 520% blasts it was 16 months (similar to the median survival of patients with RAEB). Monocytosis of >2.6 × 10^9 /L and abnormal cytogenetics also correlated with poor survival. Controversy exists regarding whether the hypocellular subtype of MDS has prognostic significance, as these patients have been reported either to experience disease progression to AML less frequently and to have a longer survival, or to have a clinical outcome similar to that of other MDS patients. [140] [141] [142] A tendency toward hypocellularity in therapy-related MDS has been reported, and these patients generally have short survival times. [150] MDS patients with myelofibrosis generally have shorter survivals than MDS patients without fibrosis.[151] According to FAB proposals, the presence of Auer rods in myeloid cells implies the diagnosis of RAEB-T. [10] However, an adverse influence of Auer rods per se has not been demonstrated.

Mortality in MDS is due to a variety of causes, including evolution to AML, infection, or bleeding complications related to the patients dominant cytopenia. Because most patients are elderly, concomitant nonhematologic diseases associated with an elderly patient population also contribute substantially to the mortality. In RAEB and RAEB-T patients, AML is the cause of death in 2055% of patients, whereas infection and hemorrhage due to marrow failure cause 3650% of deaths and nonhematologic causes account for 1020%.[249] [250] [251] [252] [253] [254] [255] In RA and RARS, these figures are somewhat reversed, with AML causing death in 029%, infection and hemorrhage causing death in 1544%, and nonhematologic causes accounting for 2542% of deaths.

As adjuncts to FAB morphologic categorization, other evaluative systems using clinical or cytogenetic features have also been used for prognostic assessment. In all of these systems the proportion of type I marrow blast cells is the most useful clinical prognostic marker in MDS, contributing to the striking differences in survival and progression to AML observed among the FAB subtypes.[249] [250] [251] [252] [253] [254] [255] [256] [257] [258] Survival shortens as the percentage of marrow blast cells increases. [253] [254] [256] These studies have reported clear differences in survival for patients with <5% and 5% marrow blasts, with the survival curves of patients with 1020% and 2030% marrow blasts being almost identical (Fig. 60-7). The percentage of marrow blast cells was a significant factor in the differences in the risk of AML developing (Fig. 60-7). The cumulative probability of evolution to AML for patients with >20% marrow blasts was nearly 100% at 30 months,

Figure 60-7 Survival **(left)** and freedom from AML evolution **(right)** in patients with myelodysplastic syndrome, in relation to percentage of marrow myeloblasts (Kaplan-Meier curves). *(From Greenberg et al., [256] with permission.)*

Figure 60-8 Survival **(left)** and freedom from AML evolution **(right)** in patients with myelodysplastic syndrome, in relation to the number of cytopenias initially present (Kaplan-Meier curves). The two

heavy lines in each graph indicate patients with no or one cytopenia; the two light lines indicate patients with two or three cytopenias, respectively. *(From Greenberg et al.,[256] with permission.)*

a finding emphasizing that the border between RAEB-T and AML is somewhat arbitrary.[267] These data indicate that the use of a cutoff figure of 10% marrow blasts (i.e., including RAEB and RAEB-T patients with >10% blasts) adds substantial prognostic significance to the current FAB criteria.

Despite multiple disparate prognostic risk analysis systems for evaluating clinical outcome for MDS patients, imprecision persists with such analyses. In an attempt to improve upon these systems, an International MDS Risk Analysis Workshop combined cytogenetic, morphologic, and clinical data from 816 patients with untreated primary MDS.[256] The data were collated from seven large previously reported risk-based studies that had generated prognostic systems, and analyzed centrally. [256] A global analysis performed on the patient data and on critical prognostic variables was re-evaluated to generate a consensus prognostic system, one that used a more refined marrow cytogenetic classification. On univariate analysis, the major variables affecting evolution to AML were percentage of marrow myeloblasts, number of cytogenetic abnormalities, and number of cytopenias (Figs. 60-7 and 60-8); for survival, in addition to the above, variables included age and sex. Cytogenetic subgroups associated with relatively good outcomes were: normal cytogenetics, deletion of the Y chromosome alone, del(5q) alone, or del(20q) alone; poor: a complex karyotype (i.e., three or more abnormalities) or chromosome 7 anomalies; intermediate: other abnormalities (Figs. 60-9 and 60-10). Multivariate analysis combined this cytogenetic subclassification with percentage of marrow blasts and number of cytopenias to generate a prognostic model termed the International Prognostic Scoring System (IPSS) (Table 60-10). Weighting these variables by their statistical power allowed separation of patients into distinctive risk subgroups (low, INT-1, INT-2, high) for evolution to AML and survival (Fig. 60-11). Stratification for age further improved analysis of survival (Table 60-11 , Fig. 60-12).

Compared with prior risk-based classifications, the IPSS has provided an improved mechanism for evaluating prognosis in MDS. This effect was the result of several features of the International MDS Workshop model: the more refined cytogenetic categorizations, inclusion of cytopenias, improved subdivision of marrow blast percentages, the four defined outcome subgroups, and the separate stratification for age. The prediction of leukemia-free survival has also been possible with this method (Table 60-12). This classification system should prove

Figure 60-9 Freedom from AML evolution in 759 patients with myelodysplastic syndrome, in relation to their individual cytogenetic categories (Kaplan-Meier curves). *(From Greenberg et al.,[256] with permission.)*

Figure 60-10 Survival **(left)** and freedom from AML evolution **(right)** in patients with myelodysplastic syndrome, in relation to their risk-based categorical cytogenetic subgroupsgood, intermediate, or poor (Kaplan-Meier curves). Good denotes normal, del(5q) only, del(20q) only, or Y only. Poor denotes a complex karyotype (i.e., 3 anomalies) or chromosome 7 abnormalities. Intermediate denotes other abnormalities. *(From Greenberg et al.,[256] with permission.)*

useful for more precise design and analysis of therapeutic trials in MDS.

Studies analyzing plastic-embedded marrow biopsy specimens have suggested that the identification of small clusters of blast cells in central marrow regions, referred to as ALIP (abnormal localization of immature myeloid precursors) (Fig. 60-5E), rather than in paratrabecular locations had prognostic relevance. [251] [252] [253] [254] [255] [256] [257] [258] ALIP-positive patients had significantly shorter survival in all subtypes of MDS, including those patients with <5% blasts. ALIP-positive patients were somewhat more common in RAEB, RAEB-T, and CMML.

Marrow Cytogenetics

Approximately 4060% of patients with primary MDS have abnormal marrow karyotypes by conventional karyotyping methods; [256] [258] [259] however with more refined techniques, chromosome abnormalities have been detected in up to 73% of cases. [260] Clinical correlative studies with multivariate analyses have established that marrow cytogenetic features are an independent prognostic factor in MDS, complementing analyses based on clinical patient features. The highest prevalence of aberrations is concentrated in the poor prognostic subgroups of the FAB classification (RAEB and RAEB-T). In early studies, MDS patients with normal karyotypes had better prognoses than patients with abnormal chromosomes. However, investigations using more precisely defined abnormal karyotypes have modified this conclusion. Current data indicate that patients with poor prognoses are those with marrow cell clones that have complex chromosome abnormalities [256] [259] [260] [261] [262] [263] [264] [265] or who have a single chromosome abnormality involving 7 or 7q or +8 (Figs. 60-9 and 60-10). Conversely, patients with the 5q deletion

(i.e., del (5) (q12q33)) as the sole abnormality have relatively longer survivals. [33] [37] [38] However, the 5q abnormality combined with other karyotypic derangements is indicative of a poor prognosis. Survival was >2 years in cases with either normal chromosomes or 5q, 12 years in cases of trisomy 8, and <1 year in cases with either deletions of chromosome 7 or multiple changes.

In the International MDS Workshop patients, individuals with del(20q) only, del(5q) only, Y, or normal karyotypes had improved outcomes. [256] These findings regarding del(20q) as the sole abnormality are similar to those recently reported for a smaller group of MDS patients. [266] In a recent report in which patients with del(20q) had complex karyotypes, an advanced MDS stage or AML and a poor prognosis were noted. [267] Together, these data suggest that del(20q) may be associated with a favorable outcome when it occurs as a sole abnormality, but has a less favorable prognosis in the setting of a complex karyotype. This phenomenon is analogous to that observed with del(5q).

Loss of the Y chromosome in elderly men has been described in the marrows of patients with hematologic malignancies, but this abnormality has also been noted in marrow samples from hematologically normal elderly men.[268] Thus, this finding alone does not indicate the presence of a myeloid clonal hemopathy. However, once the diagnosis is established by other means, this feature conferred an improved clinical outcome. Conversely, chromosome 7 anomalies and complex cytogenetic abnormalities (variously defined) have been associated with poor prognoses. [256] [259] [261] Multiple clones were common in this group. The presence of abnormalities of chromosomes 5 and 7 has been associated with poor outcomes in MDS and AML.[259] [261] Other anomalies were associated with intermediate risk. These cytogenetic correlative findings also suggest that genomic instability and biologically important genes may be present on these chromosomes which alter survival and the potential for leukemic evolution in MDS patients.

The importance of karyotypic analysis for prognosis has been further demonstrated. When cytogenetic features were omitted from the MDS Workshop analysis, relatively poorer discrimination of clinical outcome occurred. [262] In this analysis, a substantial proportion of IPSS INT-1 and INT-2 patients would have been inaccurately categorized as low risk had cytogenetics not been included. In addition, cytogenetic analysis is potentially helpful in distinguishing patients who are likely to have evolving AML, rather than the more indolent MDS. Certain types of cytogenetic abnormalities, particularly recurring translocations, are rarely seen in MDS [259] [263] [264] [265] but are not uncommon in AML,[259] [263] [264] [265] such as trisomy 21, t(8;21), or 11q abnormalities. The International MDS Workshop data also indicated a very low incidence of these abnormalities in MDS.[256] Consistent with this thesis is the recent report indicating that t(8;21) myelodysplasia is an early presentation of M2 AML, with rapid clinical progression.[269]

The IPSS was compared to other MDS prognostic systems to determine its relative discriminatory ability for assessing the natural history of the disease. Thus, compared to prior prognostic systems for categorizing patents with MDSthe FAB system (based on marrow blast percentage), [10] the Spanish system (marrow blasts, age, platelet count),[253] and the Lille system (platelet count, marrow blasts, karyotype) [263] the IPSS effectively discriminated between the defined subgroups of the earlier categorization systems and provided an improved tool for predicting survival and AML evolution. [256]

The greater prevalence of complex chromosomal abnormalities in patients with secondary MDS partly explains their poor prognosis. [259] [261] The acquisition of a chromosomally abnormal clone in MDS patients with a previously normal karyotype or of additional karyotypic changes in a previously abnormal clone is associated with progression to a more aggressive FAB subtype or AML evolution and early death. [270] [271] However, karyotype stability does not preclude transformation to AML, as the majority of MDS patients do not show new chromosomal abnormalities at the time overt AML appears.[270] [271]

In vitro Myeloid Colony Assays

Based on the behavior of myeloid progenitor cells in vitro, MDS may be divided into leukemic and nonleukemic patterns. [40] Leukemic-type growth includes micro- or macrocluster formation with defective maturation or blasts within the aggregates, single persisting blasts, or very low colony formation (<2 colonies per 10^5 marrow cells). Nonleukemic growth is marked by persisting colony formation, even if moderately decreased in frequency. As shown in Table 60-13 , six studies involving 179 MDS patients

TABLE 60-13 -- Prognosis of Myelodysplastic Syndrome: Utility of in vitro Marrow Myeloid Clonogenic Culture Studies

Growth Patterns	Incidence (%)	Transformation to AML (%)	Median Survival (mo)
RAEB-T (n = 80)[272] [273]		51 (4560)	9 (711)
Nonleukemic growth	33 (2738)	31 (2933)	20 (1525)
Leukemic growth	68 (6273)	60 (5070)	7 (58)
RAEB (n = 17)[274] [275]		41	14
Nonleukemic growth	70	29	21
Leukemic growth	30	100	10
RA (n = 82)[273] [276] [277]		39 (3544)	24 (920)
Nonleukemic growth	54 (3074)	20 (2140)	47 (950)
Leukemic growth	46 (2670)	60 (5080)	8 (410)

with differing FAB morphologic subtypes demonstrated correlation between clinical outcome and in vitro marrow growth. [40] [272] [273] [274] [275] [276] [277] When patients were stratified according to their in vitro myeloid growth patterns, subgroups of MDS patients with nonleukemic growth patterns had a 2031% incidence of transformation to AML and 20- to 47-month median survivals. In contrast, MDS patients with leukemic growth patterns had a 60100% incidence of transformation and 7- to 10-month median survivals. MDS patients with single hemopoietic cell line defects, such as idiopathic sideroblastic anemia or idiopathic neutropenia with a low propensity to leukemic evolution, had normal marrow granulopoietic growth parameters. Patients who died without experiencing transformation to AML generally did so as a result of infectious or bleeding complications. The decreased marrow granulopoiesis in vitro (low frequency of normal CFU-GM) may reflect the diminished ability of the marrow to respond to the demand for new cells. Factors other than in vitro growth patterns contribute to transformation, as not all patients with abnormal clonal growth had poor prognoses. A correlation has been demonstrated between in vitro myeloid growth patterns, abnormal marrow cytogenetics, and poor prognoses. [40] The findings of decreasing CFU-GM plating efficiency, a higher proportion of light-density CFU-GM, and increased cluster/colony ratios are functional evidence of clonal evolution and prognostic information as these diseases progress toward acute transformation.

An in vitro colony assay permits growth of blast cell progenitors from marrow and blood of patients with AML. [278] Whereas these colonies are generally not present in cells from normal individuals, the majority of patients in a study of MDS had these circulating blast cell progenitors, some of which were in active cycle. [279] Further investigations correlating this in vitro feature with peripheral blasts, clinical status, and subsequent course will be important to determine the significance of this finding.

Therapeutic Directions

Because of the generally elderly age of patients with MDS, the relatively poor complete responses to most standard therapeutic modalities, and the variability of prognoses of patients with these disorders, the treatment of these individuals remains problematic. Needing evaluation are growth factors required to augment platelet levels in an attempt to modify a major morbidity related to the thrombocytopenia that occurs in this disease. Until results of these trials are available, the extended use of these and other HGFs in MDS should be considered experimental.

THERAPEUTIC OPTIONS FOR MDS

Supportive care: Antibiotics, transfusions, iron chelation as needed

Hemopoietic growth factors (HGFs): Eythropoietin (EPO), G-CSF, GM-CSF

Biologic response modifiers (BMRs): Amifostine, pentoxyfylline, lisofylline, interferon-, ATG, cyclosporin, retinoids, vitamin D analogs

Low-intensity chemotherapy: Low doses of cytarabine, topotecan, decitabine, azacytidine, hydroxyurea

High-intensity therapy: AML induction chemotherapy ± MDR modulator (i.e., rAML therapy); bone marrow or peripheral blood stem cell (PBSC) transplantation; allogeneicmatched sibling or matched unrelated donor transplantation; autologous

Combinations

MDS MANAGEMENT APPROACHES

The International Prognostic Scoring System is described in Greenberg et al. [256] (see Table 60-10 for scoring method). For patients lacking cytogenetic analysis, High risk includes categories RAEB-T, and RAEB and CMML in those with >10% marrow blasts. Therapy generally should be performed in the context of clinical trials. Options are given in order of preference. If patients initially in the Low or Int-1 risk category progress to Int-2 or High risk category, their therapeutic options correspondingly are those of the higher risk categories. The age determination may be based on the patients biologic or chronologic status, according to the particular institutions guidelines for high-intensity therapy, including bone marrow transplantation. Performance status is based on the institutions guidelines, with patients evaluated after remediable conditions have been corrected.

Treatment definitions: rAML induction therapy denotes chemotherapy induction for resistant or refractory AML (i.e., with MDR-1 modulators, or as part of clinical trials). Post-induction therapy includes rAML consolidation performed in the context of clinical trials. Low-intensity therapy includes chemotherapy, cytokines, and biologic response modifiers. Supportive care includes transfusions, antibiotics as needed, and the treatment of symptomatic anemia with erythropoietin with or without G-CSF, as indicated in the previous box. For bone marrow transplantation, allogeneic marrow transplantation or (PBSC transplantation) from an HLA-matched sibling is preferred, but transplants from an HLA-matched unrelated donor may be considered if no HLA-matched sibling donor is available.

IPSS RISK CATEGORY HIGH OR INTERMEDIATE-2

Age <60 years

Performance status good

Bone marrow transplantation

rAML induction with BMT at remission (versus other post-induction therapy at remission)

Low-intensity therapy

Supportive care

Performance status poor

Supportive care

Low-intensity therapy

Age >60 years

Performance status good

Low-intensity therapy

rAML induction with post-induction therapy at remission

BMT

Supportive care

Performance status poor

Supportive care

Low-intensity therapy

IPSS RISK CATEGORY INTERMEDIATE-1 OR LOW

Age 60 years *and* performance status good

Low-intensity therapy

BMT

rAML induction with BMT at remission (versus other post-induction therapy at remission)

Supportive care

Age >60 years *or* performance status poor

Supportive care

Low-intensity therapy

MANAGEMENT OF ANEMIA IN MDS

DIAGNOSTIC EVALUATION

Determine etiology of the anemia (peripheral smear, marrow)

Assess iron status (serum tests, marrow)

Rule out coexisting causes of anemia (e.g., GI bleeding, hemolysis, renal disease, nutritional deficiency, drug toxicity)

Obtain serum erythropoietin (EPO) level

TREATMENT OF SYMPTOMATIC ANEMIA (generally Hb <10 gm/dl)

Treat coexisting causes

Replete iron, folate, etc. as needed

For hypoproductive anemia:

1. RBC transfusions (leuko-reduced)
2. For patients lacking ringed sideroblasts, serum EPO <200500 mU/ml:
   a. rHu erythropoietin (concomitant treatment with oral iron may be beneficial, even without iron deficiency) 150300 U/kg/day SC × 23 months (20,000 U/ml EPO vial may be useful). If response, continue EPO and gradually decrease dose to tolerance.
   b. For nonresponders, consider adding rHuG-CSF, 1 g/kg/day SC (multi-doses may be used from G-CSF vial, stored refrigerated) (0.33 g/kg/day, general range) keeping neutrophil count in normal range (multi-doses may be used from G-CSF vial, stored refrigerated).
   c. Assess response at 23 months. For erythroid responders, continue drugs with gradual decrease of doses to tolerance; for nonresponders, discontinue the drugs.
3. For patients with ringed sideroblasts, serum EPO <500 mU/mL:
   a. Use combination of G-CSF plus EPO, with above doses.
   b. Assess response at 46 weeks. For erythroid responders, continue drugs with gradual decrease of doses to tolerance; for nonresponders, discontinue the drugs.
4. For patients with serum EPO >500 mU/mL or EPO nonresponders:
   a. Use RBC transfusions (leuko-reduced)
   b. Relevant clinical trials

The standard of care for MDS remains supportive therapy and treatment of symptoms. However, subgroups of MDS patients (based on age, clinical condition, and prognostic risk category) are considered for other specific forms of therapy. Using these criteria, some management strategies have been suggested. The National Comprehensive Cancer Network (NCCN), a consortium of medical institutions in the United States, recently attempted to provide evidence-based guidelines for developing management guidelines for a variety of neoplasms. [280] A panel of investigators from medical centers affiliated with the NCCN convened and helped to develop and expand such guidelines for MDS. The panel suggested use of the IPSS classification system, age, and performance status as major determinants for therapeutic strategies. Based on these critical variables and on evidence-based data, therapeutic approaches that attempt either to change the diseases natural history or to treat the anemia of MDS have been designed (see boxes). As there have been few controlled trials indicating improved survival or freedom from AML evolution with treatment, compared to supportive care, the panel strongly suggested that most of the approaches currently in use should be evaluated in clinical trials. The IPSS classification system improves the ability to define clinical outcome in MDS and also provides a framework for future studies to determine the possible role of molecular determinants (e.g., oncogenes, tumor suppressor genes, cytokine expression, and responsiveness) for evaluating prognosis in this disorder. Appropriately designed clinical trials evaluating these treatment approaches are needed to improve the management of patients with this disorder.

Chapter 61 - Polycythemia Vera

Ronald Hoffman

INTRODUCTION

Polycythemia vera is a hematologic malignancy that leads to excessive proliferation of erythroid, myeloid, and megakaryocytic elements within the bone marrow. Vaquez[1] first described this clinical entity in 1892, noting the characteristic physical findings. At the turn of this century, Cabot [2] and Osler[3] independently associated the name polycythemia vera with this newly described clinical disorder. Polycythemia vera is a clonal, chronic, progressive myeloproliferative disorder, often of insidious onset, characterized by an absolute increase in red cell mass and also usually by leukocytosis, thrombocytosis, and splenomegaly. [4] [5]

New insight into the pathogenesis of this disorder has been gained. Studies have been performed that demonstrate the hypersensitivity of hematopoietic progenitor cells derived from the malignant clone to a number of regulatory factors. [6] [7] [8] [9] In the absence of evidence for changes in the number or structure of receptors for the known hematopoietic growth factors, this heightened responsiveness has been attributed to an undefined event that occurs at the level of a cytokine receptor or an event triggered following activation of these cytokine receptors. [10]

Polycythemia vera differs from many other hematologic malignancies, in that prolonged survival is enjoyed by most patients if the excessive production of red blood cells and platelets can be controlled. [11] This prolonged survival, however, is punctuated by the development of other syndromes, such as myelofibrosis and acute leukemia (Table 61-1).[11] [12] [13] Frequently patients present asymptomatically to a physician only to find that they

TABLE 61-1 -- Evolution of Polycythemia Vera

Stage	Clinical Findings
Asymptomatic	Splenomegaly
	Isolated erythrocytosis
	Isolated thrombocytosis
Erythrocytotic phase	Erythrocytosis
	Thrombocytosis
	Leukocytosis
	Splenomegaly
	Thrombosis
	Hemorrhage
	Pruritus
Inactive phase	No longer requires phlebotomy or chemotherapy
	? Iron deficient
Postpolycythemic myeloid metaplasia	Anemia
	Leukoerythroblastosis
	Thrombocytopenia or thrombocytosis
	Enlarging splenomegaly
	Systemic symptoms (fever, weight loss)
Acute myeloid leukemia	

have either splenomegaly, isolated erythrocytosis, or thrombocytosis; left untreated, these patients will become symptomatic, owing to the consequences of the excessive production of red blood cells or platelets, or both. After a number of years, the erythrocytotic phase of the disease frequently becomes inactive, and the patient may no longer suffer from the sequelae of excessive red cell production. Subsequently, these patients can develop so-called spent-phase or postpolycythemic myeloid metaplasia, which is frequently indistinguishable from another myeloproliferative disorder, agnogenic myeloid metaplasia. [11] [12] [13] Finally, a significant proportion of these patients will eventually go on to develop acute myeloid leukemia.

The transition from one phase of this myeloproliferative disorder to another is not necessarily unidirectional. A number of cases of presumed agnogenic myeloid metaplasia have been described in which chemotherapy treatment has resulted in a striking decrease in marrow fibrosis associated with the development of an elevated red cell mass and a syndrome which was virtually indistinguishable from de novo polycythemia vera. [14]

The constantly changing clinical picture of this malignant hematologic disorder requires careful observation and treatment to deal with the numerous problems that can be encountered.

EPIDEMIOLOGY

Polycythemia vera is a rare disorder, with an annual incidence in Western Europe and the United States of approximately 517 cases per 1 million population per year.[15] [16] [17] Actual determination of its prevalence is a difficult process because of the need for an extensive diagnostic evaluation to differentiate this disorder from other causes of spurious or absolute erythrocytosis. [18] The prevalence of polycythemia vera has been stated by several investigators to be higher among American Jews and lower among African Americans.[15] [19] [20] The incidence of the disorder is greater among Ashkenazi Jews, who originate from eastern and central Europe, than among Arabs and Sephardic Jews.[21] Interestingly, extremely low occurrence rates have been reported from Japan, where the incidence was found to be two cases per million per year.[22] These findings suggest that important environmental or genetic factors might be involved in the biogenesis of this disorder. One notable exception to the low prevalence of polycythemia vera in Japan has been the higher incidence observed among populations exposed to atomic bomb explosions. [23] The possibility that radiation exposure is an etiologic factor in the generation of polycythemia vera was also raised by the observation in the United States of four cases of polycythemia vera 1020 years after a nuclear explosion to which 3,000 military observers were exposed. [24]

An epidemiologic investigation focused on occupational exposure among petroleum refinery and chemical plant workers has revealed an increased incidence of polycythemia vera relative to the general population. [25] In this study, the increased incidence of polycythemia vera was linked to similar increases in the frequency of multiple myeloma and non-Hodgkins lymphoma, suggesting involvement of a putative environmental toxin that may have broad hematopoietic toxicity. [25]

The importance of genetic factors in the origin of this disease is further emphasized by several case reports of polycythemia vera within families. [26] [27] [28] [29] [30] [31] [32] A greater than expected prevalence has been reported in the parents of patients with this disorder. [30] In addition, one family of three sisters all having the disorder has been reported.[31] An additional report describes a father and son who were both exposed to organic solvents and in whom polycythemia vera subsequently developed.[32] These forms of familial polycythemia vera must be distinguished from primary familial congenital polycythemia (PFCP) which is characterized by isolated erythrocytosis and is inherited as an autosomal dominant. The erythrocytosis in these patients is manifested at birth. [33] [34] [35] [36] To date, there have been seven different reported mutations of the erythropoietin receptor reported in patients with PFCP or probable PFCP. [33] [34] [35] [36] [37] Each of these mutations are located in exon 8 of the gene for the erythropoietin receptor resulting in a truncated protein that lacks a portion of the negative regulatory domain that leads to progenitor cell hypersensitivity to erythropoietin. Although this was originally perceived as a benign disorder, there have been recent reports of premature cardiovascular events, including myocardial infarction, ischemic cerebrovascular events, and intracranial hemorrhage occuring in these patients. [36] [37] The reports of families in which multiple members have polycythemia vera have also raised the possibility that a genetic predisposition occurs in concert with several additional external insults which might lead to the development of polycythemia vera. Slightly more males than females develop this disorder; the male/female ratio is approximately 1.2:1. [15] The average age at diagnosis is 60 years,[15] and the disease is extremely rare in patients <30 years of age. In several large studies, 5% of patients with polycythemia vera were <40 years of age, 1% were <25 years old at diagnosis, and 0.1% were calculated to be <20 years old. [4] [12] [38] To date, only a handful of patients with polycythemia vera have been reported who presented with this disorder during childhood. [39]

BIOLOGIC AND MOLECULAR ASPECTS

Considerable speculation has centered on the pathobiology of the erythrocytosis that characterizes polycythemia vera. [10] [40] London et al.[41] established that the expanded red cell mass of polycythemia vera was due to a two- to threefold increase in the production of red blood cells by a hyperplastic marrow and was not attributable to prolongation of the red cell life span. Granulocyte and platelet production are also increased in this disorder. This overly exuberant production of all cellular elements of the blood suggests that the basic defect resides at the level of the cell from which each of these cells originates, the pluripotent hematopoietic stem cell.

The hematopoietic growth factor, erythropoietin (EPO) is considered to be the physiologic regulator of the later phases of erythropoiesis. [42] Alterations in its production are followed by adjustments in the rate of formation of red blood cells. [43] In humans, EPO production is controlled by the relative supply of oxygen to the kidney, the major site of erythropoietin formation.[42] Studies in animals have indicated that in response to anemia the liver may contribute 1025% of the total EPO mRNA. EPO production appears to be regulated by alterations in the rate of gene transcription. [44] [45] Hypoxic stimulation of the oxygen sensor present in renal interstitial cells results in increased production of hypoxia inducible factor-1 (HIF-1), which is the major enhancer of EPO gene transcription. [46] EPO stimulates red cell production by increasing proliferation, decreasing apoptosis, and promoting differentiation of erythroid progenitor or precursor cells. [47] [48] Committed erythroid progenitor cells ultimately originate from a pluripotential hematopoietic stem cell also capable of producing myeloid and megakaryocytic elements. [42] Steel factor, the ligand for c-*kit*, is also strongly implicated in the earliest steps of erythropoietic development from the pluripotential hematopoietic progenitor cell. [49] [50] Interleukin-3 (IL-3), granulocyte-macrophage colony stimulating factor (GM-CSF) and insulin-like growth factor-1 (IGF-1) may contribute to the early proliferative expansion of these multipotential progenitors. [49] [50] [51]

Alterations in EPO production can lead to the development of anemia and erythrocytosis. [43] [52] An increased red cell mass, for instance, can be the result of EPO elaboration resulting from chronic hypoxia or can be the consequence of EPO secretion by a tumor or cyst, which is independent of physiologic control mechanisms.[52] [53] By contrast, decreased production of EPO is an important component in the pathobiology of the anemia of chronic renal failure. [54] This deficiency was the initial focus for pharmaceutical development of EPO, an endeavor that has been highly successful. [54]

A large body of information has been accumulated over the years addressing EPO physiology in patients with erythrocytosis. [52] [53] A variety of assays for quantitation of levels of this hormone have been developed. EPO concentrations in the past have been estimated by in vivo bioassays using posthypoxic polycythemic mice. [55] Following phlebotomy of a healthy person, urinary EPO excretion increases, and an inverse logarithmic relationship between hematocrit and EPO excretion rate is observed.[43] Patients with secondary erythrocytosis due to chronic hypoxia have either normal or increased basal values, but all have increased values following reduction of hematocrit to normal levels by phlebotomy. [43] By contrast, urinary EPO excretion is invariably subnormal in patients with polycythemia vera, which demonstrates that this disorder is not a result of excessive EPO production. [43] [56]

Following the purification of EPO and its subsequent cloning, radioimmunoassay (RIA) and enzyme-linked immunosorbent assay (ELISA) techniques for quantitating this hormone have been developed and have now entered widespread clinical use. [56] [57] [58] These assays have proven useful in further defining the role of EPO in the biogenesis of erythrocytosis.

A variety of studies have documented serum EPO levels in patients with primary polycythemia vera, secondary erythrocytosis, and relative polycythemia, and in normal adults. Serum EPO levels have been shown to be subnormal in patients with polycythemia vera, elevated in all cases of secondary erythrocytosis, and normal in patients with relative polycythemia (Fig. 61-1)[39] [56] [57] [58] Numerous studies have indicated that classification

of 90% of patients with erythrocytosis can be achieved by quantitating serum EPO. [43] [56] [57] [58]

These studies have indicated that patients with polycythemia vera most frequently exhibit serum EPO levels below the 95% confidence intervals for the range observed in normal controls. [56] [57] [58] The subnormal serum EPO levels are maintained even after several phlebotomies have been performed that normalize the serum hemoglobin concentration in polycythemia vera patients. [56] [57] [58]

In 1951 Dameshek [5] postulated that chronic myeloid leukemia (CML), polycythemia vera, primary thrombocythemia, and agnogenic myeloid metaplasia with myelofibrosis were related disorders, which he called myeloproliferative syndromes. He concluded that these disorders resulted from a generalized hyperresponsiveness of marrow cells to myelostimulatory factors and speculated that these disorders were neoplastic in origin. [5]

Since the mid-1970s, a substantial amount of data has accumulated that conclusively demonstrates polycythemia vera to be the result of a neoplastic proliferation of hematopoietic cells.[59] The cellular origin of the disorder was first established by the analysis of glucose-6-phosphate dehydrogenase (G6PD) isoenzymes in African-American women who were heterozygous for this X-linked gene (Fig. 61-2). This approach was based on the random irreversible inactivation of one X chromosome in each female somatic cell during embryogenesis. Inactivation of the same X chromosome occurs in the progeny of these cells. [60] A normal African-American female heterozygous for G6PD will therefore have approximately equal populations of marrow cells with a different G6PD isoenzyme. [60] The G6PD isoenzymes can be readily distinguished by electrophoretic methods.

This approach was exploited in a seminal study by Adamson and coworkers[61] in an effort to determine the cellular origin of polycythemia vera. They presumed that cells composing a tumor that arises from a single cell in a G6PD heterozygote would express a single isoenzyme type, whereas a neoplasm originating from multiple cells would express both isoenzyme types. [60]

Figure 61-2 Schematic presentation of X chromosome inactivation in an embryo heterozygous at the G6PD locus (Gd^{b}/Gd^{a}). In this diagram, the maternal X chromosome bears an A gene for G6PD(X^{A}) and the paternal X chromosome a B gene (X^{B}). During embryogenesis, one X chromosome in each somatic cell is randomly inactivated, so that half the somatic cells will have an active X^{A} and the other half an active X^{B}. Inactivation is fixed for a particular cell and its progeny. All progeny of an active X^{A} gene will express X^{A}. Female G6PD heterozygotes are mosaics, with some

cells active X^A and others X^B . A tumor with clonal origin will consist entirely of either X^A or X^B cells and therefore will contain only G6PD type A or B but not both. Tumors with multicellular origin will contain both X^A and X^B cells and therefore both G6PD types. *(From Fialkow,[290] with permission.)*

[a]Contaminated with erythrocytes.

These investigators found that circulating red cells, granulocytes, and platelets obtained from African-American females who were G6PD heterozygotes express the same isoenzyme, while skin and cultured marrow fibroblasts obtained from these same patients demonstrate both isoenzymes[61] [62] (Table 61-2). They concluded that polycythemia vera represented a clonal proliferation of neoplastic hematopoietic stem cells and was not multicellular in origin or the consequence of excessive proliferation of normal hematopoietic stem cells. [61]

The clonality of blood cell production in polycythemia vera has subsequently been confirmed using restriction fragment length polymorphisms of the active X chromosome.[63] [64] [65] A monoclonal pattern of X chromosome inactivation has been defined in red cells, granulocytes, monocytes, and platelets in females with polycythemia vera.[63] [64] [65] Such studies confirm the clonal cellular origin of the disorder.

Presently, it remains controversial whether lymphocytes are also the product of the malignant clone in polycythemia vera. This data is of some importance since it would provide insight into whether polycythemia vera is a disorder that originates at the level of a myeloid stem cell that is capable of producing red cells, granulocytes, platelets, and monocytes or rather originates at the level of a totipotent stem cell that is capable of producing not only myeloid cells but also lymphocytes. Alternatively, the presence of polyclonal lymphocytes in patients with polycythemia vera could be attributed to a neoplastic event occuring at the level of a totipotent stem cell resulting in a limited or total inability to give rise to lymphocytes. In a limited number of cases of polycythemia vera lymphocytes have been shown to originate from the malignant clone.[64] [65] The basis and significance of this apparent heterogeneity of cellular origin of polycythemia vera remains unknown.

On the basis of their knowledge that red cell production in polycythemia vera is not associated with excessive EPO production, several investigators have hypothesized that the erythroid progenitor cell in this disorder is no longer subject to physiologic regulators. [10] With the development of clonal assay systems for hematopoietic progenitor cells, it has become possible to analyze the effect of EPO on in vitro colony formation.

Two classes of erythroid progenitor cells, the burst-forming unit-erythroid (BFU-E) and the colony-forming unit-erythroid (CFU-E) present in the marrow and peripheral blood of patients with polycythemia vera were studied. Prchal and Axelrad[66] first reported that polycythemia vera bone marrow can form substantial numbers of erythroid colonies in vitro in the absence of exogenous EPO, whereas normal human bone marrow is incapable of forming such colonies without the addition of EPO. These erythroid colonies have been termed endogenous colonies.[66] [67] When both polycythemia vera and normal bone marrow were subsequently assayed in the presence of EPO, polycythemia vera marrow was characterized by a higher cloning efficiency.[66] [67] [68] Mixed colony formation has also been shown

to be enhanced in polycythemia vera.[68] Mixed colonies originate from multilineage progenitor cells. Their formation by polycythemia vera marrow, but not by normal marrow, also occurs in vitro in the absence of exogenous EPO.[69] These observations suggest that the altered response to EPO in polycythemia vera is characteristic not only of erythroid progenitor cells but of more primitive hematopoietic progenitor cells as well. Cell cycle analysis of polycythemia vera colony-forming unit-multilineage (CFU-GEMM) BFU-E, CFU-E, and colony-forming unit-granulocyte/macrophage (CFU-GM) revealed another cell progenitor abnormality; [69] [70] a higher proportion of polycythemia vera progenitor cells were in the synthetic phase of the cell cycle than was observed in normal subjects. [69] [70]

Further insight into the cellular defects in polycythemia vera was provided by the studies of Prchal et al. [70] (Table 61-3). These workers cloned marrow cells from African-American female G6PD heterozygotes with polycythemia vera both in the presence and in the absence of exogenous EPO and demonstrated that the erythroid colonies that formed in the absence of exogenous EPO contained the same G6PD isoenzyme type as that expressed by peripheral blood elements. [71] Thus, the so-called endogenous colonies arose from the abnormal clone that was responsible for supplying red cells, granulocytes, and platelets to the peripheral blood. When exogenous EPO was added, increasing numbers of colonies were formed containing cellular elements expressing the other G6PD isoenzymes; presumably these colonies originated from cells not involved in the malignant process. Similarly, small numbers of granulocyte/macrophage colonies not originating from the polycythemia vera clone were also observed in these assays. These data collectively indicate the existence of both malignant and nonmalignant populations of hematopoietic progenitor cells in polycythemia vera marrow. The relative frequency of the neoplastic clone in relationship to normal progenitor cells was further examined by Adamson and coworkers,[62] who, by monitoring the proportion of neoplastic erythroid clones and their numerical relationship to normal clones over a period of several years, showed disease progression to be associated with a significant decline in the frequency of normal colony-forming cells and increasing preponderance of the neoplastic clone. [62]

The clonal assay systems first used to obtain endogenous erythroid colonies contained serum contaminated with trace amounts of EPO. [67] This EPO contamination led to confusion about the responsiveness of the polycythemia vera cells to the actions of this hormone. Two conflicting hypotheses were entertained, one suggesting that proliferation of abnormal populations of erythroid progenitor cells is completely independent of EPO and the other consistent with hypersensitivity of polycythemia progenitors to EPO. Using an anti-EPO antiserum to remove trace amounts of EPO present in serum, Zanjani et al. [67]

concluded that erythroid progenitor cells from polycythemia vera patients do not proliferate in the absence of EPO but are, in fact, abnormally sensitive to the actions of this hormone. This increased responsiveness allowed these cells to form colonies in the presence of serum containing small amounts of EPO. By constructing EPO dose-response curves from polycythemia vera marrows and comparing them with those obtained from normal marrow cells, Eaves and Eaves[72] drew similar conclusions. Their studies showed that most polycythemia patients possess two distinct populations of erythroid progenitor cells: a normally EPO-responsive population and a population of cells similar in proliferative and maturational behavior in vitro but requiring little or no EPO. [72] These investigators suggested that because of the exquisite EPO sensitivity of the malignant clone, the proliferation of the normal progenitor cells in vivo was at a disadvantage. [72] The EPO dependence of polycythemia vera progenitor cells was further demonstrated by Casadevall and coworkers, [73] who used a serum-free culture system, which no longer was contaminated with EPO. They were unable to demonstrate endogenous erythroid colony formation by normal or polycythemia vera marrow and were able to show that polycythemia vera erythroid progenitor cells were exquisitely sensitive to EPO as compared with normal progenitors [74] (Fig. 61-3). These data collectively indicated that the abnormality in the erythroid progenitor cell in polycythemia vera is not only quantitative but also qualitative.

More recently, using semipurified populations of blood and bone marrow BFU-E, Krantz and colleagues [6] [7] demonstrated that the increased responsiveness of these marrow progenitor populations extends to their response to steel factor, IL-3, and GM-CSF. These studies also demonstrated that bone marrow fractions enriched for granulocyte/macrophage progenitors as well as megakaryocyte progenitors from the patients had a heightened responsiveness to IL-3 and GM-CSF.

The dogma that the hyperresponsivity of polycythemia vera progenitor cells to a variety of growth factors (EPO, IL-3, GM-CSF, steel factor) is the underlying defect that leads to polycythemia vera has, until recently, been universally accepted. [59] [163] [166] [167] [168] [169] [170] [171] [172] Several groups have, however, provided data that challenges this hypothesis. Fisher et al. used neutralizing monoclonal antibodies that bind to either EPO or EPO receptors to study the dependence of polycythemia vera progenitor cells on EPO.[74] Their results indicate that both EPO-dependent and EPO-independent erythroid progenitors are present in the blood and marrow of patients with polycythemia vera. The EPO-dependent progenitors had sensitivity to EPO similar to that of normal controls. In contrast, the EPO-independent progenitor cells cloned from the hematopoietic tissues of polycythemia vera patients in the presence of high concentrations of anti-EPO and anti-EPO receptor monoclonal antibodies appeared to be truly independent of free EPO. [74] The EPO-independent progenitors comprised approximately 30% of the total polycythemia vera erythroid progenitors and were not hypersensitive to EPO. [74] Furthermore, Correa et al., using an improved serum-free medium, have shown that peripheral blood BFU-E from polycythemia vera patients are not hypersensitive to EPO but actually exhibit a greater than 100-fold sensitivity to insulin-like growth factor-1 (IGF-1).[9] In addition, this IGF-1 hypersensitivity could be abolished by an anti-IGF-1 receptor antibody indicating that the effect was mediated via the IGF-1 receptor.[9] Recently this same group demonstrated that tyrosine phosphorylation of the subunit of the IGF-1 receptor was increased in polycythemia vera cells in the absence of exogenous IGF-1 and that phosphorylation of polycythemia cells occurred more rapidly at lower concentrations of IGF-1 attaining a higher level of phosphorylation than normal cells.[75] Usually, most circulating IGF-1 is bound to specific high-affinity IGF binding proteins, which can regulate the activity of this hormone.

Figure 61-3 Comparison of the EPO dose-response curves in serum-free cultures of colonies derived from CFU-Es and BFU-Es of marrow cells obtained from normal (dotted line) patients or individuals with polycythemia vera (solid line). *(From Casadevall et al.,[73] with permission.)*

Although plasma IGF-1 levels are not increased in polycythemia vera, the levels of IGF binding protein-1 (IGFBP-1) was reported to be strikingly elevated in the plasma of polycythemia vera patients.[76] The cause of this elevation remains unknown. In addition, IGFBP-1 alone was shown to be capable of stimulating BFU-E formation.[76] The increase in circulating IGFBP-1, a positive regulator of erythropoiesis, could account, in part, for the excessive erythropoiesis that characterizes polycythemia vera. One possible hypothesis that might result in a resolution of this apparently conflicting data is to suggest that the polycythemia vera progenitors respond to IGF-1 and IGFBP-1 by increasing the sensitivity of various classes of hematopoietic progenitor cells and/or stem cells to a variety of other growth factors including EPO, IL-3, and SCF. Alternatively, IGF-1 and/or IGFBP-1 might be capable of promoting the autocrine production of hematopoietic growth factors by polycythemia vera stem/progenitor cells. The importance of this new data remains uncertain and will require further investigation in a number of different laboratories before a unifying hypothesis can be generated.

Many investigators have examined the possibility that the hematopoietic defect in polycythemia vera could be accounted for by genetic alteration of cytokine receptors expressed by affected hematopoietic cells.[75] [76] [77] [78] [79] [80] [81] A growing body of information indicates that the EPO receptor is structurally similar to the normal EPO receptor and that a mutation in the EPO receptor is not directly involved in the pathobiology of polycythemia vera. [75] [76] [77] [78] Furthermore, no significant differences in the number, dissociation constant, or internalization rate of receptors for steel factor has been detected in the erythroid progenitor cells of polycythemia vera patients.[71]

Chiba et al. have, however, recently presented data which supports a potentially novel role of the EPO receptor in the pathobiology of polycythemia vera. [81] The major EPO receptor protein is encoded by an mRNA comprising exons I through VIII with all the introns spliced out and is designated EPOR-F. Another EPO receptor mRNA species has been reported, termed EPOR-T, and has a dominant negative function against EPOR-F, possibly by preventing homo-oligomerization of EPOR-T.[82] [83] Transgenic mice overexpressing EPOR-T are anemic, indicating that the absence of EPOR signaling through EPOR-T results in defective erythropoiesis.[83] This group has shown that EPOR-T mRNA is markedly decreased in the blood cells of patients with polycythemia vera and hypothesized that this might account for the EPO hypersensitivity observed in polycythemia vera. [81] They suggest that an acquired defect in regulation of the EPO receptor transcript system might account for the profound decrease in EPOR-T mRNA in polycythemia and in part lead to a shift in the maturation profile of erythroid progenitor cells. Since both forms of the EPO receptor are known to be expressed by normal CFU-GEMM, which are capable of producing not only erythroid cells but also megakaryocytes, granulocytes, and macrophages, dysregulation of these two forms of the EPO receptor at the level of the CFU-GEMM might account for the leukocytosis and thrombocytosis characteristic of polycythemia vera. This attractive hypothesis will require confirmation and additional study.

The increased sensitivity of polycythemia vera erythroid progenitor cells to a wide variety of growth factors and the structural integrity of the receptors for these growth factors have led a growing number of groups to attempt to define an as yet unknown molecular abnormality within a common intracellular signaling pathway in the progenitor cells of patients with polycythemia vera. [84] [85] [86] [87] [88] Growth factors upon binding to their receptors initiate tyrosine phosphorylation of their receptors, and transduction of their appropriate signals occurs through shared downstream pathways such as RAS/MAP kinase and JAK/STAT to targets in the nucleus. [89] [90] [91] Tyrosine phosphorylation in the signal pathways occurs by a delicate balance between protein tyrosine kinase (PTK) and protein tyrosine phosphatases (PTP). [89] [90] [91] [92] Dai et al. have reported that incubation of normal erythroid progenitor cells in the presence of

orthovanadate, an inhibitor of PTP, results in the formation of increased numbers of erythroid colonies and enhanced protein tyrosine phosphorylation. [86] These studies suggest that a defective PTP, caused by an acquired genetic mutation, might lead to polycythemia vera. The SHP-1 gene encodes an intracellular phosphatase which is expressed primarily in hematopoietic cells. [89] [90] [91]

This phosphatase is an extremely attractive candidate gene, the abnormal function of which could lead to the development of the polycythemia vera phenotype. SHP-1 has been shown to negatively regulate signaling from a number of receptors including the receptors for EPO, IL-3 and steel factor. [89] [90] [91] In addition, several forms of the EPO-receptor defect that accounts for PFCP are associated with defects that delete or mutate the negative regulatory domain containing the SHP-1 binding site.[35] [36] [37] Furthermore, the erythroid progenitor of mice cells with a defective SHP-1 gene (motheaten) are hypersensitive to EPO. [92] [93] Asimakopoulos et al. have reported, however, that the levels of SHP-1 protein are normal in granulocytes isolated from patients with polycythemia vera. [85] By contrast, Wickrema et al. have recently shown that purified CFU-E from polycythemia vera patients have diminished or absent expression of SHP-1 mRNA, suggesting that the hyperproliferation of the malignant clone might be in part due to defective expression of SHP-1. [88] The precise role of SHP-1 in the pathogenesis of polycythemia vera requires further careful study. Interestingly, Sui et al. have recently isolated a potentially novel membrane-associated PTP distinct from SHP-1, the activity of which was reported to be increased threefold in isolated erythroid progenitor cells. [87] These authors suggested that hyperactivation of this novel PTP might play a role in biogenesis of polycythemia vera. Further studies of intracellular signaling in polycythemia vera during the next decade are likely to provide new insight into the genetic basis for polycythemia vera.

Certain clonal chromosomal abnormalities have been found in some polycythemia vera patients at diagnosis (see the section, Laboratory Evaluation). Because these

karyotypic abnormalities are not present in most patients, it remains unclear what role the putative products of these clonal chromosomal aberrations might play in the biogenesis of polycythemia vera. Some have conjectured that multiple etiologies of this disorder might be possible, because of the presence of different nonrandom karyotypic abnormalities in a number of cases. However, in one case of polycythemia vera characterized by the presence of trisomy 8, endogenous erythroid colonies derived from bone marrow cells were analyzed by fluorescence in situ hybridization in order to determine the number of colonies containing cells with this cytogenetic abnormality.[94] The bone marrow progenitors that presumably represent the malignant clone were found to produce not only colonies containing cells with trisomy 8, but also colonies with a normal complement of chromosome 8. This study strongly suggests that the acquisition of trisomy 8 occurs as a secondary event during the biogenesis of the malignant polycythemia vera clone.[94]

ETIOLOGY AND PATHOGENESIS

The most frequent cause of mortality in polycythemia vera patients is vascular thrombosis. [12] [95] [96] This increased thrombotic tendency is a direct consequence of the expanded red cell mass that characterizes this disorder. [105] Although the contributions of coexisting thrombocytosis and qualitative platelet abnormalities to this thrombotic tendency have remained uncertain, there is increasing evidence that abnormal platelet metabolism occurs in all polycythemia vera patients.

A markedly increased number of thrombotic events in polycythemia vera patients >70 years of age, particularly those with a history of prior thrombosis, has been reported. [103] [104] The relationship between risk of thrombosis and age suggests that coexisting vascular disease is an important contributory factor in the development of thrombosis in polycythemia vera patients. In a study of the natural history of 1213 patients with polycythemia vera for 20 years, the relationship between age and the incidence of thrombotic events was further defined. [104] These results indicate definitively that the risk for thrombosis increases with age, from 1.8 events/100 patients per year in patients younger than 40 years of age to 5.1 events/100 patients per year in those older than 70 years.

This information does not negate the increased incidence of thrombotic incidents also observed in younger patients with this disorder. [106] In a series of 58 polycythemia vera patients diagnosed at <40 years of age, a disturbingly high incidence of life-threatening thrombotic events was observedin fact, 7 of the 10 patients in this series who died during the period of observation died from thrombotic events4 from Budd-Chiari syndrome, 1 from a pulmonary embolism, and 2 from cerebral thrombosis. [81] Therefore, although a significant factor, preexisting atherosclerotic disease is not the sole etiologic factor in the genesis of thrombosis in polycythemia vera. Some have suggested an important role for smoking as a secondary factor leading to the increased incidence of thrombotic events in this patient population. [103]

The principal hemorrheologic abnormality in polycythemia vera is an elevated whole blood viscosity. [99] The blood viscosity in polycythemia vera is higher than that of normal controls at all shear rates. [99] In a retrospective analysis of the records of 69 polycythemia vera patients with a history of vascular thrombosis, Pearson and Wetherley-Mein [97] demonstrated a strong correlation between hematocrit level and development of thrombotic episodes, including many cerebrovascular occlusions (Fig. 61-4). Thomas et al. showed that cerebral blood flow is reduced in patients with polycythemia vera in whom the hematocrit is 5362%. [100] These abnormalities were observed even in patients with hematocrits at the lower levels of normal, 4652%. [100] Reductions in cerebral blood flow were correctable with phlebotomy. Reduction of the hematocrit by relatively small amounts frequently led to substantial improvements in whole blood viscosity and cerebral blood flow. Some polycythemia vera patients apparently still maintain a higher than normal whole blood viscosity despite the normalization of the hematocrit, suggesting that an increase in hematocrit may not be the only factor responsible for increased blood viscosity. [101]

A number of possible explanations have been suggested for the observed relationship between hematocrit and development of thrombotic events in polycythemia vera patients. Turrito and Weiss [102] presented evidence to indicate that platelet adhesion and thrombus formation on the vascular subendothelium are determined in part by the rate at which platelets are transported to the vascular surface. In a polycythemic condition in which increased numbers of red cells are present, a greater number of intercellular collisions between red cells and platelets occur. These collisions could lead to increased platelet movement in a direction perpendicular to blood flow. This facilitation of platelet transport to the vessel wall may be an important factor in the development of thrombosis. [102] An alternative explanation for the association between hematocrit level and risk of thrombosis is based on the knowledge that blood viscosity is particularly sensitive to hematocrit levels. [103] [104] Increased hematocrits lead to increased blood viscosity, in turn leading to increased peripheral vascular resistance and an actual reduction in blood flow to a variety of organs, predisposing them to the development of thrombosis. [103] [104]

Additional factors have been implicated in the development of thrombosis in polycythemia vera patients. Almost all patients with this disorder are iron-deficient. [105] Decreased red cell deformability has been said to accompany iron deficiency, leading

Figure 61-4 Relationship of hematocrit to number of vascular occlusive episodes per 10 years in patients with polycythemia vera. *(From Pearson and Wetherley-Mein, [97] with permission.)*

to increased blood viscosity and a decreased ability of red cells to pass through small-bore polycarbonate filters. [106] [107] Such abnormalities have been shown by Tillman and Schröter [108] and Yip et al. [109] to be due to increased membrane stiffness rather than to reduced surface/volume ratio, as has been suggested by others. This increased membrane stiffness, however, might be counterbalanced by the effect of a reduced red blood cell size on the adherence of blood platelets to arteriolar subendothelium. Aarts et al. [110] have shown that red cell size is a major determinant of platelet adherence, with larger red blood cells leading to increased and smaller red cells to decreased platelet adherence. Whether the increased membrane stiffness associated with iron deficiency is counterbalanced by the decreased platelet adherence associated with smaller red blood cells is yet to be determined.

Study of patients with hemoglobinopathies due to abnormal oxygen binding who have secondary erythrocytosis provides further support to the belief that hematocrit elevations are not the sole cause of the thrombotic tendency in polycythemia vera. A survey of 200 patients with these types of hemoglobinopathies has not demonstrated a higher incidence of myocardial ischemia or any other form of thrombosis, even though the red cell mass is frequently as elevated as that in patients with polycythemia vera. [111]

Thrombocytosis and qualitative platelet abnormalities occur frequently and are likely to be important contributory factors to the development of thrombosis. [13] [112] [113] Dawson and Ogston [114] have implicated uncontrolled thrombocytosis as a cause of thrombosis in these patients, but this relationship has not been confirmed by Kessler et al. [112] or Berk et al. [95] Increased plasma and urinary thromboxane production has been linked to increased platelet activation in these patients. [113] A low-dose aspirin regimen selective for inhibition of platelet cyclo-oxygenase has been found to suppress increased thromboxane production in vivo and to clinically benefit patients with polycythemia vera. [115] [116]

Polycythemia vera patients are also at an increased risk of developing life-threatening hemorrhagic complications. [117] [118] [119] Abnormalities in platelet function and number have been implicated as the cause of this hemorrhagic tendency. [12] [13] Qualitative platelet abnormalities frequently found in these patients include platelet hypofunction as demonstrated by defective in vitro platelet aggregation, acquired storage pool disease, platelet membrane defects, increased platelet reactivity as demonstrated by enhanced platelet aggregation, increased plasma -thromboglobulin levels, and shortened platelet survival. [117] [118] [119] [120] With platelet counts >1000 $\times 10^9$ /l, the development of acquired von Willebrand syndrome has been reported and is associated with life threatening hemorrhagic episodes. [118] [119]

Despite conflicting data, no clear clinical relationship between platelet number or function and the incidence of hemorrhage or thrombosis in polycythemia vera has been found. [95] [97] [99] In primary thrombocythemia, however, reduction of excessive platelet numbers has been shown to reduce the risk of the thrombotic events. [121] In addition, selected patients with polycythemia vera have been afforded prompt resolution of vascular complications such as erythromelalgia or transient ischemic

attacks following institution of platelet antiaggregating agents or cytoreduction. [121] [122] [123] It is important to emphasize that erythromelalgia does not resolve in polycythemia vera patients with phlebotomy alone or with anticoagulation but requires the use of platelet antiaggregating agents or reduction of platelet numbers. [123] What distinguishes the clinical course of these patients from that of others is unknown. These reports, coupled with the knowledge of abnormal thromboxane metabolism of platelets in polycythemia vera, provide substance to the belief that platelets contribute to generation of the thrombotic and hemorrhagic tendencies observed in polycythemia vera (Fig. 61-5).[117] [118] [119] [120]

The high number of white cells which occurs in 5060% of polycythemia vera patients may also have a detrimental effect on the rheology of the microcirculation in polycythemia vera.[99] Although a variety of clinical assessments of platelet function have been used to identify patients who are potentially at a high risk of developing a life-threatening hemorrhagic or thrombotic

Figure 61-5 Pathophysiology of arteriolar and arterial thrombosis and inflammation as well as hemorrhage as a multicellular process in polycythemia vera. *(Modified from Michiels JJ,[117] with permission.)*

event, the results of these studies to date have been very disappointing. [117] [118] [119] [120] One is left with the impression that the etiology of thrombosis and hemorrhage in polycythemia vera is multifactorial and that the available tools are inadequate to identify those patients at highest risk.

A major cause of morbidity and mortality in polycythemia vera results from the transition from the polycythemic phase of the disease to postpolycythemic myeloid metaplasia (PPMM) and to acute leukemia. PPMM is characterized by cytopenias, myelofibrosis, and extramedullary hematopoiesis. [123] [124] [125] [126] In a variety of myeloproliferative disorders, the fibroblastic component of the bone marrow has been shown not to be directly involved in the malignant process but to be a reactive event to the neoplastic clone.[59] Several investigators have suggested that release of growth factors, particularly platelet-derived growth factor from megakaryocytes or platelets, which are present in abundance in patients with myeloproliferative disorders, might be responsible for this fibroblastic proliferation. [127] [128]

Whether the use of any particular therapeutic agents for treatment of polycythemia vera accelerates the development of the spent phase remains hotly debated. Some have suggested that the use of radioactive phosphorus (^{32} P) favors such a transition, although others have not noted any relationship between the treatment modality used and more rapid progression to PPMM.[129] [130] [131] [132] Najean et al. have reported the long-term follow-up of polycythemia vera patients and noted a high incidence of myelofibrosis in patients treated by phlebotomy alone. [133] [134] In this study, myelofibrosis was rarely observed before the 10th year of follow-up, but occured in 20% of patients surviving after 15 years and 50% surviving after 20 years. Messinezy and Pearson have also reported that of 20 patients known to have survived 15 years with polycythemia vera, 25% developed myelofibrosis.[135] These studies suggest that myelofibrosis will be a major problem due to the increased survival of polycythemia vera patients. Surprisingly, in the Italian Natural History Study with a follow-up of 20 years, myelofibrosis was a rare cause of death. [96] After treatment with alkylating agents or irradiation during the proliferative phase, patients with PPMM have been reported to be more likely to transform to acute leukemia.[136]

CLINICAL MANIFESTATIONS

The principal clinical manifestations of polycythemia vera are a direct consequence of the excessive proliferation of cellular elements of the various hematopoietic cellular lineages involved in the neoplastic process. With the current widespread use of laboratory screening tests during routine patient examinations, increasing numbers of persons are being diagnosed with polycythemia vera before the development of symptoms related to this neoplastic process. Symptomatic patients with polycythemia vera may present to a physician with a myriad of nonspecific complaints, including headache, weakness, pruritus, dizziness, excessive sweating, visual disturbances, paresthesias, joint symptoms, epigastric distress, and weight loss. [4] [11] At diagnosis, in fact, one-third of patients have already lost 10% of their body weight, presumably secondary to the hypermetabolism associated with this disorder. [10] Arthropathies that are frequently observed in these patients are largely due to the clinical manifestations of gout. The hyperproliferative bone marrow state characteristic of polycythemia vera and the increased nucleoprotein degradation are contributing factors in the development of hyperuricemia.

The principal findings on physical examination of a patient with polycythemia vera include ruddy cyanosis, conjunctival plethora, hepatomegaly, splenomegaly, and hypertension. [4] [11]

Untreated patients are at particularly high risk of both thrombotic and hemorrhagic events. [4] [11] [12] [117] [118] [119] [120] In several large series of patients with polycythemia vera, thrombosis was the cause of death in 3040% of patients (Table 61-4). [4] [11] [95] [96] Patients may present with deep venous thrombosis in the lower extremities, pulmonary embolism, or cerebrovascular, coronary, and peripheral vascular occlusions. [122] [123] [124] It is not unusual for patients with polycythemia vera to develop thromboses at unusual anatomic sites; in particular, thromboses are relatively frequent in the splenic, hepatic, portal, and mesenteric vessels. [4] [11] [117] [120]

TABLE 61-4 -- Fatal and Nonfatal Thrombotic Events (*n*= 254) During Follow-up in 1,213 Patients with Polycythemia Vera

Type of Complication	Nonfatal Event	Fatal Event
	n (%)	*n*(%)
Arterial thrombosis	101(50.5)	44(81.5)
Myocardial infarction	28(14.0)	27(50.0)
Ischemic stroke	19(9.5)	17(31.5)
Transient ischemic attack	39(19.5)	
Peripheral arterial thrombosis	15(7.5)	
Venous thrombosis or embolism	77(38.5)	10(18.5)
Deep venous thrombosis	35(17.5)	
Superficial thrombophlebitis	37(18.5)	
Unknown	5(2.5)	
Unknown	22(11.0)	
Total	200(100)	54(100)

Reisner et al. have demonstrated by echocardiography that cardiac valvular abnormalities are common in patients with myeloproliferative disorders. [137] In fact, aortic or mitral valve lesions were found in 77% of patients with polycythemia vera. The most common echocardiography lesion was leaflet thickening in 40% of patients, and vegetation occurred in 16%. The presence of such lesions were closely associated with the occurrence of arterial or venous thrombosis or embolism. Such vascular abnormalities may account for a significant number of thrombotic events in this patient population. [137]

A particularly serious thrombotic event associated with polycythemia vera is Budd-Chiari syndrome, [106] [138] [139] [140] [141] resulting from hepatic venous or inferior vena caval thrombosis and obstruction. This syndrome is characterized by hepatosplenomegaly, ascites, edema of the peripheral extremities, jaundice, abdominal pain, and distension of superficial abdominal veins due to resultant portal hypertension. [140] Routine biochemical determinations of hepatocellular function and injury are frequently of little diagnostic value in patients with suspected Budd-Chiari syndrome. [140] Liver scans using ^{99}Tc-labeled sulfur colloid may provide important diagnostic information, a characteristic pattern being central accumulation of the tracer and an enlarged hypertrophic caudate lobe of the liver, with apparent diminished or even absent tracer accumulation over the right lobe. [140] Percutaneous liver biopsy specimens usually reveal intense congestion and cellular atrophy. Hepatic venous and inferior vena cava catheterization are key diagnostic procedures that indicate the sites of venous obstruction. [140]

Of patients with Budd-Chiari syndrome reported in the literature, 10% have had coexisting polycythemia vera. [138] [140] Therefore, anyone who develops Budd-Chiari syndrome should be suspected of having polycythemia vera, and that diagnosis should be quickly excluded. It has recently been emphasized that patients with polycythemia vera can present with portal or hepatic vein thrombosis with normal hemoglobin or hematocrit valves. Such patients have leukocytosis, thrombocytosis, or splenomegaly. [141] The diagnosis of inapparent polycythemia vera in this patient population can only be made after red cell volume measurements are performed. [141] Gastrointestinal bleeding and/or an increase in plasma volume that is a consequence of splenomegaly often accounts for the normal blood counts in such patients with Budd-Chiari syndrome. The factors operational in the polycythemia vera patient that lead to the development of hepatic vein thrombosis are thought to be multiple. Splenomegaly causes increased portal blood flow while extramedullary hematopoiesis within the hepatic sinusoids frequently obstructs hepatic blood flow. [140] These processes are surely important contributory factors, in addition to the other previously discussed risk factors that lead to the development of thrombosis in this patient population. [120]

Neurologic abnormalities occur in almost 6080% of untreated or poorly controlled polycythemia vera patients and include transient ischemic attacks, cerebral infarction, cerebral hemorrhage, fluctuating dementia, confusional states, and choreic syndromes. [114] [117] [122] [123] [142] [143] In addition, complaints of dizziness, paresthesias, visual disturbances, tinnitus, and headache have been attributed to the increased blood viscosity [100] [143] and reduced cerebral blood flow caused by

erythrocytosis. The transient neurologic symptoms can also be the consequence of small infarcts in the region of the basal ganglia, which can be detected by computed tomography.[143] These small infarcts are known as lacunae and result from the occlusion of small penetrating arteries, which are particularly susceptible to thrombosis.[143] Cerebrovascular thrombosis occurs more often in polycythemia vera patients than in the general population. [120] [122] [143] [144] Symptoms due to intermittent carotid or vertebral basilar artery insufficiency (or both) occur so frequently in polycythemia vera that Millikan et al. [145] suggest that every patient with focal cerebrovascular insufficiency should at least have a complete blood count to rule out an underlying myeloproliferative disorder.

Cavernous sinus thrombosis is usually associated with a primary infectious etiology involving a focus in the face, throat, mouth, ear, or sinuses. [146] Aseptic cavernous sinus thrombosis is an extremely rare phenomenon that has been reported in patients with polycythemia vera. [147] [148] These patients present with monocular blindness and the characteristic features of ipsilateral cavernous sinus thrombosis, and only retrospectively is the diagnosis of polycythemia vera made. [148] Therefore, patients found to have this symptom complex who have no known infectious predisposing causes should be carefully evaluated to rule out this diagnosis.

Thrombosis of large-caliber arteries is a relatively rare event in polycythemia vera patients, but there have been case reports of thromboses within the chambers of the heart leading to refractory congestive heart failure and acute aortic occlusion. [149] [150] Such catastrophic thrombotic events in the heart or large vessels would suggest that cardiac catheterization be performed with some caution. [150]

Polycythemia vera frequently presents with symptoms due to peripheral vascular disease. [117] [151] [152] [153] In these cases, patients may first be seen by surgeons or dermatologists.[151] Intense redness or cyanosis of digits with or without burning, classical erythromelalgia, digital ischemia with palpable pulses, or thrombophlebitis without other known cause may be the presenting symptoms.[123] [152] [153] [154] [155] [156] [157]

Erythromelalgia is characterized by burning pain in the digits, an objective sensation of increased temperature, and relief by cooling. [123] [153] [154] [155] [156] [157] [158] Polycythemia vera is the most common cause of erythromelalgia and is one of the few disorders in which digital ischemia with or without ulceration may exist in the presence of palpable pulses.[156] Other disorders that can lead to this abnormality include embolism, trauma, cutaneous infarction, neuritis, infection, and various types of arteritis.[156] Painful and ulcerating toes and fingers have frequently been observed to be a presenting symptom in patients with polycythemia vera. [123] [153] [154] [155] [156] [157] [158] The likelihood that arterial insufficiency is the cause of such ulceration is quite small in patients who have a palpable dorsalis pedis and posterior tibialis pulses; in this situation, the possibility of an underlying hematologic disorder such as polycythemia vera should be entertained. Foot pain at rest is a distressing but not widely recognized symptom of polycythemia vera. In patients with this complaint, peripheral pulses are of normal character and cutaneous circulation appears to be adequate.[123] [153] [154] [155] [156] [157] [158] The pain is most severe at night, is dull in nature, and occurs primarily in the feet or legs. These symptoms have been shown to be the result of platelet activation and aggregation in vivo, which preferentially occurs in arterioles. [123] If untreated,

erythromelalgia can progress to ischemic acrocyanosis or gangrene. Phlebotemy alone in polycythemia vera does not improve erythromelalgia. [123] [157] [158] These symptoms can be abolished by reducing the platelet counts to normal levels and can be rapidly reversed after the institution of antiplatelet aggregation therapy. Therefore, the cause of erythromelalgia appears to be closely linked to abnormal arachidonic acid metabolism that occurs within platelets in this disorder. [123]

Hemorrhagic complications are the cause of death in 210% of polycythemia vera patients. [12] [15] [117] [118] [119] [120] The gastrointestinal tract is the most frequent site of hemorrhage. These patients have an increased incidence of peptic ulcer disease and, frequently, esophageal varices due to portal hypertension. Cerebral hemorrhage is a common cause of morbidity and mortality.[142] As many as 3040% of patients with polycythemia vera experience some sort of hemorrhagic event, [12] [119] [159] which can be relatively trivial, such as epistaxis or gingival hemorrhage, or can be life-threatening, such as gastrointestinal hemorrhage or hematomas involving vital organs.[12] In large part this hemorraghic tendency has been attributed to qualitative platelet abnormalities. [117] [118] [119] [120]

Bleeding events frequently occur with the use of antiinflammatory agents; [160] [161] an association between the hemorrhage and the use of high doses of these platelet-paralyzing drugs has been made in almost one-third of such instances. [159] [160] [161] Low-dose aspirin therapy has, however, been recently shown not to lead to an increased incidence of life-threatening hemorrhagic events. [115] [116] [120] Spontaneous bleeding in patients with polycythemia vera is relatively rare, [159] [160] [161] although spontaneous retropharyngeal hematomas leading to acute upper airway obstruction or hematomas in the groin have been reported. [162]

The polycythemia vera patient who undergoes a surgical procedure is at a very high risk of developing postoperative complications. [163] [164] [165] In one series of 62 major operations on 54 patients with polycythemia vera, postoperative complications occurred in 47%; [165] 52% of complications were due to hemorrhage, 18% to thrombosis, and 14% to hemorrhage and thrombosis.[165] The postoperative mortality in this patient population was 18%. [165] In another series of 15 patients, 5 suffered serious complications secondary to thrombosis and hemorrhage.[164] Data analysis of polycythemia vera patients undergoing surgery has shown the complication rate to be highest in those who had uncontrolled erythrocytosis before surgery. Patients with inadequately controlled disease had a 79% incidence of complications, while in those who enjoyed adequate hematologic control prior to surgery the rate of perioperative and postoperative complications was reduced to 28%. [163] In addition, duration of disease control was an important factor in decreasing surgical risk; [163] a prolonged period of effective disease control prior to surgery reduced the complication rate to 5%.[163] Complication rates following surgery can therefore be dramatically reduced by appropriate therapeutic interventions with normalization of blood counts. The chief deterrent to such an approach has been the failure by physicians to recognize the risk associated with polycythemia vera in the surgical setting.

Generalized pruritus occurs in approximately 50% of cases of polycythemia vera. [4] [15] [167] Water contact, such as during showers or bathing, induces attacks of intolerable pruritus. [168] There appears to be no clear relationship between the degree of the pruritus and severity of the disease, [169] and 20% of patients continue to experience itching despite reduction of their red blood cell masses to the normal range. [169] The degree of pruritus is so severe in some patients that they are unable to tolerate bathing at all and find it necessary to substitute gentle skin swabbing or to simply not bathe. The etiology of the pruritus in polycythemia vera remains uncertain. Several groups have attempted to implicate elevated blood and urine histamine levels in its pathobiology. [167] [169] Steinman et al.[168] have presented data suggesting that water exposure in patients with polycythemia vera actually leads to elevated histamine levels, which would provide an explanation for the exacerbation of the pruritus frequently observed with water contact. Jackson et al. [169] have been able to establish a strong correlation between skin mast cell numbers and the severity of itching. However, the failure of the pruritus to respond to antihistamine therapy in many patients suggests that abnormally high histamine levels probably do not constitute the sole factor in its development. [171]

Iron deficiency has also been implicated as a factor contributing to pruritus in polycythemia vera patients who are almost invariably iron deficient. [171] Iron substitution therapy has resulted in symptomatic improvement,[171] but this approach is less than optimal because it frequently results in uncontrollable erythrocytosis.

Several investigators have suggested that patients suffer from serious nonhematologic symptoms secondary to iron deficiency. [173] [174] [175] Rector et al.[175] evaluated these sequelae in patients with polycythemia vera who were uniformly iron deficient and followed these patients for >25 years. Their data are unique in that they indicate that quantitative evaluation of symptoms fails to provide convincing evidence that undue fatigue occurs as a result of iron deficiency. [175] In fact, treadmill performance by six patients was equivalent to that observed among normal subjects.[175] None of the patients experienced dysphagia or the esophageal changes associated with chronic iron deficiency.[175] The one symptom that was observed to occur regularly, particularly in women, was picophagia, a pica consisting of compulsive ice eating.[175]

PPMM occurs in 550% of patients with polycythemia vera.[12] [13] [96] [124] [125] [126] [131] [132] The transition to this stage of the disease occurs, on average, 10 years after initial diagnosis, but in individual cases it can occur after either shorter or longer intervals. [123] [124] [125] Najean et al. have reported that 15 years or more after initial diagnosis, this complication is a major clinical problem affecting almost 50% of patients. [133] [134] PPMM is characterized by (1) increasing splenomegaly, (2) teardrop red blood cell morphology, (3) extensive bone marrow fibrosis, (4) a leukoerythroblastic blood picture, and (5) a normal or decreasing red blood cell mass. The patients may be entirely asymptomatic but often complain of fatigue, dizziness, weight loss, and anorexia. [124] [125] [126] Splenomegaly can lead to abdominal pain due to repeated splenic infarcts and to early satiety due to mechanical obstruction of the upper gastrointestinal tract.

The anemia that characterizes the spent phase is primarily a result of splenic pooling, ineffective erythropoiesis, and extramedullary production of red blood cells with a shortened red cell survival. Occasionally, the anemia is exacerbated by folate or iron deficiency. [125] [126] [176] Before assuming that a patient has entered the spent phase, it is prudent to assess bone marrow iron stores. Replacement therapy with iron may lead to the resurgence of erythropoiesis and prevent the faulty categorization of disease progression.

Bleeding abnormalities due to thrombocytopenia or qualitative platelet abnormalities are especially common during this phase of the disease. Frequent instances of

epistaxis or ecchymoses occur,[126] and gastrointestinal hemorrhage due to esophageal varices arising from portal hypertension is a recurrent problem. [124] [125] [126] Frequently, patients suffer from generalized wasting characterized by progressive asthenia and weight loss. Severe hyperuricemia, leading to secondary gout or uric acid nephropathy, may also complicate the clinical course.

Patients with PPMM are at high risk for the development of acute leukemia.[96] [132] [136] [177] Of those patients who enter the spent phase of polycythemia vera, 2050% will eventually undergo leukemic transformation.[124] [125] [126] Approximately 70% of patients who enter the spent phase will be dead 3 years after this transition; however, the other 30% of these patients will have a much longer survival, averaging 6.5 years. [124] [125] [126]

The leukemic transformation of polycythemia vera has been

extensively described.[136] [178] [179] [180] [181] [182] [183] The possibility that a relationship exists between the therapeutic modality used during the erythrocytotic phase and the frequency of development of acute leukemia has been a point of heated discussion. [178] [179] [180] [181] [182] [183] [184] [185] [186] [187] [188] [189] [190] Some of the controversy surrounding this question was formerly due to a lack of understanding of the basic origins of polycythemia vera. Clinical hematologists in the 1950s and 1960s frequently thought of polycythemia vera as a benign hematologic abnormality and believed that therapeutic interventions either with alkylating agents or radiotherapy were solely responsible for the development of acute leukemia. That concept has proved erroneous, and polycythemia vera, like the other myeloproliferative disorders, has been shown to be a clonal malignant hematologic disorder.[59] The evolution to acute leukemia can therefore be thought of as a natural consequence of this malignant disorder, which can be accentuated by the therapeutic interventions discussed above.

Further insight into relationships between acute leukemia and polycythemia vera has been best provided by the published results of the Polycythemia Vera Study Group (PVSG), which described a randomized trial comparing the use of phlebotomy, chlorambucil, and ^{32}P for the treatment of this disorder.[184] The incidence of acute leukemia was approximately 1.5% in patients treated with phlebotomy alone, 17.5% in patients treated with chlorambucil, and 10.9% in patients treated with ^{32}P after over 15 years of follow-up.[185] [186] [187] [188] The incidence of acute leukemia in the patients treated with phlebotomy alone is therefore much higher than that expected in a normal age-matched control group, again indicating that leukemia is a natural evolutionary event in the clinical course of an individual with polycythemia vera. The incidence of acute leukemia can be increased, however, by institution of therapy with either alkylating agents or ^{32}P.[185] [186] [187] [188] The time course for the development of acute leukemia appears to be dependent on the treatment used to control the polycythemia. The development of acute leukemia in patients treated with phlebotomy in the Polycythemia Vera Study Group trial was limited to the first five years of treatment, suggesting that the development of acute leukemia is not due solely to the prolongation of survival. In contrast, analysis of the hazard function (Fig. 61-6) was virtually flat for patients treated with chlorambucil from years two to seven after randomization; however, the risk for acute leukemia became alarmingly high after 10 years of study, suggesting that the risk of acute leukemia increases with time, even after the drug has been stopped.[188] One half the cases of acute leukemia in the chlorambucil arm occured in the first five years with the remainder equally split between the second and third five-year periods. In contrast, 60% of the cases of acute leukemia in the group treated with radioactive phosphorus occurred six to 10 years after randomization. Of particular concern is the high incidence of leukemia in patients who were initially treated with radioactive phosphorous and then switched to maintenance therapy with hydroxyurea, previously thought to be a nonleukemogenic agent. [188] [189] These findings suggest that a combination of radiotherapy (^{32}P) and chemotherapy (hydoxyurea) may particularly augment the risk of leukemia.[188] [189] Approximately 3050% of patients with polycythemia vera who develop acute leukemia have previously entered the spent phase. [128] [188] [189] In contrast, approximately 50% of patients progress directly from the erythrocytotic phase to acute leukemia.[136] [177] [185] [186] [187] [188] The phenotype of the leukemia cells that characterize the leukemic phase is overwhelmingly myeloid.[136] [186] Unusual cases of lymphoblastic transformation of polycythemia vera have, however, been reported, as have rare cases of biphenotypic leukemias. [191] [192] [193] [194] Another adverse effect solely associated with the use of chlorambucil has been the development of large cell lymphoma in 3.5% of patients. [185] [186] [187] [188]

The development of leukemia sometimes can be abrupt, however. In some instances, a preleukemic phase characterized by refractory anemia with excess blasts has been described.[178]

Figure 61-6 Hazard function for development of acute leukemia in PVSG protocol 01. The function shown is the instantaneous rate of acute leukemia at the midpoint of the study year, given survival without acute leukemia at the start of the year. The open circles represent the chlorambucil-treated patients, closed circles represent the ^{32}P-treated patients and the half-closed circles represent the phlebotomy. *(Data from Berk et al.)*[185]

In fact, one-half of such cases of acute leukemia in one series were preceded by a myelodysplastic disorder. [178]

In addition, the incidence of nonhematological malignancies has been shown to be increased in patients treated with either chlorambucil or radioactive phosphorous but not with phlebotomy therapy.[185] [186] [187] [188] The rates of nonhematological cancers were highest in sites in the skin and gastrointestinal tract. These malignancies are presumed to be treatment-related.

LABORATORY EVALUATION

Laboratory evaluation of the patient with erythrocytosis involves the careful use of a broad range of diagnostic studies. These studies must be employed in a rational manner, or the evaluation can become extremely costly. Since polycythemia vera is a panmyelosis, the overwhelming number of patients have elevated hematocrits, white blood cell counts, and platelet counts.[4] Hematocrit values over 50% in males and over 45% in females are abnormal and require further evaluation. In order to document the absolute increase in red cell mass, the performance of a blood volume study with direct quantitation of both the red cell mass and plasma volume is frequently necessary.[195] A hematocrit greater than 60% in men or greater than 55% in women is almost always associated with an absolute erythrocytosis.[196] [197] In such cases, it is frequently unnecessary to order blood volume studies. In men suspected of polycythemia with a hematocrit below 60% and women with hematocrits below 55%, blood volume measurements are required to determine whether the elevated hematocrit is actually due to an expanded red cell mass.[196] [197] Occasionally, an elevated red cell mass can actually be present in the face of a normal hematocrit. In cases of splenomegaly due to portal hypertension, an expanded plasma volume may mask an elevated red cell mass.[141] [167] In addition, iron deficiency can also lead to a fall in hematocrit in polycythemia vera making the diagnosis difficult.[141] Polycythemia vera is associated with a 2030% frequency of gastric ulcers and gastritis which can be associated with blood loss.[141] In this situation, thrombocytosis may be exacerbated as a consequence of the

iron deficiency. Iron supplementation and correction of the bleeding lesion may permit the diagnosis to be established. Administration of iron to such patients must be performed carefully, thereby avoiding a rapid increase in red cell mass, which can be associated with a high risk of thrombosis. Lamy et al. have recommended that increased hematocrit and hemoglobin levels do not constitute the only criteria for proceeding with a red cell mass determination in order to make a diagnosis of polycythemia vera.[141] They suggest that red cell mass determinations be performed in patients with normal hemoglobin and hematocrit values with portal or hepatic vein thrombosis, splenomegaly, leukocytosis, or thrombocytosis. The use of red cell measurements in these settings is intended to aid in the diagnosis of so-called inapparent polycythemia vera.[141]

Indirect calculations of the red cell mass from plasma volume measurements assume a normal body venous hematocrit ratio. Unfortunately, this ratio may be abnormal in patients with spurious polycythemia vera, and calculations derived from venous packed red cell volumes may overestimate the red cell mass.[195]

The criteria for establishing a red cell mass has previously been based upon values expressed as ml/kg of total body weight. Because adipose tissue is considerably less vascular than lean tissue, it may not contribute equally to the red cell mass.[195] [196] Red cell mass measurements, therefore, based solely on body weight can be misleading.[195] Red cell mass measurements more closely correlate with lean body mass than total body weight. Measured red cell mass values in obese subjects are regularly lower when expressed as ml/kg total body weight than those observed in lean individuals.[195] In order to overcome this difficulty, the International Council for Standardization in Haematology has presented formulas to calculate normal red cell mass values, based upon lean body mass, surface area, height, and weight.[195] Implementation of this approach is suggested due to the high incidence of obesity in our society.[195] Modification of the Polycythemia Vera Study Groups criteria for definition of elevation of the red cell mass has been suggested. An elevated red cell mass is now defined as being 25% greater than the mean predicted value of a red cell mass for that individual rather than basing evaluations on the volume per kg of total body weight.[195]

Leukocytosis is present in approximately two-thirds of cases, and thrombocytosis is observed in 50%.[4] Abnormalities of red blood cell, white blood cell, and platelet morphology are frequently observed. The morphologic red blood cell changes observed during the erythrocytotic phases are characteristic of iron deficiency and include microcytosis, hypochromia, and frequently polychromatophilia.[181] Some anisocytosis and poikilocytosis can be seen. Fetal hemoglobin levels and the number of red cells containing fetal hemoglobin, known as F cells, may be increased.[198] The white blood cells are characterized by normal morphology, although the numbers of basophils, eosinophils, and immature myeloid forms can be increased.[4] Platelet morphology is also quite striking in polycythemia vera. Frequently, megathrombocytes (platelets having the size of red blood cells) are seen on the peripheral blood smear. Patients frequently have platelet counts of $<1 \times 10^{6}$ /mm[3] , but it is not unusual to observe a patient with a platelet count higher than this value. The PPMM phase of the disease is characterized by a leukoerythroblastic blood picture, with the appearance in the peripheral blood of teardrop red blood cells, myelocytes, metamyelocytes, and, rarely, blasts and promyelocytes in addition to nucleated red blood cells in the peripheral blood.[124] [125] [126]

Platelet aggregation studies and bleeding times are frequently abnormal in patients with polycythemia vera, but many patients have normal values.[119] Prothrombin time (PT) and partial thromboplastin times (aPTT), as well as fibrinogen levels, are usually normal.[199] Profound abnormalities of both the PT and aPTT are, however, frequently reported. This is largely a laboratory artifact caused by the extreme erythrocytosis which results in a relative smaller volume of plasma being present in the whole blood sample. Coagulation assays are performed on blood anticoagulated with sodium citrate and the citrate concentration in the anticoagulant is calibrated to chelate the plasma calcium and inhibit coagulation reactions. All coagulation assays include the addition of calcium chloride to neutralize the excess citrate and provide free calcium to mediate coagulation reactions. In patients with extreme erythrocytosis, the ratio of citrate in the collection tube to the volume of plasma is too high; therefore, excess citrate is present and the standard amount of calcium chloride added during the performance of the PT and aPTT is insufficient to neutralize the excessive citrate and the coagulation assays are frequently artifactually prolonged. In order to avoid this problem, one should calculate the relative amount of plasma compared to normal and remove the corresponding volume of sodium citrate from the blood collection tube. Normal values can then be confidently anticipated in patients with erythrocytosis. Tytgat et al.[199] have detected a shortened fibrinogen half-life in some polycythemia vera patients and a significantly increased fractional catabolic rate of the plasma fibrinogen pool per day. Boughton and Dallinger[200] have confirmed these findings. In addition, elevated platelet -thromboglobulin and plasma -thromboglobulin levels are observed. The constellation of findings is indicative of increased platelet turnover rates.

An acquired von Willebrand defect (vWF) occurs frequently in patients with polycythemia vera and primary thrombocythemia who have extreme elevations of platelet numbers. This syndrome is characterized by a normal or prolonged bleeding time, a normal factor VIII level and normal vWF antigen level but abnormal vWF ristocetin cofactor actively associated with a decrease or absence of large vWF multimers.[119] [201] [202] This acquired defect resembles type II vWF disease. Since the molecular size of vWF is a major determinant of its adhesive function and the larger multimers are most active in achieving hemostasis, the deficiency of large vWF multimers is associated with a bleeding tendency. The decrease in the frequency of large vWF multimers occurs in patients with platelet counts over 1000×10^{9} /l.[201] [202] This abnormality has been reported not only with patients with severe thrombocytosis due to myeloproliferative disorders, but also in patients with reactive thrombocytosis.[202] An inverse correlation between the proportion of large vWF multimers and platelet numbers has been observed.[118] [202] In addition, normalization of the platelet count is accompanied by restoration of a normal vWF multimer pattern.[118] These findings suggest that thrombocytosis of any etiology may favor the adsorption of larger forms of vWF multimers onto platelet membranes, resulting in their removal from the circulation and subsequent degradation by platelet-associated proteases.[118] Although patients with myeloproliferative disorders frequently have bleeding tendencies, this is not the case in secondary thrombocytosis, possibly because of the limited periods of extreme thrombocytosis observed in such patients.[118] Patients with polycythemia vera with clinical courses punctuated by hemorrhagic events, extreme thrombocytosis, and acquired von Willebrand syndrome should not receive aspirin therapy if they are suffering from a thrombotic episode but should be phlebotomized and platelet reduction therapy should be initiated.[118] Patients with polycythemia vera and acquired vWF syndrome suffer from recurrent bleeding from mucous membranes and the digestive tract and easy bruisability. These symptoms frequently resolve with normalization of the

platelet count.

Deficiencies of one or more natural anticoagulants have been observed in patients with polycythemia vera and thrombosis. [203] These studies indicate that either familial or acquired antithrombin III deficiency, protein C or S deficiency, or resistence to activated protein C may contribute to the hypercoagulable state observed in polycythemia vera.[203] Such inherited disorders

associated with the erythrocytosis of polycythemia vera provide a scenario that frequently favors thrombosis in affected individuals.

The leukocyte alkaline phosphatase activity level is elevated in 70% of patients. [4] Serum B_{12} concentrations have been found to be elevated in 40% of patients, whereas serum B_{12} -binding proteins are elevated in 70% of cases. [4] Hyperuricemia occurs in an overwhelming number of patients, while elevated histamine levels are also frequently observed.[166] Bone marrow aspirates and biopsies obtained at the diagnosis of patients with polycythemia vera are hypercellular and display characteristic erythroid, granulocytic, and megakaryocytic hyperplasia. [105] [132] [204] [205] [206] This is not a uniform finding, as 13% of the pretreatment biopsies in one series demonstrated an initial marrow cellularity of <60%, which lies within the normal range. [97] The cellular elements are frequently morphologically normal. Iron stores are almost uniformly absent in pretreatment biopsy specimens.[105] [132] [204] [205] Significant increases in bone marrow reticulin may be present in biopsies obtained early in the course; but also may develop during the erythrocytotic phase and may be present for long periods before the onset of the spent phase. [105] [204] [205] The presence of increased reticulin at diagnosis is not predictive of imminent development of PPMM. In those patients who enter the spent phase of the disease, a moderate to marked increase in reticulin fiber is observed, either simultaneously with or within 1 year of this clinical transformation. [105] [132] [204] [205]

Several investigators have attempted to use bone marrow biopsy morphology as a differential diagnostic tool to discriminate between polycythemia vera and secondary forms of erythrocytosis. The marked hypercellularity and megakaryocytic hyperplasia that are the hallmarks of myeloproliferative disorders are useful parameters for distinguishing such individuals (Fig. 61-7).[204] [205] It is imperative to use the bone marrow biopsy rather than to aspirate specimens for this purpose. [105] [132] [204] [205]

The pathologic appearance of the spleen in polycythemia vera depends on the stage of the disease at which that organ is examined. [206] Spleens from patients in the erythrocytotic phase of the disease are characterized by striking congestion with mature erythrocytes. [206] Small numbers of hematopoietic precursor cells are frequently present. By contrast, spleens examined during the PPMM phase are characterized by prominent numbers of foci of extramedullary hematopoiesis, with representation of all marrow precursor elements.[206]

TABLE 61-5 -- Study of Diagnostic Utility of Marrow Erythroid Progenitor Cell Cultures in Patients Suspected of Polycythemia Vera Based on Standard Clinical Criteria

Diagnosis	Standard Criteria[a]	Endogenous Erythroid Colonies[b]
Group A[c]		
Polycythemia vera	46	43 (93%)
Secondary polycythemia	12	0
Unclassifiable polycythemia	29	18
Total	87	61 (70%)
Group B[c]		
Secondary polycythemia	5	0
Unclassifiable polycythemia	16	4 (25%)
Total	21	4 (20%)

From Lemoine et al.,[207] with permission.

[a]Standard criteria were criteria proposed by the PVSG and criteria routinely used for the diagnosis of causes of secondary polycythemia. [4]
[b]Endogenous erythroid colonies derived from bone marrow cells developing without exogenous EPO.
[c]Group A is defined to include male patients having a red cell mass of 36 ml/kg and female patients with a red cell mass of 32 ml/kg. Group B is defined as male patients having a red cell mass of 3036 ml/kg and female patients with a red cell mass of 2532 ml/kg.

The proliferative capacity of polycythemia vera hematopoietic progenitor cells has been shown to be a useful laboratory adjunctive study. [207] [208] [209] Lemoine et al.[207] prospectively used the formation of endogenous erythroid colonies as a diagnostic tool to confirm the diagnosis of polycythemia vera in the evaluation of a group of patients with isolated erythrocytosis (Table 61-5). In this study, the clinical course of those patients with marrow cells that formed endogenous colonies was very similar to that of patients who met standard criteria for the diagnosis of polycythemia vera. [207] Slightly >70% of these patients developed difficulties that eventually required treatment. Conversely, those patients whose marrow cells did not form colonies in the absence of EPO enjoyed a benign clinical course not requiring therapeutic intervention. The utility of such assays has also been emphasized by Shih et al. who studied patients with idiopathic thrombocytosis who did not meet the diagnostic criteria for polycythemia vera. [210] Shih et al. reported that a high proportion

Figure 61-7 Photomicrograph of bone marrow biopsy obtained from polycythemia vera patient in spent phase demonstrating hypercellularity and increased number of megakaryocytes (× 160).

of patients with normal or reduced hematocrits associated with marked isolated thrombocytosis (>1 × 10^6 /mm[3]) who had marrow cells that formed endogenous erythroid colonies eventually developed polycythemia vera within a median of 24 months. [210] These findings require confirmation because other laboratories have reported endogenous erythroid colonies in 50% of patients with primary thrombocythemia. [208] [209] It is important to emphasize that although the presence of endogenous colonies in the blood is indicative of polycythemia vera, the inability to detect these colonies does not entirely eliminate the diagnosis. [211] Assays of bone marrow cells are indicated when endogenous colonies are not detectable in the peripheral blood. [211] Due to the lack of quality assurance in the performance of such clonal erythroid progenitor cell assays in some laboratories, some reservations concerning their widespread use as diagnostic tools have been expressed. [209]

Laboratory evaluation of patients with polycythemia vera has been further facilitated by the more widespread availability of quantitative assays of EPO. [56] [57] [58] At diagnosis, serum EPO levels in polycythemia vera are either reduced or at the lower limits of normal. Even following normalization of the hematocrit, the serum EPO level in polycythemia vera remains low in two-thirds of patients. [56] [57] [58] [212]

The occurrence of nonrandom cytogenetic abnormalities in polycythemia vera is not unexpected, as this is a feature of most hematologic malignancies (Fig. 61-8).[213] [214] [215] [216] [217] [218] [219] [220] Such abnormalities have been observed, with no single characteristic chromosomal abnormality defined; abnormalities of chromosomes 1, 5, 7, 8, 9, 12, 13, and 20 have been detected. [213] [214] [215] [216] [217] [218] [219] [220] These cytogenetic abnormalities can be categorized according to the phase of disease (onset, erythrocytotic, or spent phase) in which they are most frequently observed. [213] [214] [215] [216] [217] [218] [219] [220] Also, certain cytogenetic abnormalities are clearly a result of treatment-induced mutation, associated with the use of ^{32} P or alkylating agents (Fig. 61-8).[213] [214] [215] [216] [217] [218] [219] [220] The frequency of detection of cytogenetic abnormalities in polycythemia vera is a cumulative function, with clonal cytogenetic abnormalities being observed in 820% at diagnosis; in 35 55%

following a number of years of treatment; and in >80% in those patients in whom acute leukemia eventually develops. [218] [219] [220] Therefore, clonal progression from a normal to abnormal karyotype, especially acquisition of abnormalities involving chromosomes 5 and 7, is an important adverse prognostic parameter. [218] [219] [220]

Trisomy of chromosomes 8 and 9 and deletion of the long arm of chromosome 20 (20q) are most frequently observed at diagnosis. [213] [220] In several studies, the single most common abnormality was 20q (q11),[213] [214] [215] [216] [217] [218] [219] [220] which is a recognized genomic constitutive fragile site subject to mutagenic insult in vitro. [221] This cytogenetic defect is common but is not diagnostic of polycythemia vera. The 20q (q11) deletion is due to an interstitial deletion. [222] [223] [224] [225] [226] To date, an extensive search for a putative tumor suppressor gene at the site of the 20q deletion that might play a role in the biogenesis of polycythemia vera has been unrewarding.[226] Using the microsatellite polymerase chain reaction spanning the common deleted region on 20q, this cytogenetic abnormality has been shown to be absent in peripheral blood granulocytes but to be simultaneously present in most marrow metaphases. These cytogenetically normal granulocytes have, however, been shown to be clonal in origin in females with polycythemia vera. [224] Such data suggest that 20q deletions occur as secondary events in polycythemia patients with preexisting clonal hematopoiesis and that the absence of cells with 20q in the peripheral blood results from selective influences such as preferential retention or destruction within the marrow of granulocytes carrying this abnormality. [224]

Serial cytogenetic evaluation of previously karyotypically normal patients indicate that other abnormalities most often acquired with progression of the disease are 13q, 12q, and 1q (Fig. 61-8).[218] [219] [220] These particular abnormalities do not necessarily herald transition to acute leukemia, but leukemia or myelofibrosis was observed in 8 of 12 patients with the 1q abnormality in one study. [201] Deletion of the long arm of chromosome 13 has been observed during the myelofibrotic phase of polycythemia vera, but this abnormality has been detected also during the erythrocytotic phase. It does not appear, therefore, that a chromosome 13q abnormality heralds disease transition.[217] PPMM occurring after the use of chemotherapy is often accompanied by additional karyotypic abnormalities, with chromosomes 5 and 7 being most frequently involved.[214]

One can conclude that chromosomal abnormalities such as

Figure 61-8 Common chromosome abnormalities in untreated and treated patients with polycythemia vera at time of chromosome study, shown by number of years after initial diagnosis. Abn, abnormal. *(From Diez-Martin et al.,[216] with permission.)*

+8,+9, and 20q might be related to the biogenesis of the disease rather than to the treatment employed. [219] [220] In addition, it appears that, at best, in some patients, an abnormal clone (abnormalities of chromosome 5 or 7) and hypodiploidy develop as a consequence of therapy with chemotherapeutic agents. [218] [219] [220] Diez-Martin et al. have also suggested that patients with a cytogenetic abnormality at diagnosis have a statistically significantly poorer survival rate than those in whom a normal karyotype is observed.[218] This influence of cytogenetics on prognosis has not been confirmed by others. [215] [219] [220]

DIFFERENTIAL DIAGNOSIS

In the overwhelming number of patients, establishing the diagnosis of polycythemia vera is not difficult. Characteristically, the patient will present with erythrocytosis, leukocytosis, and thrombocytosis.[4] The bone marrow biopsy shows hypercellularity with trilinear cellular hyperplasia. [105] [204] [205] A direct determination of a red cell mass is not universally necessary.[196] [197] Many patients with a raised hematocrit, however, will require blood volume studies to document an elevated red cell mass.[196] [197] A hematocrit greater than 60% on several occasions in men or greater than 55% in women, however, is associated in the preponderance of cases with an elevated red cell mass.[196] [197] In those situations, it would be reasonable not to proceed with blood volume studies. If the hematocrit is below 60% in men or below 55% in women, blood volume studies are required. It has become increasingly apparent that an elevated hematocrit should not be the only criteria for proceeding with a red cell mass determination.[141] Splenomegaly can lead to an expanded plasma volume, which can mask the diagnosis of polycythemia. It is suggested that red cell mass determinations be performed in patients with normal hemoglobin or hematocrit determinations in the context of portal vein thrombosis, isolated leukocytosis, or splenomegaly.[141] The presence of splenomegaly is an important finding on clinical examination, and adjunctive laboratory findings include normal arterial oxygen saturation, elevated leukocyte alkaline phosphatase activity, elevated serum vitamin B_{12} levels and B_{12}-binding proteins.[4] Splenic sizing by ultrasound can be useful in documenting splenic enlargement when the spleen is not palpable by physical examination. [227]

It is initially important to discriminate polycythemia vera from the large number of other causes of secondary erythrocytosis (see Chap. 25). Two tests that are especially useful for this purpose are a determination of the ability of bone marrow cells to form erythroid colonies in the absence of exogenous EPO, and quantitation of serum EPO levels by either RIA or ELISA assays.[56] [57] [58] [212] The availability of newly defined genetic markers employing DNA restriction fragment length polymorphisms to establish clonality of a bone marrow proliferative disorder may also expedite the diagnosis in affected females. [63] [64] [65] The impact of these new diagnostic tools in establishing the diagnosis of polycythemia vera in an individual patient is now apparent.

Clinical criteria for the diagnosis have been defined by the PVSG and have been used successfully to obtain a uniform patient population with polycythemia vera for evaluation of therapeutic modalities.[13] [184] It is important, however, for the clinician to realize that some patients undoubtedly have a myeloproliferative disorder resembling polycythemia vera but do not fulfill all the diagnostic criteria of the PVSG. [141] The diagnostic criteria of the PVSG do not include determination of elevation of the red cell mass based upon mean predicted values, a measurement of bone marrow proliferative capacity, a measurement of serum EPO, or ultrasound documentation of splenomegaly. More usefuland, it is hoped, more flexiblecriteria for the diagnosis of polycythemia vera are suggested in Table 61-6 . There will always be unusual cases with clinical characteristics that cannot be pigeonholed into a particular diagnostic category. If asymptomatic, these patients should be followed carefully until the

TABLE 61-6 -- Clinical and Laboratory Criteria for Diagnosis of Polycythemia Vera[a]

1. Elevated red blood cell mass of (>25% above mean predicted value)
2. Normal arterial oxygen saturation (92%) in the presence of erythrocytosis as defined in criterion 1
3. Splenomegaly
4. Thrombocytosis (platelet count of 400,000/mm^3) and leukocytosis (white blood cell count of 12,000/mm^3)
5. Bone marrow hypercellularity associated with clustered mature megakaryocytes with hyperlobulated nuclei and absent iron stores
6. Low serum EPO levels (<3.0 U/l) in the presence of an increased red blood cell mass as defined in criterion 1
7. Abnormal marrow proliferative capacity as manifested by formation of erythroid colonies in the absence of exogenous EPO

[a]The presence of criterion 1 and any three additional criteria are diagnostic of polycythemia vera.

disorder evolves into a more recognizable entity. This would appear prudent in order to avoid unnecessary therapeutic interventions. If these patients have serious symptoms, the individual physician must make treatment decisions on the basis of the risk/benefit ratio for that patient.

A particularly difficult dilemma occurs when evaluating patients with isolated pure erythrocytosis. These patients have elevated red blood cell masses, normal white blood cell counts, normal platelet counts, no evidence of splenomegaly, and no evidence of any recognizable cause of secondary erythrocytosis. Russell and Conley[228] and Modan and Modan,[229] as well as Najean et al.,[230] believe that these cases represent a clinical entity distinct from polycythemia vera. In contrast, Pearson and Wetherley-Mein[231] have suggested that at least some of these cases can be reclassified as polycythemia vera at a later time in their clinical course. In the report of Najean et al., 7 of 51 such patients after prolonged follow-up developed a clinical picture similar to that of polycythemia vera or agnogenic myeloid metaplasia with myelofibrosis, or both.[230] The clinical course of patients with primary pure erythrocytosis was also frequently complicated by thrombotic vascular episodes. These patients were treated with myelosuppressive therapy to avoid additional complications. [230] Of these 51 patients, five eventually developed acute myeloid leukemia.[230] On the basis of this information, a significant number of these patients appear to have a disorder that closely resembles polycythemia vera and should be treated accordingly. The familial congenital form of polycythemia, characterized by increased sensitivity of erythroid progenitor cells to EPO, can be easily distinguished from polycythemia vera. These patients frequently present in childhood, and this disorder is characterized by isolated erythrocytosis that is associated with an increased risk of thrombotic events.[33] [34] [35] [36] [37] There is a strong family history of polycythemia.[33] [34] [35] [36] [37] In contrast to polycythemia vera, the marrow progenitor cells are hypersensitive to EPO, yet no colonies form in the absence of EPO. [33] [34] [35] [36] [37]

Polycythemia vera must also be distinguished from an endemic, familial form of congenital polycythemia that occurs commonly in the Chuvash population of the Russian Federation.[232] The extreme elevations of hemoglobin in these patients are accompanied by elevated EPO levels. [232] This disorder is thought to be inherited as an autosomal recessive trait.[232] Patients frequently present with a history of fatigue and headaches and are plethoric on physical examination. The recently reported mortality of more than 10% of a very young cohort of patients over a period of 10 years of observation indicates that this form of polycythemia is not benign.[232] Chuvash polycythemia is thought to be due to an abnormality in the oxygen sensing mechanism resulting in increased EPO production. Chuvash polycythemia is the only endemic form of familial and congenital polycythemia described to date. [232]

The ability of bone marrow cells to form endogenous erythroid colonies has also been used to analyze etiologic factors in the development of Budd-Chiari syndrome.[133] [233] Valla et al.[233] studied the marrow proliferative capacity of 20 patients with this syndrome and observed endogenous erythroid colony formation in 16 cases. In two of these 16 patients, it was quite obvious that a myeloproliferative disorder was the underlying etiologic factor in the development of hepatic vein

thrombosis. This abnormality in the other 14 patients suggests that the development of Budd-Chiari syndrome may represent, in some cases, a forme fruste of a myeloproliferative disorder.[233]

Polycythemia vera must also be differentiated from the other myeloproliferative disorders, such as CML, primary thrombocythemia, and agnogenic myeloid metaplasia with myelofibrosis. Such classification has major prognostic implications and influences important therapeutic decisions. With the distinctive cytogenetic abnormalities and molecular genetic abnormalities that are unique to CML (Philadelphia chromosome, *bcr-abl* gene fusion), these two disorders should not be difficult to differentiate.[59] A less complex test, the leukocyte alkaline phosphatase activity, may also be of assistance. The leukocyte alkaline phosphatase score is elevated in polycythemia vera but is decreased in patients with CML.[4] [59] In addition, the incidence of elevated red cell masses in patients with CML is low.

Patients with agnogenic myeloid metaplasia with myelofibrosis can present with abnormalities that are virtually indistinguishable from those of patients with PPMM. [124] [125] [126] The survival of patients with the latter disorder is much shorter than that of patients with the former condition. [124] [125] [126] Some patients with presumed agnogenic myeloid metaplasia may actually develop, after the institution of chemotherapy, the clinical features of polycythemia vera. [14] A preceding history of polycythemia vera permits differentiation between these two situations. Primary thrombocythemia and polycythemia vera with marked thrombocytosis can easily be confused. When the red blood cell mass is used as a definitive diagnostic test, a distinction between primary thrombocythemia and the erythrocytotic phase of polycythemia vera is usually readily apparent. [234] [243] This measurement, however, can be normal or actually low in the patient with polycythemia vera who is iron-deficient because of bleeding or excessive phlebotomy. [133] To avoid this difficulty, Iland et al. [234] have developed a logistic regression algorithm on the basis of clinical characteristics; this algorithm appears useful in differentiating primary thrombocythemia from polycythemia vera in cases in which either a red blood cell mass quantitation is unavailable or iron deficiency cannot be excluded. Because the marrow cells of over 50% of patients with primary thrombocythemia form endogenous erythroid colonies, hematopoietic progenitor cell assays are not useful in differentiating these two disorders. [209]

THERAPY

Dramatic prolongation of survival over that expected from the natural history of untreated polycythemia vera has been achieved with several therapeutic strategies. [134] [185] [186] [187] [188] Historical evidence for an untreated median survival of approximately 18 months is derived from descriptive accounts. [12] [192] Median survivals of >10 years are now commonplace with optimal management.[134] [185] [186] [187] [188]

A series of studies performed over a 17-year period (19671984) by the PVSG has answered several very important questions regarding the efficacy and associated complications of particular therapeutic modalities. These investigations have aided in the identification of optimal therapy for individual patients, which must be selected on the basis of age and co-morbid disease status in order to minimize treatment-related complications. [184] [185] [186] [187] [188]

The first PVSG randomized trial (01 trial) examined three

GENERAL PRINCIPLES OF THERAPY

1. Etiology of erythrocytosis must be correctly categorized in order to be certain the patient has polycythemia vera. This will avoid inappropriate exposure of patients with nonmalignant disorders to radiation or chemotherapy.
2. Therapy should be individualized.
3. Initially blood volume should be reduced to normal as rapidly as possible. The speed of phlebotomy will depend on patients general medical condition (250500 ml every other day). Elderly patients with compromised cardiovascular or pulmonary systems should be more carefully phlebotomized (twice a week), or smaller volumes of blood should be removed.
4. Hematocrit should be maintained at 4245%.
5. Excessive doses of chemotherapeutic agents should be avoided. Supplementary phlebotomy rather than potentially toxic doses of chemotherapeutic agents should be used in order to avoid excessive marrow and systemic toxicity.
6. Hyperuricemia is treated with allopurinol (100300 mg/day).
7. Pruritus is treated with cyproheptadine 416 mg/day; if unsuccessful, interferon- therapy 3.0×10^6 units, subcutaneously three times a week should be instituted.
8. Elective surgery or dental procedures should be delayed until red cell mass and platelet counts have been normalized for 2 months. If emergency surgery is contemplated, phlebotomy and cytopheresis should be pursued.
9. Women and men who are contemplating having children should be treated by phlebotomy plus low-dose aspirin therapy (40 mg/day or with interferon-) in order to avoid teratogenic effects of chemotherapy and radiotherapy. Such avoidance will also prevent deleterious effects on fertility. During pregnancy therapy is frequently not necessary; if it is, phlebotomy plus low-dose aspirin should be exclusively used. If phlebotomy control is inadequate, treatment with interferon- should be pursued.

treatment arms: (1) phlebotomy alone, to maintain the hematocrit at <45%; (2) intravenous ^{32}P, 2.3 mCi/m[2] repeated every 12 weeks if needed (maximum 5 mCi per dose), supplemented by phlebotomy to maintain the hematocrit at less than 45%, and (3) myelosuppression with chlorambucil 10 mg/day PO for 6 weeks, then daily on alternate months, with necessary dose reductions and supplemental phlebotomy. [184] [185] More than 400 patients were randomly assigned to this protocol. Median survival from entry into the study until death was 9.1 years for patients treated with chlorambucil, 10.9 years for those treated with ^{32}P, and 12.6 years for the phlebotomy group.[185] [188] Long-term survival was inferior for patients treated with chlorambucil when compared to those treated with ^{32}P or phlebotomy.[185] [188] An early finding was the appearance during the first 5 years of a significant excess of deaths from acute leukemia in the chlorambucil arm which has reached 17% after 15 years of follow-up.[185] [186] [187] [188] As a result, the chlorambucil arm was discontinued, and patients were assigned randomly to one of the other two arms. Even though no statistical difference in overall survival between ^{32}P and phlebotomy alone was apparent through the first 10 years, the morbidity and mortality associated with each type of therapy were attributable to distinctly different causes. [185] [186] [187] [188] Thrombosis as a cause of death was much more frequent in the phlebotomy-only group during the first 57 years of

ALGORITHM FOR MANAGEMENT OF PATIENTS WITH POLYCYTHEMIA VERA

follow-up.[186] Analysis of factors associated with thrombosis revealed that the performance of phlebotomy, the rate of phlebotomy, advancing age, and history of previous thrombosis were statistically significant factors predictive of this outcome. [187] In contrast, the use of^{32}P led to a lower rate of thrombosis during the first 5 years, but the incidence of leukemias, lymphoma, and nonhematologic malignancies increased during the next 5 years to nearly 10%. [185] [186] [187] [188] Following a

15-year period of observation, the incidence of leukemia and lymphoma in the chlorambucil group had risen to 17%. [185] [186] [187] [188] A statistically significant increase in skin and gastrointestinal cancers occurred in the ^{32}P and chlorambucil-treated cohorts, as compared with the group treated with phlebotomy alone. [185] [186] [187] [188]

Given the paradox of equal 10-year survivals, but demise

due to distinct causes, in comparable populations of patients treated by phlebotomy alone or by phlebotomy plus ^{32}P, the PVSG pursued strategies to reduce the thrombotic risk in the phlebotomy-only group. One study attempted reduction of the thrombotic risk by combination antiplatelet therapy. It appeared possible that therapy directed toward altering platelet function might reduce the frequency of thrombosis. [160] Therefore, a randomized trial was performed in which phlebotomy supplemented with the platelet antiaggregating agents aspirin and dipyridamole was compared with ^{32}P (PVSG trial 05). The outcome for the phlebotomy/aspirin/dipyridamole-treated group was disappointingly inferior to the ^{32}P results.[160] In fact, more thromboses occurred in the former than in the latter group, but surprisingly, there was also a significantly greater incidence of severe gastrointestinal hemorrhages. [160]

Renewed impetus for the use of nonchemotherapeutic agents for the treatment of polycythemia vera was provided by an extensive natural history study of 1,213 patients reported by the Gruppo Italiano Studio Policitemia. [96] They showed that the ageand sex-standardized mortality rate of patients with polycythemia vera was 1.7 times greater than the mortality of controls in the general Italian population. [96] In addition, four times as many patients who had previously received ^{32}P, alkylating agents, or hydroxyurea died of cancer compared to patients treated with phlebotomy alone. [96] When this group combined the total number of deaths and the number of nonfatal myocardial infarctions and strokes, they found an unsatisfactory risk:benefit profile in patients treated with chemotherapeutic agents and suggested that antithrombotic strategies, such as low-dose aspirin, be carefully evaluated for use in the care of polycythemia vera patients. [96]

In light of more recent knowledge of the dose requirements for selective antiplatelet therapy with aspirin, it appears that the PVSG study of platelet antiaggregating agents might have failed due to the use of excessive aspirin dosages (900 mg/day). Such aspirin doses appear to diminish vascular endothelial production of the platelet antiaggregatory factor, prostacyclin I_2 (PGI_2).[113] [115] [116] [119]

Polycythemia vera platelets are known to have a generalized abnormality of arachidonate metabolism that is characterized by enhanced synthesis of thromboxane A_2 which likely reflects stimuli to platelet activation. [113] [117] [119] The exact mechanism responsible for enhanced platelet synthesis of thromboxane A_2 in polycythemia vera remains unknown and requires further investigation. A low-dose aspirin regimen (50 mg/day for 7 to 14 days) has been shown to suppress greater than 80% of the excretion of the metabolites of thromboxane A_2 .[113] Recently a pilot study was performed in which the toxicity of low-dose aspirin therapy in polycythemia vera patients was evaluated.[115] A very-low-dose aspirin regimen (40 mg/day) was chosen to prevent thrombosis yet minimize the risk of bleeding. After follow-up of the low-dose aspirin treatment group and control group for a mean of 16 ± 6 months, low-dose therapy was shown not to be associated with an increased incidence of bleeding complications. Aspirin therapy was well tolerated and was associated with complete inhibition of platelet cyclooxygenase activity. [115] A large, randomized, placebo-controlled clinical trial testing the risk:benefit ratio of low-dose aspirin therapy in preventing thrombotic episodes in polycythemia vera is currently being pursued.[115] The results of this trial are eagerly awaited. Until the results of this trial become available, the employment of phlebotomy therapy alone is not terribly attractive since the addition of low-dose aspirin therapy appears to be innocuous and possibly effective in diminishing the risk for thrombotic events.

It is interesting to compare the results of the PVSG with those of a randomized trial of ^{32}P versus busulfan for the treatment of polycythemia vera conducted by the European Organization for Research and Treatment of Cancer (EORTC). [234] [235] The two studies were comparable in size, design, and duration of follow-up. In the EORTC trial induction courses of busulfan 46 mg/day for 48 weeks were compared with ^{32}P treatment.[221] Patients treated with busulfan enjoyed a survival advantage over ^{32}P-treated patients.[235] [236] This difference was due primarily to a threefold greater incidence of fatal thrombotic events in the ^{32}P group. Interestingly, the incidence of leukemia in both groups was very low (<2%), with an overall malignancy rate of <10% (involving mostly solid tumors). [235] [236]

It is reasonable to conclude from this trial that busulfan is a myelosuppressive agent of limited leukemogenic potential when used on an intermittent schedule. [235] [236] A retrospective study of patients in England treated with phlebotomy and intermittent busulfan supports these same conclusions. [237]

After the disappointing results experienced with the alkylating agent, chlorambucil, the PVSG began a nonrandomized phase II investigation of hydroxyurea, an S-phase-specific ribonucleotide reductase inhibitor. [238] [239] The hope was that this agent would be nonleukemogenic. Of 53 patients with polycythemia vera treated with hydroxyurea who had never received other forms of myelosuppression, after follow-up for a median period of 8.6 years and a maximum follow-up of 795 weeks, 5.4% developed acute leukemia in comparison with 1.5% of patients treated with phlebotomy alone on the original PVSG randomized study. [188]

In a comparable trial reported by Sharon et al., 71 patients were treated with hydroxyurea for a mean duration of 7.3 years. [240] Remarkably, the incidence of thrombosis was only 6%, indicating the impressive potential of hydroxyurea to lower the incidence of thrombosis in patients with polycythemia vera, confirming an observation previously made by Kaplan et al.[239] The incidence of leukemia in the Israeli trial was 5.6%. [241] Several other reports are also available reporting the incidence of acute leukemia in polycythemia vera patients treated with hydroxyurea. [183] [240] [241] [242] [244] [245] [246] The incidence varies from 10.5% in the 30 patients treated by Weinfeld et al. to 6.2% in the 65 patients treated by Lovfenberg et al. and 10% in the 150 cases treated by Najean et al. [183] [240] [241] [242] [244] [245] [246] Furthermore, in a randomized trial including 296 patients comparing the efficacy of hyroxyurea to piprobroman, an alkylating agent, for the treatment of polycythemia vera, the incidence of leukemia was similar in both treatment arms; the incidence of PPMM was, however, statistically greater in the patients treated with hydroxyurea.[245] One must conclude that the leukemogenic potential of hydroxyurea in this patient population remains inadequately evaluated and that each of the published series are limited in size and duration of follow-up. [183] [188] [240] [241] [242] [244] [245] [246] In lieu of a randomized trial, the author concludes that the incidence of leukemia is somewhat higher in hydroxyurea-treated patients than in phlebotomy-treated patients. However, the documented ability of hydroxyurea to lower the incidence of thrombotic events, even in the face of increasing documentation of its leukemogenic potential, still makes this drug a very useful chemotherapeutic agent in patients with disease that cannot be controlled with phlebotomy alone. Excessive myelosuppression, macrocytosis, hypersegmentation of polys, stomatitis, leg ulcers, creatinine elevations, and jaundice have been attributed to the use of hydroxyurea. [245] [247] In one series, apthous and leg ulcers occured in 20% of patients, usually after 5 years of hydroxyurea maintenance therapy.[245] In addition, the use of hydroxyurea requires good patient compliance and careful monitoring of blood counts to avoid the sequelae of excessive myelosuppression.

Some clinical investigators have suggested that a program of phlebotomy alone would be the most appropriate for younger patients, in whom the risk of cerebrovascular or cardiovascular events might be predicted to be low. [11] [95] [174] In fact, analysis by Najean et al.[98] of a series of patients with polycythemia vera presenting <40 years of age indicated that such suppositions are erroneous. A striking incidence of serious thrombotic events was observed, with Budd-Chiari syndrome (hepatic vein thrombosis) and cerebrovascular accidents being the leading

causes of death.[98] [115] These investigators recommended a program of myelosuppression for the treatment of these young patients. There was a low incidence of acute leukemia in this group of 58 patients, who were followed for >15 years (only one developed acute leukemia). This finding is surprising, because most patients received either ^{32}P, an alkylating agent, or hydroxyurea as supplemental therapy.[98] The use of hydroxyurea in patients who had previously been treated with ^{32}P is to be discouraged because this form of sequential therapy is associated with an especially high risk of leukemia. [189] Strong consideration should be given to the use of phlebotomy therapy in conjunction with low-dose aspirin therapy in addition to the use of such apparently nonleukemogenic drugs as interferon- or anagrelide in this younger patient population.[98]

Silverstein et al.[248] [249] have used anagrelide, a selective inhibitor of platelet production, to treat thrombocytosis in polycythemia vera patients with thrombotic or hemorrhagic complications. This agent appears to be nonleukemogenic and acts by impairing megakaryocyte maturation. [250] [251] Its use leads to a selective reduction in platelet numbers, and it has been effective in patients refractory to hydroxyurea and interferon. [248] [249] [252] [253] [254] This drug does not effectively control the erythrocytosis or systemic symptoms associated with polycythemia vera.

Recently, Pettit et al. have reported that anagrelide usage in polycythemia resulted in a complete resolution of thrombocytosis as defined as a platelet count less than 600,000 or a 50% reduction of pretreatment levels in 66% of 113 patients with polycythemia vera. [252] In nearly all responders, platelet reduction was observed within a

week. The time to complete response generally ranged between 17 and 25 days.[252] The dose of anagrelide required to control thrombocytosis remained constant over time in most patients. When anagrelide is discontinued, platelet counts returned to pretreatment levels within 5 to 7 days. The average daily dose required to control thrombocytosis in polycythemia vera patients was 2.4 mg.[252] Anagrelide should not be used in pregnant patients because it can easily cross the placenta, leading to adverse effects on the platelet count of the fetus.[252] The incidence of life-threatening hemorrhagic and thrombotic events that accompany severe thrombocytosis in patients with myeloproliferative disorders has been shown to be dramatically reduced following the reduction of platelet numbers resulting from the use of anagrelide.[253]

Approximately 1520% of patients treated with anagrelide discontinued the medication due to nonmyelosuppressive side effects.[248] [249] [252] [253] [254] The spectrum of adverse effects involved neurologic (headaches and dizziness), cardiac (vasodilation, fluid retention, congestive heart failure, palpitations, and tachycardia), and gastrointestinal (nausea) toxicities. These toxicities reflect the novel mechanism of action of anagrelide as a cyclic nucleotide phosphodiesterase inhibitor. Anagrelide should be used with caution in patients with known or suspected cardiac disease because of its ability to promote fluid retention.[252] [253] [254] Because a large fraction of the patients with polycythemia vera are elderly, careful attention to fluid status should be maintained in order to avoid patients slipping into congestive heart failure following the initiation of anagrelide.

Another potential approach to controlling the erythrocytosis and thrombocytosis in polycythemia vera involves use of interferon-.[247] [255] [256] [257] [258] [259] Interferon- has global effects on hematopoiesis.[247] [260] It inhibits both in vitro erythropoiesis and thrombopoiesis and antagonizes the action of platelet-derived growth factor, which likely plays a major role in the pathobiology of myelofibrosis.[127] [128] Silver has suggested that treatment with interferon potentially might alter the natural history of polycythemia by interrupting the development of PPMM and myelofibrosis.[247] Reports of small groups of patients treated with interferon indicate that the erythrocytosis can be controlled in 6 to 12 months, virtually eliminating the need for phlebotomy in approximately 70% of cases.[247] [255] [256] [257] [258] [259] In addition, interferon is capable of eliminating or reducing the degree of splenomegaly, leukocytosis, and thrombocytosis in the majority of polycythemia vera patients.[247] [255] [256] [257] [258] [259] Importantly, interferon treatment has been shown to be capable of diminishing the severity of pruritus in 80% of patients.[247] [255] [256] [257] [258] [259] Occasionally the effect on pruritus can occur in days.[242] The mechanism by which interferon eliminates pruritus remains unknown. The usual dose of interferon used to control polycythemia varies between 1.9 and 25 × 10^6 units/weekly with a median maintenance dose to 10.5 × 10^6 units/weekly administered subcutaneously in divided doses three times a week.[258] [259] A loss of biological effect can be attributed to the development of interferon- neutralizing antibodies which may be overcome by retreatment with lymphoblastoid interferon- N3.[247] Disease control persists in most patients only as long as interferon- therapy is continued. Rare patients have, however, enjoyed sustained remissions after discontinuation of interferon.[247] Silver has recently reported remarkable results in 16 patients who had been followed for more than 6 years.[247] In this patient group, albeit limited in size, no patient has developed a malignancy or any thrombohemorrhagic event during the treatment period.[247] Although these results are promising, treatment of larger numbers of patients for longer periods of time is required before the results of long-term interferon therapy in the treatment of polycythemia vera can be appropriately evaluated.[247] Although one would anticipate that this form of therapy would be non-leukemogenic, insufficient data is available to justify this conclusion. In addition, although interferon- has a profound effect on PDGF and megakaryocytopoiesis, no data is available to suggest that its use delays or prevents the development of PPMM. Interferon- has, however, been reported to be capable of suppressing the abnormal clone in polycythemia vera, similar to its ability to induce cytogenetic remissions in chronic myeloid leukemia.[261] Intolerance to therapy with interferon- leads to drug withdrawel in 14% of patients.[243] [258] [259] Initially, all patients suffer flu-like symptoms, which are controllable with acetaminophen or aspirin. Such symptoms usually resolve spontaneously after several months of therapy. More serious side effects, including high fevers, severe asthenia, and reversible lower extemity bilateral neuritis, may require cessation of interferon- therapy. It is anticipated that further evaluation of interferon- therapy will be pursued in the future.

Symptomatic management of the polycythemia vera patient may be complicated by the occurrence of intractable pruritus.[4] [163] [165] [166] [262] Classically the pruritus occurs on exposure to sudden body cooling, especially after a warm bath,[4] [166] [169] and is experienced by as many as 4060% of patients treated with phlebotomy.[262] The frequency of pruritus appears to be somewhat lower in patients treated with myelosuppressive agents.[262] This observation is related to the probable relationship between pruritus and degranulation of tissue mast cells and circulating basophils.[163] [164] [165] Some uncontrolled studies have attributed pruritus to hyperhistaminemia or severe iron deficiency, with relief associated with the use of histamine antagonists or ferrous sulfate.[163] [165] [166] Iron replacement is frequently not possible since it can lead to dangerous elevations of the red cell mass. In a number of instances, however, iron replacement has been possible with disease control with interferon-.[247] [255] [256] [257] [258] [259] In one study, myelosuppressive therapy in combination with aspirin resulted in relief from pruritus.[169] The association between pruritus and tissue infiltration by mast cells would appear to explain the response of occasional patients to photochemotherapy with psoralens and ultraviolet irradiation.[263] [264] At present optimal therapy for pruritus appears to be interferon- therapy.[247] [255] [256] [257] [258] [259] Taylor reported that significant pruritus control occurred in 83% of patients treated with appropriate doses of interferon-.

[259] This use of interferon- represents a significant advance in the treatment of a frequently disabling symptom in this patient population.

Budd-Chiari syndrome is a catastrophic illness, which can lead to significant morbidity and mortality in a patient with polycythemia vera.[134] Patients with myeloproliferative disorders are at a high risk of developing this syndrome.[134] Independently, use of oral contraceptive pills is a risk factor for its development; a number of cases of hepatic vein thrombosis have been reported in nonpolycythemic women taking oral contraceptives.[265] Although no data are available, one must be concerned about use of oral contraceptives in women with polycythemia vera.

The optimal approach to the problem of Budd-Chiari syndrome is obviously preventive and involves maintenance of normal blood values in the patient with polycythemia vera.[138] [139] [140] Once the Budd-Chiari syndrome develops, the prognosis without treatment is dismal. The goals of therapy are to prevent further propagation of thrombus, relieve the intense hepatic congestion, and manage the severe ascites that often plague these patients.[140] If untreated, these patients often have a slowly progressive course, with deterioration and death within 3.5 years.[132] Spontaneous resolution of the hepatic vein occlusion rarely occurs. Diuretics may be of value in the treatment of the ascites but do not affect the long-term outcome.[140] Thrombolytic therapy may be expected to have some role in the treatment of patients with acute thrombosis.[132] Anticoagulant therapy may have a role in the prevention of further clot formation, but there has been no definitive evidence that such therapy promotes resolution of established thromboses.[140]

The clinical deterioration of patients with Budd-Chiari syndrome results from damage to the hepatocytes from necrosis associated with marked elevation in sinusoidal pressure, coupled with ischemia from reduced hepatic arteriole perfusion.[132] The only rational therapeutic intervention therefore involves some sort of portal decompression to achieve effective reduction of sinusoidal pressure.[138] [140] A variety of surgical procedures resulting in portal-splenic decompression have been shown to be of value in patients with Budd-Chiari syndrome.[138] [140] [266] [267] Transjugular intrahepatic portosystemic shunt placement has recently been used as a bridge to liver transplantation.[268] [269] [270] Liver transplantation is a potential option for treatment of those patients with continued hepatic decompensation.[271] The hematologic consequences of polycythemia must be aggressively treated in the post-transplant setting, since the hepatic vein occlusion may recur in the transplanted liver.[140]

The performance of any surgical procedures on patients with polycythemia vera is, as previously discussed, accompanied by excessively high morbidity and mortality.[163] [164] [165] Elective surgery should not be contemplated unless the patients hematologic values have been normalized for several months.[163] [164] [165] The longer the hematologic control has been in effect, the lower the incidence of postoperative complications. If emergency surgery is required, the patient should be phlebotomized rapidly until a normal hematocrit is reached and platelets should be available in case excessive perioperative or postoperative bleeding occurs.[163] [165] Following both emergency and elective surgery, the patient should be mobilized as soon as possible and strong consideration should be given to anticoagulation with low-molecular-weight heparin, unless the patient has some contraindication. Dental extractions can also result in excessive hemorrhage and should not be performed unless the patient is under strict hematologic control.[163] [165]

Perhaps the most difficult and frustrating period encountered during the clinical course of a patient with polycythemia vera is the development of PPMM.[123] [124] [125] [126] With more extensive follow-up of patients treated with a variety of therapeutic strategies (1520 years), PPMM appears to be becoming a greater problem in long-term survivors.[133] [134] [135] These patients are frequently symptomatic, as a result of the sequelae of anemia, infection, bleeding, and splenic enlargement.[124] [125] [126] Because few of these patients have been treated in a uniform, controlled fashion, it is difficult to make strict therapeutic recommendations.

The anemia that characterizes the spent phase is usually multifactorial in origin. An important factor is splenic pooling of red cells and expansion of the plasma volume, which occurs as a consequence of splenomegaly.[272] It is therefore important in these patients to obtain red blood cell mass measurements and to quantitate the degree of anemia directly in order to detect those patients who have a low hematocrit but normal red cell mass. Folate or iron deficiency may be important in anemic patients and should be corrected.[124] [125] [126] Almost 20% of patients with PPMM develop overt hemolytic anemia.[124] [125] [126] Some of these patients respond to prednisone therapy, but most require splenectomy. By far the most common cause of anemia is ineffective erythropoiesis,[273] and these patients often require

transfusion therapy. Androgen therapy may be effective in stimulating effective hematopoiesis and diminishing transfusion requirements. [274] Iron overload syndrome secondary to ineffective erythropoiesis or transfusion therapy is a dangerous possibility. In this situation, some consideration should be given to chronic iron chelation therapy.

The clinical course of these patients is frequently punctuated by pressure symptoms secondary to splenic enlargement and repeated splenic infarcts. [124] [126] [275] [276] [277] Treatment must be directed toward decreasing the expansion of a rapidly enlarging spleen. Small doses of busulfan, hydroxyurea, or interferon- therapy may result in the relief of such symptoms;[124] [125] [126] [278] radiotherapy in small doses is also sometimes helpful. [279] [280] Unfortunately, its effect is frequently transient. [126] [279] The chemotherapy or radiation dose must be carefully determined because overzealous use may lead to granulocytopenia and thrombocytopenia. Often, as a last resort, splenectomy is the only reasonable therapeutic maneuver. This procedure in advanced disease is associated with an operative mortality of 25% and should be performed by only the most experienced of surgeons.[275] [276] [277] Surgical intervention should not be inappropriately delayed. [275] [276] [277] Splenectomy in such patients is frequently complicated by excessive hemorrhage and infected hematomas.[275] [276] [277]

Thrombocytopenia may lead to life-threatening hemorrhage in PPMM patients. [124] [125] [126] [280] Its development is due to ineffective thrombopoiesis and/or platelet sequestration by an enlarged spleen and patients may respond to splenectomy. [275] [276] [277] [280] Bleeding due to qualitative platelet abnormalities has been noted in these patients;[119] when it is severe, platelet transfusions are often required, although because of marked splenomegaly such transfusions frequently do not increase platelet numbers. The clinician therefore must follow the extent of hemorrhage as a means of determining the effectiveness of such transfusions. Disseminated intravascular coagulopathy occasionally complicates PPMM and can lead to life-threatening hemorrhage. [275] After careful laboratory documentation, replacement therapy with fresh frozen plasma should be pursued; if that is unsuccessful, a course of low-dose heparin therapy is warranted. If bleeding increases with institution of heparin therapy, the heparin should be quickly discontinued. [275] Some mention should also be made of the use of biological response modifiers for the treatment of PPMM. A number of investigators have suggested that interferon might be useful in the treatment of agnogenic myeloid metaplasia and might be successful in reducing spleen size.[254] [258] [259] [280] Experience with this drug for the treatment of PPMM is limited but occasional remarkable results have been reported. [254] [258] [259] [280]

Information is available concerning the treatment of those patients who develop acute leukemia following polycythemia

---

vera.[186] [262] [281] [282] [283] The overwhelming majority of such cases involve myeloid leukemias, but a small number of patients have a lymphoblastic phenotype. [186] [191] [192] [193] [194] The optimal treatment of such patients is unknown. In the elderly, the choice not to institute chemotherapy is a reasonable option, since results with treatment are so poor. The PVSG has treated 13 patients, irrespective of phenotypic markers, with vincristine and prednisone without a successful response. [186] This group treated the remaining nine patients with a regimen including cytosine arabinoside and adriamycin and were able to achieve a complete remission in one patient and a partial remission in another.[186] The survival for the 13 patients, however, was 32 days from the time of institution of chemotherapy. [186] Hoyle et al., [281] however, have reported more favorable results with an induction regimen of daunomycin, cytosine arabinoside, and 6-thioguanine.

Rare prolonged remissions of acute leukemia following polycythemia vera have been reported in the literature. [282] Some investigators have suggested that the poor prognosis of these patients merits immediate treatment with high-dose cytosine arabinoside in combination with either daunomycin or adriamycin. [281] Because these patients are frequently elderly, poor results with standard regimens have been reported. Alternative approaches to standard therapy are required in these elderly patients with secondary leukemias.[186]

Polycythemia vera occurs infrequently during the childbearing years. [262] When it does, it has been reported to lead to an increased incidence of fetal wastage, with 30% of pregnancies in polycythemia vera patients terminating in spontaneous abortions. [262] [284] [285] In addition, pre-eclampsia occurs more frequently in these women.[262] [284] [285] Pregnancy in polycythemia vera patients is frequently associated with a gradual normalization of blood values, and it is not unusual for a woman who has required extensive therapy for control of her disease to no longer require phlebotomies during pregnancy. [262] [284] [285] Delivery appears not to be complicated by excessive hemorrhage or by an increased risk of venous thrombosis.[262] [284] [285]

The normalization of the hematocrit during pregnancy in polycythemia vera has been associated with lowering of the red cell mass into the normal range in the few patients in whom these measurements have been performed.[262] Although some degree of hematocrit normalization can be explained by expansion of the plasma volume or by nutritional deficiencies that occur during pregnancy, it is unlikely that these factors can be solely responsible. [262] It seems more reasonable to assume that the high estrogen levels characteristic of pregnancy suppress erythropoiesis. In the few male patients with polycythemia vera who have been treated with estrogen, suppression of red cell production has been noted. [262] After termination of the pregnancy, the patients hematologic values slowly drift back to their previously elevated values in parallel with the return to normal estrogen levels. [262] Because pregnancy is usually associated with spontaneous control of the polycythemic state, no specific therapy is required, except for careful observation. If needed, therapy should be limited to phlebotomy and low-dose aspirin therapy because of the mutagenic effects of chemotherapeutic agents.[287] If this management strategy therapy is unsuccessful, interferon therapy is suggested because it is not known to be leukemogenic or teratogenic and does not cross the placenta. [287]

Because polycythemia vera is ultimately a stem cell disorder, it should be potentially curable by bone marrow transplantation. [60] Stobart et al.[288] reported a successful allogeneic transplant of an adolescent with polycythemia vera while De Revel has successfully performed an allogeneic transplant in a 48-year-old female with PPMM.[289] The proper role of allogeneic bone marrow transplantation for polycythemia vera has yet to be defined. Its use should likely be limited to high risk young patients.

PROGNOSIS

The prognosis of a patient with polycythemia vera depends on the nature and severity of the complications that occur during the clinical course of that particular patients disorder.[12] [13] [96] [117] [120] [131] [133] [177] [187] [188] In addition, an individual patients prognosis depends on the duration of the erythrocytotic phase or the time for transition to PPMM or acute leukemia.[11] [96] [117] [120] [131] [133] [177] [187] [188] Survival is also influenced by whether appropriate treatment is instituted during the erythrocytotic phase of the illness. Patients who have uncontrolled erythrocytosis are at an extremely high risk for the development of thromboses. [97] [117] [120] The median survival from onset of symptoms may be as short as 1.5 years in untreated patients.[11] Determination of the optimal management of patients with polycythemia vera has been a difficult task, as the disease, when treated, is associated with a survival of 1015 years. Studies of new potential therapeutic interventions therefore require prospective study with prolonged follow-up before meaningful results can be generated. [185] [186] [187] [188]

The PVSG has shown quite conclusively that survival is significantly poorer for patients treated with chlorambucil than for those treated with either ^{32}P or phlebotomy.[185] [186] [187] [188] On the basis of this study, chlorambucil is not a desirable choice. [185] [186] [187] [188] In this particular study, at least, median survival from entry until death was 10.9 years for ^{32}P-treated patients, 9.1 years for chlorambucil-treated patients, and 12.6 years for the phlebotomy-treated group. [185] [186] [187] [188]

Thrombosis occurred predominantly among the phlebotomy-treated patients, especially during the first 4 years of this study. [185] [186] [187] [188] However, longer follow-up demonstrates a greater number of deaths due to both hematologic and nonhematologic malignancies in patients treated with either of the myelosuppressive regimens.[185] [186] [187] [188] One is left with a serious dilemma in defining treatment for a particular patient. Those who are treated with phlebotomy alone for the first 57 years of their course appear to be at a very high risk of dying from thrombosis. However, with more prolonged follow-up after this 57-year period, patients treated with ^{32}P or one of the other alkylating agents would appear to be at a much higher risk of dying from a malignant disorder. [185] [186] [187] [188]
