APPENDIX: Glossary of Terms

Amphotropic: Term used to describe a retrovirus capable of infecting nonmurine (human) as well as murine cells.

Antisense: Nucleic acid (RNA or DNA) complementary in sequence to the mRNA transcript of a target gene. Antisense molecules are thought to inhibit translation of the target mRNA.

Ecotropic: Term used to describe a retrovirus capable of infecting murine cells.

Gene marking: The introduction of foreign viral sequences into the chromosomal DNA of a patients bone marrow to mark or track cells.

Insertional mutagenesis: Occurs when the retroviral genomes insert into the human genome at or near a gene and cause that nearby gene to behave in a deranged manner that disrupts normal control of cell growth or differentiation.

Integration: Process whereby exogenous genetic material becomes incorporated into the host cell genome. Usually refers to the latent or proviral state of certain viruses in infected cells.

Intracellular immunization: Genetic alteration of a cell to induce resistance to viral (e.g., HIV) replication or infection.

Locus control region: Control elements that flank the human -globin gene cluster and modulate globin gene expression.

Long terminal repeat: Terminal sequences of a retrovirus that usually contain the transcriptional control elements (promoters), polyadenylation signals, and sequences involved in replication and integration.

Promoter: Control element responsible for transcription of a gene.

Provirus: Integrated form of a transducing virus, such as a retrovirus.

Selectable marker: To optimize and enrich for transduced cells, genes encoding for bacterial antibiotic resistance proteins (such as neomycin or hygromycin) are incorporated into the vector. Following transduction, incubation with the antibiotic selects for transduced cells resistant to the antibiotic.

Transduction: The stable transfer of genetic material into a cell, usually implying integration of DNA into the nuclear genome.

Transfection: The uptake of foreign genetic material into a cell. Transfection is usually accomplished by physical means such as co-precipitation of the DNA with insoluble calcium phosphate. Transfected DNA can either exist in the cell as an episomal (extrachromosomal) element or be integrated within the nuclear genome. The efficiency of DNA transfer into cells depends on the particular method used.

Vector: Vehicle for gene transfer.

Chapter 96 - Experimental Cell Therapy

Robert S. Negrin

INTRODUCTION

The use of cellular populations for therapeutic purposes is an attractive alternative to conventional treatment modalities. The exquisite functional specificity of certain cellular populations, as well as advances in our basic understanding of cell biology, hematology, and cellular immunology, has brought these concepts forward. Technical progress in cytokine biology, cellular manipulation, cell separation, and purification have made the idea of isolating a specific cell type and expanding relatively pure populations of cells that are activated and functional a reality. In addition, the prospects for inserting and controlling genetic programs, thereby using cellular populations for gene therapy delivery are improving. This chapter presents some of the basic principles, as well as potential clinical applications, of cellular therapy.

HISTORICAL CONSIDERATIONS

The concept of using cells for therapeutic purposes in hematologic practice is not new. The best example of this is the field of stem cell transplantation (SCT). Early studies following the development of the atomic bomb led investigators toward understanding how radiation injures living organisms. In these experiments, it became clear that mice could withstand an otherwise lethal dose of radiation if their spleens were shielded before exposure. [1] Soon thereafter it was discovered that the infusion of marrow provided similar protection from lethal irradiation. [2] At first this was thought to result from a humoral factor and later it became clear that the transfer of cells was responsible for radioprotection.

Seminal studies in dogs firmly established the role of marrow cells in protecting animals from the lethal effects of radiation. [3] These studies also demonstrated the adverse effects of donor-derived cells, namely that of graft-versus-host disease (GVHD). Further investigation demonstrated that animals surviving long-term not only had a fully intact hematopoietic system but were also tolerant to skin grafts from the donor animals. [4] These studies, and many others, ushered in the modern era of stem cell transplantation. Initially, the beneficial effects of allogeneic SCT were thought to result from the high-dose chemotherapy and radiation therapy used before the transplant. Subsequent studies have demonstrated that SCT is far more complex, with much of the benefit being derived from the transfer of immunoreactive cells capable of exerting a graft-versus-tumor or graft-versus-leukemia (GVL) effect. The existence of a GVL phenomenon was initially based upon the observation that relapse rates were lower in those patients who developed some degree of GVHD, especially chronic GVHD. [5] [6] Further indications of a GVL effect were observed in clinical situations where the effect is absent, such as following an identical twin or syngeneic SCT, [7] [8] or following rigorous T-cell depletion. [9] [10] Direct demonstration of a GVL effect following the transfer of donor-derived lymphocytes has been an important advance in SCT as well as a further demonstration of the powerful therapeutic benefits of cellular therapy. [11]

CLINICAL APPLICATIONS OF CELL THERAPY

Allogeneic and autologous SCTs are examples of cellular therapy routinely used in the clinical setting. This topic is discussed thoroughly in Chapters 85 , 86 , 87 , 88 . Other applications of cellular therapy include the use of donor lymphocyte infusions (DLI) for the treatment and prevention of relapse following an allogeneic SCT, the use of autologous cellular populations for the treatment of malignancies and to prevent relapse following SCT, the use of cytotoxic T lymphocytes for the treatment of viral infections and the use of cell therapy for a vehicle for gene delivery (Table 96-1).

The major cellular populations that have been proposed for cell therapy fall into several broad categories. For a successful SCT, the graft must contain adequate numbers of hematopoietic stem cells. Stem cells and hematopoietic progenitor cells have also been targeted for gene insertion and gene therapy protocols. This population of cells is discussed in Chapter 95 . The other cellular populations useful for cell therapy fall into the general category of immune reactive cells. These include natural

killer (NK) cells and cytotoxic T lymphocytes (CTLs). Some basic biologic features of these cellular populations will be reviewed before discussion of preclinical studies and clinical trials of cellular therapy.

IMMUNOLOGIC EFFECTOR CELLS

The evaluation of immune reactive cells capable of recognizing and lysing tumor cell targets has been the subject of intense investigation. These cellular populations can be divided into two categories. The first category of cells, exemplified by NK cells, are capable of lysing a broad array of tumor cell targets without prior exposure. NK cells have been termed non-major histocompatibility complex (MHC)-restricted, although evidence suggests an important role for certain HLA alleles in NK cell function.[12] The second broad category, characterized by CTLs, are MHC-restricted and recognize cells based upon the appropriate presentation of peptide in the context of MHC proteins. Some overlap exists between NK cells and CTLs; this will be discussed in detail later in this chapter. Despite this overlap, the distinction between MHC- and non-MHC-restricted cytotoxicity continues to be useful.

NK cells have been extensively characterized in both rodent and human systems.[13] [14] [15] These cells generally lack expression of CD3 or other proteins of the T-cell receptor (TCR) complex on the cell surface.[15] [16] [17] [18] Most NK cells express CD56 (neural cell adhesion molecule) and CD16 (the Fc receptor). NK cells are capable of lysing a broad array of tumor cell lines, multidrug-resistant cell lines and autologous tumor cells. [16] NK cells have intracellular cytolytic granules that contain perforin and granzymes. Upon appropriate engagement, these cytolytic granules are secreted into the extracellular space between the NK cell and its target. [19] The perforin molecules, in the presence of Ca^{++} , induce pore formation of the target cell membrane resulting in osmotic lysis, as well as the introduction of granzymes that induce apoptosis.[20] NK cells are capable of cytolysis through a Ca^{++} -independent mechanism controlled by expression of fas-ligand (fasL) which in turn binds to fas on some target cells and induces apoptosis directly.[21] [22] NK cells also express CD16 and are therefore capable of antibody-dependent cellular cytotoxicity (ADCC) which may be important in some clinical settings. In addition to these mechanisms, which require cellular contact, NK cells are also capable of cytokine production such as interferon- (INF-), granulocyte macrophage colony-stimulating factor (GM-CSF) and tumor necrosis factor- (TNF-). [23] The production of cytokines may play a local role in cytolysis of virally infected and malignant cells, as well as in recruiting other immunoreactive cellular populations. Among these mechanisms, the granzyme/perforin mediated cytolysis is thought to be the most important as demonstrated by the marked reduction in NK cell function in knockout animals deficient in these proteins.[24] [25]

NK cells can in turn be activated by several interleukins, resulting in enhanced function. The most potent of these is interleukin-2 (IL-2), which results in modest proliferation and marked activation of NK cells. Activation of NK cells by IL-2 results in a population of cells that have been termed lymphokine activated killer (LAK) cells. LAK cells have been shown to lyse a broad array of tumor cell lines including autologous tumor cells and multidrug-resistant cell lines. Neither NK cells nor LAK cells recognize normal hematopoietic stem cells; however, NK cells do lyse endothelial cells. [26] [27] Several other cytokines have also been characterized that activate NK cells in addition to IL-2. The most potent of these cytokines was initially called natural killer cell stimulating factor and later renamed IL-12. [28] [29] IL-12 binds to a distinct heterodimer receptor on the surface of NK cells, resulting in enhanced activity. [30] [31] IL-15 is another cytokine that has been characterized and cloned and which also activates NK cells by binding to components of the IL-2 receptor. [32] [33] Both IL-2 and IL-12 have been used clinically with promising results in some clinical settings.

Recently, a number of investigators have identified specific receptors on the surface of NK cells that serve an inhibitory function. [34] These receptors, termed killer inhibitory receptors (KIRs), are present on the surface of some NK cells and upon engagement inhibit NK function. Genes for several of the KIRs are located on chromosome 19.[35] Interestingly, KIRs recognize certain HLA class I alleles that inactivate the NK cells. [36] KIRs recognizing HLA-A, -B, and -C alleles have been characterized and cloned.[37] [38] [39] [40] The role of peptide has been somewhat controversial because some KIRs do not appear to be peptide-specific; whereas others are peptide-specific. [41]

A functionally analogous but structurally dissimilar family of receptors has been identified on murine tissue. These receptors are clustered in a region designated the NK cell complex, which is found on murine chromosome 6. [42] Two families of proteins, termed NKR-P1 and Ly-49, have been identified. Like human KIRs, engagement of Ly-49 molecules inhibits NK cell function. [43]

NK cells are thought to form the first line of defense against viral infections and may also play a role in tumor surveillance. The finding of inhibitory receptors on NK cells suggests that viral infection or malignant transformation may either down-regulate certain HLA alleles or may alter peptide presentation so that these molecules no longer block NK function resulting in engagement and cytolysis. Alternatively, activatory receptors may be expressed on these abnormal cells, and these may be recognized by NK cells and overcome any inhibitory signal. [44]

In contrast to NK cells, the mechanistic aspects of CTLs are well described. CTLs recognize their targets through engagement of the TCR, which specifically binds to HLA class I and II molecules expressing an appropriate peptide. [45] In order for a productive interaction to occur, accessory and costimulatory molecules are also necessary.[46] In the absence of costimulatory molecules, anergy results. However, if the TCR is engaged along with costimulatory molecules, a productive interaction results in the synthesis of cytokines such as IL-2 and clonal expansion. [47] The best-characterized system of costimulatory molecules is the CD28-B7 system of which at least two members, B7.1 and B7.2, have been cloned and extensively studied. [46]

The expansion of CTLs occurs through the presentation of peptide antigens by accessory cells termed antigen presenting cells (APCs) These APCs not only express HLA molecules but are capable of processing antigens and presenting peptides. APCs also express costimulatory molecules and are capable of cytokine production. Several different APC populations have been described, the most potent of which are cells termed dendritic cells.

In addition to these protein molecules, adhesion molecules such as leukocyte function antigen-1 (LFA-1) and its counter-receptor, intracellular adhesion molecule-1 (ICAM-1), play important roles in both NK and CTL function.[48] Binding of the TCR

TABLE 96-2 -- Possible Mechanisms of Tumor Cell Evasion of the Immune System

Inhibition of NK cell function through the appropriate expression of HLA molecules
Lack of expression of tumor-specific antigen or peptide
Lack of costimulatory and/or adhesion molecule expression by the malignant cells
Resistance to apoptosis
Expression of fas-ligand on the tumor cell, thereby inactivating fas-expressing effector cells

results in an increased affinity of LFA-1 toward ICAM-1 for a finite period of time, which allows a stable interaction. [49] Cytotoxic granule contents are then recruited along the cytoskeleton and released into the space between the two cells, resulting in pore formation by perforin and induction of apoptosis by the granzymes. [50] [51] For perforin to function properly, Ca^{++} is required. In addition to granzyme/perforin-mediated lysis, a Ca^{++} independent pathway mediated through fasLfas interactions also plays an important role in CTL-mediated cytotoxicity. [21] [52]

These mechanistic studies suggest strategies for therapeutic intervention, many of which are discussed later in this chapter. They also demonstrate the complexity of the system and suggest mechanisms by which tumor cells may escape recognition by the immune system (Table 96-2). With respect to NK cell-mediated killing, tumor cells may merely inactivate the effector cells through the appropriate expression of MHC molecules to escape lysis. The fact that many investigators have demonstrated autologous cytolysis of tumor cell targets suggests that this inhibition can be overcome. In regard to CTL recognition of tumor cell targets, a number of mechanisms of escape are possible. First, there may not be tumor-specific antigens that can be recognized by CTLs. Investigators have searched intensively for tumor-specific Ags, which have been identified for a minority of malignant cells. [53] Second, if tumor cells do not express costimulatory molecules, anergy results. This has been shown in a number of tumor cell types.[54] Third, tumor cells may be relatively resistant to apoptotic signals. Finally, recent evidence has indicated that certain tumor cell types express fasL. FasL expression was initially demonstrated on melanoma cells, and has subsequently been found on a variety of other tumor cell types including myeloma cells. [55] [56] Therefore, tumor cells expressing fasL could inactivate CTLs by inducing apoptosis of the effector cell through engagement of fas. The significance of these various mechanisms of tumor cell escape and the development of strategies designed to overcome them is an area of intense basic and clinical investigation.

CLINICAL APPLICATIONS OF CELL THERAPY IN HEMATOLOGY

Clinical settings in which cell therapy has been applied in hematologic practice are outlined in Table 96-1 and in the following sections.

Donor Leukocyte Infusions for Treatment and Prevention of Relapse

The use of DLI to treat patients who have suffered a relapse following allogeneic SCT has been an exciting advance that further documents the importance of GVL reactions. The first patient treated with DLI was a 2.5 year old child with ALL who was treated in 1986. [57] [58] This patient reentered a complete remission and continues to survive in CCR at least 10 years later. Kolb et al. reported on three allogeneic SCT recipients with relapsed CML who were treated with interferon- and DLI, all of whom entered complete hematologic and cytogenetic remissions. However, the clinical course of these patients was complicated by GVHD. [11] Since that time, a significant number of patients have been treated throughout the world with exciting results. A summary of these results is presented in Table 96-3 . Drobyski and colleagues treated eight patients with CML who suffered a hematologic relapse after allogeneic SCT, six of whom were in accelerated phase and two in blast crisis (BC). These patients received a predetermined T-cell dose between 2.55 × 10^8 T cells/kg.[59] Some patients were also treated with interferon-. Seven patients developed GVHD that was fatal in one, and four patients developed marrow aplasia. Both patients with BC died, whereas all six patients who received the DLI treatments in accelerated phase were alive and in cytogenetic remission at a median of 42 weeks from the infusion at the time of the report. These early studies pointed out much of the promise, as well as some of the problems of DLI therapy such as GVHD and aplasia.

An additional 11 patients with CML were reported who were treated with a combination of IFN- and DLI. Three patients developed significant GVHD and limited cGVHD developed in five patients. Six of eight patients with chronic phase CML after SCT had complete remissions, whereas none of the three patients with accelerated phase CML entered remission. [60]

Collins et al. reported on an additional 18 allogeneic SCT recipients, eight of whom had diseases other than CML. Six patients responded to DLI treatments, including two of five patients with AML. [61] GVHD was reported in seven patients; however, no patient developed marrow aplasia in this study.

The Hadassah group used DLI combined with IL-2. Seventeen relapsed allogeneic SCT recipients were reported of whom 10 were reinduced into CR. [62] Four patients with cytogenetic relapses responded to DLI alone, whereas five of six responding patients treated at the time of hematologic relapse appeared to require both DLI and IL-2.

Two large retrospective analyses of DLI for post-SCT relapse have been reported from Europe and North America. The results of the European Group for Blood and Marrow Transplantation have further documented the beneficial effects of DLI. In a series involving 27 transplant centers, 84 relapsed SCT patients had CML and of these 54 (73%) were induced into CR with DLI. Only five (29%) of the patients developed a CR, and none of the 22 patients with ALL had a CR. [63] These results are presented in Figure 96-1 . Fifty-two patients (41%) developed clinically significant GVHD and 41 patients (54%) had myelosuppression from the DLI. Seventeen patients (12.6%) died of causes other than their underlying leukemic disorder.

A similar review of 25 North American bone marrow transplant programs was performed. In this study, 140 SCT recipients with relapsed disease underwent DLI. [64] Again, CML patients

TABLE 96-3 -- Cumulative Results of Donor Leukocyte Infusions for the Treatment of Relapse Following an Allogeneic Stem Cell Transplant

Author	Number of Patients	Cell Dose × 10^8 /kg	GVHD	Myelo-suppression	CR

			(41.2%)	(25.5%)	(41.2%)

GVHD, graft-versus-host disease; CR, complete response.

[a] T cells.

Figure 96-1 Probability of survival of patients who have relapsed following an allogeneic stem cell transplant and who were subsequently treated with donor leukocyte infusions. Survival is based from the time of the donor leukocyte infusion. Results are for patients with CML (chronic myelogenous leukemia), PCV (polycythemia vera), ALL (acute lymphocytic leukemia), AML (acute myelogenous leukemia) and MDS (myelodysplastic syndrome). *(Reprinted with permission from Kolb et al.[65])*

responded the best, with 60% CR rates following DLI. Responses were better for patients with cytogenetic and chronic phase relapses, compared to patients with accelerated or blastic disease. Responses were durable, as actuarial probability of remaining in CR at two years was 89.6%. Results were not as favorable for SCT recipients with relapsed AML (15.4% CR) or ALL (18.2% CR). It is interesting to note that two of four patients with multiple myeloma responded to DLI. Complications included GVHD (60%) and pancytopenia (18.6%).

Overall, these results indicate that DLI has substantial efficacy in the control of relapse following allogeneic SCT. This is especially true for SCT recipients with CML detected in cytogenetic or early hematologic relapse. Upon progression to accelerated or blastic phase of the disease, DLI clearly has less efficacy. Studies are currently in progress to determine whether SCT recipients with only molecular evidence of recurrence detected by the polymerase chain reaction (PCR) will also benefit from DLI. Donor leukocyte infusions in SCT recipients with relapses of acute leukemia have been less successful. This may be a result of the more rapid proliferative capacity of these cells. Some groups have advocated the use of chemotherapy to gain control of the disease before DLI is performed. Importantly, the responses achieved with DLI in a variety of diseases, especially CML, have been durable.

Donor leukocyte infusion has also been used to treat patients who develop Epstein-Barr virus-induced lymphoproliferative disease (EBV-LPD), which occurs following allogeneic SCT, especially in patients who have undergone T-cell depleted SCT. [65] [66] Anti-EBV cytotoxic T-lymphocyte precursors have been assessed and found to be deficient in the time period when patients develop EBV-LPD. [67] Papadopoulos and colleagues performed DLI treatment for five patients with EBV-LPD. These tumors were of B-cell origin, and in at least four of the patients were of donor origin. In this study, patients were treated with DLI at a dose calculated to provide 1×10^6 CD3+ T cells/kg of recipient body weight. In all five patients, there were complete pathological or clinical responses first documented within 821 days following the infusion. [68] In at least three of these patients, long-term durable remissions were achieved, and the other two patients died of respiratory failure without evidence of lymphoma.

Despite these encouraging results, both DLI and myelosuppression complicate therapy. Timing of therapy following DLI is complicated by the fact that GVHD has been related to tumor response with DLI. Some groups have explored the concept of a defined dose of T cells for infusion. In one study, a T-cell dose of 1×10^7 T cells/kg resulted in a low incidence of GVHD with a clear antitumor cell response. [69] Other groups have attempted to deplete CD8+ cells in an effort to reduce the incidence of GVHD while retaining GVL activity. [70] [71] These studies are difficult to interpret because of patient and disease heterogeneity. Additional studies are required to determine whether this approach improves results.

Another approach involves genetically modifying the donor lymphocytes so that they are susceptible to certain drug treatments that will allow for their eradication if the patient develops GVHD. Ganciclovir treatment of cells containing the herpes simplex virus thymidine kinase (HSV-TK) gene results in cell death. Donor lymphocytes have been transfected with the HSV-TK gene by retroviral mediated gene transfer, and those transfected donor lymphocytes have been infused into patients who have relapsed or developed an Epstein-Barr virus-induced lymphoma. In one study of eight patients, the transferred lymphocytes survived for up to 12 months and resulted in anti-tumor activity in five of the patients. Three patients developed GVHD, which could be controlled by treating the patients with ganciclovir. [72] These exciting data pave the way for engineering cell types with specific functions whose activities can be controlled with certain drug treatments.

The other major complication associated with DLI has been myelosuppression, and in some instances severe pancytopenia requiring retransplantation. The more severe cases have been observed in patients who have no evidence of donor-derived hematopoiesis at the time of DLI. [73] Work is needed to define the optimal approach to DLI and to determine which population(s) of cells is responsible for the observed clinical effect.

Ex Vivo Activated Cellular Therapy for Treatment of Malignancies

Natural Killer Cell-based Cellular Immunotherapy

The observation that effector cell populations are capable of recognizing autologous tumor cell targets and that these cells can be activated with ex vivo treatment such as IL-2 has generated enthusiasm for clinical application. Treatment with IL-2 and IL-2-activated NK cells or LAK cells has met with some success; however, the requirement for IL-2, which has severe toxicities, has dampened enthusiasm. [74] In addition, many of the patients treated with LAK cells had advanced and/or refractory disease. Clinical responses have been observed, some of which are dramatic; however, most patients have not responded or have progressed.

Improvements in cell selection and cell culturing techniques, as well as basic advances in cytokine biology and cellular immunology, have renewed interest in the use of ex vivo activated cellular immunotherapy. Cellular immunotherapy could be used in a variety of ways; however, following SCT appears to be an ideal clinical time to test the effectiveness of this approach. The majority of patients are in a state of minimal residual disease following the transplant, and cellular immunotherapy is more likely to be effective. In addition, the precursor populations required, as well as the expertise in cellular manipulation, is readily available.

Autologous LAK cells have been obtained from patients with hematologic disorders such as lymphoma, acute leukemias, and CML. One approach has been to culture marrow cells in the presence of IL-2 for 24 hours, which results in tumor cell purging and a graft-versus-tumor effect in murine model systems. [75] [76] Similar results have been obtained using human marrow

cells purposefully spiked with tumor cells. Incubation with IL-2 resulted in effective purging of the malignant cells without excessive toxicity against normal hematopoietic stem cells. [77] [78] This approach has been extended to human phase I/II clinical trials with the hope that the in vitro activation of marrow cells with IL-2 will provide effective tumor cell purging and transfer of a graft-versus-tumor effect. [79]

Several studies have been performed using LAK cells with IL-2 following autologous SCT. Benyunes and colleagues performed a study of 16 patients with malignant lymphoma and five patients with AML who underwent apheresis to obtain peripheral blood lymphocytes (PBLs) following autologous SCT. The apheresis products were incubated with IL-2 at 300 U/ml for 5 days and then reinfused. The infusion of the cells was associated with transient dyspnea requiring O_2 therapy and which resolved within several hours. Four of five patients with AML were in continuous complete remission (CCR) from 1325 months at the time of the initial report. [80] Seven of the 16 lymphoma patients were relapse-free at the time of a subsequent report two years later. [81] In these studies, it was technically difficult to obtain the PBLs by apheresis following autologous SCT due to thrombocytopenia, especially in AML patients in whom prolonged thrombocytopenia is common following an autologous SCT using marrow as a source of stem cells. Presumably, the use of peripheral blood as a source of stem cells for transplant would make it easier to perform apheresis following transplantation due to the more rapid recovery of platelets. In addition, IL-2, which may have substantial biologic activity of its own, was also administered to these patients. [82] Therefore, it is difficult to know whether the cellular component or the IL-2 itself was responsible for any positive results in these studies. A further difficulty has been the relatively poor expansion of NK cells ex vivo. However, advances have been made in the cultivation of NK cells. [83] [84]

Another population of adherent NK (ANK) cells has also been used for immunotherapy. ANK cells are selected by binding to plastic surfaces and cultured in the presence of IL-2 and concanavalin-A activated allogeneic feeder cells. After several days in cultures, these cells develop enhanced cytotoxicity against a variety of target cells and have a phenotype similar to that of NK cells. ANK cells have been used to treat patients with hematologic malignancies following autologous transplantation. These studies are in an early stage, and to date minimal toxicity has been encountered. [85] IL-2 was also used following the infusion of the cells.

Lymphokine-activated natural killer cells have been utilized outside of the transplant setting for the treatment of solid tumors. Responses have been noted in some patients with malignant melanoma and renal cell carcinoma. [86] [87] [88] Relatively few patients with hematologic malignancies have been treated with LAK cells outside the SCT setting. In one study of 117 patients, an overall response rate of only 9% was observed. Of six patients with lymphoma, none responded. [89]

In addition to the toxicities noted previously, immunotherapy with IL-2 and LAK cells has also been associated with a number of hematologic toxicities. In one study of 42 patients, the majority (88%) of patients developed anemia that required >4 units of red cell transfusions, and 43% developed thrombocytopenia with platelet counts <50,000/l. Mild neutropenia was also observed. [90]

There is much room for improvement in defining biologically active cell populations, in activation ex vivo, and in careful selection of patients to improve upon current results.

Cytokine-Induced Killer Cells

Other approaches have been developed to expand populations of effector cells with antitumor cell activity. In addition to CD3-CD56+ NK cells, certain populations of CD3+ cells have also been shown to have antitumor cell cytolytic activity. [91] [92] One population of CD3+ T cells that co-express the NK cell marker CD56 has

demonstrated activity against a number of tumor cell lines.[93] CD3+CD56+ cells are rare in peripheral blood and represent only 15% of T cells from normal individuals.

Novel protocols have been developed by combining T cell mitogenic stimuli with cytokines such as IL-2. This results in the expansion of T cells that are further activated and are capable of recognizing tumor cell targets.[94] One approach has been to pretreat cells with interferon- followed one day later with anti-CD3 monoclonal antibody (MAb) and IL-2. Cells expand rapidly under these culture conditions, and the resultant effector cells have been termed cytokine-induced killer (CIK) cells.[95] [96] In these cultures, the cells with the greatest cytolytic activity have the phenotype CD3+CD16CD56+.[97] The CD3+CD56+ cells are derived from CD3+CD56 T cells and not from CD3CD56+ NK cells. CD3+CD56+ cells do not express CD16 and are therefore not capable of ADCC, yet do contain granzymes and perforin, which are released in the presence of tumor cell targets, or by crosslinking of CD3.[98] The expansion of CD3+ CD56+ T cells is augmented by other cytokines in addition to IL-2, with IL-12 being the most important.[99] Under these cultures, endogenous IL-12 is released by monocytes upon activation with IFN-.[100]

The in vivo activity of CIK cells has been tested using mice with severe combined immunodeficiency (SCID) that lack functional B and T cells and accept human tumors.[101] [102] In one series of experiments, human PBLs were purposefully contaminated with SU-DHL-4 tumor cells, which are a B cell NHL cell line with a t(14;18) chromosomal translocation that can be sensitively amplified using the PCR.[103] The mixed cells were incubated with or without CIK cells for 24 hours and then injected into SCID mice. The CIK-treated cultures did not result in tumor cell growth and animal death whereas the control cultures resulted in animal death after approximately 40 days (Fig. 96-2).[95] Further experiments were performed in which SU-DHL-4 tumor cells were injected into SCID mice and were followed one day later by CIK cells or LAK cells. In these experiments, CIK cells were found to have significantly greater antitumor activity compared to the LAK cells.[97] Approximately 3040% of the animals became long-term survivors and were completely free of disease as assessed by t(14;18) PCR. Using CIK cells in this animal model, IL-2 is not required for in vivo activity in contrast to LAK cells. CIK cells have also been expanded from a number of patients with hematologic diseases. Notably, the cells expanded from patients with CML are Philadelphia

Figure 96-2 Effect of treating SCID (severe combined immunodeficiency) marrow cells purposefully contaminated with SU-DHL-4 cells (human B-cell lymphoma) with cytokine-induced killer cells. *(Reprinted with permission from Schmidt-Wolf IGH, Negrin RS, Kiem H et al: Use of a SCID mouse/human lymphoma model to evaluate cytokine-induced killer cells with potent antitumor cell activity. J Exp Med 174:139, 1991. Copyright The Rockefeller University Press.)*

chromosome-negative and are capable of exerting antitumor cell activity against autologous CML cells engrafted in SCID mice.[104] The ability of the CIK cells to expand ex vivo and their biologic activity observed in the absence of IL-2 makes this population of cells attractive for clinical application.

Cytotoxic Cell Lines

A problem with the use of ex vivo activated cell populations has been the variability in expansion and biologic activity of the effector cells. One approach to overcoming this limitation is to isolate stable cell lines with cytotoxic activity. Several such cell lines developed from patients with leukemia and lymphoma have been adapted to tissue culture. These cell lines have phenotypic and biologic characteristics that are very similar to those of NK and CIK cells.

The cell line TALL-104 was developed from a child with acute T-cell lymphoblastic leukemia. TALL-104 cells lyse a broad panel of tumor cell lines yet do not lyse normal tissues.[105] These cells are CD3+, TCR+, CD4, CD8+, CD16, CD56+, a phenotype similar to that of cells expanded in CIK cultures. TALL-104 cells have been used in vivo in SCID mice experiments using the human myelomonocytic leukemia cell line U937. In this model system, the TALL-104 cells protected the mice from an otherwise lethal challenge of U937 cells.[106] Irradiated TALL-104 cells have been used to treat dogs with a variety of different malignancies without toxicity. A number of the animals whose malignancies were refractory to other therapies responded to this form of cellular immunotherapy.[107]

The NK-like cell line NK-92 has been used for in vitro purging studies. NK-92 cells are CD3CD16CD56+ and react against a wide variety of target cells.[108] [109] Another cell line termed NKL, which is CD3CD16+CD56+, has morphology similar to that of a typical NK cell.[110] These cells are capable of lysing target cells via a typical granzyme-perforin mediated mechanism, as well as by ADCC resulting from the presence of CD16.

These cell lines have the theoretical advantage that a continuous source of cellular material is available. However, the cell lines are genetically dissimilar to those of the recipient and therefore would be rapidly cleared if used in vivo. If they are not cleared, they may result in GVHD.

Cytotoxic T Lymphocytes

The specificity of CTLs has made their clinical application an attractive goal. As discussed previously, CTLs recognize their target cells through the appropriate expression of a peptide associated with the MHC molecule in the context of a specific T-cell receptor expressed on the surface of the T cells. Other molecules such as costimulatory molecules and adhesion molecules must also be present in order for a productive interaction to occur. Considerable effort has been made to identify and expand CTL populations capable of lysing target cells. This has proceeded in two areas, namely the recognition of virally infected cells and the recognition of tumor cell targets. The recognition of virally infected cells is theoretically a simpler proposition due to the exogenous nature of the viral infection and the ability to replicate such interactions in vitro. The clinical settings that have been explored for CTL therapy most extensively are those of EBV and CMV infection.

Human EBV-specific cytotoxic T lymphocytes have been selected from PBLs isolated from seropositive donors and expanded ex vivo. These CTLs exhibit strong EBV-specific and HLA-restricted activity in vitro. In order to study their in vivo activity, SCID mouse models have been developed in which animals are inoculated with PBLs from EBV seropositive donors or with EBV-transformed lymphoblastoid cell lines. These animals develop lethal human EBV+ B-cell lymphoproliferative disorders that are similar to those that arise in immunodeficient patients. Using this model system, EBV-specific CTLs were capable of enhancing SCID mouse survival.[111] The EBV-specific CTLs were active when injected either intraperitoneally or intravenously. In addition, SCID mice that were tumor-bearing with large subcutaneous EBV+ tumor cells had regression following the injection of 10^7 EBV-specific CTLs. Prior experiments with adoptive transfer of peripheral blood mononuclear cells, purified T cells, IL-2 activated PBLs, or anti-CD3 activated T cells derived from EBV seropositive donors into EBV-infected SCID mice did not result in improved survival of the mice.[111]

Studies have also been performed using EBV-specific CTL cell lines in patients. In one report, 10 allograft recipients who were at risk for EBV-LPD received infusions of EBV-specific CTLs. The infusions were well-tolerated without significant toxicity. Three patients showed signs of EBV reactivation with an increase in EBV-DNA copy number. In these three individuals who received CTL injections, all three showed a marked decrease in EBV copy number following the infusion (Fig. 96-3).[112] In addition, one patient, who received four infusions, had resolution of an immunoblastic EBV-associated lymphoma. These CTLs had been gene-modified before infusion, and these investigators showed, using PCR analysis, that the cells persisted for 10 weeks after administration.[112]

CD8+ cytotoxic T-cell clones have also been generated against CMV-infected cells. These CD8+ CTLs were isolated from the blood of the patients donor. In 14 patients, the CTLs were infused into recipients beginning at 3040 days after SCT. In these patients, cellular immunity against CMV was monitored before, during, and after the infusions of the CTLs.[113] The infusion of the cells did not result in toxicity. In vitro studies of blood samples isolated from these individuals demonstrated that cytotoxic activity against CMV was significantly increased after the infusions in 11 of the patients who were deficient in this activity before therapy (Fig. 96-4). By performing PCR analysis of T-cell receptor genes in the individuals, it was demonstrated that the transferred cells persisted for up to 12 weeks. None of these individuals developed CMV disease.[113]

These striking results underscore the potential clinical efficacy of CTL-mediated immunotherapy. The positive results demonstrate not only feasibility but also that these effects can be persistent and have clear biologic activity. The isolation and expansion of CTLs is laborious and costly, and despite these successes, there are considerable obstacles that need to be overcome to make CTL therapy a treatment option for patients with malignancies. Another major drawback has been the lack of tumor-specific antigens that can be recognized by T cells. Significant advances have been made in this field, and a number

of human tumor antigens have been identified that are recognized by T cells. [114] [115] These have primarily been identified on the surface of melanoma cells, particularly the MAGE system. Tumor-specific HLA A2 restricted CTLs have also been developed against metastatic breast cancer cells that showed tumor-specific recognition of the tumor cells yet no detectable lysis of normal cells or of K562 tumor cells. [116] The cytotoxicity of these CTLs against HLA A2 positive allogeneic targets was significantly higher than that of HLA A2 negative tumor cell lines. In this particular study, the target antigen was not identified. CTLs have been isolated and expanded that recognize tumor-associated mucins, which are frequently expressed on breast cancer cells. [117] Other researchers have developed CD3 + + CTLs from peripheral blood lymphocytes of breast cancer patients that also had cytolytic activity against autologous tumor cells yet lacked lysis of NK-sensitive lines. [118] The cytotoxic activity of these clones could be inhibited with anti-LFA-1 MAbs but could not be abolished by MAbs against CD3, class I, or class II MHC molecules. This suggests that these CTLs will recognize their tumor cell targets independent of the T-cell receptor by a not-yet-defined mechanism. [118]

A number of groups have attempted to generate CTLs against leukemic cells. In one study, irradiated leukemic cells from a patient with AML were used as stimulator cells, and the peripheral blood from the HLA matched identical sibling donor was used as responder cells. Several CTL lines were generated that had specific lysis against the recipient leukemic cells in chromium release cytotoxicity assays. Two such CTL lines were cloned by limiting dilution and were found to be HLA class I and II restricted.[119] These studies demonstrate the feasibility of generating CTLs against these types of malignancies; however, they also underscore the difficulty in obtaining and expanding such clones to a sufficient number of cells for clinical use. An alternative approach has been to use CTLs that are reactive against minor histocompatibility antigens and determine whether or not these cells will also recognize clonogenic leukemic cells. Faber and colleagues have performed such studies and demonstrated that the CD8+ CTL clones were able to recognize minor histocompatibility antigens HA-1 and HA-2. [120] However, these minor histocompatibility antigens are also expressed on immature hematopoietic progenitor cells.

An alternative approach has been to extract and culture lymphocyte infiltrating tumors (tumor-infiltrating lymphocytes [TILs]). The cells with the majority of activity in these cultures are typical CTLs with the phenotype of CD3+CD8+CD56 and are MHC-restricted. [121] [122] Tumor infiltrating lymphocytes are reported to be more potent than LAK cells; however, the generation of sufficient numbers of TIL cells with antitumor activity is difficult. In addition, TILs are often difficult to obtain or are not available from patients with hematologic malignancies.

A number of reports have suggested that tumor cells may lack the appropriate costimulatory molecules necessary for a productive interaction between tumor cells and CTLs. In an attempt to overcome this, follicular lymphoma cells were preactivated with CD40, which is known to upregulate expression of costimulatory molecules including the B7 proteins. Using this approach, autologous TILs could be expanded by the addition of IL-2 and further expanded in the presence of IL-4, IL-7, or gamma interferon.[123] These activated T cells showed cytotoxicity against follicular lymphomas in four of five patients tested. These studies suggest that CTLs may not be stimulated by the appropriate microenvironment of the tumor. This may occur because tumor cells lack expression of the appropriate costimulatory molecules that may be upregulated ex vivo to enhance the generation of CTLs. In fact, many tumor cells do not express the costimulatory molecules B7-1 and B7-2. [124] [125] Another approach has been to introduce these costimulatory molecules into the tumor cells by transfection. This has been performed successfully and results in enhanced recognition or rejection of transfected tumor cells using in vivo model systems. [126] These observations have also been extended to hematopoietic tumors such as murine AML cells that have been found not to express B7-1, which was then transfected into the tumor cells with a B7-1 containing retrovirus. The resulting transduced AML cells were used in murine models that induced immunity against the wild type AML cells. [127] However, these studies were performed in animals that had not been previously exposed to the leukemic cells. It remains to be seen whether the injection of B7-expressing tumor cells into diseased hosts or patients will overcome anergy.

Antigen-Pulsed Dendritic Cells

Antigen-presenting cells (APCs) present peptide antigens to T cells and thereby initiate a cellular immune response. These professional APCs also express critical accessory molecules required in this process and produce cytokines. The most potent APCs identified to date are a population of cells termed dendritic cells (DCs). Dendritic cells are characterized by the morphologic appearance of large cells with an elongated stellate process. Dendritic cells express high levels of MHC molecules B7-1, B7-2, CD40, ICAM-1, and LFA3. Dendritic cells lack expression of surface markers typical for T, B, and NK cells, as well as monocyte markers, and have been identified and purified based on their density characteristics. [128] [129] [130] [131] [132] Dendritic cells can be isolated from PBLs or expanded from CD34+ progenitor cells by culture in the presence of cytokines such as TNF, IL-4, c-kit ligand, GM-CSF, and CD40 ligand. [133] The hematopoietic growth factor flt3 ligand has been reported to increase the number of functional DCs in the bone marrow, gastrointestinal lymphoid tissue, liver, lymph nodes, peripheral blood, spleen, and thymus of treated animals.[134]

Cultured cell lines, such as the T2 line, have also been developed that can serve as APCs under the appropriate culture conditions. T2 cells lack the transporter proteins required for peptide presentation of endogenous proteins and are unable to present endogenous antigens. T2 cells, however, when pulsed exogenously, can present peptide to T cells. [135] This approach has been used to generate CTLs specific for a peptide derived from proteinase 3, and these CTLs preferentially recognize and lyse

human myeloid leukemia cells expressing HLA A2.[136] In this particular instance, the T2 cells were pulsed with a 9-mer peptide termed PR1 that was synthesized and tested for binding to HLA A2. A similar approach has been performed using peptide antigens that span the breakpoint of the *bcr-abl* gene of CML and bind with high affinity to HLA molecules. These peptides could elicit specific class I restricted CTLs in vitro from HLA-matched healthy donors. In this initial study, these peptides were specific for HLA A3 and HLA A11.[137] A second group has identified a 17 amino acid peptide that again spans the *bcr-abl* infusion region and which resulted in specific CD4+ T cell lines that were HLA DR4-restricted. [138] An alternative approach has been to use CD34+ cells isolated from patients with CML that are then cultured in vitro under conditions that stimulate their differentiation into DCs. These cells are then able to present antigen to T cells in vitro. [139]

The in vivo application of DCs that were pulsed in vitro has been demonstrated in murine models. Murine DCs pulsed with tumor antigens induced tumor resistance even after a single treatment in vivo. [140] [141] [142] The protective tumor immunity is antigen-specific and CTL-mediated as shown in Figure 96-5 . In this study, a peptide antigen corresponding to the amino acid sequence of ovalbumin residues 257264 was synthesized and used to pulse murine DCs. The DCs were expanded from lymphocyte-depleted marrow cells in the presence of GM-CSF and IL-4. These DCs were then pulsed for 2 hours with or without the ova peptide plus beta-2 microglobulin and then washed extensively before being injected into mice. The animals were then challenged with a syngeneic melanoma cell line (B16) or a second cell line formed by a transfection of B16 with an ovalbumin-containing plasmid (MO5). The animals treated with DCs rejected the MO5 but not the B16 tumors, and this required CD8+ T cells for activity. [143]

Pulsed DCs have been used to treat patients with follicular lymphoma by Hsu and colleagues. In these studies, human DCs were harvested from PB by differential centrifugation and pulsed with patient specific idiotype antigen. The pulsed DCs were then infused into patients with non-Hodgkin lymphoma. In this study, four patients with follicular B-cell lymphoma were treated with a series of idiotype pulsed autologous DC infusions followed by subcutaneous injections of soluble idiotype. Antitumor immunity was demonstrated in vitro, and significant tumor regressions were noted in two patients with the resolution of molecular disease in a third patient (Fig. 96-6).[144] This powerful approach is limited by the requirement for a purified tumor-specific protein or peptide for each patient that is currently available only in a minority of tumor types. In addition, these peptides react with certain HLA alleles. Currently clinical trials are ongoing using antigen-pulsed DCs to treat patients with low grade non-Hodgkin lymphoma and multiple myeloma following autologous and allogeneic SCT.

Figure 96-5 Tumor immunity induced by peptide-pulsed dendritic cells. C57 BL/6 mice were immunized with either PBLs (open symbols) or peptide-pulsed dendritic cells using an ovalbumin peptide.

The MO5 cell line (panels A and D) has been transfected with ovalbumin whereas the B16 cell line (panels B and E) is the parental non-transfected line. CD8+ cells are responsible for the biological effect because depletion of this population of cells in vivo with an anti-CD8 MAb results in increased tumor size (panel C) and loss of the protection afforded by the peptide pulse dendritic cells (panel F). *(Reprinted with permission from Celluzzi CM, Mayordomo JI, Storkus WJ et al: Peptide-pulsed dendritic cells induce antigen-specific CTL-mediated protective tumor immunity. CONCLUSION

The use of cellular therapy to treat a variety of conditions is under intense laboratory and clinical investigation. Some forms of cellular therapy are part of routine clinical care, whereas others are only now being developed. The rapid expansion in basic biologic understanding of the types of effector cells and the role of accessory cells and molecules, as well as the cytokines that expand and activate these cells, has resulted in renewed optimism. Ongoing and future clinical studies will determine where this novel therapeutic approach will be best applied in clinical medicine.

Chapter 97 - Complications After Stem Cell Transplantation

Daniel J. Weisdorf

The high-dose therapy used in hematopoietic stem cell transplantation (SCT) results in clinical toxicities induced directly by the treatment and secondarily by the prolonged immunodeficiency and extended recovery process. Recognition of clinical risk factors for particular complications allows risk-specific supportive care regimens to be designed that can reduce the overall morbidity and mortality accompanying transplantation (Table 97-1).

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

EARLY TRANSPLANT-ASSOCIATED COMPLICATIONS

High-dose chemotherapy and radiation regimens are used before transplantation for both antineoplastic and immunosuppressive effects. However, these treatments may also damage host tissues, resulting in significant clinical morbidity. [1] These toxicities may include oropharyngeal mucositis, [2] hepatic veno-occlusive disease (VOD), interstitial pneumonitis (IP), and hemorrhagic cystitis. [3] Each of these toxicities may simulate infections or be compounded by concurrent infections. In addition, because epithelial tissue repair may be delayed by ongoing neutropenia and local microinvasive infection, delay in hematopoietic engraftment can exaggerate and prolong these toxicities.

Graft Failure After Stem Cell Transplantation

Failure to establish hematologic engraftment (primary graft failure) and loss of an established graft (late graft failure) are serious complications of both autologous and allogeneic marrow or blood stem cell transplantation. Delayed or poor graft function can exaggerate and prolong the risks of infection and can increase peritransplantation mortality. Failure to engraft can occur if insufficient stem cells are infused. Approximately 2×10^4 colony-forming cells from bone marrow per kilogram recipient weight are needed to establish autologous engraftment. This is accomplished by infusing a minimum of approximately 1×10^8 autologous marrow mononuclear cells/kg. Most investigators recommend infusion of a minimum of 2×10^8 cells/kg to ensure establishment of an allogeneic graft. Stem cells may be damaged by cryopreservation or by ex vivo purging, and additional cells are required if intensive purging, especially with alkylators such as 4-hydroperoxycyclophosphamide, is used.

Recently, hematopoietic stem cells and progenitors harvested from the blood by apheresis have become widely used for autologous and, to a lesser extent, allogeneic transplantation. Grafts are collected after mobilization of marrow-derived progenitors into the blood by cytokine (granulocyte colony-stimulating factor [G-CSF], granulocyte-macrophage colony-stimulating factor [GM-CSF]) therapy or during recovery from myelosuppressive chemotherapy, often in combination with growth factors. [4] [5] Progenitor content in these grafts is now assayed by quantitation of mononuclear cells expressing the stem cell-associated surface marker, CD34.

Graft failure is uncommon if 2×10^6 CD34+ cells/kg are collected, cryopreserved, and later reinfused as an autologous graft. [6] [7] The minimum CD34 content for an allogeneic graft is less well defined, but $>5 \times 10^6$ CD34 cells/kg is frequently cited as a target collection for a sibling donor allograft. [8] [9] In general, these mobilized blood stem cell transplants yield satisfactory and rapid trilineage hematologic recovery, but the risks of graft failure or ongoing poor hematopoietic function (especially thrombocytopenia) are uncertain. [10] [11]

Recipient myelofibrosis or splenomegaly may also interfere with engraftment. Splenomegaly may delay hematologic recovery, [12] presumably because both progenitors and mature blood

TABLE 97-1 -- Major Noninfectious Complications of Stem Cell Transplantation

Time After Transplant	Complication	Incidence
Early (030 days)	Regimen-related toxicity	
	Mucositis	6075%
	Cyclophosphamide/radiation myocarditis or pericarditis	Rare
	Hemorrhagic cystitis	10%
	Veno-occlusive disease	540%
	Pneumonitis	1020%
	Alveolar hemorrhage	510%
	Infections	75%
	Graft failure	210%
	Adverse drug reactions from polypharmacy	Common
Intermediate (13 months)	Acute GVHD	2050%; more frequent with nonsibling donors
Late (beyond 3 months)	Chronic GVHD	2040%
	Hypothyroidism	3050%
	Growth disturbances	Common in prepubertal children
	Sterility/hypogonadism	Common
	Cataracts	2540%
	Avascular necrosis of bone or demineralization of bone	515%
	Malignant relapse	Variable
	Second malignancy	210%, but total incidence is uncertain

GVHD, graft-versus-host disease.

cells are sequestered in the spleen. Prior splenectomy is associated with a shorter interval to engraftment. [13] The presence of moderate or severe myelofibrosis also delays engraftment, perhaps because of faulty homing of stem cells in the marrow microenvironment. [14] [15]

Post-transplantation therapy may also jeopardize engraftment. Graft failure or poor graft function with continuing pancytopenia has been associated with use of methotrexate, antithymocyte globulin (ATG), acyclovir, ganciclovir, trimethoprim-sulfamethoxazole (TMP-SMX), 5-fluocytosine, as well as histamine blockers.

Post-transplantation complications such as cytomegalovirus (CMV), mycobacterial, or fungal infection, acute and chronic graft-versus-host disease (GVHD), or, rarely, Epstein-Barr virus-associated lymphoma may also compromise successful engraftment.

Allogeneic SCT, especially using unrelated or mismatched donors, poses unique problems with engraftment. Transplants between siblings matched at human leukocyte antigen (HLA)-A, -B, and -DR loci are rarely (15%) associated with graft failure; however, the probability of graft failure in the related donor transplantation setting increases up to 1020% with greater degrees of HLA incompatibility. [16] [17] [18] [19] [20] [21] The problem is frequent (515%) in the unrelated donor setting, where graft failure may occur even after transplantation from donors serologically matched at the HLA-A, -B, and -DR loci. [22] [23] [24] In some cases, failure of unrelated donor stem cells to engraft may result from reactivity against important histocompatibility determinants not recognized by current HLA typing methods. [25] Early failure of an allogeneic graft may be accompanied by emergence of cytotoxic T lymphocytes of host origin, [26] presumably representing immune-mediated graft rejection.

T-lymphocyte depletion of donor marrow performed as GVHD prophylaxis can also adversely affect engraftment, even from matched sibling donors. [16] [20] [27] [28] [29] Ex vivo marrow manipulation may deplete stem cells. Alternatively, T-cell depletion may render the graft immunoincompetent and functionally less capable of preventing host rejection of the graft. In addition, T-cellderived soluble factors that support engraftment may not be available after T-lymphocyte depletion. [30] Correction of this deficiency by preservation of specific T-cell subsets in the graft is under study. [31] [32]

The availability of recombinant human growth factors such as G-CSF and GM-CSF, which stimulate myelopoiesis, has revolutionized the treatment of graft failure. [33] Fifty to 60% of patients experiencing poor graft function have a myelopoietic response within 1421 days after initiation of growth factor therapy, although patients receiving purged autografts may be less likely to respond. Clinical trials testing the relative merits of different growth factors, growth factor combinations, and dose schedules are underway.[34] These studies may resolve the possibilities that growth factors may stimulate either residual host cells (augmenting mixed chimerism) or residual myeloid leukemia cells (increasing the risks of relapse). Available growth factors increase peripheral blood leukocytes but have no major effect on platelet recovery.[35] Recombinant human thrombopoietin has been tested in conjunction with myelosuppressive chemotherapy and in limited trials for stimulating platelet recovery after marrow or stem cell transplantation.[36] Limited experience suggests the possible value of erythropoietin in reducing red cell transfusion needs. [37]

A second stem cell infusion may be useful if graft failure occurs.[38] In the case of a failed autograft, infusion of previously harvested and frozen marrow or peripheral blood cells frequently reestablishes a graft. Procurement and storage of back-up stem cells should be considered in the case of autograft protocols in which a high rate of graft failure is anticipated. In the case of marrow failure after related donor transplantation, a second infusion of donor marrow or cytokine-stimulated peripheral blood stem cells, sometimes after reconditioning with reduced doses of cytotoxic agents or after further immunosuppression with ATG, corticosteroids, or cyclosporine, may allow successful engraftment.

The incidence of graft failure after unrelated donor transplantation is high and poses special problems. [16] [22] [24] [39] Unrelated donors may not be available for a second donation or may not have recovered sufficiently from the first harvest to undergo marrow extraction. Even if the unrelated donor is willing to undergo a second harvest, delays of more than 4 weeks from the time of request may occur. For these reasons, it is prudent to store autologous stem cells from patients undergoing unrelated donor transplantation.

Host Defense Defects After Stem Cell Transplantation

Multiple immunologic deficiencies are induced by SCT (Table 97-2). Mucocutaneous barriers to invasion of colonizing pathogens are disrupted. Early neutropenia and hypogammaglobulinemia further compromise the ability to eliminate these organisms. [40] Severe cellular immune dysfunction, including T-cell lymphopenia and anergy, persists for some months after engraftment

TABLE 97-2 -- Host Defense Defects After Stem Cell Transplantation

Time After Transplant	Immune Defects	Major Infections
Early (030 days)	Mucosal + skin injury Neutropenia	Aerobic bacteria Gram-positive, especially coagulase-negative staphylococci, *viridans* streptococci Gram-negative bacilli Fungi *Candida* sp. Molds (*Aspergillus* sp.) Viruses Herpes simplex virus Respiratory viruses (respiratory syncytial virus, parainfluenza virus)
Intermediate (13 months)	T-cell dysfunction Hypogammaglobulinemia Acute GVHD	Fungi: molds, *Candida* sp., PCP Viruses CMV, respiratory viruses Encapsulated bacteria pneumococci, *Hemophilus influenzae*
Late (312 months)	Slow T-cell reconstitution Chronic GVHD	PCP Varicella zoster virus Encapsulated bacteria CMV

CMV, cytomegalovirus; PCP, Pneumocystis carinii pneumonia.

INFECTION PROPHYLAXIS FOR STEM CELL TRANSPLANT RECIPIENTS

A typical comprehensive regimen for SCT recipients has all patients supported in single, HEPA-filtered, positive-air-pressure, sealed rooms with strict hand washing as the primary protective isolation measure. All patients should receive trimethoprim-sulfamethoxazole (TMP-SMX) or ciprofloxacin plus fluconazole daily. Fevers occurring during the initial conditioning and neutropenic period are first treated with a semisynthetic penicillin plus an aminoglycoside, or with ceftazidime for patients receiving cyclosporine. Vancomycin or alternate gram-positive bacterial coverage is indicated if coagulase-negative staphylococci or *viridans* streptococci are identified. After 72 hours of unexplained fever, patients should be treated with empiric amphotericin (0.5 mg/kg/day or 0.3 mg/kg/day in patients receiving cyclosporine), but amphotericin should be initiated earlier and in higher doses in those colonized with yeasts or with lesions suspect for invasive mycotic infection (sinusitis or nodular pulmonary lesions). Lipid amphotericin preparations may be as effective and less nephrotoxic, but need further study as antifungal prophylaxis.

Herpes simplex virus-seropositive patients require acyclovir prophylaxis to prevent viral reactivation. CMV-seronegative patients receive seronegative or leukocyte-depleted (by filtration) blood products, and CMV-seropositive patients should receive antiviral suppression with ganciclovir and perhaps with intravenous immunoglobulin (see later).

Anti-infection prophylaxis later in the course includes oral fluconazole or mycostatin until day 100 for all patients and ongoing anticandidal therapy for patients being treated for continuing GVHD. Heightened fungal risks in unrelated donor or mismatched donor allograft recipients may indicate a need for ongoing protection against *Aspergillus*. However, the value of itraconazole or continuing low-dose amphotericin (conventional or lipid) is unproven. All patients should receive *Pneumocystis* prophylaxis for 1 year post-transplant (TMP-SMX double strength bid 2 days per week, or aerosolized pentamidine 300 mg once monthly).

Patients with ongoing GVHD receive continuing *Candida* and *Pneumocystis* prophylaxis until 1 month after discontinuation of all immunosuppression, and also receive daily penicillin or erythromycin for protection against pneumococcal bacteremia. Intravenous immunoglobulin for those with documented hypogammaglobulinemia and infections can be beneficial as well.

and is usually prolonged in patients with ongoing GVHD. Interestingly, natural killer cell activity regenerates much earlier, often by 48 weeks post-transplantation. [41] [42]

In the early post-transplantation period, nearly all patients have fever, although infectious pathogens are identified in only 50% of patients. Fevers may also be due to tissue inflammation (oropharyngeal or enteric mucositis), transfusions, or amphotericin or other drug fever. During initial neutropenia, the most common infections identified are due to aerobic bacteria (frequently coagulase-negative staphylococci, *viridans* streptococci, and enteric gram-negative bacilli). Colonizing yeasts also invade because of neutropenia and disruption of normal host flora, thus leading to systemic mycotic infections in 1015% of patients. [43] [44]

Prophylactic strategies[45] may include suppressive antibiotics such as vancomycin, quinolones, or TMP-SMX. In some centers, a pathogen-free environment with laminar flow isolation, gut sterilization, special diets, and broad-spectrum prophylactic antibiotics is used to reduce risks of infection. However, these intensive isolation measures are both cumbersome and expensive, and have not been proven helpful in preventing early post-transplantation mortality. Newer antifungal agents, including fluconazole, have been strikingly effective in preventing systemic candidiasis, although resistant species (*Candida krusei* or *Torulopsis glabrata*) have emerged as secondary pathogens and may require additional attention. [46]

Treatment of fever in the neutropenic transplant recipient requires strategies similar to the ones that have been effective in patients with leukemia. [47] Broad-spectrum antibacterial coverage should be initiated early. Patients with persistent unexplained fever, particularly those colonized with yeast, should receive empiric amphotericin. Repeated vigorous investigation to identify sources of infection, even for fever recurring after initial defervescence, is essential. In many centers, third-generation cephalosporins and aminoglycosides have been effective in treating the most common gram-negative enteric bacilli (*Escherichia coli*, *Klebsiella* sp., *Enterobacter* sp., and *Pseudomonas* sp.).[48] However, resistant gram-negative pathogens, including *Citrobacter* sp., *Acinetobacter* sp., and *Xanthomonas* sp., have emerged in recent years as secondary pathogens in the antibiotic-exposed neutropenic population. Institutional antibiotic sensitivity profiles must guide empiric and therapeutic antibiotic choices and should, of course, be individualized based on specific pathogenic isolates and their sensitivities. Extensive use of vancomycin and broadly active cephalosporins may also promote colonization or enteric infection with vancomycin-resistant enterococci, which can be highly virulent in the compromised or neutropenic host. Isolation measures to reduce nosocomial acquisition of vancomycin-resistant enterococci may become more important as these organisms become more prevalent.[49]

Infection with invasive fungal organisms remains a significant hazard despite the use of protected environments, HEPA (high-efficiency particulate air) filters, and reverse isolation.[50] [51] Up to 10% of transplant recipients may have invasive fungal infections, usually with *Aspergillus* sp. but *Fusarium* sp., *Alternaria* sp., and other, less common isolates have been reported. Therefore, aggressive and repeated evaluation for mycotic infection, particularly in the persistently febrile neutropenic host, is essential along with early initiation of amphotericin. Liposomal amphotericin preparations, itraconazole, or growth factors designed to accelerate neutrophil recovery or activate inflammatory phagocytes (i.e., GM-CSF, G-CSF, macrophage colony-stimulating factor [M-CSF]) have all been proposed as newer therapies for fungal infection, but their specific role and value are as yet unclear. [52] [53]

All categories of infection are seen more frequently in allogeneic transplant recipients in whom immune reconstitution (even after resolution of neutropenia) is delayed. Chronic GVHD (see later) is accompanied by persistent hypogammaglobulinemia, cellular immune dysfunction, and a continuing risk of infection with bacterial, fungal, and viral pathogens. Although intravenous immunoglobulin supplementation has been given [54] to reduce risks of infection, one prospective trial suggested that its prophylactic use does not prevent later post-transplantation infection and could impair humoral immune reconstitution. [55] Late infections may include varicella zoster virus (usually dermatomal shingles, which may disseminate); encapsulated bacterial infections (pneumococci or *Hemophilus influenzae*), suggesting an immunologic defect similar to that seen with hyposplenia or asplenia; and *Pneumocystis carinii* pneumonia. These all are common in the late (312 months) post-transplantation period and require additional prophylaxis or prompt therapy, especially in allograft recipients with chronic GVHD. [56] [57] [58] [59] [60] [61] [62] Augmented infection risks in recipients of unrelated

donor allografts have been recognized, even beyond the reportedly higher infection risks associated with acute and chronic GVHD. [63] [64] More intensive prophylaxis and surveillance measures may be required for this subgroup.

Veno-occlusive Disease

Veno-occlusive disease (VOD) is a serious liver disorder complicating up to 50% of marrow transplants. [65] [66] [67] Signs of VOD usually occur within 1 month of stem cell infusion, but may be recognized much sooner, even during administration of the preparative regimen. [68] Clinical evidence of VOD includes hyperbilirubinemia,

hepatomegaly, ascites, and weight gain.[69] [70] VOD is a hepatotoxic lesion involving obstruction of small, intrahepatic venules and damage to the surrounding centrilobular hepatocytes and sinusoids.[71] Concentric fibrosis with obliteration of the hepatic venules, fibrosis of the centrilobular zone, and atrophy of adjacent hepatocytes may occur.[72] Deposition of fibronectin and factor VIII/von Willebrand factor at the site of the damaged endothelium may be associated with activation of the coagulation system and subsequent postsinusoidal obstruction.[69] [73] [74] Such changes are often associated with depressed plasma protein C levels,[75] and may be associated with other evidence of procoagulant activity, including depressed factor VIII and antithrombin III levels as well as elevated fibrinogen levels.[71] [76] [77] [78] Tumor necrosis factor- (TNF) levels are elevated in VOD,[79] [80] and may be causally related to endothelial damage.

Veno-occlusive disease can result in encephalopathy, renal failure, pulmonary failure, or multiorgan failure.[70] [71] [81] The mortality rate of VOD is highly variable in different series, perhaps due to differing stringency of diagnostic criteria,[70] [71] [82] but severe VOD is often fatal within several weeks of onset.[66] [70] [81]

Establishing a definite diagnosis of VOD is difficult. Most investigators require two of three clinical criteria, including jaundice, hepatomegaly, or ascites occurring within 2 weeks of stem cell infusion.[65] [69] [70] [82] However, other causes of hyperbilirubinemia and weight gain early after transplantation (e.g., drugs [especially cyclosporine, TMP-SMX, methotrexate, or estrogens], capillary leak, salt and colloid overloading) complicate the differential diagnosis. Percutaneous or transabdominal needle biopsy of the liver is extremely hazardous in thrombocytopenic transplant recipients, and should be avoided.[83] Transvenous biopsies may provide sufficient histologic material for diagnosis and may allow determination of hepatic wedge pressure product (greater than 10 mm is associated with VOD),[84] but may be associated with hemorrhagic complications as well.[84] [85] [86] Ultrasound Doppler flow studies demonstrating reversal of portal flow or a higher portal vein resistive index have been suggested as a noninvasive means of confirming the diagnosis, but their validity has recently been questioned.[87] [88] [89] [90] [91]

Risk factors associated with development of VOD include history of pretransplantation hepatitis, intensive preparative regimens, increased radiation dose and dose rate, and increased busulfan dose.[1] [65] [68] [70] [81] [92] [93] [94] [95] [96] VOD may also be more frequent after mismatched related or unrelated donor transplantations.[65] [68]

Effective methods for prevention and treatment of VOD have not been defined. Promising approaches include preventive therapy with low-dose heparin,[97] [98] [99] prostaglandin E,[100] pentoxifylline (a TNF blocking agent),[101] [102] or ursodiol.[103] [104] Recombinant tissue plasminogen factor has been used successfully to treat established VOD,[105] [106] [107] [108] [109] as has administration of urokinase;[109] however, both agents are associated with substantially increased risks of hemorrhage. Transjugular portosystemic shunts have also been used.[110]

Interstitial Pneumonitis

Interstitial pneumonitis (IP) is a common and frequently fatal complication, affecting up to 35% of allogeneic transplant recipients,[111] [112] although recent advances in supportive care may substantially reduce this risk.[40] It is less common after autografting.[113] It is characterized by diffuse, nonbacterial interstitial inflammation. Risk factors associated with development of IP include (1) prolonged methotrexate therapy for GVHD prophylaxis; (2) age >21 years; (3) severe GVHD; (4) >6-month interval from diagnosis of hematologic disease until transplantation; (5) <100% pretransplantation Karnofsky performance score; and (6) radiation dose rate >4 cGy/minute.[112] Remarkably, when none of these factors was present, the reported risk of IP was 8%, and that risk rose to 94% when all six were present. It has been hypothesized that unrelated donor transplantation is more immunosuppressive and thus associated with more severe opportunistic infections and greater risks of IP, but this has not been rigorously investigated.

The course of IP is often catastrophic, presenting with rapidly progressive tachypnea, dyspnea, hypoxemia, and hemodynamic compromise. Therefore, therapeutic intervention must frequently occur before the return of definitive diagnostic tests, and must be initiated based on the assessment of clinical risk factors, associated clinical clues, and the clinical setting (especially the type of transplant and the time of onset).

Infectious Causes of Interstitial Pneumonitis

CMV Infection

Prevention of CMV Infection.

Interstitial pneumonia due to CMV is the most common cause of IP, responsible for 50% of all cases.[114] Prevention of CMV pneumonia as well as other manifestations (enteritis, hepatitis, retinitis) depends on understanding of risk factors and institution of specific preventive measures.

Seropositive Recipients.

The most powerful risk factor predisposing to CMV infection is seropositivity of the recipient.[115] [116] Clinical observations strongly suggest that reactivation of latent CMV is the most important mechanism resulting in CMV disease; however, virologic and molecular confirmation of this suspicion has been difficult. The approach to CMV prevention in the seropositive patient must include chemoprophylaxis or immunoprophylaxis as well as aggressive surveillance to allow prompt detection of infection. An additional role for preventing exogenous exposure (through choosing seronegative bone marrow or blood donors) is not proven. Chemoprophylaxis has been very useful in preventing CMV pneumonia among seropositive recipients. The use of acyclovir was associated with a decrease in CMV pneumonia incidence from 40 to 19% among seropositive recipients,[117] whereas ganciclovir given prophylactically[118] [119] or when administered at the time of viremia, CMV antigenemia,[120] [121] [122] [123] [124] or bronchoalveolar lavage (BAL) recovery of virus[125] [126] [127] [128] [129] from asymptomatic patients has reduced the incidence of CMV pneumonia to under 5%. Ganciclovir induced significant neutropenia in these trials and sometimes secondary sepsis as well. Intravenous immunoglobulin may also be useful in reducing CMV infections, perhaps through its effect in reducing risks of GVHD.[40] [111]

Seronegative Recipients.

It is clear that the nearly all CMV infections in seronegative recipients are the result of exogenous exposure (primary CMV infection), either from a seropositive stem cell donor or from cellular blood products from seropositive donors. Noncellular blood products do not transmit CMV.[130] Delivery of CMV-seronegative blood products only to seronegative recipients reduces the risk of CMV infection to less than 5% and nearly eliminates the risk of CMV pneumonia.[131] [132] Unfortunately, the demand for CMV-safe blood is greater than the supply of seronegative blood donors at most centers. Excellent clinical and laboratory data point to leukocytes as the carriers of infectious CMV in blood products. Several recent studies, including one large, prospective trial, have shown that removal of white blood cells from transfused unscreened products by sedimentation or filtration is an effective alternative in prevention of primary CMV infections.[133] [134] [135] [136] The frequent use of

intravenous immunoglobulin for CMV prevention,[137] [138] which has limited efficacy, has largely been supplanted by delivery of CMV-safe blood products to seronegative patients.

Autologous Recipients.

A second powerful risk factor for CMV pneumonia is allogeneic (compared with autologous) SCT.[139] [140] Enright et al. reported CMV pneumonia complicating the course of 12% of over 400 allogeneic recipients, but only 3% of 229 autologous recipients.[139] However, CMV pneumonia was as severe in autologous as in allogeneic recipients, with a high-case fatality rate. Other studies have also defined a similar incidence of CMV pneumonia among autologous recipients,[141] or have shown delayed engraftment among autologous recipients in whom CMV infection developed.[121] [142] Thus, prevention of CMV infection through use of noninfective blood products (for seronegative recipients) or chemoprophylaxis (for seropositive recipients) is still indicated.[143] Viremia or recovery of virus from BAL fluid should likewise be treated aggressively.

Treatment of Viremia.

Post-SCT CMV viremia is a strong predictor of CMV pneumonia[144] and should probably be treated regardless of the patients previous risk group. CMV pneumonia follows 60% of asymptomatic viremias within 14 days (median). Treatment of viremia with ganciclovir can reduce the incidence of CMV pneumonia to 5%.[120] [121]

Surveillance for CMV pp65 antigenemia or polymerase chain reaction assay of CMV DNA has markedly augmented the sensitivity of blood testing for early infection.[121] [122] [127] The clinical consequences and best pre-emptive therapeutic intervention after detection of antigenemia are still under study. The cost and myelosuppression associated with ganciclovir or foscarnet therapy must be weighed against the risks of inadequately treated antigenemia progressing to active CMV disease.[121] [123] [124] [127] [129]

Diagnosis of CMV Pneumonia.

Cytomegalovirus pneumonia usually presents as an IP associated with fever and hypoxia. Although lung biopsy showing CMV inclusions is the gold standard for diagnosis of CMV pneumonia, shell vial culture of BAL fluid is positive in most cases of CMV pneumonia [145] and is a less risky approach to diagnosis. Shell vial culture of CMV from BAL is not, however, specific to CMV pneumonia, and is frequently positive in asymptomatic seropositive people who are shedding CMV in oral or respiratory secretions without pneumonia.[146] [147] [148] Despite this lack of specificity, even in asymptomatic people, finding CMV in BAL is a strong predictor for development of CMV pneumonia and should be treated. The practical approach is to use the combination of a compatible clinical syndrome (especially in the presence of CMV antigenemia) plus either BAL direct staining, shell vial cultures, or polymerase chain reaction to diagnose CMV pneumonia. [126] [127] [128] [149] If BAL is undertaken for other indications and CMV is found coincidentally, it should be treated to prevent development of clinical CMV pneumonia.

Treatment of CMV Pneumonia.

Cytomegalovirus pneumonia should be diagnosed and treated as promptly as possible. If patients are already respirator dependent at the time of institution of therapy, therapy is nearly always ineffective and the mortality rate is nearly 100%. [139] The combined use of ganciclovir and immunoglobulin has been the most successful treatment for CMV pneumonia, with resolution in 5075% of patients (nonrespirator dependent). [139] [150] [151] [152] Prolonged therapy (2 months) with the combination is indicated because shorter treatment regimens have been associated with recurrence of CMV pneumonia. [141] Foscarnet can be effective in clinical settings where ganciclovir fails or is associated with excess toxicity, usually myelosuppression. [143]

Fungal Infections

Pulmonary fungal infections may be associated with an interstitial pattern, alveolar infiltrates, or nodules on chest radiography. [50] [51] [153] *Aspergillus* pneumonia has been very difficult to treat, partly because of the difficulty in making the diagnosis

APPROACH TO PREVENTION AND TREATMENT OF CMV INFECTION

PREVENTION

1. Seronegative recipient with seronegative donor (allogeneic and autologous): Transfuse only CMV-safe blood products. Leukocyte depletion by filtration and blood from CMV-seronegative donors are clinically equivalent alternatives.
2. Seronegative recipient with seropositive donor (allogeneic): Deliver only CMV-safe blood products (seronegative or leukocyte depleted), but administer chemoimmunoprophylaxis as well to prevent reactivation of endogenous virus.
3. Seropositive recipients: Prophylaxis with acyclovir appears to be useful. Use of immunoglobulin may be beneficial (especially by modulation of GVHD). There is no proven role for seronegative blood products. Ganciclovir is highly effective when given prophylactically, but is toxic to marrow cells. Patients who must interrupt the course of ganciclovir because of leukopenia are at risk for development of CMV pneumonia. Ganciclovir is the current best prophylaxis in high-risk patients, but probably is not indicated for autologous recipients.

TREATMENT

1. Asymptomatic infections (all types of transplants): Ganciclovir treatment of asymptomatic CMV infection detected by either bronchoalveolar lavage (BAL) antigenemia or blood culture is recommended to prevent development of CMV pneumonia. Intensive treatment followed by a maintenance phase of 5 days/week therapy is necessary. The requisite duration of treatment for CMV antigenemia or viremia is uncertain, but a minimum of 3 weeks of therapy with resultant negative testing is advised, along with close surveillance of therapy. Asymptomatic viruria suggests a need for close follow-up and for serial blood viral testing, but does not usually require therapy.
2. CMV pneumonia: Ganciclovir in combination with immunoglobulin is the recommended regimen. This should be instituted as promptly as possible. Once the disease has progressed to cause respiratory failure and ventilator dependence, therapeutic success is rare.

NO TREATMENT

The following situations are important negatives in which ganciclovir is not indicated for empiric therapy of interstitial pneumonitis; in these circumstances, CMV pneumonia is unlikely to be present:

1. Seronegative recipients with seronegative marrow and blood donors.
2. Any patient in whom BAL is negative by direct staining and shell vial culture. However, BAL CMV studies do have a small (<5%) false-negative rate, so CMV interstitial pneumonitis cannot be absolutely excluded.

antemortem. [50] *Aspergillus* infections may occur early post-SCT (during the neutropenic phase) or later, especially complicating the immunosuppression associated with acute or chronic GVHD.[50] [154] [155] Allogeneic (vs. autologous) SCT, prolonged neutropenia, and GVHD all predispose to *Aspergillus* infections.[155] [156] [157] Exposure to construction sites has also been associated with *Aspergillus* infections.[158] Measures to prevent aspergillosis include prophylactic low-dose amphotericin, inhaled amphotericin,

early empiric use of amphotericin, itraconazole, and close attention to air filtration in patient care areas, although the relative effectiveness of these approaches has not yet been defined. More recent approaches include prophylactic hemopoietins (GM-CSF, G-CSF) for their prophagocytic as well as neutrophilic potency.

Nasal and bronchial washings for *Aspergillus* may be inadequately sensitive,[159] [160] and lung biopsy may be required to obtain a definitive diagnosis. The pattern of the infiltrate may be helpful diagnostically and can sometimes be better defined by computed tomography scan of the chest. [161] Persistent high-grade fever that does not improve on antibacterials is often assumed to be due to fungal infection.

Although unquestionably the treatment of choice for fungal infections, the use of high-dose amphotericin may be limited by renal dysfunction. Promising but costly new approaches to treatment of fungal pneumonia include several newly licensed lipid formulations of amphotericin, itraconazole, and GM-CSF or M-CSF. [162] [163] [164]

Pneumocystis carinii Pneumonia

Pneumocystis carinii causes IP, typically bilateral with a butterfly pattern on radiography. [59] Although the 515% risk of *P. carinii* pneumonia (PCP) has largely been eliminated by the use of trimethoprim-sulfamethoxazole (TMP-SMX) given 2 consecutive days/week,[165] TMP-SMX is not tolerated by all patients because of allergy or marrow depression by the drug. Recently, use of inhaled pentamidine (300 mg every 4 weeks) or dapsone has offered effective alternatives. [60] [62] [166] TMP-SMX therapy virtually eliminates PCP from the differential diagnosis, but only if patient compliance with the prophylaxis is certain. Inhaled pentamidine or dapsone, although partially effective, does not totally eliminate the risk of PCP. PCP can be diagnosed by cytologic evaluation of silver-stained preparations of BAL cells or sputum. It is effectively treated by high-dose TMP-SMX or parenteral pentamidine. Supplemental steroid therapy has improved therapeutic results in patients with acquired immunodeficiency syndrome,[167] and may be helpful after SCT as well. Prophylaxis against PCP should be continued during the period of immunosuppression (6 months to 1 year after SCT) and for the duration of any therapy for chronic GVHD. PCP has been recognized as late as 13 years after BMT, especially after relapse of a malignancy that is not rapidly fatal (e.g., chronic myeloid leukemia or low-grade lymphoma). [59] Ongoing prophylaxis for such patients should be considered.

Respiratory Syncytial Virus

Respiratory syncytial virus (RSV) is a potentially fatal cause of IP [168] [169] that is seasonal, occurring most frequently in the fall and winter months. RSV should be suspected if the patient has had nasal congestion and if RSV has been frequently recognized either in the community or in the hospital. Diagnosis may be made by rapid antigen testing on nasal washings or BAL specimens. Because of the possibility of horizontal transmission, patients with RSV should be isolated. Treatment is with inhaled aerosolized ribavirin (usually 6 g/day) for 37 days. [168] [170] A similar but nonseasonal syndrome due to parainfluenza virus has been described. [171] [172] No rapid antigen test for parainfluenza is available, and its response to ribavirin therapy is uncertain.

Noninfectious Causes of Interstitial Pneumonitis

Idiopathic Interstitial Pneumonitis

Idiopathic interstitial pneumonitis (IIP) is a diagnosis of exclusion based on typical findings and ruling out infectious causes. Its timing is somewhat earlier than other causes of IP,[111] [114] [172] typically occurring within the first 27 weeks post-SCT. Interestingly, the recognized clinical risk factors for IIP have been similar to those for IP, and include (1) extensive pretransplantation chemotherapy; (2) high-dose cyclophosphamide; (3) total-body irradiation (TBI; increased by higher total dose and dose rate); (4) blood transfusions; (5) administration of methotrexate; and (6) GVHD. [173]

The observation that IIP is as frequent among syngeneic as among allogeneic recipients [174] suggests that immunosuppression is less of a risk factor for IIP than it is for infectious IP. Clinical observations support a toxic cause of IIP, [173] and radiation-induced lung damage appears to be the major contributor. [175] These clinical observations are supported by animal studies suggesting that irradiation is the major contributor to post-SCT lung damage, [176] whereas cyclophosphamide makes only a minor contribution.[177] In addition, in controlled trials, higher-dose TBI has increased the incidence of IIP. [96] Effective therapy has not been established, although high-dose corticosteroid therapy is often administered.

Diffuse Alveolar Hemorrhage

Diffuse alveolar hemorrhage (DAH) has been recently recognized primarily, but not exclusively, in autologous SCT recipients. [178] [179] [180] It is likely that some allogeneic SCT recipients acquire a similar complication that, because of its early timing, has been included with the diagnosis of IIP. Diagnostic criteria include (1) diffuse consolidation on chest radiography, (2) hypoxia requiring oxygen supplementation, and (3) progressively bloody BAL on aliquots from more than one lung segment.[178] Although alveolar hemorrhage is the critical diagnostic criterion, the most typical radiologic findings at presentation are bilateral interstitial infiltrates, with alveolar infiltrates developing rapidly through the course. [181] DAH presents early (within the first 2 weeks post-SCT) with dyspnea, hypoxia, and cough, but usually not overt hemoptysis. This syndrome is very serious, with a reported mortality rate of 77100%. Treatment includes correction of any coagulopathy and aggressive ventilatory support. Limited, uncontrolled experience suggests that high-dose corticosteroids may be effective therapy for this syndrome. [182] [183]

It seems likely that DAH is a subcategory of IIP, and is due to lung injury from chemotherapy and irradiation. Two observations suggest that neutrophils may contribute to its pathogenesis by causing inflammatory damage to injured lung cells. First, DAH often appears at the time of neutrophil recovery. Second, when BAL was undertaken before autologous SCT for 123 patients (of whom 14 eventually acquired DAH), the presence of >20% polymorphonuclear neutrophils or >0% eosinophils before SCT both predicted development of DAH (43% if both were present, 4% if neither). [184]

Graft-versus-Host Disease

Acute GVHD develops in the first 13 months after allogeneic transplantation and can involve the skin, the liver, or the gastrointestinal tract. It manifests in the skin as a maculopapular dermatitis that, when severe, can lead to large bullae or even resemble toxic epidermal necrolysis. GVHD can produce cholestatic hepatitis with marked elevation of serum bilirubin and alkaline phosphatase, but usually only mild transaminase alterations. Hepatocellular function (protein synthesis, coagulation factor production) is not impaired. In the intestine, upper gastrointestinal tract GVHD can produce nausea, vomiting, and anorexia, [185] whereas small bowel and colon GVHD produce large-volume secretory diarrhea.[186] Histologically, acute GVHD is manifest as single-cell degeneration and necrosis in the stem cell compartment of the skin epidermis or the intestinal or biliary epithelium. This yields basal epidermal cell vacuolization with dyskeratosis, exocytosis, and, when more advanced, dermal-epidermal clefting with bullae formation. These changes

APPROACH TO INTERSTITIAL PNEUMONITIS

The presentation of interstitial pneumonitis (IP) after SCT should be considered an urgent medical situation, and empiric, broad-spectrum therapy must be initiated. The choice of therapy is influenced by the following:

1. Timing: Within the first 3 weeks after SCT, IP is more likely to be idiopathic (including diffuse alveolar hemorrhage) or fungal than due to CMV infection. Beyond 6 weeks, idiopathic pneumonitis is unusual and the etiology is more likely infectious. PCP is rare beyond 1 year after transplant. RSV infections are seasonal (fall and winter), and community outbreaks may be prevalent.
2. CMV serology and prophylaxis: If a seronegative recipient has received seronegative graft and noninfective (seronegative or leukocyte-depleted) blood, CMV pneumonia is unusual. Seropositive recipients are at higher risk, although with ganciclovir prophylaxis the risk is markedly reduced. Other prophylactic regimens for CMV, such as acyclovir or intravenous IgG, have still been associated with significant risk for serious CMV infection in the seropositive recipient.
3. Prolonged neutropenia: This factor is associated with infectious etiologies, particularly with fungal pneumonias.
4. Type of transplant: Diffuse alveolar hemorrhage (early post-SCT) has been reported more frequently, although not exclusively in autologous recipients. CMV pneumonia is unusual (23%) in autologous recipients, but it still has a high case fatality rate. All infectious causes are more common after allogeneic SCT. More intensive conditioning regimens (e.g., higher-dose TBI, carmustine) are associated with more frequent pneumonitis.
5. Compliance and prophylaxis: A thorough assessment of what the patient has actually been receiving (e.g., TMP-SMX, penicillin, CMV prophylaxis, transfusions outside the SCT center, etc.) is critical to assess risk.
6. Chest radiograph: The pattern and distribution of the infiltrate may narrow the differential diagnosis. Cardiac enlargement or pleural effusions may suggest pulmonary edema. A chest computed tomography scan may be useful, especially if nodularity or cavitary lesions (possibly fungal) are suspected.
7. Epidemiology: What are the etiologies of other recent cases of IP? This may be most helpful with infections that are horizontally transmitted (RSV) or have common environmental risk factors (*Aspergillus* infection associated with construction).
8. Bronchoalveolar lavage: This can be extremely useful establishing a specific diagnosis or excluding others. CMV rarely causes pneumonia without positive BAL findings (either direct staining of CMV-associated antigens in BAL cells or shell vial culture). BAL also usually detects RSV and *P. carinii*, and can identify alveolar bleeding. It is less sensitive for fungal pneumonias.
9. Lung biopsy: Although this is the gold standard for definitive diagnosis of most of the possible causes of IP, it can often be avoided through use of the clinical data listed previously. It may be necessary for definitive diagnosis of fungal pneumonias, pulmonary changes associated with chronic GVHD (lymphocytic bronchitis or bronchiolitis obliterans), or idiopathic interstitial pneumonitis.
10. Ventilator therapy: Progressive respiratory failure after SCT is rarely (<5%) reversible, especially in adults. Although aggressive diagnostic and therapeutic measures are essential, some centers offer patients (and their families) the option of foregoing mechanical ventilatory support if survival is unexpected. Preliminary discussion of this possible complication in pretransplantation patient counseling may facilitate decision making if respiratory failure does occur.

are accompanied by a modest lymphoid infiltrate, typically of CD8+ T lymphocytes. Similarly, the basal cells of the intestinal glands or the colonic crypts show single epithelial cell degeneration, satellite (lymphocyte) cell necrosis, and sometimes crypt abscesses progressing to mucosal sloughing. In hepatic portal tracts, single cells of bile ducts are affected first with eventual disruption or disappearance of the bile ducts.

Current understanding of the pathogenesis of GVHD suggests that alloreactive donor T lymphocytes recognize histocompatibility antigens on host cells and initiate secondary inflammatory injury, leading to the clinical symptoms of GVHD.[186] The process may be primed or accelerated by conditioning regimen-induced tissue injury and by proinflammatory cytokines (e.g., interleukin-1, TNF), which can augment the alloreactive response.[187] [188] [189] [190] The antigenic targets of GVHD are not well defined. Developing even after major histocompatibility complex (MHC)-identical sibling donor allografts,[191] [192] the frequency of GVHD suggests that minor histocompatibility antigens may be involved. In addition, antigens expressed after tissue damage from chemoradiation therapy conditioning or by environmental pathogens can serve as immune targets for GVHD. GVHD is more frequent and more severe in recipients of partially matched or histoincompatible transplants,[22] [193] suggesting that MHC-encoded molecules may be the prime antigenic targets initiating the alloreactive T-cell response. However, autologous recognition of host tissue antigens may also occur (autologous GVHD) because of poor immune regulation, which can be exaggerated by cyclosporine therapy.[194] This initiating T-cell response leads to a modest lymphoid infiltrate of primarily cytotoxic (CD8+) T cells within the injured tissue targets. However, recent evidence strongly suggests that secondary cytokine release (possibly including TNF and interleukin-1) may amplify and exaggerate the clinical severity of GVHD.[188] [189] [195] [196] [197]

Acute GVHD develops more commonly in older patients, in those with previously alloimmunized donors (usually parous women), or in recipients of marrow from other than a histocompatible related donor. Even with current immunoprophylaxis, 2550% of patients receiving HLA-identical sibling donor marrow[191] [192] and 7090% of patients receiving unrelated donor marrow acquire GVHD.[17] [22] [23] [198] [199] [200] [201] [202] The diagnosis is established by the clinical symptomatology (diffuse maculopapular skin rash, cholestasis, or watery diarrhea), but frequently requires histologic confirmation to distinguish it from other frequent toxicities in the early post-transplantation period (e.g., hypersensitivity drug rash, drug-induced cholestasis, or infectious enteritis). Severe GVHD (clinical grades IIIIV) is associated with poor survival because of the ongoing morbidity and the debility of chronic illness, because of progression to chronic GVHD, and, most important, because of secondary opportunistic infection with bacterial, viral, and fungal pathogens.[203] [204] [205] GVHD of lesser severity (grades III) is less often life threatening and may be accompanied by a graft-versus-leukemia effect that offers protection against malignant relapse.

Prophylaxis of GVHD

The most effective techniques for GVHD prevention have involved depletion of donor T lymphocytes from the donor marrow inoculum, most often coupling immunologic recognition (monoclonal anti-T-cell antibodies) with depletion techniques (immunomagnetic beads, complement cytotoxicity, or toxin immunoconjugates). Although vigorous T-cell depletion prevents acute GVHD, it also increases the risk of graft failure and neoplastic relapse after transplantation (because of absence of the graft-versus-leukemia effect).[206] [207] [208] [209]

Pharmacologic immunosuppression administered in the first several months after transplantation can prevent or blunt the initiating T-cell recognition and proliferative response that triggers GVHD and can allow the development of immune tolerance and complete lymphohematopoietic chimerism. Methotrexate, corticosteroids, ATG, cyclosporine, and, recently, tacrolimus have been used for prophylaxis of GVHD and have successfully reduced both the frequency and severity of clinical GVHD.[193] [210] [211] [212] [213] [214] The balance of complications has made it impossible to demonstrate a clear survival advantage for the use of either T-cell depletion or pharmacologic GVHD prophylaxis. It is clear, however, that some form of GVHD prophylaxis is needed after allogeneic SCT.

Treatment of Acute GVHD

Therapy of acute GVHD requires both immunosuppression to blunt the T-cell-induced inflammatory tissue injury and appropriate supportive care. Therapy should be intensified to achieve a complete or partial response to GVHD therapy, because effective treatment of acute GVHD can both protect against chronic GVHD and improve survival. Limited area (<50%) skin GVHD can be treated with topical corticosteroids alone. Corticosteroids (prednisone 12 mg/kg/day), ATG, and cyclosporine (for those not receiving it as prophylaxis) have been the mainstays of immunosuppressive therapy for GVHD.[203] [204] [205] [206] [215] Steroids produce a complete or partial response in approximately 40% of patients, whereas salvage therapy with ATG can control GVHD in 2540% of the remainder. GVHD of lesser severity and involving only single organs responds to immunosuppressive therapy in 5060% of patients, whereas only 2530% of patients with multiorgan GVHD, especially involving the liver, respond to therapy.[203] [204] [216] GVHD after unrelated donor SCT may also be relatively more resistant to therapy.[213] [214] [217]

Newer immunosuppressive agents, including monoclonal antibodies or immunotoxins directed against T cells or inflammatory cytokines, may be used to limit the severity of GVHD.[195] [196] However, in addition to effective immunosuppression, successful management of acute GVHD involves attention to supportive care to reduce the morbidity and opportunistic infections that accompany GVHD. Adequate nutritional support and fluid replacement for severe diarrhea are required. Avoidance of unnecessary medications can simplify the therapeutic regimen and lessen the chances of adverse drug interactions or hypersensitivity skin rashes. Most important, infection prophylaxis directed against fungi, encapsulated bacteria, CMV, and PCP is an essential element of GVHD treatment.

Chronic GVHD

A related syndrome that occurs later after allotransplantation is called chronic GVHD.[218] [219] This syndrome develops in 3040% of allograft recipients[220] [221] [222] and

usually manifests between 50 and 200 days after transplantation. It occurs most frequently in patients with preceding acute GVHD, but may also occur in 10% of sibling allograft recipients de novo, without any preceding acute GVHD. Chronic GVHD may develop more frequently after mismatched or unrelated donor grafts, or after peripheral blood stem cell transplantation. [9] [223] The manifestations of chronic GVHD resemble autoimmune disease, somewhat similar to scleroderma. An inflammatory dermatitis may progress to severe dermal and periarticular fibrosis with loss of skin appendages (hair and sweat glands) as well as significant skin tightness and loss of joint flexibility. Additional manifestations may include dry eyes and dry mouth, which can resemble Sjögrens syndrome clinically and histologically; enteritis with anorexia, early satiety, malabsorption, weight loss, and wasting;

GRAFT-VERSUS-HOST DISEASE AND STEM CELL TRANSPLANTATION

1. Donor selection: Lower risks of GVHD follow SCT from a genotypically identical sibling donor versus a closely matched related or an unrelated donor. Given equivalent donor: recipient histocompatibility, GVHD risks are lower with younger donors; those who are not previously alloimmunized (by prior pregnancy or transfusion); and gender pairings other than female donormale recipient. If the recipient is CMV seronegative, a seronegative donor is also a better choice.
2. GVHD prophylaxis: Near-complete T-lymphocyte depletion (to $<10^5$ T cells/kg recipient weight) offers the best protection against acute GVHD, although outcome is compromised by greater risks of graft failure and leukemia relapse. Short-course methotrexate (15 mg/m^2 intravenously [IV] day +1 and 10 mg/m^2 +3, +6, +11) plus cyclosporine 6 mg/kg IV from day1 to day +50, then taper); or cyclosporine/steroids; or methotrexate/cyclosporine/steroids have been the most effective chemoprophylaxis regimens.[211] [212] [213] [214]
3. GVHD diagnosis: Early recognition of GVHD symptoms is important in successful management. Skin biopsy to distinguish a GVHD rash from a drug eruption is advised. Nausea, vomiting, or diarrhea suggest gastrointestinal tract GVHD, and endoscopy is necessary to distinguish gut GVHD from infectious or peptic upper gastrointestinal tract symptoms or from infectious, toxic, or osmotic diarrhea.
4. Acute GVHD treatment: Corticosteroids (usually methylprednisolone 12 mg/kg/day) for several weeks and a slow tapering schedule are the usual initial therapy.[203] [204] [205] [215] [216]
5. Chronic GVHD treatment. Initial therapy with modest dose prednisone (0.51 mg/kg/d) and cyclosporine followed by 912 months of maintenance therapy with alternate-day prednisone + cyclosporine has been widely used. Chronic GVHD induction therapy with high-dose methylprednisolone (15 mg/kg IV weekly × 68 weeks) can be added to this regimen. Azathioprine (1 mg/kg/day) can be used, but may enhance the risks of infection without better symptom control. Adequate nutrition, vitamin and mineral supplementation, and liberal fluid intake are also important.
6. Infection prevention during GVHD treatment: Prophylaxis against fungi (*Candida* sp.: fluconazole 100 mg po daily or mycostatin); encapsulated bacteria (penicillin VK 250 mg bid or erythromycin 250 mg bid if allergic); *P. carinii* (TMP-SMX DS bid 23 days/week or pentamidine 300 mg by aerosol once monthly); and CMV (dependent on serostatus) is essential during immunosuppressive therapy of GVHD (acute or chronic). Consider IV IgG replacement if hypogammaglobulinemia persists. Prompt and aggressive treatment of all infections is important.

or severe cholestatic jaundice. Bronchiolitis obliterans occurs in up to 10% of patients with chronic GVHD. [224] [225]

The pathogenesis of chronic GVHD may differ from acute GVHD. Autoimmune manifestations (the clinical similarity to scleroderma) and autoantibody formation (antinuclear antibodies, anti-erythrocyte antibodies, rheumatoid factor, lupus-like anticoagulants) are frequent. In addition, the major complications of chronic GVHD include secondary infection due to hypogammaglobulinemia, severely impaired cellular immune responses (skin test anergy and hypoproliferative T-cell mitogen responses), and splenic dysfunction. This chronic inflammatory syndrome may also be accompanied by stable lymphohematopoietic engraftment, but poor myeloid function with leukopenia, anemia, and, often, an immune complex or autoimmune consumptive thrombocytopenia.

The treatment of chronic GVHD, even more than acute GVHD, demands particular attention to prophylaxis and aggressive therapy of secondary opportunistic infection in addition to specific immunosuppressive treatment. Consequently, ongoing antibacterial, antifungal, and antiviral prophylaxis should be continued as well as intravenous immunoglobulin support for patients manifesting persistent hypogammaglobulinemia. After the onset of chronic GVHD, 2540% of patients die within 2 years, often of secondary infections.

Like acute GVHD, the specific immunosuppressive therapy of chronic GVHD is most often corticosteroids. [226] [227] However, the ongoing and long-lasting nature of the syndrome demands that reduced doses and, if possible, alternate-day steroid therapy be used to minimize the chronic complications of corticosteroid treatment, including osteoporosis, avascular necrosis of bone, [228] [229] cataracts, muscle wasting, hyperglycemia, and cutaneous atrophy. In addition to corticosteroids, azathioprine, cyclosporine, or thalidomide have been used to blunt the T-cellmediated proliferative responses that sustain the autoimmune syndrome. [230] [231] In addition, investigational therapies using ultraviolet light as photoimmunotherapy have shown some, albeit limited activity. [232] [233] Most successful strategies for chronic GVHD, however, incorporate reduced-dose immunosuppressive treatment, aggressive antimicrobial prophylaxis, and long-term therapy for 69 months beyond any active GVHD symptoms, followed by slow withdrawal of therapy. Much longer therapy may be required for some patients, and early withdrawal of therapy has been frequently accompanied by flares of chronic GVHD.

LATE COMPLICATIONS

Beyond the initial post-transplantation period, subsequent complications result from cumulative organ injury induced by the pretransplantation conditioning, from residual ill effects of any acute complications, and from ongoing immunodeficiency leading to late infections. [234] TBI, alkylating agents, and corticosteroids all contribute to the formation of cataracts, which develop in over one-third of patients by 5 years post-transplantation and often require surgical therapy. [235] Hypothyroidism (3050% of patients) and hypogonadism (6090%) are also common. [236] [237] [238] Therefore, appropriate follow-up care should include monitoring of thyroid and gonadal function, with particular attention to menopausal symptomatology and sexual dysfunction, which may be ameliorated by appropriate hormone replacement. Permanent sterility is expected in nearly all men and most women undergoing transplantation, [238] although transplantation without TBI may be fertility sparing in nearly one-third of men and women. Prepubertal children may retain fertility, although secondary sexual development may be delayed.

Growth retardation is frequently seen in children receiving TBI, [239] with 4050% of children having markedly depressed growth rates for 2 years after SCT. This may be complicated by nutritional deficiency and chronic illness, and especially by chronic GVHD. Regimens without TBI have been proposed as less likely to cause the late growth and development complications in children, [240] but definitive evidence of lesser toxicity is not available. Neurologic complications, including toxic encephalopathy, peripheral neuropathy, and seizures, may result from damage due to previous high-dose therapy and radiation, neurotropic viral infections (e.g., herpes group viruses), or from cyclosporine. Destructive or inflammatory arthropathy may develop. Radiation, steroid therapy, and GVHD may produce avascular necrosis of bone [228] [229] or periarticular contractures that limit mobility.

Finally, pretransplantation chemoradiaton therapy conditioning may be carcinogenic. Secondary neoplasia may develop after SCT, especially if extensive antineoplastic therapy was administered before transplantation. [241] [242] [243] [244] A six- to eightfold higher risk of cancer for SCT recipients has been reportedmostly non-Hodgkin lymphomas, but recently secondary myelodysplastic syndromes and leukemia have been seen, as well. [245]

Stem cell transplantation survivors eventually return to full and complete functional status. Several quality-of-life studies have shown that by 1 year after transplantation, more than three-fourths of patients are back to work, and nearly 90% of autologous SCT recipients report an above-average to excellent quality of life. [246] Allograft recipients recover more slowly, especially those older than 30 years of age and those with chronic GVHD, in whom ongoing physical and psychological problems delay a return to good health. [247] [248] [249] [250]

Part VIII - Hemostasis and Thrombosis

Chapter 98 - Megakaryocyte and Platelet Structure

Dorothea Zucker-Franklin

INTRODUCTION

The megakaryocyte is not only the most conspicuous and largest cell in mammalian bone marrow, but arguably, it is also unique among species. First, it is polyploid, a term not to be confused with polynucleated. Polyploidy connotes multiple reduplications of chromosomes (from the usual 2N to 64N or even 128N) contained within the same nuclear envelope. Secondly, megakaryocytes generate their progeny, the blood platelets, not by the usual process of cell division, but by cytoplasmic fragmentation. Thus platelets are anuclear pieces of cytoplasm, have no DNA, and have little, if any, biosynthetic machinery. Their indispensible hemostatic functionwhich during normal homeostasis is maintained at levels ranging from 150,000 to 450,000/mm ^{3} is almost entirely conferred to them by substances synthesized in the mother cell. However, platelets are metabolically extremely active using glycolysis as well as oxidative phosphorylation to support their endocytic and secretory activities. Under normal circumstances, they survive in the circulation for 710 days. Platelets are not migratory and do not diapedese into tissues. Megakaryocytes, on the other hand, are motile cells. Most of them appear to leave the bone marrow intact and shed their platelets in the capillary bed of the lungs (see following). Some fragmentation occurs in the marrow sinusoids, where elongated extensions of megakaryocyte cytoplasm consisting of many platelet fields have been referred to as "proplatelets." Such proplatelets can also be observed to form in vitro, when megakaryocytes are allowed to settle on a surface. Although they are motile, megakaryocytes are not known to leave the vasculature to migrate back into tissues as is the case for most leukocytes. The finely tuned mechanism whereby the number of megakaryocytes in the bone marrow and the number of platelets released into the circulation is maintained is largely attributable to a newly characterized hormone, thrombopoietin, which is described in greater detail elsewhere in this volume (see Chap. 17).

MEGAKARYOCYTES

Space restriction permits communication of only the most basic information necessary to understand how the structure of megakaryocytes subserves their main function, which is the production of platelets. More detailed accounts have been published elsewhere. [1] [2] [3] Megakaryocytes are believed to derive from the same pluripotential stem cells that generate other blood cells. Their precursors are morphologically indistinguishable from mononuclear cells, even after their commitment to the megakaryocyte/platelet lineage has occurred. Lineage commitment becomes immunologically detectable, by virtue of the lineage-specific epitope GpIIb/IIIa [4] (Fig. 98-1). In rodents, acetyl cholinesterase can be used as an early marker for this cell series. [5] From thence on, morphologic differentiation of megakaryocytes deviates from all other bone marrow elements and the cell is, therefore, easily recognized.

Nucleus

The round or slightly indented diploid (2N) nucleus of the megakaryoblast undergoes a series of endomitosesusually from 2N up to 64N (with an average of 16N)increasing the number of chromosomes from 46 to 368 or even 1,472. During endomitosis the nuclear membrane disappears (Fig. 98-2) and depending on the previous ploidy attained, several mitotic spindles form each with its own centrosome. The number of centrioles seen during interphase probably correlates with the ploidy of the cell (Fig. 98-3). (For a review see reference 6 .)

After endomitosis, the nuclear membrane reforms and the reduplicated DNA disperses. The result is a very large, multilobed nucleus, which distinguishes the cell from an osteoclast, also a large cell, but with many separate nuclei. The nucleoli of megakaryocytes are small and the abundant biosynthetically inactive heterochromatin is distributed along the nuclear membrane. Thus the megakaryocyte nucleus resembles that of a mature cell rather than a "blast" (Fig. 98-4). After the platelets have been shed, there remains a naked or denuded nucleus, which on light microscopy of marrow smears or sections looks like an oversized pyknotic erythroblast (Fig. 98-5). Regeneration of cytoplasm from a denuded nucleus has never been observed. It is noteworthy, however, that a physiologically denuded megakaryocyte nucleus does not have the appearance of a nucleus that has undergone apoptosis as is the case when normal thrombopoiesis has been artificially stimulated with cytokines, such

Figure 98-1 A "mononuclear" cell seen in the inset was isolated from human umbilical cord blood with anti-CD34-coated beads. Subsequently, the specimen was incubated with anti-GpIIb/IIIa. The epitope was detected by the immuno-gold technique (arrow indicating black particles), which revealed that this cell had been committed to the megakaryocyte/platelet lineage. (For details see reference [69] .) (Magnification of whole cell in inset × 6000; detail × 22,000.

Figure 98-2 Megakaryocyte in the process of endomitosis. Note absence of nuclear membrane and arrangement of chromosomes in the configuration of several metaphases. (× 3,000.)

as interleukin-6. [7] Denuded megakaryocyte nuclei are difficult to find in normal bone marrow, which supports the contention that most megakaryocytes leave the medullary space intact.[8] On the other hand, numerous denuded megakaryocyte nuclei are seen in the bone marrow of individuals infected with human immunodeficiency virus (HIV), where their presence has diagnostic significance. [9] This phenomenon may be attributable to impaired migration of the infected cells or inability of the phagocytic system to remove the effete material.

Figure 98-3 Section through the pole of a megakaryocyte in interphase (nucleus is not within the plane of section). There are at least 14 centrioles (arrow). Diploid cells have only two centrioles. (× 10,500.)

Figure 98-4 Mature, fully granulated megakaryocyte exhibiting the extensive membrane system demarcating platelet territories (arrows). Note multilobed nucleus with inconspicuous nucleoli and peripherally distributed heterochromatin. The peripheral zone (PZ) is devoid of organelles. On light microscopy, blebbing of the peripheral zone is often mistaken for "budding" platelets. However, platelets are not released by budding (see text). (× 4,000.)

Cytoplasm

Conventionally, maturation of the megakaryocyte cytoplasm has been divided into three stages, which is of little relevance to the thrust of this chapter. Suffice it to say that maturing megakaryocytes, like other granulated cells, have an abundance of ribosomes and profiles of rough endoplasmic reticulum, where protein synthesis occurs. They have several Golgi stacks from

Figure 98-5 Section of a bone marrow aspirate stained with hematoxylin and eosin, obtained from an HIV-infected patient illustrates two mature megakaryocytes (M) and a denuded megakaryocyte nucleus (arrow). (× 1,000.)

where the synthesized proteins are packaged into granules. The largest granules, which are referred to as -granules, measure 200500 nm in diameter and contain the lineage-specific proteins, such as -thromboglobulin, platelet factor 4 (PF4), thrombospondin, von Willebrand factor, as well as endocytosed plasma proteins, such as fibrinogen, albumin, IgG, factor V, and others. [10] [11] [12] Recently, the amyloid precursor protein APP has been identified in DAMI cells, a megakaryocyte cell line, which differs from primary megakaryocytes in many respects.[13] The author has been unable to detect APP in freshly isolated megakaryocytes by immunoelectron microscopy. In addition to the -granules, there are smaller vesicles and granules measuring 50100 nm in diameter. These are considered lysosomes because they contain acid phosphatase, aryl sulfatase, and cathepsin. [14] [15] The mechanism whereby sorting of these substances from the Golgi to different organelles is

accomplished can only be deduced from studies carried out on other cell types, but has not yet been fully elucidated in megakaryocytes.

By far the most interesting feature of megakaryocyte cytoplasm is a system of membranes referred to as the demarcation membrane system (DMS). Its main function appears to be the demarcation of cytoplasmic areas likely to delineate future platelets. The literature dealing with the formation of the DMS is confusing because most investigators have focused on a single mechanism.[16] [17] Yet, it is evident, that the DMS is derived from multiple sources, including Golgi vesicles, coated vesicles (Fig. 98-6), and components of invaginated plasma membrane (Fig. 98-7). As holds true for circulating platelets, the peripheral zone of the megakaryocyte cytoplasm is devoid of membranes or organelles (Fig. 98-4). Conceptually, one may assume that some trigger is necessary to induce invagination of the plasma membrane and its fusion with the DMS. This would result in extrusion of cytoplasmic fragments of variable size and in essence constitute platelet release. Much has been made of the term proplatelet, (reviewed in reference [19]), , when this signifies nothing more than protrusion of megakaryocyte cytoplasm or a pseudopod, which, in the case of the megakaryocyte, comprises many platelet fields extending into a sinusoidal space and destined

Figure 98-6 Detail of a megakaryocyte that had been incubated with cationized ferritin (CF) before fixation. Ferritin coats the surface membrane and, subsequently, is seen to line the entire DMS. The arrow indicates fusion of a coated vesicle with the DMS. The arrowhead indicates a segment of the DMS that did not react with CF. (× 60,000.) *(From Behnke,[17] with permission.)*

Figure 98-7 Detail of a megakaryocyte that had first been incubated with cationized ferritin like the cell depicted in Fig. 98-6 . Subsequently, latex particles (L) were added to the suspension. Coalescence of invaginated membrane compartments is clearly evident. Also note that some segments of the DMS did not react with CF (arrowheads). (× 34,000.)

to fragment into individual platelets at a later time in the circulation (Fig. 98-8). When maturing megakaryocytes are fixed in suspension culture, fragmentation of cytoplasm occurs randomly into pieces comprising one or more platelet fields (Fig. 98-9). On the other hand, when freshly collected bone marrow is placed on a glass surface, megakaryocytes will spread.

Figure 98-8 "Pseudopod" or "proplatelet" extending into the sinusoidal space. The nucleus of the cell is not in this plane of section. Arrows indicate sinusoidal endothelium. L, leukocytes; E, erythrocyte. (× 3,000.)

Figure 98-9 Megakaryocyte grown in a suspension culture system clearly shows fragmentation process. Putative platelets are of variable size and the peripheral zone of the megakaryocyte (PZ) does not necessarily form part of the platelet envelope. (× 3,000.) *(Reproduced with permission from Zucker-Franklin D, Petursson S: Thrombocytopoiesis: analysis by membrane tracer and freeze-fracture studies on fresh human and cultured mouse megakaryocytes. J Cell Biol 99:420, 1984. Copyright The Rockefeller University Press.)*

Under such in vitro conditions, the development of long filiform processes showing constrictions presumed to demarcate platelet territories has been recorded by time-lapse cinematography[20] (Fig. 98-10). Although interesting, these conditions can hardly be equated with those prevailing in vivo. The author encourages use of the term "compound" platelet denoting a large platelet consisting of multiple platelet territories (Fig. 98-11A), rather than the terms descriptive of size or shape, such as proplatelet, giant platelet, or megathrombocyte.

PLATELETS

Platelets circulate as lenticular pieces of membrane-bound cytoplasm measuring 23 m in diameter and having an average volume of 68 femtoliter (fL). These measurements are important because, in clinical situations, platelet number may not always reflect total platelet volume. [2124] Yet, very large compound platelets (see previous discussion) may partially compensate for a shortage in their numbers. Figures 98-12 and 98-13 depict equatorial and cross sections, respectively, of a resting "unit" platelet as opposed to a giant or "compound" platelet, consisting of many platelet territories depicted in Figure 98-11A . The lenticular shape of the platelet is maintained by a microtubule coil, which in most sections appears as a bundle of microtubules. Any shape change, no matter what the stimulus, be it mechanical or receptor mediated, causes depolymerization of the microtubules. As in other cells, the microtubules are also sensitive to low temperature, colchicine, and vinca alkyloids, whereas they are stabilized by Taxol and its derivatives. [25] Microtubules reform in pseudopod-like structures when shape change is complete, i.e., after platelets have participated in the stabilization of a clot. No band of microtubules seems to exist in compound platelets, although microtubules can be seen to be oriented in various directions.

Organelles

Practically all platelet organelles have been preformed in megakaryocytes. The most conspicuous among these are the -granules (Figs. 98-11 and 98-13). They contain the lineage-specific proteins, mentioned above, as well as endocytosed substances. [26] [27] Because platelets continue to endocytose plasma proteins, platelet -granules may be larger than those of megakaryocytes, though this has not yet been precisely measured. The granule proteins have been identified mostly by immunologic means (e.g., Fig. 98-14). Some of them, e.g., P-selectin (PADGEM, GMP-140, CD62) and GpIIb/IIIa, are located almost exclusively on the granule membrane.[28] [29] [30] Others, like von Willebrand factor, appear to be associated with intragranular tubular structures [31] or in vaguely delineated regions, only defined on the basis of varying electron opacity. [32] Whether such stratification is due to a substructure within the granule matrix, not preserved by currently used fixatives, or whether there is a differential effect of embedding materials on various substances contained in the granules is not known (Figs. 98-13 , 98-15 , and 98-16). In addition to the aforementioned proteins, the presence

Figure 98-10 Scanning electron photomicrograph of a megakaryocyte that has been allowed to spread on glass. The cell unravelled into many filamentous processes showing constrictions, which are presumed to separate platelet territories. N, nucleus. *(From Haller and Radley,[20] with permission.)*

Figure 98-11 (A) A compound platelet, which customarily has been referred to as a giant platelet, when examined by light microscopy, is seen to consist of numerous platelet territories separated by membranes akin to the DMS in megakaryocytes. At higher magnification, many structures, usually not seen in mature platelets, such as rough endoplasmic reticulum and clustered ribosomes, can be resolved. (× 8,000.) **(B)** Detail of the area indicated by the arrow in **(A)**

of protease Nexin II (amyloid -protein precursor) in -granules has also been well established, [33] even though it is not yet clear whether this enzyme is endocytosed or synthesized in this cell line. Lastly, there are a few extremely electron-opaque granules, also called dense bodies, which contain the nonmetabolic pool of adenine nucleotides, serotonin, pyrophosphate, and calcium ions, [34] [35] [36] the content of which is also released during platelet activation.

As in other cells, glycogen particles and mitochondria are the organelles subserving the platelets' metabolic activities (Figs. 98-15 and 98-16), whereas small vesicles are representative of lysosomes discussed before. [14] [15] [37] As would be expected, compound platelets, or even single platelet units, which may be prematurely released during accelerated thrombocytopoiesis, such as following hemorrhage or stimulation with thrombopoietin, [38] may show ribosomes, rough endoplasmic reticulum,

Figure 98-12 Equatorial section through a platelet showing the microtubule coil with a "loose" end to good advantage (arrow). G, -granule; M, mitochondrion. (× 22,000.)

or even other organelles not seen in mature platelets during normal homeostasis (Fig. 98-11B). Another structure, the dense tubular system is usually not enumerated among the organelles, but this designation would be justified because it consists of a membrane-bounded sac containing platelet-specific peroxidase [39] and glucose-6-phosphate dehydrogenase. [40] By analogy with the sarcoplasmic reticulum, it has also been postulated to be a major site of prostaglandin synthesis. [41] [42]

The Canalicular System (Endocytosis and Secretion)

The system of membrane-bound channels, which is likely derived from the DMS of the megakaryocyte, is often referred to as the open or surface connected canalicular membrane system. It is by no means "open" because energy is required for even solutes to be taken into these channels. [43] However, as illustrated in the megakaryocyte (Fig. 98-7), large objects, such as latex particles, bacteria, and viruses (Fig. 98-18), can be engulfed by invagination of the plasma membrane, which subsequently coalesces with the canalicular system. Fusion of the invaginated membrane containing endocytosed objects with -granules, akin to what occurs between lysosomes and phagocytic vacuoles in granulocytes, [44] has never been observed in platelets. On the other hand, the uptake of plasma proteins, such as fibrinogen and IgG, is likely to be accomplished by specific receptor-mediated vesicular transport. [45] Apart from a storage function, the endocytotic activity of the platelet appears to be of only minor physiologic significance. In this context, it should be remembered that the platelet has little, if any, proteolytic or bactericidal ability and that, therefore, microorganisms, including HIV (Fig. 98-18), might be stored or transported by platelets to other sites, such as the macrophage/phagocytic system, with impunity.[46] This could have adverse consequences.

The so-called release phenomenon or the mechanism whereby platelets secrete much of their granule content is still controversial. Even before the advent of electron microscopy,

Figure 98-13 Resting platelet seen in cross section. The peripheral band of microtubules is indicated by arrows. Note compartmentalization of substances in several -granules as evidenced by different electron opacity. C, canaliculus. (× 30,000.)

it was noted that, almost immediately on stimulation by any aggregating agent, be it adenosine diphosphate (ADP), thrombin, epinephrine, collagen, or others, the granules move to the center of the platelet (Fig. 98-19). This is in marked contrast to what happens in any other secretory cell where, as a rule, the granule membranes fuse with the surface membrane when their content is discharged. In the case of platelets, there is little doubt that coalescence of granules occurs within the cytoplasm (Fig. 98-20A and B), and with diligent search, images suggesting that the granule content exits via the surface connected canalicular system can be found (Fig. 98-20C).[47] However, during this process, the canalicular membrane does not seem to become incorporated into the plasma membrane as is the case for other exocrine cells (e.g., basophils and mast cells). [48] On the other hand, several granule membrane proteins (e.g., P-selectin) appear to be translocated to the surface.[28] This occurs even before degranulation is conspicuous. The determination of P-selectin or activated GpIIb/IIIa [49] by flow cytometry is rapidly becoming one of the most sensitive and efficient methods for the detection of platelet activation (Fig. 98-21).[50] This is of particular interest because

Figure 98-14 Detail of a platelet that was embedded in Lowicryl and reacted with an antibody to fibrinogen by the immuno-gold method. The gold particles (black) indicate the presence of fibrinogen in the -granules. (× 91,000.)

subtle forms of in vivo platelet activation may have significant clinical implications in the area of cardiovascular and thrombotic diseases. [51] [52] It is likely that such membrane proteins are laterally translocated by flow within the plane of the membrane by means of a process akin to the "capping" phenomenon, [53] rather than by physical evagination of entire membrane regions. It has also been suggested that the pores seen by freeze fracture on the external membrane leaflet of resting platelets may widen during the secretory process.

Adhesion/Cohesion, Contraction

A chapter meant to cover structure cannot do justice to the most important function of plateletstheir role in hemostasis and clot retraction. What is there to be seen that makes platelets sticky, allows them to adhere to each other as well as to tissue matrices denuded of endothelium? Obviously, this capacity must be vested in their surface membrane.

To begin with, the so-called glycocalyx of the platelet surface membrane is much thicker than that of other circulating blood cells. This can be shown most dramatically, when the cells are fixed in the presence of ruthenium red (Figs. 98-15 , 98-16 , and 98-17). During aggregation, "bridges" form between adjacent platelets, which do not appear to alter the structural integrity

Figure 98-15 Detail of a platelet fixed in the presence of ruthenium red to show the thickness of the glycocalyx (arrow) as well the variation in electron opaqueness within -granules. M, mitochondrion; MT, microtubules. (× 38,000.)

Figure 98-16 Detail of a platelet taken from the same specimen as the platelet depicted in Figure 98-15 showing glycogen particles to good advantage. Gl, glycogen. (× 45,000.)

of the membrane itself (Fig. 98-22). The bridges can be resolved during all phases of adhesion, aggregation, and release, even after the platelets are completely degranulated and have undergone what used to be called "viscous metamorphosis" because of the refractility of the thrombus by light microscopy. [54] [55] Fibrinogen as well as fibrin have been detected at the site of the bridges by immunohistochemical means, [56] but the chemical nature of these structures remains to be more completely defined.

Even more intriguing than the thickness of the glycocalyx is the observation that, on freeze fracture, the partition coefficient of the intramembranous particles (IMP) of the platelet plasma membrane has been observed to be the reverse of that seen in any other mammalian cell, including the megakaryocyte, [43] i.e.,

Figure 98-17 Detail of an erythrocyte that was present in the same specimen as the platelets depicted in Figures 98-15 and 98-16 to illustrate the difference in comparative thickness of the glycocalyx between the cells. (× 44,000.)

Figure 98-18 Platelet from a specimen of platelet-rich plasma prepared from a healthy donor and incubated with HIV-infected cultured lymphocytes. Numerous virus particles (arrow) were seen to have been endocytosed. (× 29,000.) *(From Zucker-Franklin et al.,[46] with permission.)*

twice as many particles remain associated with the external than with the internal leaflet of the bimolecular membrane. Although little progress has been made in recent years to identify the biochemical nature of the IMP, it is likely that they represent integral membrane proteins. Therefore, proteins intimately associated with the external leaflet may be assumed to be more susceptible to external triggering. By teleologic reasoning, this may preclude activation and degranulation of megakaryocytes, when platelets are activated to function in hemostasis.

The contractility of platelets and their role in clot retraction were noted more than 100 years ago. Bettex-Galland and Lüscher extracted the contractile protein, which they called thrombosthenin.[57] It was also shown that thrombosthenin constitutes more than 20% of the platelet's protein. [57] [58] Subsequent advances in biochemical and ultrastructural techniques permitted more definitive recognition of actin and myosin. [59] [60] [61] [62] [63] When

Figure 98-19 Platelet from a specimen of platelet-rich plasma fixed 1 minute after addition of ADP. The granules are crowded in the center. The peripheral band of microtubules has depolymerized. No granules are seen in contiguity with the surface membrane. (× 34,000.)

Figure 98-20 (A) and **(B)** Details of platelets from a specimen of platelet-rich plasma fixed 30 seconds after the addition of 0.1 U thrombin. Although no granules are seen at the plasma membrane, coalescence of granules evidenced by size, contour, and differing electron opacity, has clearly occurred. (A × 52,000; B × 35,000.) **(C)** Platelet from the same specimen as **(A)** and **(B)**

platelets are subjected to hypotonic media, an amazing network of cytoskeletal filaments can be resolved (Fig. 98-22B). Such filaments are much more prominent in platelets than in other mammalian nonmuscle cells, which are also known to contain actin and myosin.

Even more significant may be the observation that these cytoskeletal filaments are closely associated with the plasma membrane as well as with the membranes constituting the canalicular system, but they do not appear to be associated with the membranes of the -granules. [62] Although the role of the

cytoskeletal proteins in platelet contractility is beyond question, the mechanism whereby a transmembrane connection between surface receptor/ligand complexes (GpIIb/IIIa/fibrinogen), located on the external aspect of the membrane, and the contractile elements (e.g., actin) located in the cytoplasm, remains to be elucidated. Only a very small portion of membrane actin has been shown directly associated with GpIIb/IIIa. [64] Other cytoskeletal proteins, such as vinculin, fibulin, and talin may be involved. Among these, talin has emerged as the most important, because it has been proven to be instrumental in the formation

Figure 98-23 (A) Talin appears to be uniformly distributed in the cytoplasm of resting platelets. **(B)**

Figure 98-24 Platelet aggregate formed on enzyme-treated cartilage to uncover collagen fibrils (arrow). As a rule, platelets do not adhere to cartilage because proteoglycan precludes interaction with underlying collagen. (× 13,000.) *(From Zucker-Franklin D, Rosenberg L: Platelet interaction with modified articular cartilage. J Clin Invest 59:641, 1977, with permission.)*

of adhesion plaques between fibroblasts and substrates to which they attach. [65] Talin is a 235,000 d protein, which is very abundant in human platelets, making up more than 3% of total platelet protein. [66] [67] In the resting platelet, talin is diffusely distributed throughout the cytoplasm, but on stimulation, either in suspension or when adherent, talin assumes a submembranous location [68] (Fig. 98-23). This relocation is mediated by calcium-dependent proteolysis of talin [69] and facilitates colocalization of talin with -chains of integrins. [69]

Following adhesion, cohesion, and contraction, there remains a refractile thrombus, referred to as a "hemostatic plug" in earlier literature. [70] The pathophysiologic function of this structure in hemostasis is so well recognized that it requires no comment. It is, however, remarkable, that within this aggregate, individual platelet territories remain distinct (Figs. 98-24 and 98-25). Mechanical trauma would be just as likely to rupture adjacent tissue as renting the thrombus along cleavage planes between platelet membranes.

For the sake of completeness, the mechanism whereby thrombi are removed to permit revascularization and wound healing should be briefly addressed. This process appears to be accomplished by phagocytic cells. The event can be simulated in vitro by adding an aggregating agent, such as ADP or collagen, to a suspension of platelets and leukocytes. As illustrated in Figure 98-25 , granulocytes appear to be attracted to the thrombus and can be seen in the process of ingesting platelet debris. It is not difficult to extrapolate this image to conditions prevailing in vivo. It may be assumed that substances released

Figure 98-25 Platelet aggregate following the addition of collagen to a suspension of leukocytes and platelets in heparinized plasma. Monocytes and neutrophils are seen in the process of ingesting platelet debris. (× 2,800.) *(From Zucker-Franklin, with permission.)*

by aggregating platelets are chemotactic for leukocytes. These still remain to be identified.

Chapter 99 - The Molecular Basis for Platelet Function

Edward F. Plow
Mark H. Ginsberg

Platelets ordinarily circulate in blood vessels as individual entities that do not interact with other platelets or other cell types. A transition from this nonadhesive to an adhesive state can be rapidly initiated if platelets are exposed to an appropriate stimulus. A scenario of the platelet adhesive reactions initiated in response to an injury to a blood vessel wall, as exemplified by rupture of an atherosclerotic plaque, is illustrated in Figure 99-1 . Disruption of the endothelial cell lining of the vessel exposes constituents within the subendothelial matrix, including a variety of adhesive proteins that can support initial platelet attachment. After attachment, platelets may undergo a spreading reaction that permits formation of multiple and tight contacts between the cell surface and the matrix. These additional contacts may be critical in stabilizing the association of the platelets with the matrix in flowing blood. In conjunction with these adhesive reactions, the cells often encounter agonists in the microenvironment that can trigger platelet secretion. The secretory response results in the release of the contents of intracellular storage granules from within the platelet. Granule constituents include substances that can stimulate circulating platelets and cause them to acquire new adhesive properties. These stimulated platelets interact with one another, during platelet aggregation, to form an effective plug to seal the injured vessel wall and prevent excessive blood loss. This series of platelet responsesattachment, spreading, secretion, and aggregationis essential for the hemostatic function of platelets. Nevertheless, these same events, occurring on an injured endothelial cell or on an atherosclerotic plaque, may result in the formation of a platelet-rich thrombus, which can compromise the patency of the blood vessel and lead to thrombosis. At the other extreme, abnormalities in platelet adhesive reactions of either a genetic (e.g., Glanzmanns thrombasthenia or Bernard-Soulier syndrome) or an acquired origin can result in bleeding episodes. Thus, platelet adhesive reactions and secretion are central events in health and disease processes; bleeding, hemostasis,

Figure 99-1 Hemostatic response of platelets to injury. **(A)** Disruption of the endothelial cell lining of the blood vessel exposes constituents of the subendothelial matrix. **(B)** Platelets attach to, and spread on, the matrix constituents. **(C)** Platelet secretion may be initiated. **(D)** Released platelet constituents can activate additional platelets, which aggregate with one another to form a thrombus.

and thrombosis are delicately balanced on these platelet functions.

This chapter addresses the molecular basis of platelet adhesive reactions and secretory responses. Great strides have been made in defining the mechanisms that govern these functional responses. At the heart of these platelet responses are ligand-receptor interactions. Indeed, the platelet has often served as a model cell type for studying ligand-receptor interactions and establishing basic mechanisms of cell adhesion and secretion.

MOLECULAR BASIS OF PLATELET ADHESION

Substrates for Platelet Attachment and Spreading

Some of the major subendothelial matrix proteins that support platelet attachment or spreading reactions are listed in Table 99-1 . From the extent of this list, it is clear that the platelet can adhere to a variety of substrates once the endothelium has been disrupted. The endothelium must also create an effective barrier to prevent circulating platelets from reaching the matrix and initiating thrombus formation. In addition to serving as a physical barrier, endothelial cells synthesize and elaborate components, notably prostaglandin I_2 , nitric oxide, and an enzyme that degrades adenosine diphosphate (ADP), which prevent platelet activation and impart a nonthrombogenic character to the normal endothelium (see Chaps. 100 and 101).

Several considerations have an impact on the role of the individual matrix constituents in mediating platelet adhesion:

1. Not all of the adhesive proteins listed in Table 99-1 support the same spectrum of platelet adhesive responses. For example, under some conditions, platelets attach to, but do not spread on, laminin,[1] whereas von Willebrand factor (vWF) and fibronectin support cell attachment and spreading. [2] [3] [4] Collagen not only supports the attachment and spreading of platelets but can provoke a secretory response. [5] Of the multiple forms of collagen, types I, III, and VI are regarded as being particularly important in supporting platelet adhesion.

2. There is growing evidence that the phenotypic properties of endothelial cells from different blood vessels vary; it also is likely that the composition of the subendothelial matrix varies. Thus, certain proteins may play a dominant role in supporting platelet adhesion in certain blood vessels. Moreover, even at the same anatomic location, the nature of the injury can expose different substrata.
3. Shear rate developed by flowing blood varies with vessel caliber and greatly influences platelet adhesion. Shear is particularly important in defining the contribution of vWF to platelet adhesion. Patients with von Willebrand disease (see Chap. 114) have a bleeding diathesis, attesting to the importance of vWF in supporting platelet function. Yet, in in vitro experiments, a role of vWF in platelet adhesion is demonstrable at high but not at low shear rates. [3] [6] By contrast, a role for fibronectin in supporting platelet adhesion can be demonstrated at both high and low shear. [7] [8]
4. A variety of these adhesive proteins interact with one another. For example, vWF, fibronectin, and thrombospondin all bind to collagen [9] [10] [11] (although they exhibit differential reactivity with different collagen types). These interactions may bridge the platelet to a matrix protein or may modulate the adhesive properties of a matrix protein.
5. Several of the adhesive proteins are present in platelet secretory granules or in plasma, or both, as well as being matrix constituents. vWF and fibronectin are present in all three locations, and thrombospondin is a major platelet granule constituent. [12] [13] Proteins from all three sourcesthe matrix, the platelet, and the plasmacontribute to platelet adhesion. The adhesive proteins derived from these different sources may be functionally distinct because they are not structurally identical. For example, the degree of vWF and fibronectin multimerization differs for molecules derived from plasma and the matrix.
6. Matrix proteins are subject to degradation by a variety of proteolytic enzymes. Such proteolysis can modulate the adhesive properties of the matrix proteins. In some cases, cryptic adhesive sequences can be exposed that interact with additional sets of platelet adhesion receptors. [14] [15]

TABLE 99-1 -- Subendothelial Matrix Constituents That Support Platelet Adhesion

Matrix Constituent	Comment
Collagens	Large family of proteins with certain members supporting platelet adhesion, aggregation, and secretion
von Willebrand factor	Large multimeric protein critical for the hemostatic function of platelets
Fibronection	Dimeric or multimeric protein that supports attachment and spreading of platelets
Thrombospondins	Trimeric proteins exhibiting both adhesive and antiadhesive properites
Laminins	Proteins supporting platelet attachment
Microfibrils	A fibular bundle of protein constituents found in certain matrices

Overall, the subendothelial matrix should be viewed as a dynamic and mutable interface that provides multiple substrates to support platelet adhesion.

Platelet Adhesion Receptors

The individual adhesive proteins come in contact with the platelet by serving as ligands for specific cell surface receptors (Table 99-2). Because several nomenclature systems have been used to identify the membrane proteins of the platelet, the same receptor may have multiple designations. One of the most widely used nomenclatures is based on electrophoretic mobility of the membrane proteins on polyacrylamide gel systems, in which the highermolecular-weight proteins move more slowly. This separation gave rise to glycoprotein (GP) I, II, III, and so on, with GPI having the highest molecular weight. As the gel systems used became more discriminating, several proteins were discerned in the GPI position, hence GPIa, GPIb, and GPIc, and so forth. [16] Further refinement is still required; for example, there are at least three distinct polypeptides in the GPIc position. Several of the membrane proteins exist on the platelet surface as noncovalent complexes; thus, GPIb-IX, GPIc-IIa, and GPIIb-IIIa can be regarded as single-membrane proteins. Other nomenclature systems have arisen from the fact that several platelet membrane proteins are present and have been assigned different names on other cell types. This is the basis for the VLA (very late antigens) designations for some of the platelet membrane proteins. Similarly, certain proteins may also have extracellular matrix (ECM) and leukocyte differentiation antigens

TABLE 99-2 -- Platelet Receptors for Adhesive Proteins

Ligand	Receptor(s)	Other Designations

Collagen	GPIa-IIa	VLA-2, $_{2\ 1}$
	GPIIb-IIIa	$_{IIb\ 3}$
	GPIV	GPIIIb, CD36
	GPIV	
Fibrinogen	GPIIb-IIIa	$_{IIIb\ 3}$
Fibronectin	GPIc-IIa	VLA-5, $_{5\ 1}$
	GPIIb-IIIa	$_{IIIb\ 3}$
Thrombospondin	Vitronectin receptor	$_{V\ 3}$
	GPIV	GPIIIb

	GPIIb-IIIa	
Laminin	GPIc-IIa region	VLA-6, $_{6\ 1}$

VLA, very late antigen.

(CD) designations. These latter nomenclature systems are used inconsistently in the platelet literature. Some receptors have been named on the basis of their function (e.g., the vitronectin and the fibronectin receptors). Although functional designations seem highly appropriate from a descriptive standpoint, at least two membrane proteins on platelets can serve as receptors for vitronectin and fibronectin (see Table 99-2), and several platelet constituents have been referred to as collagen receptors. Beyond creating a nomenclature complexity, the redundancy of the platelet receptors enables the cell to establish multiple contacts with a single matrix constituent; thus, a single ligand may initiate several distinct functional responses by engaging different receptors.

The Integrin Family of Adhesion Receptors

Many of the adhesive protein receptors on platelets are members of the integrin family. The integrins are broadly distributed heterodimeric (two subunits) cell surface molecules that share certain structural, immunochemical, and functional properties. [17] [18] [19] [20] [21] [22] [23] [24] [25] [26] The -subunits, of which eight are known, are highly homologous to one another, exhibiting at least 3545% identity at the primary amino acid sequence level. The -subunits, of which 14 are known, are also similar to one another but exhibit less extensive sequence identity. [21] [27] The -subunits are synthesized as single-chain polypeptides; some, such as GPIIb, are proteolytically processed to a two-chain form.[28] [29] [30] [31] Each -subunit combines in a noncovalent complex with an -subunit to form an adhesive protein receptor. A single -subunit can combine with several -subunits. Platelets express two major -subunits, $_{1}$ and $_{3}$ ($_{2}$ has been reported to be present at low levels[32]), and five -subunits (Table 99-3). Of the integrins expressed

TABLE 99-3 -- Platelet Integrins

Integrin	Ligand
GPIa-IIa (VLA-2, $_{2\ 1}$)	Collagen
GPIc-IIa (VLA-5, $_{5\ 1}$)	Fibronectin
GPIIb-IIIa ($_{IIb\ 3}$)	Fibrinogen, fibronectin, vitronectin, von Willebrand factor
Vitronectin receptor ($_{V\ 3}$)	Fibrinogen, fibronectin, vitronectin, von Willebrand factor, thrombospondin
GPIc-IIa region ($_{6\ 1}$)	Laminin

VLA, very late antigen.

on blood cells, GPIIb-IIIa is the most narrowly distributed and is restricted predominantly to platelets/megakaryocytes. GPIIb-IIIa may contribute to the association of platelets with tumor cells, an interaction important to the metastatic dissemination of neoplastic cells. [33] [34] [35]

Role of GPIb-IX in Platelet Adhesion

GPIb-IX is a notable example of a cell surface molecule involved in platelet adhesion that is not a member of the integrin family. Platelets from patients with Bernard-Soulier syndrome lack GPIb-IX; these patients have a marked bleeding diathesis [36] [37] [38] (see Chap. 130). A major role of GPIb-IX in hemostasis can be traced directly to its function as a receptor for vWF. vWF is made up of multiple functional domains, including domains involved in binding to GPIb and to matrix constituents such as collagen and microfibrils [9] [39] [40] [41] [42] [43] [44] [45] (see Chap. 113). Thus, vWF in the matrix may directly mediate platelet adhesion, and the plasma or platelet forms of the molecule may bridge the cells to other matrix components. In vitro, vWF does not interact directly with GPIb on platelets. An interaction can be measured in the presence of ristocetin, an antibiotic, or botrocetin, a snake venom peptide. Altered forms of vWF, asialo-vWF (the protein treated to remove the sialic acid residues from its carbohydrate moieties) and bovine vWF can interact directly with platelets. [46] [47] [48] It appears that high shear serves as the physiologic counterpart of ristocetin or botrocetin in humans. High shear alters the conformation of vWF or GPIb-IX, permitting their high-affinity interaction. [45] Such high shear stress can be attained in the microcirculation or in narrowed arteries.

GPIb is multifunctional because it can also serve as a binding site for thrombin. [50] [51] It is also a target for certain of the drug-induced platelet antibodies. [52] The full primary structures of both GPIb[53] [54] and GPIX[55] have been determined from cDNA cloning approaches. GPIb is composed of a heavy chain () and a light chain (), and both span the platelet membrane. GPIb associates with the cytoskeleton within the platelet. [56] [57] [58] This chain is highly susceptible to proteolysis, and a large proteolytic fragment, glycocalicin, can be detected in the plasma of some patients with thrombocytopenic disorders. [59] GPIX is a small, single-chain polypeptide with a molecular weight of 20,000 d. The contribution of GPIX to the function of GPIb-IX is uncertain. GPV also is deficient in Bernard-Soulier platelets and forms a loose association with GPIb-IX.[36] [37] An important consequence of occupancy of GPIb-IX by vWF is the induction of intracellular signaling events that ultimately lead to activation of GPIIb-IIIa and then platelet aggregation [60] (see later discussion). Such communication between adhesion receptors is a repeating theme for platelets as well as other cells.

PLATELET SECRETION

The foregoing discussion has emphasized the adhesive functions of platelets in mediating the physical closure of breaks in blood vessels. Another important function of platelets is the release of a variety of substances that stimulate or inhibit platelets or other blood and vascular cells, which can covalently modify the thrombus to affect its mechanical properties, as well as regulate coagulation, contribute to cell adhesive events, and modulate the growth of cells of the vessel wall. Thus, the platelet is not simply the stop leak of the vasculature, but also has the capacity to signal its presence in a thrombus in a variety of ways.

The majority of these substances are actively and selectively secreted from platelets either from preformed storage granules or by being synthesized de novo from membrane phospholipids. There are also factors in the platelet cytoplasm that can have effects on thrombus structure or on vascular cell growth; they are released as a result of minor degrees of platelet lysis during hemostasis. Some of these factors and their intraplatelet sources are illustrated in Figure 99-2 . The dense bodies (see Chap. 98)

Figure 99-2 Substances released by platelets and their intraplatelet sources. Illustrated are some of the bioactive substances released from dense bodies, -granules, lysosomes, the cytoplasm, and the platelet membrane. PDECGF, platelet-derived endothelial cell growth factor; PAF, platelet-activating factor; HETEs, hydroxyeicosatetraenoic acids; HMWK, highmolecular-weight kininogen; C1 INH, C1 inhibitor; PAI-1, plasminogen activator inhibitor 1; vWF, von Willebrand factor; PDGF, platelet-derived growth factor; CTAP, connective tissue activating peptide; TGF-, transforming growth factor .

and platelet membranes are a source of a group of rapidly secreted mediators that are short acting; that is, they are either rapidly inactivated or rapidly diffuse away from the site of the thrombus. Their effects are rapid on surrounding cells, and they serve to modulate both the behavior of platelets as well as the behavior of vessel wall cells, particularly as regards vascular tone. The platelet dense bodies, the most rapidly secreted of platelet organelles, [61] release ADP, which is a potent agonist to recruit other platelets, as well as adenosine triphosphate, which is an agonist for other cells of the blood. [62] [63] They also release biogenic amines such as serotonin, which can influence vascular tone. The dense bodies are also rich in divalent cations. The physiologic role of released dense body calcium is not clear; however, one could speculate it serves to ensure adequate calcium for some of the calcium-dependent enzymes involved in coagulation or cross-linking of the thrombus. Finally, dense body, but not -granule membranes, contain granulophysin, [64] a tetraspanin membrane protein of unknown function, that is deficient in Hermansky-Pudlak syndrome.[65]

Arachidonate-derived mediators, such as thromboxane A_2 , are generated as a consequence of hydrolysis of membrane phospholipids; [66] their role in recruitment of other platelets and as vasoactive substances is extensively discussed in Chapter 91 . Mention should also be made of platelet activating factor [67] (alkyl-2-acetyl-*sn*-glycero-3-phosphocholine), which was originally described as platelet activator released from stimulated mast cells. It is clear that its biologic effects are much more widespread than on platelet activation, [68] [69] although its effects on platelets clearly play a role in some of the platelet sequestration that occurs during allergic injury. Similarly, it is produced by a variety of cells in addition to platelets. Is it possible that this important mediator, produced locally, may contribute either to recruitment of other platelets or to some of the vascular phenomena associated with hemostasis.

Platelets contain lysosomes [24] whose enzymes are released, but platelets are probably a minor source of lysosomal hydrolases in the blood compared with neutrophils. Nevertheless, mention should be made of platelet-associated heparatinase, [70] probably a lysosomal enzyme, which can cleave vascular endothelial cell surface glycosaminoglycans to produce an antiproliferative fragment. Factor XIII, a major transglutaminase, which catalyzes the formation of isopeptide bonds between the -glutaminyl residues and the amino groups of lysines, forming stable covalent cross-links between proteins, is contained in the platelet cytosol. [71] Factor XIII functions in the cross-linking of fibrin, as well as in the cross-linking of other components of a thrombus, such as fibronectin [72] or $_2$ -antiplasmin,[73] to fibrin. Moreover, platelet factor XIII has been suggested to play a role in cross-linking and stabilizing cytoskeletal elements. [74] [75] It is likely that small quantities of platelet factor XIII are released into thrombi, where it may also affect their stability.

Platelets contain a wide variety of peptides, primarily in alpha granules, that can modulate the growth and patterns of gene expression of cells of the vessel wall. The first of these to be described was the platelet-derived growth factor [76] (PDGF), which has three isoforms and two distinct receptors on smooth muscle cells and fibroblasts.[77] PDGF probably plays an important role in the smooth muscle cell proliferation that may occur consequent to platelet interaction with the vessel wall. Its receptors are transmembrane tyrosine kinase-type receptors, and signal transduction from the PDGF receptor [78] is similar to that from other tyrosine kinase receptors such as the insulin and epidermal growth factor receptors. Another -granule growth factor is connective tissue activating peptide (CTAP) III, which stimulates fibroblast proliferation. CTAP III is a probable precursor of -thromboglobulin, [79] and its structure is related to another -granule protein, platelet factor 4. Both platelet factor 4 and CTAP III are members of a large protein family involved in growth control and inflammation. [80] [81] Interleukin-1 is expressed on the surface of activated platelets, [82] but the mechanism whereby it is found there is unclear. Transforming growth factor (TGF)- was first isolated from platelets, [83] and platelets are a rich source of this peptide mediator, which is a potent stimulus for the biosynthesis of matrix molecules and their receptors. TGF- has complex effects on cell proliferation, in some cell systems stimulating and in other systems inhibiting cellular proliferation. In addition, thrombospondin, of which platelets are the major source in blood, is a large (450 kd) protein that, as noted previously, may play a role in platelet aggregation, regulation of angiogenesis, and activation of TGF-. [84] Thrombospondin is produced by endothelial and smooth muscle cells [85] [86] and its mRNA is inducible by growth factors such as PDGF. [86] Indeed, thrombospondin appears to play a role in regulating the proliferation of smooth muscle cells [87] and angiogenesis. [88]

Multimerin is a novel platelet granule and endothelial protein that exists as massive disulfide-linked multimers of a 155-kd subunit. [89] [90] Multimerin has a repeating structure and its sequence contains the adhesive motif Arg-Gly-Asp-Ser, central coiled-coil sequences, several epidermal growth factor-like motifs, and a globular domain that is similar to a protein binding domain found in complement C1q and in collagens type VIII and X. [91] Multimerin binds the coagulation protein factor V and its activated form, factor Va. In platelets, but not in plasma, all of the biologically active factor V is complexed with multimerin. [92] Multimerin may also have functions as an extracellular matrix or adhesive protein. Members of two Canadian families with autosomal dominant bleeding disorders are deficient in platelet multimerin. [93] This novel granule protein may play important roles in platelet procoagulant activity and in platelet adhesion.

A large number of plasma proteins involved in coagulation and cell adhesion are present in platelet -granules. It is clear that during thrombopoiesis, plasma proteins are taken up by megakaryocytes and stored in -granules [94] [95] (see Chap. 98). Thus, it is important to have some basis to evaluate the significance of literature reporting a variety of plasma proteins in -granules. Three points should be borne in mind in reading any work that describes the presence of a plasma protein in platelets: (1) Is the plasma protein enriched in platelets relative to plasma? A simple way to calculate this is to determine the concentration of the plasma protein in plasma per milligram of protein, and compare it to its concentration in platelets per milligram of protein. (2) Is the plasma protein synthesized by megakaryocytes? (3) Is there a structural or functional difference between the platelet protein and the plasma protein? Thus, it is clear that plasma proteins such as albumin and IgG are present in -granules; [71] [96] however, their concentrations do not appear to be greater than those in plasma. Moreover, clear structural differences between the plasma

and platelet proteins have not been demonstrated, and they are probably not synthesized in megakaryocytes. Evidence [95] has been presented that they arrive in -granules strictly by transport from the plasma. Special note should be made of the IgG component in -granules, because measurement of platelet-associated IgG has in the past been used as an attempt to classify patients with thrombocytopenia. Clearly, its presence predominantly in -granules, rather than on the cell surface, has required a re-evaluation of the significance of this measurement (see Chap. 126).

With respect to coagulation proteins present in and released by platelets, a wide variety of procoagulant and anticoagulant enzymes and cofactors have been reported in platelets. It is clear that megakaryocytes synthesize factor V, [97] [98] and more factor V is present in platelet -granules [99] than can be accounted for by uptake from plasma. Moreover, platelet factor V plays a clear role in assembling the platelet prothrombinase, [100] which is involved

in the final step in blood coagulation (i.e., the generation of thrombin). Megakaryocytes take up fibrinogen, [95] and its biosynthesis by megakaryocytes remains controversial. Platelets also contain cofactors protein S [101] and plasminogen activator inhibitor-1 [102] (PAI-I). Protein S is a cofactor for the action of activated protein C (see Chap. 104) and PAI-1 is an inhibitor of urokinase and tissue plasminogen activators (see Chap. 103). Thus, the concentration of these proteins in platelets suggests that platelets may be a favored site for the anticoagulant action of protein C, a tempting idea considering the local concentration of factor V, a protein C substrate, on the platelet surface. Similarly, the local release of PAI-1 from platelets may play a role in modulating the fibrinolytic events in the vicinity of thrombi. [103] [104]

Platelets are the major peripheral blood source of -amyloid precursor protein (APP). [105] APP is a membrane protein, thought to be localized to -granules, [106] that serves as the precursor of the 40 residue peptides found in amyloid deposits in the brains of patients with Alzheimers disease. APP is a protease inhibitor, and is processed by proteolytic cleavage. [107] Its inhibition of factors Xa, XIa, and IXa [108] [109] suggests a possible role as a natural anticoagulant. The effects of platelet APP on the spectrum of coagulation and fibrinolytic proteases will clearly be of interest, in addition to its potential role in deposits of amyloid in the brain.

P-Selectin [110] [111] [112] [113] (GMP-140, GPIIa, PADGEM, CD62) is an -granule membrane protein that is absent from the surface of resting platelets. It is structurally similar to E- and L-selectins, [114] a family of carbohydrate binding proteins involved in adhesive interactions of circulating leukocytes (see Chap. 5). Platelet P-selectin mediates interactions of monocytes and neutrophils with platelets. [114] These interactions are important in cross-talk between these cell types [115] and in the recruitment of leukocytes to thrombi. [116] Some of the speculated pathogenetic roles of platelet P-selectin are in promoting thrombogenesis [116] and platelettumor cell interactions, [117] and in monocyte recruitment. It may play a physiologic role in the leukocyte phagocytosis of platelets. In addition, P-selectin plays an important role in leukocytevessel wall interactions [118] and hemostasis. [119]

As noted earlier, platelet -granules [13] contain the adhesive plasma proteins fibrinogen, fibronectin, vWF, and vitronectin, as well as the platelet and cellular adhesive protein thrombospondin. Platelet fibrinogen has been previously discussed. Platelet vWF is concentrated in the platelets, megakaryocytes synthesize it, [120] and the platelet form is enriched in the larger, presumably more hemostatically effective multimers. [121] Platelet fibronectin appears to be enriched in alternatively spliced forms that are relatively lacking in plasma, [122] suggesting a possible role for platelet fibronectin in events such as matrix assembly. Vitronectin is present in platelets; [123] however, its concentration suggests that it is probably passively taken up from the plasma. PAI-1 binds vitronectin, [124] and these two proteins are released as a complex. [125]

Secretory Mechanisms

Platelet secretion is triggered by a variety of strong agonists such as thrombin. Induction of secretion by weak agonists (e.g., ADP) occurs when the cells are brought into close contact such as occurs during aggregation. [126] The latter secretory mechanism is clearly dependent on thromboxane A2 generated as a consequence of arachidonic acid release. Discussion of signaling pathways involved in secretory events is in Chapter 91 .

As noted previously, the two morphologically prominent platelet storage granules, -granules and dense bodies, contain a variety of substances important in platelet function. Since these granules have a limiting membrane, it would seem likely that the final secretory event would involve exocytosis [127] (i.e.,

Figure 99-3 Three possible exocytotic pathways for -granule contents. **(A)** Simple exocytosis in which the granule membrane fuses with the plasma membrane. **(B)** Fusion of the granule with an invagination of the plasma membrane, the open canalicular system. **(C)** Fusion of granules with each other to form a compound granule that then fuses with the plasma membrane. Note that the final morphologic appearance of **(B)** and **(C)** are quite similar.

fusion of the secretory granule membrane with the plasma membrane). This has been observed in dense body secretion. [128] [129]

In -granules, the incorporation of a membrane marker into the plasma membrane [130] [131] [132] directly established that exocytosis occurs, [133] and simple exocytosis occurs occasionally as depicted in Figure 99-3A . Nevertheless, in human platelets, most of the -granules are seen to move centripetally during secretion, and are thus not in a locale that would permit fusion with the peripheral plasma membrane. [61] [133] [134] [135] [136] Two hypotheses, illustrated in Figure 99-3B and C, have been proposed to account for exocytosis when the granules are centralized. The mechanism illustrated in Figure 99-3B suggests that there are invaginations of the plasma membrane deep into the center of the platelet and that -granule membranes fuse with these invaginations, and the secretory products then are moved to the outside of the cell through a conduit termed the open canalicular system or surface-connected canalicular system. [137] [138] [139] The other mechanism, illustrated in Figure 99-3C , suggests that -granules fuse with each other or with another cellular compartment to form a compound granule that is morphologically distinct from the -granule. It is the compound granule that then moves toward and fuses with the plasma membrane. [61] [133] [140] Whatever the route by which granule components reach the cell surface, it is clear that there is substantial inward membrane traffic in platelets as well. [130] [141] [142] [143] This inward traffic can serve to clear adhesive and procoagulant proteins from the cell surface, and hence limit prothrombotic events. [144]

MOLECULAR BASIS OF PLATELET AGGREGATION

The Aggregation Response of Platelets

Platelets in blood, in plasma, or as an isolated cell population do not interact with one another. If an appropriate agonist is added to the cells, however, rapid aggregation of the cells can ensue. Thus, a key element of this response is that platelet aggregation is a stimulated event. Some agonists that can initiate this response are listed in Table 99-4 . Of particular physiologic relevance are the platelet-derived agonistsADP, serotonin, platelet activating factor, and arachidonate metaboliteswhich provide a means for stimulated platelets to recruit additional cells; collagen, which supports platelet adhesion and secretion as well as aggregation; thrombin, which links platelets and the

TABLE 99-4 -- Common Platelet Aggregating Agonists

Agonist	Comment
Adenosine diphosphate	Released from platelet -granule; acts synergistically with many other agonists
Thrombin	Formed by activation of the coagulation system
Collagen	In subendothelial matrix
Epinephrine	May allow for hormonal regulation of hemostasis
Calcium ionophore	Not naturally occurring; mobilizes calcium in platelets
Arachidonate + metabolites	Active metabolites are formed and released form stimulated platelets
Serotonin	Released from platelets, may primarily sensitize platelets to other agonists
Platelet-activating factor	Lipid mediator produced by other cells that can activate a variety of cells, including platelets

blood coagulation system in thrombus formation; and epinephrine, which permits hormonal regulation of platelet function. These agonists activate platelets by interacting with specific receptors. Receptor occupancy triggers a complex series of intracellular reactions (detailed in Chap. 91) that ultimately converge to a set of common steps that permit the cells to aggregate. Platelet aggregation is energy dependent and can be distinguished on this basis from platelet agglutination induced by ristocetin or certain platelet antibodies.

At blood concentrations of 13×10^8 /ml, platelet suspensions are opalescent. On addition of an agonist, a stirred suspension of normal platelets aggregates, and a visible decrease in turbidity can be observed. Dedicated instruments, platelet aggregometers, for measuring the changes in light transmission through platelet suspensions, are used extensively in clinical laboratories to evaluate platelet function (see Chap. 106). Certain instruments also provide simultaneous measurements of other platelet functions, such as secretion.[126] Although the information gained from aggregometry can be extremely useful, aggregation in vitro does not necessarily reflect platelet function in vivo. In particular, clinical bleeding and the aggregation response of platelets need not precisely coincide.

A typical aggregometer tracing obtained with a suspension of isolated human platelets is shown in Figure 99-4A . From this pattern, the three essential components required for this functional response can be identified.

1. *Platelet agonist.* The agonist used in Figure 99-4 is ADP. This agonist induces platelet shape change, from discoid to a more spherical form, a transition that can be detected in the aggregometer as a slight decrease in light transmission. This transformation is not a prerequisite for platelet aggregation; epinephrine aggregates platelets but does not cause a shape change that is recordable in most conventional aggregometers. At the molecular level, shape change reflects a reorganization of the platelets actin cytoskeleton.
2. *Divalent cations.* Calcium and magnesium as well as some other, but not all, divalent cations, support platelet aggregation. Trace amounts of calcium may be a prerequisite for platelet aggregation under all circumstances, and divalent cations can influence the specificity of GPIIb-IIIa for its ligands. [145]
3. *Fibrinogen.* Fibrinogen is not only a major plasma protein but is present in, and secreted from, platelets [146] [147] (see Chaps. 102 and 112). By virtue of its capacity to form fibrin and support platelet aggregation, fibrinogen plays a dual role in thrombus formation. These activities, as well as the contribution of fibrinogen to blood viscosity, are believed to account for the increased risk of cardiovascular disease associated with elevated levels of fibrinogen. [148] The dependence of platelet aggregation on fibrinogen concentration is evident from the tracings illustrated in Figure 99-4B .

In certain circumstances, vWF may substitute for fibrinogen in supporting platelet aggregation. It is postulated that, at the high shear rates encountered in certain blood vessels, vWF may play a dominant role in aggregation. [149] Certain pathologic circumstancesplatelet-type von Willebrand disease and type IIB von Willebrand diseasemay also favor a role for this protein in platelet aggregation. [150] [151] [152] [153] [154]

The Molecular Mechanisms Involved in Platelet Aggregation

The basis for the requisite roles of the agonist, calcium, and fibrinogen in platelet aggregation becomes evident when the direct interaction of fibrinogen with the cell is examined. Little fibrinogen binds to nonstimulated platelets (Fig. 99-5). If an agonist is added, however, time-dependent binding is observed. Stimulated platelets can bind 40,000 or more fibrinogen molecules per cell, a considerable number, in view of the small size of platelets. [155] [156] [157] If the system is depleted of divalent ions, fibrinogen no longer binds to the stimulated platelets. Thus, the role of the agonist is to induce fibrinogen receptors, and calcium is required to support fibrinogen binding to its receptors.

These series of events define the fibrinogen-dependent pathway of platelet aggregation, [158] [159] [160] [161] [162] [163] schematically depicted in Figure 99-6 . All the platelet agonists listed in Table 99-4 can initiate this pathway of platelet aggregation. The common event triggered by these platelet agonists is receptor inductionthe conversion of a latent cell surface receptor to a state in which it can bind fibrinogen. Receptor induction is very rapid, and the cell is fully competent to bind fibrinogen within seconds after its initial encounter with an appropriate agonist.

Reversible binding of fibrinogen to the stimulated platelet is

Figure 99-4 Aggregation response of human platelets. **(A)** To aggregate, isolated human platelets require divalent ions (calcium, Ca^{++}), an agonist (adenosine diphosphate [ADP]), and an adhesive protein (fibrinogen [Fg]). Shape change is observed as a slight decrease in light transmission induced by ADP and is followed by an increase in transmission as the platelets aggregate. **(B)** Both the rate and extent of platelet aggregation depend on the concentration of fibrinogen. The concentration of fibrinogen (in micrograms per milliliter) is indicated below each tracing.

Figure 99-5 Binding of fibrinogen to human platelets. ^{125}I-fibrinogen binds minimally to platelets in the absence of an agonist but does bind when an agonist such as adenosine diphosphate (ADP) is added. A divalent ion, calcium, must be present for fibrinogen binding to occur.

a typical equilibrium interaction. The dissociation constant, K_d, of fibrinogen for the stimulated platelet is approximately 0.3 M.[155] [156] [158] [159] [160] Although this value indicates a relatively low-affinity interaction (hormone receptors can often bind their ligands with 10^3 to 10^6-fold higher affinities), the plasma concentration of fibrinogen (10 M) exceeds its K_d by approximately 30-fold. These interrelationships indicate that the fibrinogen binding sites on stimulated platelets can become saturated with the ligand under physiologic circumstances. The reversible binding of fibrinogen to its platelet receptor requires divalent cations. Millimolar concentrations of calcium or magnesium can meet these requirements.[155] [156] [159] [164]

After reversible fibrinogen binding, the interaction undergoes a time-dependent stabilization.[160] [161] [164] [165] [166] This transition is termed *irreversible fibrinogen binding* and correlates closely with irreversible platelet aggregation. Conditions that initially dissociate fibrinogen from the cell and disaggregate platelets, such as the removal of divalent ions or the agonist, are no longer effective in removing the bound ligand or dissociating the platelets after a period of time. The molecular basis for irreversible fibrinogen binding remains controversial. Either bound fibrinogen remains on the cell surface, but its exposure changes considerably,[167] or the ligandreceptor complex is internalized.[141] [142] The stability of platelet aggregates imparted by irreversible fibrinogen binding may be important for maintaining a thrombus in a microenvironment in which agents that prevent additional platelet activation and thrombus growth are being generated.

GPIIb-IIIaThe Platelet Receptor for Fibrinogen

A single-membrane protein, GPIIb-IIIa, serves as the platelet receptor for fibrinogen.[155] [168] [169] [170] Occupancy of this receptor is essential for platelet aggregation. It is the most abundant cell surface protein of platelets, accounting for approximately 15% of the protein mass of the platelet membrane. GPIIb-IIIa is also a constituent of platelet -granule membranes;[130] this internal pool can become surface expressed and functional during platelet activation.[147] [148] The resting platelet has 40,00080,000 copies of GPIIb-IIIa on its surface, and platelet activation can increase this number by 0100%. Each GPIIb-IIIa is capable of binding one fibrinogen molecule.

GPIIb-IIIa is a member of the integrin family of cell adhesion receptors (see earlier). GPIIb, the -subunit, is largely specific for cells of the platelet/megakaryocyte lineage. GPIIIa, the -subunit, has been designated $_3$. This -subunit is known to complex with a different -subunit to form the vitronectin receptor, $_v{}_3$.[171] $_v{}_3$ is expressed by a variety of cell types, including platelets, megakaryocytes, and endothelial cells.[172] [173] [174] These two sister receptors bind many of the same ligands and antagonists, but their specificities are not identical.[175] The complete amino acid sequences of both GPIIb and GPIIIa subunits have been deduced from their cDNAs;[29] [176] the carbohydrate side chains and disulfide linkages have also been placed.[177] [178] [179] [180] A schematic model illustrating some of the important structural features of the two subunits is illustrated in Figure 99-7. GPIIb is synthesized in megakaryocytes as a single chain, but becomes proteolytically processed to the two-chain form during its transit to the cell surface.[181] The two subunits interact noncovalently in a 1:1 stoichiometry to form the GPIIb-IIIa complex.[182] Complex formation occurs soon after biosynthesis of the individual subunits and is required for efficient cell surface expression.[181] [183] Micromolar calcium concentrations are required to maintain the subunits in a complex,[184] [185] [186] [187] [188] as compared with the millimolar requirements for fibrinogen binding. Platelet activation is necessary to transform GPIIb-IIIa to a state in which it is competent to bind ligand. The biochemical basis for this transformation is unknown. At extremes, access of ligand to the receptor could be regulated by a change either directly in GPIIb-IIIa or in its microenvironment. Although there is support for both possibilities,[189] [190] [191] [192] most evidence favors a direct conformational change within the receptor to induce ligand binding function.[193] [194] The process by which a signal is transmitted from within the platelet to convert the extracellular domain of GPIIb-IIIa from a ligand incompetent to a ligand competent state is referred to as inside-out signaling.[194] [195] [196]

Figure 99-6 Fibrinogen (Fg)-dependent pathway of platelet aggregation. Stimulation of platelets with an agonist causes induction of fibrinogen receptors. The reversible binding of fibrinogen to the competent receptor requires divalent ions. Irreversible fibrinogen binding occurs with time as the ligandreceptor interaction becomes nondissociable.

Figure 99-7 Schematic model illustrating structural features of GPIIb-IIIa, the platelet fibrinogen receptor.

Several mechanisms can be envisioned to explain how fibrinogen binding to GPIIb-IIIa can result in platelet aggregation. The simplest possibility is that a single fibrinogen molecule, by virtue of its dimeric structure, bridges two GPIIb-IIIa molecules symmetrically on adjacent platelets. Indeed, evidence can be cited to support this possibility.[197] [198] [199] Because multiple sites within each fibrinogen molecule can be recognized by GPIIb-IIIa (see later), asymmetric variations of direct bridging can be envisioned. Still another possibility is that changes subsequent to fibrinogen binding are required for platelet aggregation. Irreversible fibrinogen binding,[161] conformational changes in bound fibrinogen[200] [201] and in occupied GPIIb-IIIa,[202] clustering of fibrinogen/GPIIb-IIIa,[203] and additional interactions of the receptor with the cytoskeleton of the cells[204] [205] [206] occur after the initial binding of fibrinogen to the cells. Moreover, a series of intracellular signaling events are initiated and propagated, including tyrosine and serine/threonine kinase and phosphatase activation, as a consequence of receptor occupancy and platelet aggregation.[194] [195] These events are referred to as outside-in signaling. Whether such postreceptor occupancy events play a direct role in platelet aggregation is unknown, although circumstances have been described in which fibrinogen is bound to GPIIb-IIIa without induction of platelet aggregation.[194]

Although the exact mechanism of platelet aggregation is not fully resolved, it is clear that occupancy of GPIIb-IIIa by ligand is essential for eliciting the cellular response. Accordingly, antagonists of ligand binding to GPIIb-IIIa provide a means of blocking platelet aggregation and thrombus formation. Antagonists of ligand binding include monoclonal antibodies, small peptide ligands (see later), and nonpeptidic ligand mimetics. Representatives of these classes of antagonists are being evaluated in animal models and in patients as antithrombotic agents.[207] [208] [209] [210] [211] [212] [213] The first of these GPIIb-IIIa antagonists to receive U.S. Food and Drug Administration approval was a humanized chimeric Fab fragment of a monoclonal antibody to GPIIb-IIIa.[214] Intravenous lowmolecular-weight antagonists have had promising antithrombotic effects in clinical trials,[215] and orally active GPIIb-IIIa antagonists loom on the horizon. Together, these inhibitors of platelet aggregation will undoubtedly signal a new era of antithrombotic therapy.[213] [216]

Recognition Specificity of GPIIb-IIIa

Discrete amino acid sequences establish the way in which GPIIb-IIIa recognizes fibrinogen and its other ligands (see later). Two peptides define this recognition specificity of GPIIb-IIIa (Table 99-5). One peptide corresponds to the extreme COOH-terminus of the -chain,[197] [217] one of the three constituent chains of fibrinogen. The recognized amino acid sequence may be as small as the extreme six amino acid residues.[218] The second peptide is as small as four amino acids and contains the following three amino acids in sequence: arginyl-glycyl-aspartic acid (RGD).[219] [220] [221] [222] RGD sequences occur in two sites within the A chain of fibrinogen.[223] RGD sequences are also found in a variety of other proteins, including several that bind to GPIIb-IIIa. In addition, several other integrin receptors recognize RGD sequences within their ligands.[25] [224] [225] [226] [227] [228] [229] Thus, the RGD amino acid sequence is a broadly used recognition code in cellular adhesive reactions. By contrast, the -chain sequence appears to be unique to fibrinogen. Synthetic peptides containing either the -chain peptide sequence or the RGD sequence interact

directly with GPIIb-IIIa and bind to the same or mutually exclusive sites within the receptor. [230] [231] However, the preponderance of evidence indicates that it is the COOH-terminus of the -chain that is critical for fibrinogen binding to GPIIb-IIIa. [232] [233] [234] Nevertheless, in the design of GPIIb-IIIa antagonists, the RGD sequence has often served as the starting compound because of its smaller size. [235]

Fibrinogen is not the only ligand that binds to GPIIb-IIIa. Several other adhesive proteins that can serve as ligands are noted in Table 99-2 . All these adhesive proteins contain at least one RGD sequence, and RGD peptides interfere with the binding of fibronectin, [219] vWF, [220] and vitronectin [236] to platelets. Because plasma fibrinogen concentrations are 10-fold higher than its dissociation constant for GPIIb-IIIa, under physiologic conditions, the receptor is nearly saturated with fibrinogen. Thus, fibrinogen is the dominant ligand for GPIIb-IIIa in this environment. However, all these ligands, except fibrinogen, are present in subendothelial cell matrices, and these other interactions may dominate in this microenvironment. In addition to its role in platelet aggregation, GPIIb-IIIa may also be involved in platelet adhesion, particularly in stabilizing cellmatrix interactions. It may be in this latter function that these other GPIIb-IIIa ligands play a key role. Thrombospondin associates with the surface of resting and stimulated platelets. [237] [238] [239] On the surface, it plays an auxiliary role in platelet aggregation by stabilizing platelet aggregates. [240] This activity may arise from its capacity to bind to fibrinogen. [241] Several candidate receptors for thrombospondin have been proposed, [242] [243] [244] [245] [246] and the interaction may be mediated by a complex of several of these candidate receptors, including CD36, integrin-associated protein, and GPIIb-IIIa. [247] Complexation of GPIIb-IIIa with other platelet membrane proteins also may play a role in controlling its activation and ligand binding functions.

TABLE 99-5 -- Recognition Peptides of GPIIB-IIIa[a]

Peptide Designation	Structure[b]
Fibrinogen -chain	-XXKQAGDV
RGD	RGDX

[a]The naturally occurring sequences in human fibrinogen; S (serine) or F (phenylalanine) at the COOH-terminus of the two RGD sequences within the -chain; and H (histidine) -H-L (leucine) -G-G-A at the NH_2 -terminus of the -chain peptide.

[b]Amino acids: K, lysine; Q, glutamine; A, alanine; G, glycine; D, aspartic acid; V, valine; X, one of several amino acids.

Chapter 100 - The Molecular Basis for Platelet Activation

Lawrence F. Brass

Broadly speaking, platelets support hemostasis in three ways. First, by sticking to collagen and then to each other, platelets form part of the barrier that physically limits the loss of blood at sites of vascular injury. Second, by accelerating the rate at which coagulation proteins are activated, platelets accelerate fibrin deposition; and third, by releasing the contents of their storage granules, platelets cause local vasoconstriction and promote eventual wound healing. This chapter summarizes current information about the molecular basis for these events, focusing in particular on the earliest events of platelet activation.

In general, cells are activated when they encounter agonists that can activate receptors on their surface. This generalization applies to platelets as well. Platelet activation begins when vascular injury exposes collagen fibrils and causes the local generation of thrombin, both of which activate platelets (Fig. 100-1). Platelets are normally shielded from collagen by a continuous barrier of endothelial cells, but when the endothelial cells are damaged or removed, platelets adhere to the exposed collagen fibrils, forming a discontinuous carpet. In vitro adhesion to collagen can occur without the help of accessory molecules, but in vivo, the shear forces and turbulence caused by blood flow would strip platelets away from collagen were it not for the stabilizing effects of von Willebrand factor. Having adhered to

Figure 100-1 Platelet activation at the vessel wall. Platelet activation begins when vascular damage exposes collagen and tissue factor. Circulating platelets adhere to the collagen, either directly or through von Willebrand factor (vWF), and are activated by locally generated thrombin. These events are followed by a change in the platelets shape, storage granule secretion, and the formation of multicellular aggregates as additional platelets are recruited into the growing platelet plug. The recruitment of nonadherent platelets is facilitated by the release of soluble factors from the platelets, such as adenosine diphosphate (ADP) and thromboxane A_2 (TxA_2). This phase of hemostasis is completed when the platelet plug is stabilized by a meshwork of fibrin.

the collagen with the help of von Willebrand factor, platelets change their shape, spreading along the fibrils and releasing into the circulation thromboxane A_2 (TxA_2) and adenosine diphosphate (ADP). The released TxA_2 and ADP recruit additional platelets, activating them in turn and causing them to stick to each other and to the platelets directly adherent to collagen. This growing mound of adherent platelets is stabilized by a cross-linked fibrin clot, but the critical contact between adjacent platelets depends on the binding of fibrinogen or fibrin to $_{IIb\ 3}$ on the platelet surface, and this occurs only after platelets have been activated. Because fibrinogen is a symmetric molecule, it can bind to two platelets. Repeated as many as 50,000 times per platelet, this allows platelets to stick to each other. Like collagen, soluble platelet agonists cause platelets to change their shape, losing the discoid appearance characteristic of resting platelets and transforming them into an irregular sphere with pseudopodia. Underlying this change of shape is a rapid reorganization of the platelet cytoskeleton as actin filaments are uncapped, severed, and rebuilt.

Collagen, ADP, and TxA_2 are not alone in their ability to activate platelets. At the same time that collagen is exposed, so is tissue factor, and formation of the tissue factor/factor VIIa complex leads to the local generation of thrombin from prothrombin (Fig. 100-1). Thrombin is a potent agonist, activating platelets at concentrations in the picomolar range by interacting with receptors on the platelet surface. Platelets facilitate this process by providing procoagulant phospholipids that accelerate thrombin generation. As a result, platelet activation and fibrin deposition are intimately associated with one another, maximizing the growth and strength of the hemostatic plug. The platelet receptor for thrombin was identified relatively recently and provided a fresh insight into the interaction of extracellular proteases with cells in general, much as the interaction of $_{IIb\ 3}$ with fibrinogen on the surface of activated platelets has historically provided insights into the interaction of other types of cells with adhesive proteins. It also provides another potential target for pharmacologic intervention in platelet activation.

The process of transforming a freely circulating platelet into an adherent platelet is one of the most fascinating aspects of platelet biology. It is also the final common denominator in platelet responses to most agonists, making it a frequent target for drug development. Stated succinctly, the central issue is this: although resting platelets are surrounded by plasma fibrinogen, they normally do not stick to each other to form circulating aggregates that would lodge in the arterial and capillary circulation. The reasons for this are multiple, but it is ultimately due to the inability of the resting conformation of $_{IIb\ 3}$ to bind fibrinogen or fibrin. As long as the resting conformation is maintained, platelet aggregation does not occur. Left to themselves, platelets pass each other by without sticking to each other. However, even in the absence of substantial vascular injury, it is likely that the buffeting that platelets withstand as they move through the circulation, perhaps encountering low concentrations of thrombin or being smashed against exposed atherosclerotic plaques, would push them toward activation. Working against this tendency are a number of internal and external controls that dampen the intracellular signals that would otherwise

promote platelet activation. These include tight regulation of the cytosolic Ca^{2+} concentration, intracellular phosphatases that defeat signaling through kinase-dependent pathways, extracellular ADPases that hydrolyze released ADP, and the increase in platelet cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate levels produced, respectively, by prostaglandin I_2 (PGI_2) and nitric oxide (NO) released from endothelial cells. Collectively, these provide a threshold that prevents spontaneous platelet activation.

PLATELET AGONISTS AND THEIR RECEPTORS

With the exception of collagen, most platelet agonists trigger platelet activation by binding to G-protein-coupled receptors on the platelet surface. The agonists whose receptors fall into this category include thrombin, TxA_2 , ADP, epinephrine, platelet-activating factor, and vasopressin (Table 100-1). The number of copies of each of these receptors per platelet at first glance appears small, but given the limited surface area of human platelets, the density of the receptors is actually substantial. Platelet activation by collagen is thought to work somewhat differently. Collagen binds directly or indirectly to at least four different molecules or molecular complexes on the platelet surface, glycoprotein (GP) Ib/IX, $_{2\ 1}$, $_{IIb\ 3}$, GP IV, and GP VI. These receptors range in number to as high as 50,000 per platelet.

G-protein-coupled receptors are formed by a single polypeptide with an extracellular N-terminus, an intracellular C-terminus, and seven membrane-spanning domains (Fig. 100-2). The sites on the receptor for interactions with agonists and antagonists are located in the extracellular and transmembrane domains. The cytoplasmic domains determine which G proteins interact with which receptor. G proteins are molecular switches consisting of a guanosine triphosphate (GTP)-binding subunit plus a heterodimer. G proteins are inactive when guanosine diphosphate (GDP) is bound to the subunit and active when GTP is bound. Activated receptors promote the replacement of GDP with GTP, switching on the G protein. G-protein-coupled receptors typically have a limited duration of activity, after which they are turned off by phosphorylation and, in some cases, cleared from the cell surface by endocytosis. The sites involved in phosphorylation and endocytosis are also located in the cytoplasmic domains of the receptor, particularly the cytoplasmic tail.

Platelet agonists are sometimes classified as strong or weak, although the distinctions are often blurred. By one definition, strong agonists are those that can trigger granule secretion even when aggregation is prevented. Thrombin and collagen are examples of strong agonists. In contrast, weak agonists, such as

Figure 100-2 Signaling through G proteins and G-protein-coupled receptors. There is only one mechanism known for signaling through G-protein-coupled receptors: agonist binding to the receptor causes the exchange of guanosine triphosphate (GTP) for guanosine diphosphate (GDP) on the guanine nucleotide binding site of the G-protein subunit. This causes the dissociation of G from G , both of which can activate intracellular effectors and ion channels. Each activated receptor can activate multiple G proteins before desensitization of the receptor and hydrolysis of the G -bound GTP eventually shuts down signaling.

ADP and epinephrine, require aggregation for secretion to occur. Presumably the real differences between strong and weak agonists reflect differences in the sets of intracellular effectors that are coupled to their receptors. Strong agonists potently stimulate phosphoinositide hydrolysis and TxA_2 formation, and are relatively unaffected by inhibitors of cyclooxygenase such as aspirin. The weaker agonists, on the other hand, have little or no ability to cause phosphoinositide hydrolysis and are more dependent on TxA_2 formation for their effects.

Thrombin and the Family of Protease-Activated G-Protein-Coupled Receptors

Thrombin is arguably the most potent activator of platelets in vivo. When added to platelets in vitro, it causes phosphoinositide hydrolysis, TxA_2 formation, protein phosphorylation, and an increase in the cytosolic free Ca^{2+} concentration, as well as shape change, granule secretion, and aggregation. These responses can be detected at thrombin concentrations as low as 0.1 nM. Thrombin also suppresses cAMP synthesis in platelets by inhibiting adenylyl cyclase. All of these effects require thrombin to be proteolytically active. In 1991, two laboratories independently cloned thrombin receptors from the human megakaryoblastic Dami cell line [1] and from hamster fibroblasts.[2] The predicted sequences of these receptors resembled others that interact with G proteins, with the notable presence of an extended N-terminus containing a potential cleavage site for thrombin between residues Arg41 and Ser42 [1] (Fig. 100-3). Mutations at this

AC, adenylyl cyclase; GP, glycoprotein; GPCR, G-protein-coupled receptor; PAF, platelet-activating factor; PAR, protease-activated receptor; PGI_2 , prostaglandin I_2 ; PLC, phospholipase C; PI3K, phosphatidylinositol 3-kinase; TxA_2 , thromboxane A_2 .

[a] PGI_2 receptors are an exception on this list because they stimulate adenylyl cyclase and cause an increase in cyclic adenosine monophosphate formation, antagonizing platelet activation.

Figure 100-3 Protease-activated receptor 1 (PAR1), a typical G-protein-coupled receptor. The predicted sequence of the human PAR1 is shown. [1] Potential sites are indicated for cleavage by

thrombin and cathepsin, N-linked glycosylation, and phosphorylation by protein kinases, including protein kinase C (PKC), protein kinase A (PKA), and -adrenergic receptor kinase (ARK).

site prevent receptor activation by thrombin,[1] [3] and synthetic peptides containing at least the first five residues beyond the cleavage site (SFLLRN) were found to mimic the effects of thrombin. These and subsequent observations suggest that thrombin receptors are activated by cleavage at a specific site, exposing a new N-terminus (the tethered ligand) that interacts with residues in the second extracellular loop and proximal N-terminus of the receptor initiating signaling [1] [4] (Fig. 100-3). Once activated, each receptor generates signals only briefly before it is turned off and desensitized by the phosphorylation of serine and threonine residues located in the cytoplasmic domains of the receptor. The kinases responsible are members of the family of G protein receptor kinases (GRKs). [5] [6]

The thrombin receptor that was cloned first is now known as protease-activated receptor 1 (PAR1) to distinguish it from two similar receptors, PAR2 [7] and PAR3[8] (Table 100-2). PAR1 is expressed on human platelets, endothelial cells, vascular smooth muscle cells, fibroblasts, and neurons. Knockouts of the PAR1 gene in mice are notable for the death in utero of approximately half of the homozygous (/) mice at a point in development at which thrombin is not thought to be present [9] [10] (Table 100-3). The surviving mice appear normal. However, although their fibroblasts lack the ability to respond to thrombin, their platelets do notan observation that led to the eventual identification of PAR3. PAR2 is expressed on human endothelial cells, keratinocytes, vascular smooth muscle, and gastrointestinal epithelium. It is not expressed on human platelets and is not activated by thrombin, but can be activated by trypsin or, with less efficiency, tryptase, a protease secreted by mast cells.[11] In contrast, PAR3, like PAR1, is a thrombin receptor. PAR3 is expressed in mouse and rat platelets (which do not express PAR1).[8] mRNA encoding PAR3 has been detected in human cells and tissues, but it remains to be seen whether PAR3 contributes to platelet activation by thrombin. PAR4 is the most recently identified member of this family. PAR4 appears to be expressed in both human and murine platelets. Its only known activators are thrombin and peptides, corresponding to the tethered ligand domain. PAR4 is 12 logs less sensitive to thrombin than are PAR1 and PAR3. [11A] [11B] Whether there are other proteases that activate PAR4 at lower concentrations or whether there is an important role for a low sensitivity thrombin receptor in normal platelet biology remains to be determined.

Based on binding studies with monoclonal antibodies and radiolabeled thrombin, there are approximately 2,000 copies of PAR1 on the surface of human platelets. Additional copies of PAR1 are initially located in the surface connecting membrane system and become exposed when platelets are activated. [12] Cleavage of PAR1 can be detected with antibodies directed N-terminal to the cleavage site [13] or with assays for the released N-terminal fragment.[14] [15] Because platelets synthesize very little protein, they have no real ability to replace cleaved receptors with new ones. As a result, human platelets usually respond to thrombin only once. This is in contrast to endothelial cells, which possess a large intracellular pool of PAR1 that can replace cleaved receptors over 23 hours. [16] [17]

Epinephrine and $_2$ -Adrenergic Receptors

In several respects, epinephrine is unique among platelet agonists because it causes aggregation and secretion, but not the cytoskeletal reorganization that underlies shape change. Phospholipase C (PLC) activation by epinephrine appears to depend on TxA $_2$ formation and can be suppressed with aspirin.[18] Aspirin also blocks second-wave, or secretion-dependent, platelet aggregation in response to epinephrine. This gives rise to a characteristic aggregometer tracing in which epinephrine-induced primary aggregation is followed by disaggregation of the initially formed platelet clumps (Fig. 100-4). Dependence on TxA_2 formation does not adequately account for epinephrines ability to aggregate platelets, however, because epinephrine can still cause fibrinogen receptor expression in aspirin-treated platelets.[19] [20] These observations suggest that there are other, as yet unknown, mechanisms involved in platelet responses to epinephrine. What might those be? Epinephrine, like thrombin, is a potent inhibitor of cAMP formation, but it does not appear that this alone can trigger platelet activation. Epinephrine has also been reported to increase the rate of Na^+/H^+ exchange across the platelet plasma membrane,[21] although this may not occur until after fibrinogen receptor exposure. [22] Platelet responses to epinephrine are mediated by $_2$ -adrenergic receptors and are both labile and variable among individuals. Some otherwise normal platelets fail to respond to epinephrine, or do so only after a prolonged delay. [23] The reasons for this variability are not entirely clear, although there are reports of families in which a mild bleeding disorder was associated with impaired epinephrine-induced aggregation and reduced numbers of $_2$ -adrenergic receptors[24] [25] (Table 100-3).

TxA_2 and TxA_2 Receptors

Thromboxane A_2 is produced from arachidonate in platelets by the aspirin-sensitive cyclooxygenase pathway. A number of stable endoperoxide/thromboxane analogs have been synthesized, including the Upjohn compound, U46619. When added

[b] Disabling proteases prevent PAR-1 activation by cleaving its N-terminus at the wrong site, amputating the tethered ligand and disabling the receptor. [202] [203]

TABLE 100-3 -- Inherited and Imposed Disorders of Platelet Activation in Humans and Mice

System Affected	Species	Disorder or Gene	Cause	Phenotype	References
Receptors	Human	Bernard-Soulier syndrome	Loss of a von Willebrand factor receptor due to decreased functional GP Ib/IX/V complex	Variable bleeding and bruising due to decreased adhesion to collagen.	[204]
Receptors	Human	$_2$ $_1$ (GP Ia-IIa) deficiency	Loss of a collagen receptor	Variable bleeding and bruising due to decreased responses to collagen.	[48] [49]
Receptors	Human	GP VI deficiency	Loss of a collagen receptor	Mild bleeding and decreased adhesion to collagen.	[46]
Receptors	Mouse (gene knockout)	PAR-1	Absence of PAR-1	No effect on platelet function because of presence of PAR-3. Absent thrombin response in fibroblasts. Fifty percent mortality on E9.	[9] [10]

Receptors	Human	$_2$ -AR	Diminished numbers of $_2$ -adrenergic receptors	Usually no apparent phenotype, but mild bleeding has been reported.	[23] [24] [25]
Receptors	Mouse (gene knockout)	PGI_2 R	Failure to increase cAMP levels in response to endothelial cell PGI_2	Increased aggregation in response to ADP. Increased thrombosis in a carotid artery injury model.	[205]
Receptors	Mouse (gene knockout)	Adenosine A_{2a} receptor	Failure to increase cAMP levels in response to A_{2a} receptor agonists, including adenosine and caffeine	Increased aggregation with ADP.	[33]
Signaling	Human	G_q	Decreased G_q	Mild bleeding disorder.	[60]
Signaling	Mouse (gene knockout)	G_q	Absence of G_q	Loss of aggregation (but not shape change) in response to thrombin, ADP, U46619, and collagen. Improved survival in an acute thrombosis model.	[55]
Signaling	Mouse (gene knockout)	G_{i2}	Absence of G_{i2}	No reported effect on platelet function.	[206]
Signaling	Mouse (gene knockout)	12-Lipoxygenase	Absence of 12-lipoxygenase	Increased aggregation in response to ADP.	[207]
Signaling	Mouse (gene knockout)	Src	Absence of Src tyrosine kinase	No apparent effect on platelet function.	[133]
Signaling	Mouse (gene knockout)	Syk	Absence of Syk tyrosine kinase	Full knockout is lethal. Syk (/) platelets from chimeric mice show decreased response to collagen, but not thrombin.	[52] [134] [135]
Aggregation	Human	Glanzmanns thrombasthenia	Decreased fibrinogen binding due to decreased functional $_{IIb\ 3}$	Variable bleeding and bruising due to absent aggregation and decreased adhesion to fibrin.	[208] [209]
Secretion	Human	Storage pool disorders	Decreased or absent - or -granules	Variable bruising and minimal bleeding due to a failure of secondary aggregation.	[210]
Procoagulant activity	Human	Scotts syndrome	Reduced procoagulant activity	Hemorrhagic disorder with potential for life-threatening bleeding.	[211] [212] [213]
ADP, adenosine diphosphate; cAMP, cyclic adenosine monophosphate; GP, glycoprotein; PAR, protease-activated receptor.					

Figure 100-4 Aggregation tracings. The four sets of tracings shown in the figure reflect changes in light transmission through suspensions of platelets that have been activated by adenosine diphosphate (ADP), epinephrine, arachidonic acid, or the stable thromboxane A_2 analog, U46619. The characteristic sequence of primary aggregation followed by secondary aggregation is best seen in the response to epinephrine shown in black. The shaded tracings were obtained using platelets from a donor who had taken aspirin, which irreversibly inhibits thromboxane A_2 formation. The effects of the aspirin are reflected in the failure to respond fully to ADP, epinephrine, or arachidonate. The response to U46619, on the other hand, is normal, because U46619 serves as a substitute for the missing thromboxane A_2 .

to platelets in vitro, U46619 causes shape change, aggregation, secretion, phosphoinositide hydrolysis, protein phosphorylation, and an increase in cytosolic Ca^{2+}, while having little effect on cAMP formation. Similar responses are seen when platelets are incubated with exogenous arachidonic acid. [26] Because the effects of arachidonate can be inhibited with aspirin, they are thought to be largely due to thromboxane formation. Once formed, TxA_2 can diffuse across the plasma membrane and activate other platelets [27] (see Fig. 100-1). Like ADP, this amplifies the initial stimulus for platelet activation and helps to recruit additional platelets. [28] This process is effective locally, but is limited by the brief (30 sec) half-life of TxA_2 in solution, helping to confine the spread of platelet activation to the original area of injury.

ADP and P_2 -Purinergic Receptors

In contrast to other platelet agonists, ADP is stored in platelet dense granules and released on platelet activation. When added to platelets in vitro, ADP causes TxA_2 formation, protein phosphorylation, an increase in cytosolic Ca^{2+}, shape change, aggregation, and secretion. ADP also stimulates GTP binding to G-protein subunits and inhibits cAMP formation. These responses are half-maximal at approximately 1 M ADP. However, ADP is at most a weak activator of PLC in human platelets, and the increase in cytosolic Ca^{2+} seen in ADP-stimulated platelets is mostly due to Ca^{2+} influx rather than the release of Ca^{2+} from intracellular stores. At least two patients with bleeding defects have been described whose platelets show greatly diminished responsiveness to ADP and reduced numbers of binding sites for ADP analogs [29] [30] a phenotype not dissimilar to that produced by ADP antagonists such as ticlopidine. Efforts to identify a single receptor that can account for all of the effects of ADP on platelets have been unsuccessful. The hypothetical receptor was originally designated P_{2T} to indicate that it was a purinergic receptor. [31] P_2 receptors have been divided into P_{2Y} receptors coupled to G proteins and P_{2X} receptors, which are ligand-gated ion channels. Recent studies suggest that human platelets express P_{2Y1} [32] and P_{2X1} [33] receptors, and it has been proposed that shape change and Ca^{2+} influx are mediated by the P_{2X1} receptors, whereas the P_{2Y1} receptors are responsible for PLC activation, inhibition of adenylyl cyclase, fibrinogen receptor exposure, and aggregation (reviewed in Mills [31] and Gachet et al. [34]). Other ADP-binding proteins on the platelet surface have also been identified, including aggregin. [35] It is unclear what role they play.

Collagen: Binding Proteins and Signaling Receptors

Collagen causes platelets to change shape, secrete, and aggregate. [36] These responses are accompanied by phosphoinositide hydrolysis, TxA_2 formation, protein phosphorylation, and an increase in cytosolic Ca^{2+}. [37] [38] [39] [40] [41] As with thrombin, cyclooxygenase inhibitors retard, but do not eliminate, platelet responses to collagen, suggesting that TxA_2 formation is not essential. Human collagen exists in a number of forms. Several of these, including connective tissue collagen (types I and III) and basement membrane collagen (types IV and V) can activate platelets. Type I collagen has a fibrillar structure in which three 100-kd polypeptides are arranged in a triple-helical array referred to as *monomeric collagen* or *tropocollagen*. These monomers polymerize to form a larger parallel array that becomes covalently cross-linked by enzymes in the connective matrix. Platelets are able to adhere to at least some forms of monomeric collagen, [42] but require the quaternary structure presented by polymeric collagen for secretion and aggregation. [43] Recently, a collagen-related, cross-linked triple helical peptide (CRP) has also been shown to activate platelets. [44]

Along with activation by thrombin, it is the initial adhesion of platelets to collagen that is believed to lead to aggregate formation in vivo (Fig. 100-1). This process can occur in vitro in the absence of additional protein co-factors. However, under the conditions of rapid flow and high shear that are normally

present in vivo, von Willebrand factor is required for platelet adhesion to the subendothelial connective tissue matrix, accounting for the hemostatic defect in von Willebrand disease. Von Willebrand factor supports the binding of platelets to collagen by forming a bridge between collagen and glycoproteins on the platelet surface, particularly GP Ib. In addition, platelets also express several other surface proteins through which they can bind to and be activated by collagen. These include the integrin $_{2\ 1}$ (GP Ia-IIa) [45] and GP VI. [46] [47] Two patients with hemorrhagic disorders and defective platelet responses to collagen had reduced expression of $_{2\ 1}$ [48] [49] (Table 100-3). Presumably, the binding of $_{2\ 1}$ to collagen initiates outside-in signaling, much as it does for other integrins. Notably, the collagen-related

peptide, CRP, activates platelets independently of $_{2\,1}$, by a mechanism that involves PLC and the tyrosine kinase, Syk.[50] Watson and co-workers have proposed that this also occurs with native collagen and is mediated by a pathway within the platelet that involves phosphorylation of platelet Fc receptors followed by the binding of Syk and the subsequent phosphorylation and activation of PLC$_2$.[51] [52] GP IV (CD36) has also been proposed to be a collagen receptor,[53] but platelets from healthy donors lacking GP IV appear to have normal responses to collagen.[54]

Finally, a recent report shows that collagen-induced platelet aggregation is abolished in platelets from mice that do not express G $_q$.[55] This suggests that collagen, either directly or indirectly, activates a G-protein-dependent mechanism in mouse platelets. This could be mediated by a hitherto unsuspected G-protein-coupled receptor or it could be due to release of TxA$_2$ and ADP and their subsequent activation of TxA$_2$ and purinergic receptors. However, aspirin does not abolish platelet activation by collagen, so this remains to be established. Recent reviews of this topic can be found in Moroi and Jung [56] and Sixma et al.[57]

INTRACELLULAR SIGNALS

In general, extracellular agonists cause platelet activation by triggering intracellular signaling pathways. Two of these pathways that are particularly central to platelet activation are the phosphoinositide hydrolysis pathway and the arachidonate or eicosanoid synthesis pathway (Fig. 100-5). The phosphoinositide

Figure 100-5 Pathways for platelet activation. Agonists such as thrombin and thromboxane A_2 (TxA_2) activate PLC through G_q and G derived from the G proteins in the G_q and G_i subfamilies. This leads to the hydrolysis of phosphatidylinositol 4,5-bisphosphate ($PI[4,5]P_2$) to yield inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DG), which raise the cytosolic Ca^{2+} concentration by releasing sequestered Ca^{2+} from the dense tubular system and activate protein kinase C (PKC). This promotes phospholipase A_2 (PLA_2) activation and, by a mechanism that is still poorly understood, leads to activation of the IIb_3 integrin, fibrinogen binding, aggregation, and outside-in signaling through the integrin. PLA_2 has been shown to be a substrate for phosphorylation by the membrane-associated protein kinases, ERK1 ($p42^{MAPK}$), ERK2 ($p44^{MAPK}$), and, possibly, $p38^{MAPK}$, but it appears that phosphorylation does not regulate arachidonate release in platelets. Activation of adenylyl cyclase by prostaglandin I_2 (PGI_2) raises cyclic adenosine monophosphate (cAMP) levels in platelets, which inhibits platelet activation. AA, arachidonic acid; ATP, adenosine triphosphate; GDP, guanosine diphosphate; GTP, guanosine triphosphate; P13K, phosphatidylinositol 3-kinase.

hydrolysis pathway begins when PLC cleaves membrane phosphatidylinositol 4,5-bisphosphate (PIP_2) to form inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol, both of which serve as second messengers. The eicosanoid pathway begins when phospholipase A_2 (PLA_2) releases arachidonate from membrane phospholipids to form TxA_2. Because so many of the agonists that activate platelets do so through G-protein-coupled receptors, the next section of this chapter begins with the G proteins that are present in platelets and then continues with a brief consideration of other participants in platelet signal transduction.

Heterotrimeric G Proteins

G proteins are heterotrimers that mediate the interaction of cell surface receptors with intracellular effectors (Figs. 100-2 and 100-5). In the inactive state, GDP is bound to G . Activated receptors promote the release of GDP and its replacement with GTP present in the cytosol. At the same time, G undergoes a conformational change, dissociating it from G and leaving both in their active states. After an interval that is determined in part by the intrinsic GTPase activity of the subunit and in part by extrinsic factors, including GTPase-activating proteins, G hydrolyzes the bound GTP to GDP and recombines with G until the next cycle of receptor-mediated activation. Originally it was thought that G was the exclusive mediator of signaling in G-protein-coupled pathways. However, it is now clear that G also serves a primary role, independently activating some forms of PLC, ion channels, G-protein-coupled receptor kinases (GRKs), and PI 3-kinase().

The G proteins that have been identified in human platelets are shown in Table 100-4 . Except for G_z and G_{16}, all of these are relatively ubiquitous. Expression of G_z is prominent in platelets and some neuronal cells, although it can also be detected elsewhere. Peptide-directed antisera show that G_{12} and G_{13} are present in platelets. G_{16} has been detected by reverse transcriptase polymerase chain reaction. The role of G_z is unknown, although one report has suggested that it can inhibit cAMP formation.[58] When expressed in Sf9 cells, G_z can couple to PAR1 among other receptors.[59] Genetic approaches are starting to be applied to understanding G-protein function. Knockout of G_q in mice results in a prolonged bleeding time and increased risk of bleeding [55] (Table 100-3). Platelets from G_q (/) mice aggregated normally when stimulated with a Ca^{2+} ionophore or phorbol esters, but failed to respond to thrombin, ADP, collagen, or the TxA_2 analog, U46619. The inhibition of the response to collagen is notable because it implies that it is completely dependent on G_q, which had not been previously suspected. Unlike mouse platelets, human platelets express G_{11} as well as G_q. However, despite this, there is a recent report of a patient with platelet dysfunction and diminished expression of G_q.[60]

Phospholipase C, Phosphoinositide Hydrolysis, and PI 3-Kinases

One of the earliest responses of platelets to most agonists is the activation of PLC. Platelets contain and forms of this enzyme. The forms are activated by G proteins, whereas the forms are regulated by tyrosine phosphorylation.[61] [62] PLC is thought to be primarily responsible for the rapid burst of phosphoinositide hydrolysis that occurs during platelet activation by agonists such as thrombin and TxA_2 analogs. In general, PLC_1 and PLC_3 respond best to G , particularly members of the G_q family,[63] [64] [65] [66] [67] whereas PLC_2 responds best to G .[67] [68] [69] [70] [71] [72] Based on studies with pertussis toxin, PAR1 in platelets is thought to be coupled to PLC_2 by G derived from G_i ,[73] [74] whereas TxA_2 receptors are coupled to $PLC_{1/3}$ by G derived from G_q or G_{11} (Fig. 100-5).

Once PLC has been activated, it hydrolyzes PI-4,5-P_2 to diacylglycerol plus 1,4,5-IP_3.[75] [76] [77] Diacylglycerol activates protein kinase C and contributes to protein phosphorylation, granule secretion, and fibrinogen receptor exposure.[78] [79] [80] IP_3 binds to receptors in the dense tubular system and releases sequestered Ca^{2+}.[81] [82] [83] [84] The most abundant of the inositol-containing phospholipids in the platelet membrane is PI (phosphatidylinositol). A 4-kinase phosphorylates the inositol ring of PI to form PIP (phosphatidylinositol 4-phosphate), which in turn is phosphorylated by a 5-kinase to form PIP_2. PLC is able to hydrolyze all three forms of the phosphoinositides. However, only PI-4,5-P_2 hydrolysis yields 1,4,5-IP_3. Production of 1,4,5-IP_3 and its subsequent conversion to 1,3,4-IP_3 takes only a few seconds in thrombin-stimulated platelets.[76] [85] Because 1,3,4-IP_3 has little, if any, second messenger activity, this effectively limits the duration of the signal carried by 1,4,5-IP_3.

Platelets also contain the p85/p110 and p101/p110 forms of PI 3-kinase and produce 3-phosphorylated phosphoinositides.[86] [87] Their involvement in platelet aggregation is suggested by the ability of inhibitors such as wortmannin and LY294002 to inhibit platelet aggregation [88] and fibrinogen receptor exposure,[89] and by the inhibitory effects of the Rho inhibitor, C3 toxin, on PI 3-kinase activation [90] and platelet aggregation.[91]

Phospholipase A_2 and the Formation of TxA_2

The second major pathway for signaling in platelets is the arachidonate or eicosanoid pathway. Eicosanoids are formed from the arachidonate released from membrane phospholipids by PLA_2 during platelet activation (Fig. 100-6). Because the availability of arachidonate is the rate-limiting step in this process, PLA_2 is tightly controlled. The cytoplasmic form of PLA_2 ($cPLA_2$) is an 85100-kd enzyme that is optimally active at micromolar and sub-micromolar Ca^{2+} concentrations. In cells other than platelets, $cPLA_2$ has been shown to increase its activity

[a]The involvement of the G_i family members as the source of the G is presumptive, but is based on the absence of any other pertussis toxin-sensitive G proteins in platelets.

Figure 100-6 Eicosanoid pathways. The formation of arachidonate and its subsequent metabolism to prostaglandins, thromboxanes, and leukotrienes is illustrated. Arachidonate is released from membrane phospholipids such as phosphatidylcholine (PC) and phosphatidylserine (PS) by the direct action of phospholipase A_2 , or is formed from phosphatidylinositol (PI) by the sequential action of phospholipase C and diacylglycerol (DG) lipase. In platelets, arachidonate is metabolized by the aspirin (ASA)-sensitive cyclooxygenase pathway to form thromboxane A_2 (TxA_2). In endothelial cells, prostaglandins such as PGI_2 are formed. In white cells, 5-lipoxygenase directs arachidonate metabolism toward leukotriene formation. Platelets also contain 12- and 15-lipoxygenase. The biologic significance of the molecules formed by this pathway is less clear, but platelet 12-hydroxyeicosatetraenoic acid (HETE) can be metabolized to 12,20-DiHETE in neutrophils, where it may competitively inhibit the metabolism of leukotriene (LT) B_4 .[223] HPETE, hydroperoxyeicosatetraenoic acid.

upon phosphorylation on Ser505 by p42/44 mitogen-activated protein kinase (MAPK), leading to the suggestion that Ca^{2+} plus phosphorylation regulates arachidonate release.[92] In platelets, phosphorylation of $cPLA_2$ has been shown to occur. However, arachidonate release was unaffected by the MAP kinase inhibitor, PD98059, at concentrations that blocked $p42/44^{MAPK}$ activation.[93] It has been proposed that $p38^{MAPK}$, rather than $p42^{MAPK}$ or $p44^{MAPK}$, regulates $cPLA_2$ in platelets, but the finding that the $p38^{MAPK}$ inhibitor, SB203580, also does not affect arachidonate release leaves this an open issue. [93] [94] [95] [96] [97] Therefore, all that can conservatively be said at this point is that platelet $cPLA_2$ is likely to be regulated by the increase in cytosolic Ca^{2+} that accompanies platelet activation with an incompletely defined contribution by phosphorylation. A recent review of the regulation of $cPLA_2$ can be found in Leslie.[98]

Once released from membrane phospholipids, arachidonate can be metabolized to prostanoids, leukotrienes, and epoxides (Fig. 100-6). Which of these metabolites are formed appears to depend in part on which enzymes are present in any particular cell. The prostanoids are formed by the cyclooxygenase pathway (COX-1 in platelets) and include endoperoxides and thromboxanes, as well as the prostaglandins. The leukotrienes are formed through the lipoxygenase pathway; the epoxides, by the cytochrome P-450 epoxygenase pathway. In platelets, the predominant route for arachidonate metabolism leads to TxA_2 [99] as opposed to endothelial cells, which synthesize PGI_2 (Fig. 100-6). COX-1 and thromboxane synthetase have been localized to the platelet dense tubular system, the apparent site of TxA_2 formation[100] (Fig. 100-5). COX-1 is irreversibly inactivated by aspirin, [101] [102] which acetylates a serine residue near the C-terminus. [103] [104] Because platelets lack the ability to synthesize meaningful amounts of protein, inactivation of COX-1 by aspirin effectively halts TxA_2 synthesis until new platelets are formed. Indomethacin and other nonsteroidal anti-inflammatory agents also inactivate COX-1, but without covalently modifying the enzyme. [105] [106]

The synthesis of leukotrienes from arachidonate begins with lipoxygenase (Fig. 100-6). Three different forms of this enzyme have been described. Each adds oxygen to arachidonate at a different site, producing 5-, 12-, or 15-hydroperoxyeicosatetraenoic acid (HPETE). Platelets express 12-lipoxygenase and 15-lipoxygenase and are able to pass 12-hydroxyeicosatetraenoic acid (HETE) to neutrophils and to receive, in turn, leukotriene A_4 for metabolism to biologically active leukotriene C_4 . Exposure of platelets to aspirin or indomethacin increases HPETE and HETE formation, but the significance of this effect is unknown.

Ca^2 +: Inside and Outside

Platelet activation is typically accompanied by a dramatic increase in the cytosolic free Ca^{2+} concentration. Ca^{2+} ions serve as intracellular second messengers and, like protein kinases, affect enzyme activity and proteinprotein interactions. Based on studies with intracellular probes such as Fura-2, the cytosolic free Ca^{2+} concentration in resting platelets is 0.1 M. Strong agonists, such as thrombin or collagen cause an increase to 1 M. Weaker agonists, particularly epinephrine, may have little or no effect on cytosolic Ca^{2+} .

The ability of resting platelets to maintain a low cytosolic Ca^{2+} concentration is due primarily to the limited permeability of the platelet plasma membrane, which restricts Ca^{2+} influx (Fig. 100-7A). In addition, platelets are able to expel Ca^{2+} from the cytosoleither back across the plasma membrane or into the dense tubular system, a structure derived from megakaryocyte endoplasmic reticulum. Like similar structures in other

Figure 100-7 Ca^{2+} homeostasis in platelets. **(A)** Resting platelets maintain their cytosolic free Ca^{2+} concentration at approximately 10^7 M by pumping Ca^{2+} out of the cell across the plasma membrane and by sequestering Ca^{2+} within the dense tubular system. Ca^{2+} uptake into the dense tubular system is driven by an adenosine triphos-phate (ATP)-dependent Ca^{2+} pump that resembles that present in muscle. The mechanism that pumps Ca^{2+} out of the cell is unknown.**(B)** When platelets are activated by agonists such as thrombin, collagen, and adenosine diphosphate (ADP), but not epinephrine, the cytosolic free Ca^{2+} concentration increases to $>10^6$ M. This is due partly to the inositol 1,4,5-trisphosphate (IP_3)-mediated release of Ca^{2+} from the dense tubular system and partly to increased Ca^{2+} influx across the plasma membrane. The mechanism that triggers Ca^{2+} influx is unknown.

cells, the dense tubular system lies close to the plasma membrane and possesses an inwardly directed Ca^{2+} -Mg^{2+} -ATPase pump that allows it to sequester Ca^{2+} . The capacity of the dense tubular system to store Ca^{2+} is finite.[107] To compensate for the steady-state influx of Ca^{2+} across the plasma membrane, platelets also need an outwardly directed Ca^{2+} efflux. In other cells, this is accomplished by either a Ca^{2+} -Mg^{2+} -ATPase or by an Na^+ /Ca^{2+} exchanger.

When platelets are activated, the cytosolic Ca^{2+} concentration increases because of a combination of Ca^{2+} release from the dense tubular system and Ca^{2+} influx across the plasma membrane (Fig. 100-7B). Platelets do not have voltage-gated Ca^{2+} channels. Instead, Ca^{2+} entry is linked to the opening of ligand-gated Ca^{2+} channels, including the P_{2X} -purinergic receptors thought to respond to ADP. The trigger for Ca^{2+} release from the dense tubular system is IP_3 .

How does the increase in cytosolic Ca^{2+} contribute to platelet activation? Part of its effect is exerted through enzymes that are not optimally active at the Ca^{2+} concentration present in resting cells, but which become active when the Ca^{2+} concentration rises. These include $cPLA_2$, PLC, phosphorylase kinase, and myosin light chain kinase. Myosin light chain kinase phosphorylates the 20-kd light chain of myosin and enhances its interaction with actin. Ca^{2+} also affects actin polymerization directly. Finally, platelets contain two proteases, calpains I and II, that are activated by Ca^{2+} . Known platelet substrates for calpain include actin-binding protein and P235 (talin). [108] [109] [110] The nature of these substrates and the high concentrations of Ca^{2+} required for calpain activity suggest that calpain

participates in the late events of platelet activation, those which follow the agonist-induced increase in the cytosolic free Ca^{2+} concentration.

Protein Kinase C and Pleckstrin

Protein kinase C is a family of ubiquitous, serine- and threonine-specific protein kinases that play an important, but still incompletely defined, role in signal transduction in platelets. At least eight members of the family have been identified and divided into groups based on structure and their interactions with Ca^{2+} and lipids. Platelets contain at least the , , and forms.[111] In platelets, as in other cells, the usual stimulus for the common forms of protein kinase C is the formation of diacylglycerol and the increase in cytosolic Ca^{2+} that occur when PLC is activated[79] (Fig. 100-5). Together, these activate protein kinase C and cause it to associate with the plasma membrane.[112] Protein kinase C can also be activated in platelets by phorbol esters and synthetic membrane-permeable diacylglycerols.[79] [80] [113] Once activated, protein kinase C appears to be involved in a variety of responses in platelets, some of which seem contradictory. These include positive effects, such as aggregation and secretion, as well as negative effects, which emerge when platelets are preincubated with phorbol esters before the addition of an agonist. The inhibitory effects are discussed later in this chapter. Several of the proteins that are phosphorylated by protein kinase C during platelet activation have been identified, including the subunits of the G proteins, G_z , G_{12} , and G_{13} , myosin light chain (P20), pleckstrin (p47), actin binding protein,[114] myosin light chain kinase, and GP180, a transmembrane glycoprotein whose function is unknown.[115] Phosphorylation of G_z appears to uncouple it from G .[116] Phosphorylation of myosin light chain occurs at a site distinct from myosin light chain kinase and is believed to affect the interaction of myosin with actin.

Arguably, the best known substrate for protein kinase C in platelets is pleckstrin, the platelet and leukocyte C-kinase substrate, a protein with an apparent molecular weight of 47 kd.[117] [118] Pleckstrin, or p47, is a 350-residue polypeptide with an internal homology between the first and last 100 residues.[119] These regions are now commonly referred to as pleckstrin homology or PH domains[120] [121] because recent analysis has shown them to be present in more than 100 proteins, forming a major structural motif for proteinprotein or proteinlipid interactions. Targets that have been identified for pleckstrin include G and PIP_2 .[122] [123] [124] [125] Protein kinase C phosphorylates pleckstrin on Ser[113] , Thr[114] , and Ser[117] [126] three residues clustered between the N-terminal PH domain and the recently described DEP domain.[127] The role of pleckstrin is still under investigation. However, when overexpressed in COS-1 cells, pleckstrin causes the formation of microvillous projections on the cell surface.[125] This process appears to require the N-terminal PH domain and phosphorylation of the protein. It suggests that pleckstrin, like other proteins that can bind to PIP_2 , plays a role in regulation of the actin cytoskeleton. In addition to this role, pleckstrin may also participate in feedback inhibition of agonist-induced phosphoinositide hydrolysis. This role is discussed later in the chapter in the section on inhibitory pathways.

Protein Tyrosine Kinases and Their Substrates

In addition to serine/threonine kinases such as protein kinase C, platelets contain a large number of tyrosine kinases, some of which become active during platelet activation. A detailed consideration of the role of tyrosine kinases in platelets is beyond the scope of this chapter, and readers are referred to several excellent recent reviews.[128] [129] [130] However, several general points are worth making. First, like other cells, human platelets contain tyrosine kinases that are receptors for extracellular ligands, such as platelet-derived growth factor receptors and Eph

receptors. They also contain a large number of nonreceptor tyrosine kinases, including Src, Fyn, Lyn, Hck, and Syk. When platelet lysates are probed with anti-phosphotyrosine antibodies, a number of proteins appear phosphorylated for the first time or show increased phosphorylation on tyrosine. Some of these turn out to be the kinases themselves. Others are substrates for the kinases. However, many of the proteins have not yet been identified. The extent of tyrosine phosphorylation of platelet proteins is determined in part by whether platelet aggregation has occurred. Some tyrosine kinases in platelets are activated by platelet agonists even when platelet aggregation is blocked or when the process is observed in thrombasthenic platelets that lack $_{IIb\ 3}$. Others, such as the focal adhesion kinase (FAK), are active only when aggregation has occurred or show enhanced activity after aggregation compared with agonist-stimulated platelets that have not aggregated. The nonreceptor tyrosine kinase Syk is a good example of a kinase whose activity is enhanced by platelet activation and further enhanced when aggregation occurs.[131] According to current models, aggregation-dependent kinase activation and tyrosine phosphorylation in platelets are due at least in part to outside-in signaling through $_{IIb\ 3}$ when it binds to fibrinogen.[128] [129] Outside-in signaling involves the formation of complexes of signaling proteins centered on the cytoplasmic domains of the integrin.[132] Some of those proteins are tyrosine kinases, others are substrates for the kinases; still others are both.

The role of most tyrosine kinases in platelets is still incompletely understood. Some of the kinases and substrates have been studied in detail, but their place in platelet signaling pathways is not necessarily clear. Platelet activation can be inhibited by some broadly specific inhibitors of tyrosine kinases, such as genistein or the tyrphostins. Inhibitors of phosphotyrosine phosphatases, such as vanadate, promote platelet activation. Techniques that are now commonly used in transfectable or microinjectable cells to understand the contribution of a particular kinase or kinase substrate have been less successfully used in platelets. Murine knockouts of kinases that are present in human platelets either produce no obvious platelet-related phenotype or are lethal for unrelated reasons. For example, deletion of Src, which is abundantly expressed in platelets, has no apparent effect on platelets or megakaryocytes, presumably because of the presence of several related kinases in the Src family[133] (Table 100-3). Knockout of Syk, which has been strongly implicated in platelet responses to a number of agonists, including collagen, proved to be lethal,[134] [135] and until recently, dissecting out the role of Syk in platelets rested on the use of doubtfully selective inhibitors such as picceatannol. However, the development of chimeric mice that lack Syk only in their hematopoietic cells has made it possible directly to observe the consequences of Syk deficiency in platelets. The initial results show impairment of collagen responses, but not thrombin responses.[52] In general, tyrosine phosphorylation can serve two roles: it can have a regulatory effect on the phosphorylated protein, perhaps by causing a conformational change, or it provides a binding site for modular domains located in other proteinssuch as SH2 and PTB domains. Either way, it is fair to say that tyrosine kinases and their substrates are among the important missing links in the pathways that couple agonist receptor occupation to downstream events in platelets such as aggregation and secretion.

Ras Family Members and MAPK Activation

In addition to heterotrimeric G proteins, platelets also contain members of the $p21^{ras}$ or Ras family. Like the heterotrimeric G proteins, the Ras family members are switches that bind GTP in their on state and GDP in their off state. The ratio of active to inactive Ras is determined in part by accessory proteins, including guanine nucleotide exchange factors, GDP dissociation inhibitors, and GTPase activating proteins. Some of the Ras family members that have been identified in platelets include RhoA, Rac1, cdc42, Ral, Rap1, and Rap2b. In cells other than platelets, members of this family are involved in the regulation of proliferation, growth, cytoskeletal reorganization, vesicular transport, nuclear transport, endocytosis, and, possibly, integrin activation. Their roles in platelets are not always entirely clear. Proteins involved in nuclear transport or proliferation serve no obvious role in platelets, but may be important in megakaryocytes. This part of the chapter ends by briefly considering some of the possible pathways for Ras activation in human platelets leading to the eventual activation of MAPK and other downstream effectors.

The best-known pathway begins with a growth factor receptor that phosphorylates itself on one or more tyrosine residues when a ligand binds. This creates site(s) on the receptor for binding the Grb2/Sos complex. Sos is an exchange factor for Ras, causing it to exchange GDP for GTP and bind to the protein kinase, Raf-1. Raf-1 in turn phosphorylates MEK, causing it to phosphorylate the p42 and p44 forms of MAPK. Pathways that begin with G-protein-coupled receptors, which are more typical in platelets, are somewhat different. Figure 100-8 illustrates these pathways with PAR1, but the same principles apply to other receptors as well. Activation of PAR1 makes G and G available and activates PLC . The subsequent

Figure 100-8 Pathways that can lead to Ras and membrane-associated protein kinase (MAPK) activation in platelets. Three pathways have been described that may lead to Ras and MAPK activation in platelets. Two are the immediate consequence of G-protein-coupled receptor activation: the first arising from the Ca^{2+} -dependent activation of PYK2 (RAFTK), the second from the PI 3-kinase() (PI 3K)-dependent activation of Shc. The third pathway is an indirect consequence of receptor activation because it results from outside-in signaling after integrin engagement, which is itself a consequence of receptor activation. DG, diacylglycerol; FAK, focal adhesion kinase; IP_3 , inositol 1,4,5-trisphosphate; MEK, MAP kinase; P. tox, pertussis toxin; PIP_2 , phosphatidylinositol 4,5-bisphosphate; PKC, protein kinase C; PLC , phospholipase C ; PMA, phorbol myristate acetate; Tyr k, tyrosine kinase.

rise in the cytosolic Ca^{2+} concentration causes the tyrosine phosphorylation of the FAK-related protein kinase, PYK2 [136] [137] (originally identified as RAFTK in megakaryocytes[138] [139] [140] [141]). The tyrosine kinase that phosphorylates PYK2 has not been identified, although Src family members can associate with PYK and

become activated.[136] [137] PYK2 is a large (1,009-residue) tyrosine kinase that lacks a transmembrane domain and SH2 and SH3 domains. [136] It includes two proline-rich domains that may interact with SH3 domains in other proteins, and has at least two tyrosine residues that become phosphorylated: Y882, which appears to be a Grb2 binding site, and Y402, which is a binding site for members of the Src family. [136] The association of Grb2 brings Sos into the complex and is one way that Ras can become activated.

A second method for coupling Ras activation to G-protein-coupled receptors in platelets involves Shc, which has been shown to become tyrosine phosphorylated and to associate with the Grb2/Sos complex in response to G .[142] This process is sensitive to inhibitors of PI 3-kinase such as wortmannin, [143] suggesting that the G -responsive form of this enzyme, PI 3-kinase(), is involved. [86] [87] [144] Finally, late in the process of platelet activation, agonist-induced integrin engagement can also contribute to and perhaps sustain the activation of Ras. Once $_{IIb\ 3}$ binds fibrinogen, it can act as a nidus for the assembly of signaling complexes that are known to include FAK[145] [146] [147] [148] and possibly PYK2.[140] [141] In this sense, activated integrins are much like activated growth factor receptors, and outside-in signaling through the integrin parallels the signals initiated by the original agonist with FAK substituting for PYK2 (Fig. 100-8). Once Ras is activated by any of these three pathways, it causes the phosphorylation and activation of MAPK in platelets, [149] particularly p42^{MAPK} , and presumably through Raf-1 and MEK.

PREVENTING OR LIMITING PLATELET ACTIVATION

Although platelet aggregation and secretion are necessary to maintain hemostasis at sites of vascular injury, inappropriate platelet activation can cause irretrievable damage. In the process of moving through the heart, arterial circulation, microcirculation, and spleen, platelets are subjected to shear forces, turbulence, and collisions with other cells. None of these should cause platelet activation; ideally, a balance should exist so that platelets activate rapidly when exposed to true vascular injury, but otherwise resist activation. The mechanisms that accomplish this are nearly as diverse as those that cause platelet activation, and play an important role in the prevention of thrombosis. The list includes processes that (1) minimize platelet contact with agonists, (2) limit platelet responsiveness to agonists, (3) limit the duration of agonist receptor activity, and (4) provide negative feedback during platelet activation. For example, contact with collagen is normally prevented by a barrier of endothelial cells. Endothelial cells also produce PGI_2 and NO, which raise platelet cAMP and cyclic guanosine monophosphate levels, and have on their surface a recently described ecto-ADPase (CD39) that metabolizes secreted ADP before it can cause platelet activation. [150] Prolonged contact between platelets and thrombin is limited by natural inhibitors such as antithrombin III and protease nexin I, and by the tendency of blood flow to dilute and wash out unbound thrombin. The effects of TxA_2 are limited by its brief half-life. Receptor activity is limited by phosphorylation and clearance. Other mechanisms exist as well, including the tight controls on cytosolic Ca^{2+} concentration that were described earlier in this chapter and, most basic of all, the inability of $_{IIb\ 3}$ to bind plasma fibrinogen until it has undergone the conformational switch that accompanies platelet activation. Collectively, these processes provide a threshold that must be exceeded for platelet activation to occur, much as minor activation of the coagulation cascade by tissue factor is limited by the extrinsic pathway inhibitor.

cAMP

Platelets contain both of the G proteins that are known to regulate cAMP formation by adenylyl cyclase in most mammalian tissues: G_s and G_i . G_s is present in at least its 45-kd form. G_i is present in all three of its known forms, with an order of prevalence $G_{i2} >> G_{i3} < G_{i1}$. [151] Traditionally, agents that increase cAMP levels in platelets, such as PGI_2 , are described as having receptors that are coupled to G_s , whereas agonists that suppress cAMP formation, such as thrombin and epinephrine, have receptors coupled to G_i . Preincubating platelets with forskolin, PGI_2 , or a membrane-permeable cAMP analog effectively increases the intracellular cAMP concentrationas does inhibiting cAMP phosphodiesterase, the enzyme normally responsible for metabolizing cAMP. Drugs such as dipyridamole (Persantine) exert weak antiplatelet effects by inhibiting phosphodiesterase. The mechanism by which cAMP dampens platelet responsiveness is incompletely understood. In general, the effects of cAMP are thought to be mediated by cAMP-dependent protein kinase, also known as protein kinase A. Platelet substrates for this enzyme include the 24-kd chain of glycoprotein Ib, actin-binding protein, and myosin light chain, as well as several unidentified proteins and the Ras-related protein, Rap1B. Agents that increase cAMP levels have been demonstrated to cause a number of specific changes in platelet function. These include a reduction in agonist binding, impaired phosphoinositide hydrolysis, a smaller increase in the cytosolic free Ca^{2+} concentration in response to agonists, and accelerated uptake of Ca^{2+} into the dense tubular system. The mechanism by which cAMP inhibits phosphoinositide hydrolysis has not been established conclusively, but data from several laboratories suggest that cAMP may inhibit the resynthesis of PI-4-P and $PI\text{-}4,5\text{-}P_2$.[152] [153] Because the PIP_2 pool in platelets is relatively small and turns over rapidly when platelets are stimulated, anything that limits its replenishment would be expected to limit IP_3 and diacylglycerol formation.

Receptor Desensitization

As a general rule, G-protein-coupled receptors, including those present on platelets, are rapidly desensitized once they have been activated. This limits the amount of time that the receptor is in the active state and can reduce or entirely prevent a second response to the same agonist. Desensitization is usually due to phosphorylation of the receptor on cytoplasmic serine and threonine residues, particularly those in the cytoplasmic tail of the receptor. Phosphorylation is accomplished by members of a family of protein kinases that have come to be called G-protein-coupled receptor kinases, or GRKs. [154] The first of these kinases to be described were rhodopsin kinase (GRK-1) and two -adrenergic receptor kinases (ARK-1 and ARK-2), but at least four others have now been cloned. ARK-2 (GRK-3) has been shown in overexpression systems to phosphorylate the human PAR1 and is presumed to be responsible for the brief period that this receptor remains active once it has been cleaved by thrombin.[5] At least some of the GRKs are stimulated by G , which provides a rational means to link receptor activation with activation of the kinase. Phosphorylation of G-protein-coupled receptors uncouples them from their associated G proteins and also facilitates the binding of arrestin family members to the tail of the receptor, leading to receptor internalization. [155] [156] Once internalized, G-protein-coupled receptors can be dephosphorylated before being recycled back to the cell surface. Recently published evidence suggests that this is accomplished by members of a newly discovered family of receptor-directed phosphatases.[157] In the case of PAR1, dephosphorylation and recycling

does not restore responsiveness because thrombin requires an intact N-terminus to cause PAR1 activation. [158]

Protein Kinase C and Negative Feedback

In addition to contributing to platelet activation, protein kinase C can inhibit platelet activation. The inhibitory effects emerge when platelets are preincubated with phorbol esters or diacylglycerol under conditions in which platelet activation does not occur. If an agonist is added several minutes later, the responses of the platelet to that agonist, especially those dependent on the products of phosphoinositide hydrolysis, are either attenuated or abolished. This phenomenon may represent a form of negative feedback. Several different mechanisms have been proposed to underlie this effect. Protein kinase C has been shown to phosphorylate platelet IP_3 -5-phosphomonoesterase, the enzyme that hydrolyzes $1,4,5\text{-}IP_3$ to $1,4\text{-}IP_2$.[159] Phosphorylation accelerates the rate of $1,4,5\text{-}IP_3$ hydrolysis and may limit the duration of the signal for Ca^{2+} release. It has also been shown that phorbol esters can block the ability of platelet agonists to stimulate phosphoinositide hydrolysis and attenuate cAMP formation.[76] [160] Additional targets for protein kinase C that may affect signaling through G-protein-coupled receptors include the receptors themselves, pleckstrin (see later), and the G proteins G_z , G_{12} , and G_{13} . In the case of G_z , phosphorylation has been shown to affect its interaction with G . [116]

Pleckstrin as an Inhibitor

The biology of pleckstrin in platelets is still not completely understood, but there is some evidence that phosphorylated pleckstrin may act as a brake on platelet activation by interfering with phosphoinositide hydrolysis and the activation of PI 3-kinase(). When overexpressed in COS-1 cells, pleckstrin has been shown to inhibit phosphoinositide hydrolysis initiated through several different G-protein-coupled receptors and the growth factor receptor, Trk-A. [161] This inhibition was dependent on the presence of an intact N-terminal PH domain, and appeared to be regulated by the phosphorylation of pleckstrin at the protein kinase C sites. Pleckstrin variants that substituted charged amino acids at the sites of phosphorylation also inhibited phosphoinositide hydrolysis, whereas neutral substitutions were relatively inactive.[126] This suggests that pleckstrin may inhibit phosphoinositide hydrolysis by virtue of its ability to bind directly to $PI\text{-}4,5\text{-}P_2$.

The other inhibitory effect of pleckstrin that has been documented is the ability of recombinant pleckstrin to inhibit PI 3-kinase activity in platelet lysates. This inhibition is specific for the phosphorylation of PI-4,5-P_2 to PI-3,4,5-P_3 by the G -activated form of the enzyme, PI 3-kinase(), and can be overcome by the addition of purified G .[162] Pleckstrin appears to have no effect on growth factor-activated, p85-associated PI 3-kinase activity. These observations suggest that pleckstrin, once it has been phosphorylated by protein kinase C, acts as a brake on further PI-4,5-P_2 hydrolysis and PI-3,4,5-P_3 formation by binding directly to PIP_2 and possibly G . Because PI-3,4,5-P_3 has been shown to activate several isoforms of protein kinase C,[163] [164] the appearance of phosphorylated pleckstrin during platelet activation may also serve to limit protein kinase C activity, although this has not been tested directly.

ONCE IT BEGINS, HOW DOES IT END?

Once an agonist binds to its receptor and initiates second messenger formation, shape change, secretion, and aggregation follow rapidly. In contrast to the initial steps of signal transduction described earlier in this chapter, comparatively little is known about the events that occur just before secretion and aggregationthat is, those events that follow the generation of second messenger molecules, but precede secretion and fibrinogen receptor expression. Clearly, there are changes in the cytosolic Ca^{2+} concentration and in the phosphorylation state of numerous platelet proteins. Previously quiescent enzymes become activated. Precisely how these changes lead to membrane fusion, granule exocytosis, and fibrinogen receptor expression is still unknown.

Cytoskeletal Arrangements

One of the more dramatic events during platelet activation is the metamorphosis that occurs when platelets adhere to and spread on exposed collagen fibrils or become activated in the circulation by soluble factors such as thrombin or ADP. In either case, platelets lose their distinct discoid shape and acquire an irregular morphology with multiple filopodial projections (illustrated in Chap. 98). This transformation is associated with and largely due to cytoskeletal rearrangements within the platelet. The platelet cytoskeleton includes at least 14 different proteins, most of which have counterparts in other cells. [165] The proteins are arranged in three major structures: a cytoplasmic meshwork, the membrane-associated cytoskeleton, and a microtubule coil. Together, these lend support to the platelet plasma membrane and give shape to both resting and activated platelets. Although each of these is considered separately, it should be remembered that in the intact cell they form an integral unit.

The cytoplasmic meshwork is composed of actin filaments and associated proteins. Actin is a globular, 42-kd protein that accounts for as much as 20% of total platelet protein. In resting platelets, 4050% of the actin is present as filamentous F-actin. This increases to 7080% during platelet activation [166] in a coordinated sequence of events in which the actin filaments present in resting platelets are severed and the resultant smaller fragments used as the nidus for new, longer actin filaments. This process is thought to be regulated in part by the increase in PI-4,5-P_2 levels that accompanies platelet activation. [167] At the same time, myosin is phosphorylated by myosin light chain kinase[168] and becomes associated with F-actin, forming filaments that are anchored to the platelet plasma membrane by attachment (by actin-binding protein) to the GP Ib/IX complex. [169] [170] [171]

Tension is generated by contraction of the anchored filaments. Anchorage of platelets to extracellular matrix proteins by way of cell surface glycoproteins also has parallels with the formation of focal adhesion plaques in fibroblasts. Recent evidence shows that activation of the $_{IIb\ 3}$ complex leads to the phosphorylation on tyrosine of a number of proteins, including the tyrosine kinase, $pp125^{Fak}$.[145] [146] [147] In fibroblasts, $pp125^{Fak}$ is localized at sites called focal adhesions where transmembrane glycoproteins of the integrin family bind to extracellular matrix proteins, on the one hand, and intracellular cytoskeletal proteins, on the other. These sites are thought to help anchor cells to the surrounding matrix and provide sites at which tension can be applied by contractile elements within the cell, but it is clear that in platelets these events also generate a new round of signaling molecules whose significance is just beginning to be understood. [172]

The membrane-associated cytoskeleton is composed of actin, actin-binding protein, P235 (talin), vinculin, spectrin, -actinin, and several membrane glycoproteins. Actin-binding protein is an elongated, 250-kd protein that is present in platelets as a dimer. [173] [174] Actin-binding protein is able to bind to both actin and the membrane GP Ib/IX complex, allowing it to link actin filaments to the platelet plasma membrane. [169] [170] [171] In resting platelets, actin-binding protein is part of a semirigid array that helps to maintain the platelets discoid shape and limits the lateral movement of GP Ib. This role is analogous to that performed by spectrin in erythrocytes. [175] When platelets are activated, actin filaments form and attach to actin-binding protein. Later,

the rising cytosolic Ca^{2+} concentration activates calpain, which cleaves actin-binding protein, severing the link to GP Ib. [108] [110] Calpain also cleaves P235, a 235-kd protein that is antigenically cross-reactive with talin. The third major structural element in platelets is the microtubule coil. [176] This coil is a single, tightly wound polymer of tubulin that encircles the platelet perimeter and helps to maintain its discoid shape. [177] During platelet activation, the microtubule coil contracts. At the same time, platelet granules move toward the center of the cell.

Secretion

Secretion occurs from at least three morphologically distinguishable types of storage granules: dense granules, -granules, and lysosomal granules (see Chaps. 98 and 99). Several of the - and dense granule constituents are capable of supporting platelet activation, including ADP, Ca^{2+} , von Willebrand factor, and fibrinogen. Therefore, the release of stored materials, like the formation of TxA_2 , helps to recruit additional platelets into expanding platelet aggregates. This phenomenon is readily demonstrated in a platelet aggregometer, where an initial primary response triggers secondary aggregation. This phenomenon is seen particularly well with weak agonists such as epinephrine or with low concentrations of ADP. In general, a maximal platelet response to injury requires granule secretion. Therefore, a defect in either signal transduction leading to secretion or the storage granules themselves adversely affects platelet function (Table 100-3). The mechanism by which platelet storage granule membranes are fused with the membranes of the surface connecting system has not been explored in detail, but is presumed to resemble the process that has been mapped out in other cells in which membrane proteins (v-SNAREs) on the granules dock with protein complexes in the target cellular membranes (t-SNAREs), allowing fusion and exocytosis to occur.[178] A recent study has shown that human platelets express at least some of the required docking proteins, lending support to this hypothesis. [179]

Aggregation

The hallmark of platelet activation is aggregation. Platelets can form multicellular aggregates because fibrinogen binds to the platelet surface and acts as a bridge between adjacent platelets. The mechanism by which fibrinogen receptors become activated on the platelet surface remains one of the great unsolved mysteries of platelet biology, although a solution to this problem seems to be drawing closer. This issue is covered in detail in Chapter 99 and is only summarized here. The platelet fibrinogen receptor is formed by the integrin $_{IIb\ 3}$. There are 4050,000 copies of this integrin per platelet. Based on the ability of complex-dependent monoclonal antibodies to bind to resting platelets as well as activated platelets, $_{IIb\ 3}$ is present on resting platelets, but unable to bind fibrinogen. In other words, platelet activation evokes a change in $_{IIb\ 3}$ that renders it competent to bind fibrinogen. [180] [181] In support of this model, other monoclonal antibodies have been developed that bind to $_{IIb\ 3}$ only after the addition of agonist, suggesting that new antigens have become available as a consequence of activation. This change occurs within seconds of agonist addition. The significance of the fibrinogen receptor to normal platelet function is reflected in the substantial bleeding disorder seen in patients with Glanzmann thrombasthenia, whose platelets lack functional $_{IIb\ 3}$ (see Chap. 130 ; Table 100-3).

The complete primary sequences of glycoproteins IIb and IIIa have been deduced from full-length cDNA clones and the proteins expressed in naive cells. The results suggest that both glycoproteins cross the platelet plasma membrane and have short cytoplasmic extensions. It is reasonable to suppose that intracellular events in the platelet signal fibrinogen receptor expression by interacting with the cytoplasmic domains of the integrin. Various strategies have been used to identify proteins that can bind to the cytoplasmic domains of $_{IIb\ 3}$ and other integrins, including $_{3}$ -endonexin,[182] CIB,[183] and the cytohesin-1.[184] However, with the exception of the cytohesin, which binds to 3-phosphorylated phosphoinositides,[185] it is unclear how these proteins might regulate integrin function. When co-expressed with $_{IIb\ 3}$, $_{3}$ -endonexin activates the integrin.[186] Whether this occurs in platelets, and how interactions between this and other proteins that interact with the cytoplasmic domains of $_{IIb\ 3}$ are hooked into the signaling pathways described earlier in this chapter, are the subjects of intense investigation.

Chapter 101 - The Blood Vessel Wall

Aly Karsan
John M. Harlan

The vasculature plays a major role in conveying and distributing hematopoietic cells, nutrients, gases, metabolites, and various chemical mediators. The interior of the vessel wall is lined by the endothelium, comprising more than 10^{12} endothelial cells, covering a surface of about 500 m^2 and weighing approximately 1 kg in total.[1] [2] The endothelium forms a continuous monolayer at the interface between blood and tissue and thus contributes significantly to the sensing and transducing of signals between blood and tissue, the trafficking of hematopoietic cells, and the maintenance of a nonthrombogenic surface permitting the flow of blood. Normally quiescent, with cell turnover measured on the order of years, endothelial cells have a remarkable capacity to proliferate and vascularize tissues in physiological (menstrual cycle) and pathological (tumorigenesis, diabetic retinopathy) situations. [3] The endothelium is critical for initiating and potentiating the inflammatory response. The pathogenesis of several disorders, such as atherosclerosis, hypertension, diabetic angiopathy, and microangiopathic hemolytic anemias, involves dysfunction of the endothelial lining. The complexity and the vast array of its functional responses has led to the description of the endothelium as a distributed organ. [4] In this chapter we will provide a conceptual framework of the structure and development of the vessel wall and the physiological functions of the endothelium as it relates to the hematopoietic system.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

STRUCTURE OF THE VESSEL WALL

The circulatory system has traditionally been divided into the macrovasculature (vessels >100 m in diameter) and the microvasculature. [5] The arterial system transports blood to tissues, resists changes in blood pressure proximally, and regulates blood flow distally. Veins return blood to the heart and act as capacitance vessels, as they contain approximately 70% of the total blood volume. Venules with luminal diameters less than 50 m are structurally similar to capillaries. [5] Capillaries, and microvessels in general, are particularly important in the exchange of gases, macromolecules, and cells between blood and tissue. Although large vessels play an important role in maintaining vascular tone, a significant proportion of peripheral resistance arises from the capillaries. [6] Capillary endothelial cells also have a metabolic role, such as in the conversion of angiotensin and hydrolysis of lipoproteins. Finally, the sprouting of new vessels is initiated in the microvasculature.

Macrovasculature

Large vessels are composed of three layers: intima, media, and adventitia. [5] [7] [8] The intima comprises the endothelium and the subendothelium. The endothelial cells of large vessels contain a distinct rod-shaped organelle, measuring about 3 m by 0.1 m, called the Weibel-Palade body. [9] Ultrastructural studies indicate the presence of a single membrane around the Weibel-Palade body with tubular structures within. This organelle contains von Willebrand factor (vWF), and P-selectin has been reported to be present on the surrounding membrane. [10] [11] [12] The abluminal face of the endothelium rests on a basement membrane, which supports the endothelial cell and can act as a secondary barrier against the extravasation of blood. [1] The subendothelial matrix contains occasional smooth muscle cells and scattered macrophages. Both smooth muscle cells and endothelial cells contribute to the extracellular matrix of the intima. [7] In large vessels the media is separated from the intima by a layer of elastin, the internal elastic lamina. The medial layer is composed primarily of concentric layers of smooth muscle cells and their secreted matrix, which is a complex mix of glycoproteins and proteoglycans. This layer is responsible for structural integrity of the wall and for maintaining vascular tone. Mutations of the fibrillin-1 gene, a microfilament protein in elastic fibers, result in disruption of the media in Marfans syndrome. [13] Defects of type III collagen can cause aortic rupture in patients with Ehlers-Danlos syndrome type IV. [14] An attenuated band of elastic fibers, the external elastic lamina, separates the adventitia from the media. The adventitia, composed of loose connective tissue, and the outer portion of the media contain small nerves and nutritive blood vessels, the vasa vasorum. The external limit of the adventitial layer is loosely defined and becomes continuous with the surrounding connective tissue of the organ. [5] [7]

Microvasculature

Capillaries and post-capillary venules are composed of two cell types: [15] [16] endothelial cells and pericytes. Pericytes and endothelial cells are invested with a basement membrane and, depending

upon the vascular bed, variable amounts of matrix separate the two cell types. Both cell types contribute to the secretion of basement membrane proteins. Long pericyte processes extend over the abluminal surface of the endothelial cell and reciprocal extensions of the endothelial cell make contact with the pericyte. Pericytes and endothelial cells have been shown to communicate via gap junctions. [17] A variety of functions has been ascribed to the pericyte, including: [15] [16] [18] (1) a contractile function, which regulates blood flow; (2) multipotential capabilities resulting in differentiation to adipocytes, osteoblasts, phagocytes, and smooth muscle cells; and (3) regulation of capillary growth. The best evidence probably exists for the last function. In animal models [19] [20] and human disease (diabetic microangiopathy, hemangiomata), [21] [22] a lack of pericytes is associated with microaneurysms and disordered microvasculature. In addition, there is a temporal correlation between pericyte contact and cessation of vessel growth in wound healing, [23] and pericyte contact suppresses endothelial cell growth and proliferation in vitro. [24] [25]

Endothelial Structure and Function

In contrast to circulating blood cells and vascular smooth muscle cells, but similar to epithelial cells, the endothelium exhibits polarity manifested by the asymmetric distribution of cell-surface glycoproteins and by the unidirectional secretion of some extracellular matrix proteins and chemical mediators. [26] [27] [28] Although in cultured endothelial cells, an apical-basal polarity is established prior to confluence, intercellular junctions may provide a role in maintaining the asymmetry in vivo. [26] [29]

Four types of intercellular junctions have been described between adjacent endothelial cells: [29] [30] tight junctions, gap junctions, adherens junctions, and syndesmos. Their distribution varies along the vascular tree with tight junctions being more frequent in the larger arteries, correlating with a more stringent requirement for permeability control. The molecular structure of endothelial tight junctions is similar to that of epithelium, consisting of a network of fibrils with the critical component being a transmembrane protein, occludin. The distribution of gap junctions tends to follow that of tight junctions. Connexin-40, connexin-37, and, in arterioles, connexin-43 are gap junction proteins that have been detected in endothelial cells. Communication between adjacent endothelial cells and between endothelial cells and pericytes or smooth muscle cells is mediated by gap junctions. Adherens junctions are formed by transmembrane glycoproteins called cadherins, which make the link between cell-to-cell contacts and the cytoskeleton. Several different types of cadherins are expressed in endothelial cells. Recently, an endothelial-specific cadherinVE-cadherin/cadherin-5was identified and found to be expressed on virtually all types of endothelium. [31] [32] Similar to other cadherins, VE-cadherin forms homotypic contacts with VE-cadherin on adjacent cells. Within the cell VE-cadherin complexes with catenins which, through other proteins, contact the actin cytoskeleton. Homotypic engagement of VE-cadherin has been reported to be responsible for the density-dependent inhibition of endothelial cell growth. [33] The structure of a fourth type of junction, the syndesmos, is not well-elucidated. Other membrane proteins that are located at interendothelial junctions include platelet-endothelial cell adhesion molecule-1 (PECAM-1), which may be important in directing the formation of junctions, and the integrins (particularly $_{2\,1}$ and $_{5\,1}$). [33] In addition to the functions listed previously, intercellular contacts are also important in maintaining cell survival. [34]

On the luminal side, endothelium is exposed to blood elements, and under pathological conditions, to circulating molecules such as cytokines and bacterial products. Engagement of endothelial receptors by these humoral factors activates a well-described series of responses including the recruitment and transmigration of leukocytes and changes in endothelial cell coagulant activity. More recently, biomechanical forces resulting from pulsatile blood flow have been shown to mediate striking changes in endothelial morphology and metabolism. Vessels must withstand three types of physical forces: radial distension (tension), longitudinal stretch, and tangential shear stress. In response to flow (shear stress), endothelial cells have been shown to reorganize their cytoskeletal architecture, rearrange focal contacts at the *basal* surface, and to align in the direction of flow. [35] [36] [37] Some endothelial cell responses following exposure to physical forces occur within seconds, such as activation of potassium channels and increased release of nitric oxide, resulting in vasodilation. Other endothelial cell responses to flow are related to changes in gene expression and occur following a delay of a few hours. Elements in the promoters of various adhesion molecule and growth factor genes have been shown to contain sequences that respond to shear stress (in a positive or negative fashion) and have been referred to as shear-stress response element (SSRE). [35] [36] [37]

Endothelial cells vectorially secrete certain extracellular matrix (ECM) proteins to the abluminal face. The matrix molecules that are secreted by endothelium include several types of collagen, elastin, fibronectin, laminins, and proteoglycans (e.g., heparan sulfate, dermatan sulfate). The exact composition of the subendothelium varies with location in the vascular tree, age, and disease states. [1] [7] [14] [38] [39] Endothelial cells bind to the ECM via heterodimeric cell-surface glycoproteins, the integrinswhich link and integrate matrix proteins to the cytoskeleton, at sites referred to as focal contacts. [40] The integrins detected in resting endothelium include $_{6\,1}$, $_{5\,1}$, $_{2\,1}$ and $_{v\,3}$. [41] Interestingly, endothelial cells express integrins on the luminal as well as abluminal surfaces. [41] The ECM serves several important functions: (1) it serves as a barrier to macromolecules in the event of disruption of the endothelium; (2) it sequesters growth factors and mediates their high-affinity binding to endothelial cells (e.g., heparan sulfate binds to fibroblast growth factor); (3) it acts as a counterstructure for the binding of endothelial cell integrins. [7] [14] [38] [42] This binding of endothelial cells to the ECM serves at least four purposes: (1) certain matrix molecules provide a physical scaffold, while others act as chemotactic agents to allow endothelial cells to migrate; [14] (2) clustering of integrins at focal adhesion contacts by certain matrix molecules can transduce survival or differentiation signals by causing the phosphorylation of various proteins and lipids. [42] Fibronectin and vitronectin provide survival signals while laminins appear to signal differentiation; [43] [44] [45] (3) maintenance of cell shape. Spreading of cells independently of the signaling resulting from integrin clustering provides an anti-apoptotic signal; [46] [47] (4) by anchoring the cell, the matrix provides a mechanism whereby blood flow at the luminal surface of the endothelium creates shear stress, which also transmits signals to cells. [35]

Endothelial Heterogeneity

Despite the common features, quiescent endothelial cells in vivo represent a widely heterogeneous population, with their phenotype depending on vessel caliber and location. While it is evident that the exposure to different physical forces and the different functions served by vessels of different caliber are reflected in different endothelial phenotypes, the molecular basis of the heterogeneity of these different populations has not been well studied. Within the microvasculature there is a structural heterogeneity of capillaries depending on the organ supplied. Even within a single organ endothelial cells exhibit different phenotypes depending on their functional role. When microvessels from different organs are harvested and cultured in vitro, they lose some of their distinctive characteristics with

progressive passaging. Some of the specialization of the different endothelial cells can be retained if they are cocultured with cells or matrix from the organ that they are derived from. Thus, matrix proteins, soluble factors from the organ, or heterotypic contacts with parenchymal cells or pericyte/smooth muscle cells are felt to be important factors in specifying endothelial cell phenotype. [48] [49] [50] [51] Specific examples of microvessels found in hematopoietic tissues are discussed in the following sections.

High Endothelial Venules (HEV)

Lymphocyte migration into secondary lymphoid sites such as lymph nodes, Peyers patches, as well as chronically inflamed nonlymphoid tissues, occurs at specialized postcapillary venules. [52] The endothelial cells of these venules exhibit a plump morphology (hence the name, HEV), display intense biosynthetic activity, and are encircled by a continuous basal lamina. They secrete a thick glycocalyx of which a proportion is GlyCAM-1, a ligand for L-selectin. [53] CD34 is another HEV addressin on peripheral lymph node endothelial cells. Endothelium of mesenteric lymph nodes and Peyers patches express MAdCAM-1 as a ligand for L-selectin and $_{4\,7}$ integrin. Expression of these different addressins may act to recruit specific subpopulations of lymphocytes to different lymphoid tissues (i.e., they facilitate the homing of lymphocytes). Tight junctions are present at intermittent spots, and there is extensive overlap between the membranes of adjacent cells, which prevents macromolecules from interendothelial transit. However, when lymphoid cells transit HEV, there is a temporary breach in the barrier. [53]

Bone Marrow Sinuses

Much less is known about the marrow sinuses than HEV. The marrow sinus endothelial cell is flat, in contrast to that of HEV, and the basal lamina is discontinuous. It has been suggested that hematopoietic cells traverse pores present at attenuated areas of the endothelium, rather than moving by an interendothelial route. [54] Clearly, the marrow sinus endothelial cell is specialized given the regulated egress of cells from the marrow. For example, if a red cell that is still nucleated begins to enter the circulation, the body of the cell is allowed to cross and is released as a reticulocyte, while the nucleus is retained extravascularly. The adventitial reticular cell (similar to a pericyte) is also thought to play an important role in controlling hematopoietic cell egress. [55] The adhesion molecule VCAM-1 expressed on marrow endothelial cells (and spleen endothelial cells in the mouse) has been implicated in a role as bone marrow addressin for hematopoietic progenitor cells expressing VLA-4 ($_{4\,1}$ integrin). [56] The VLA-4/VCAM-1 interaction may also be important in regulating the traffic of hematopoietic progenitors in and out of the marrow, but other adhesion molecules, which at present are undefined, are also likely to be important. [56] As will be described later, the marrow endothelium is also involved in regulating hematopoiesis.

VASCULAR DEVELOPMENT AND DIFFERENTIATION

The human embryo develops a vascular system by the third week when its nutritional needs are no longer met by diffusion. [57] Vascular development in the embryo proceeds in two ways. The first, occurring primarily in the embryo, is vasculogenesis, wherein blood vessels form de novo from the differentiation of mesodermal precursors. The second, angiogenesisthe outgrowth of new capillaries from preexisting vesselsis the major, and, in most cases exclusive, mode of new vessel development in the adult. Much of our early knowledge of vascularization was provided by studying the avian system. In recent years the generation of knockout mice has given us a unique insight into vascular development in mammalian systems.

Vasculogenesis

Vasculogenesis in the yolk sac proceeds initially by the differentiation of mesodermal cells into angioblasts. [58] [59] Angioblasts are vascular cells that express some, but not all, endothelial markers. These cells arise from mesodermal cells resting on the endoderm (splanchnopleuric mesoderm), but not from the mesoderm adjacent to the ectoderm (somatopleuric mesoderm). Thus, it is felt that the endoderm positively regulates vascular development, whereas the ectoderm negatively regulates vasculogenesis. Organs that are primarily of ectodermal origin, for instance, brain and kidney, are vascularized by angiogenesis and not by vasculogenesis. The mesodermal cells migrating outward from the endoderm form primitive structures termed blood islands. The cells at the center of the blood island are hematopoietic precursors, while those arranged peripherally are angioblastic precursors. Vasculogenesis within the embryo begins shortly after that in the yolk sac, again in close association with endoderm. [60] [61] However, except for a region on the ventral aspect of the embryonic aorta, intraembryonic vascular development occurs in solitary angioblasts rather than blood islands. Angioblasts differentiate in situ and form primary capillary plexi with lumens, or they migrate and fuse with other angioblasts or capillaries. Fusion of angioblasts or blood islands results in the formation of a capillary plexus that undergoes extensive remodeling over the developmental period. [58] [59]

Angiogenesis

In the normal adult, angiogenesis occurs primarily in the female reproductive system. In contrast, angiogenesis is a process that has a major impact in several pathological situations. Probably the best known and studied example of pathological neovascularization is that of tumor progression and metastasis. Angiogenesis is also important in chronic inflammation, ischemia, and wound healing. The formation of capillary sprouts from the existing microvasculature occurs secondary to an inciting stimulus that results in increased vascular permeability, accumulation of extravascular fibrin, and local proteolytic degradation of the basement membrane. [62] [63] [64] [65] The endothelial cells overlying the disrupted region become activated, change shape, and extend elongated processes into the surrounding tissue. Directed migration toward the angiogenic stimulation results in the formation of a column of endothelial cells. Just proximal to the migrating tip of the column is a region of proliferating endothelial cells. These proliferating cells cause an increase in the length of the sprout. In the region of proliferation, up to 20% of endothelial cells may enter the cell cycle. This is in marked contrast to quiescent endothelium, where less than 0.01% of cells are cycling. Proximal to the proliferative zone, the endothelial cells undergo another shape change, adhere tightly to each other, and begin to form a lumen. Secondary sprouting from the migrating tip results in a capillary plexus, and the fusion of individual sprouts at their tips closes the loop and circulates blood into the vascularized area. Activated macrophages, by secreting growth factors, monokines, proteases, and protease inhibitors, can influence all phases of the angiogenic process. [66] [67]

Recruitment of Peri-endothelial Cells

Whether formed by vasculogenesis or angiogenesis, maturation of new vessels requires the recruitment of smooth muscle cells or pericytes to re-establish vessel integrity. These peri-endothelial cells (PEC) provide structural support, assist in the production of extracellular matrix, provide contractile function so as

TABLE 101-1 -- Endogenous Peptide Inhibitors of Angiogenesis

Angiostatin (38 kDa plasminogen fragment)
Endostatin (20 kDa collagen type XIII fragment)

[a] The intact protein also has some anti-angiogenic activity.

to modulate vessel caliber, and maintain the cells in a quiescent state. In the embryo, PEC are derived from locally-available mesenchymal cells as endothelial cells invade organ rudiments. The local derivation of PEC may be one mechanism that allows for tissue-specific phenotype of the vasculature. [16] A recent report suggests that embryonic endothelial cells may transdifferentiate into vascular smooth muscle cells. [68] Genetically altered mice that fail to invest their vessels with pericytes develop microaneurysms. [19]

Extracellular Matrix

As previously discussed, the ECM plays a crucial role in vascular structure. During angiogenesis the provisional matrix is composed of fibronectin. [14] [69] Mice deficient in fibronectin die during embryogenesis and show vascular defects. Type I collagen is also important in vascular development, as mice that are null for this protein die of circulatory failure just before birth. ECM proteins and/or their proteolytic fragments have been shown to inhibit angiogenesis (Table 101-1).

Dissolution of the matrix allows endothelial cells to migrate at the initiation of angiogenesis. [67] [70] Matrix-bound growth factors are also released as a consequence of ECM degradation. The balance between positive and negative regulators is the basis of tight control in this process. Plasminogen activators (tPA and uPA), by

generating plasmin, can activate collagenases and other matrix metalloproteinases. Plasminogen activator inhibitors may block angiogenesis at this step. The action of the matrix metalloproteinases is required for angiogenesis, and their function is regulated by the tissue inhibitors of metalloproteinases.

Cell Adhesion Molecules

Of the various classes of cell adhesion molecules involved in angiogenesis, the integrins have been the most studied. [14] [69] [71] [72] The $_{v}$ $_{3}$ integrin appears to play a key role. Immunohistochemical studies localize this integrin to the tips of sprouting vessels and neutralizing antibodies abrogate angiogenesis and induce vascular cell apoptosis in vivo. Mice that are null for $_{v}$ show cerebral vascular defects consistent with the notion that brain vascularization in the embryo proceeds by angiogenesis rather than vasculogenesis. It is not clear whether $_{v}$ $_{3}$ requires a specific matrix protein for this angiogenic role, or whether any one of its ligands will suffice. One of the integrin receptors for fibronectin, $_{5}$ $_{1}$, has also been shown to be necessary for vascular development, while $_{2}$ $_{1}$ seems important for the formation of tubes by endothelial cells in vitro. The junctional proteins VE-cadherin and PECAM-1 are expressed early in development and may also have a role in assembling the vasculature. [59] [73]

Remodeling, Regression, and Apoptosis

Even though the vasculature is laid down before circulation begins, hemodynamic forces are important for maintenance and remodeling. Most of the vessels laid down during vasculogenesis regress or are remodeled. Following neovascularization, for instance during wound healing, the vessels regress when no longer needed. A chronic decrease in blood flow results in narrowing of the vessel lumen. This change in vessel caliber is dependent on an intact and functional endothelium. [74] Remodeling, which involves the loss of some vessels as well as changes in lumen diameter and wall thickness, requires both cell death and proliferation (in addition to remodeling of the extracellular matrix). In addition to survival signals transmitted by integrins, shear stress is important for endothelial survival and vessel healing following injury. [75] [76] Oxygen tension is also important in vascular maintenance. Hypoxia increases levels of vascular endothelial growth factor (VEGF) which provides signals for vessel maintenance and neovascularization. [77] [78] Hyperoxia, on the other hand, inhibits VEGF expression, which leads to regression and death of retinal vessels. [79] In some models, regression of vessels has been shown to occur by apoptosis of vascular cells. [80] [81] Endothelial cells express several anti-apoptotic molecules in order to maintain viability when quiescent and when stressed. [82] [83] [84] Most likely, there is an intricate balance between cell death and proliferation maintained by activators and inhibitors of both processes.

Role of Secreted Factors and Their Receptors

Numerous factors have been reported to regulate vascular development in a positive or negative fashion. However, definitive evidence is lacking in many cases. Some of the key molecules and their receptors that are involved in the process of vascular development and differentiation are discussed below, and a model for vascular development is depicted in Figure 101-1 .

Inducers of Angiogenesis

Fibroblast Growth Factors.

The role of fibroblast growth factors (FGFs) in vascular development is controversial. [58] [59] [85] Because of the possible functional redundancy in the numerous family members, it has been difficult to assign a specific role to the various members of the FGF family. There is evidence to suggest that FGF receptors signal an inductive pathway in differentiating mesoderm prior to vascular morphogenesis. [22] [86] [87] FGF has been reported to upregulate VEGF receptor-2 in avians, which may be a mechanism whereby mesodermal cells can respond to VEGF and commence vasculogenesis. [59]

Vascular Endothelial Growth Factors.

Five members of the VEGF family have been identified: [58] [64] [65] [85] [88] [89] [90] VEGF (also called vascular permeability factor), VEGF-B, VEGF-C, VEGF-D, and placental growth factor (PlGF). Three members of the receptor tyrosine kinase (RTK) family, [58] [65] [91] VEGF-R1 (flt-1), VEGF-R2 (flk-1/KDR), and VEGF-R3 (flt-4), differentially respond to individual members of the VEGF family. VEGF functions as a homodimer, but has also been shown to heterodimerize with VEGF-B and PlGF. [85] [86] VEGF binds VEGF-R1 and VEGF-R2, whereas VEGF-C binds VEGF-R2 and VEGF-R3, and PlGF activates VEGF-R1. [65] [85] [89] VEGF-C induces proliferation of lymphatic, but not vascular, endothelium. [85] On the other hand, VEGF has a crucial, dose-dependent effect on vasculogenesis. [58] [64] [65] Lack of VEGF-R2 prevents the development of endothelial cells and a hematopoietic system, because cells lacking VEGF-R2 do not reach the correct location to form blood islands. [92] Mice that have been rendered deficient for VEGF-R1 have normal hematopoietic progenitors and abundant endothelial cells, but do not form capillary tubes or functional vessels. [93] Both VEGF-R2- and VEGF-R1-deficient mice die at an early embryonic stage. In von Hippel Lindau disease, the development of hemangioblastomas may be due to the stabilization of VEGF mRNA. [94] VEGF is also felt to play a key role in propagating tumor angiogenesis. Finally, injection of VEGF is capable of relieving limb ischemia by the generation of collateral vessels. [62] VEGF appears to collaborate with the angiopoietins to stimulate vascular development.

Figure 101-1 A model for vascular development. Although this figure highlights the role of secreted proteins and membrane receptors in vascular development, other factors such as cell adhesion molecules and extracellular matrix components also contribute significantly. Ang, angiopoietin; ECM, extracellular matrix; FGF, fibroblast growth factor; PEC, peri-endothelial cell (smooth muscle cell, pericyte); PDGF, platelet-derived growth factor; TGF-, transforming growth factor-, VEGF, vascular endothelial cell growth factor; VEGF-R, VEGF receptor.

Angiopoietins.

Angiopoietin-1 (Ang1) and angiopoietin-2 (Ang2) are two highly related, secreted glycoproteins that share about 60% amino acid identity. [95] [96] [97] [98] Both Ang1 and Ang2 bind to the RTK, Tie-2/Tek. [95] [97] Binding of Ang1 to Tie-2 results in tyrosine phosphorylation of Tie-2, but, unlike VEGF, Ang1 does not stimulate endothelial proliferation or tube-formation. [95] Early in development, Ang1 is mainly found in the myocardium surrounding the endocardium, but it also comes to be expressed in the mesenchyme surrounding developing vessels. [95] Disruption of either Ang1 or its receptor Tie-2 in the mouse results in embryonic lethality due to similar defects. [96] [98] [99] These mice die at a slightly later stage than VEGF-receptor-deficient mice. Although endothelial cells are present, there is a lack of vascular complexity and a scarcity of peri-endothelial cells. Reciprocal interactions between the endothelial cells and surrounding matrix and mesenchyme appear to be disrupted. A Tie-2 mutation in humans causes vascular malformations that show a depletion of smooth muscle cells in the vascular wall. [100] Ang2 also binds Tie-2, but rather than inducing receptor phosphorylation, acts as a natural antagonist for Ang1 and Tie-2. [97] Mice engineered to overexpress Ang2 specifically in their vasculature show embryonic lethality and vascular defects that are reminiscent of those seen in Ang1- or Tie-2-null embryos. [97] It appears then, that Ang1/Tie-2 coupling mediates vascular maturation by sustaining endothelial cell/peri-endothelial cell/matrix interactions, and may also be involved in maintaining endothelial cell quiescence. As Ang2 is only found at sites of vascular remodeling, it has been proposed that Ang2 may act to loosen matrix contacts, thus allowing access and responsiveness to angiogenic factors such as VEGF. [97] [98] In the absence of growth factors, disruption of the vessel architecture by Ang2 may result in vascular cell apoptosis and vessel regression.

Tie-1 is an RTK that exhibits structural similarities to Tie-2. A ligand for Tie-1 has not yet been identified. [58] [91] Disruption of the Tie-1 gene in mice results in lethality at a much later point in development and Tie-1-null mice may survive up to birth. [99] [101] Tie-1$^{/}$ mice die of hemorrhage and edema, implicating Tie-1 in signaling the control of fluid exchange across capillaries and in maintenance of vessel integrity under hemodynamic stress. Chimeric mice that express Tie-1 $^{/}$ and Tie-1$^{+/}$ endothelial cells show underrepresentation of Tie-1 $^{/}$ cells in vessels primarily derived by angiogenesis, but not in embryonic vessels derived by vasculogenesis, suggesting a differential function for Tie-1 in angiogenesis. [102]

Platelet-Derived Growth Factors.

The platelet-derived growth factor (PDGF) family is made up of two chains, PDGF-A and PDGF-B, which can associate in a homodimeric or heterodimeric fashion. Similarly, the receptors, and are RTKs that can form homo- or heterodimers. PDGF-BB can bind the receptors PDGFR- or PDGFR-, but the PDGFR- only binds PDGF-BB not PDGF-AA or AB. [58] Mice null for PDGF-B die perinatally with renal, hematological and cardiovascular abnormalities. [103] The large vessels and heart of

these mice are dilated and microvessels exhibit microaneurysms due to the lack of pericytes. [19] [103] PDGFR--knockout mice do not show an overtly abnormal cardiovascular phenotype, but generation of chimeric mice demonstrates that PDGFR-$^{/}$ cells are underrepresented in all muscle lineages (smooth, cardiac and skeletal).[104] [105] Thus, it appears that PDGF-BB elaborated by the endothelial cell provides a signal to recruit mesenchymal peri-endothelial cells as part of the maturation process of vascular morphogenesis.

Transforming Growth Factors-.

Members of the transforming growth factor- (TGF-) family are multifunctional homodimeric peptides with diverse effects on cell proliferation, migration, differentiation, adhesion, and expression of cell-adhesion molecules and ECM. [58] [106] [107] They are secreted as inactive precursors and once activated, transmit signals to cells by binding heteromeric complexes of type I and type II serine/threonine kinase receptors. Contact between endothelial cells and PEC is required for the production of active TGF-.[15] Although there has been confusion as to the part that TGF- plays in angiogenesis, several recent developments attest to its key role in vascular morphogenesis. Mice lacking TGF- or TGF- receptor type II exhibit similar defects in vasculogenesis and hematopoiesis. [106] [107] Endothelial proliferation is not affected, but there are poor contacts between endothelial cell and mesothelial layers in embryos of TGF- $^{/}$ mice resulting in a disorganized and reduced vascular network lacking capillary tubes. [106] Mutations that affect a cell surface TGF- binding protein, endoglin, cause hereditary hemorrhagic telangiectasia type 1. [108] Disruption of TGF- signaling likely plays a role in the telangiectasia seen in this disorder.

Coagulation Factors.

The potential involvement of fibrinolytic factors in angiogenesis has been mentioned previously. Tissue factor is a member of the cytokine receptor superfamily. As well as having a role in initiating coagulation as a cofactor for factor VII, tissue factor may also be involved in intracellular signaling. Tissue factor knockout mice have abnormalities of their large vessels and microvasculature secondary to defects in mesenchymal cell/peri-endothelial cell accumulation and function. [20] Abnormal development of the vasculature also affects 50% of mice that are deficient in factor V. The affected mice die in utero, and the 50% embryonic lethality is similar to that observed in thrombin receptor-deficient mice that die without obvious coagulation defects. [109] It is possible that factor

V-dependent generation of thrombin is important for early vascular development by signaling through the thrombin receptor. [58]

Inhibitors of Angiogenesis

As with the angiogenesis inducers, multiple factors have been reported to negatively regulate vascular morphogenesis. [62] Of particular interest is an emerging class of endogenous angiogenesis inhibitors that are fragments of larger proteins that have little or no angiogenesis-related activity in their intact form. The mechanism of action of these protein fragments is not entirely clear. Some of these fragments have been shown to inhibit proliferation or induce apoptosis of endothelial cells. [65] [110] [111] [112] A list of some of these polypeptide fragments is outlined in Table 101-1 . Other endogenous inhibitors include interferons, chemokines and interleukin (IL)-12. In addition, several compounds such as AGM-1470, thalidomide, and synthetic metalloproteinase inhibitors, are in clinical trials in an attempt to cause regression of tumors by inhibiting angiogenesis.[62] [65]

Relationship Between Vascular Development and Hematopoiesis

Hematopoietic cells and endothelial cells are intertwined in several ways. First, there is the likely existence of a common precursor. Second, the endothelium is intimately involved in hematopoiesis in a supportive role structurally and nutritionally. Finally, the endothelium organizes the controlled egress and ingress of hematopoietic cells in hematopoietic and other tissues. The last issue will be covered in the subsequent section.

As hematopoietic cells and endothelial cells both arise from the embryonic mesoderm in a common structure, the blood island, a shared precursor for these two lineages seems intuitive. But what is the evidence for a cell that can differentiate either into an endothelial cell or a hematopoietic cell? Several lines of evidence are suggestive. Studies using quail-to-chicken embryonic transplants suggest that endothelial cells arise from two separate regions. Mesoderm from the splanchnopleural region is capable of giving rise to both endothelial cells and hematopoietic precursors, [61] [113] leading investigators to call these cells hemangioblasts, i.e., having dual potential. A study using single cell injections of a tracer indicated that a single labeled cell would give rise to cells of the ventral aortic endothelium and the hematopoietic precursors that aggregate in that region. [114] Further evidence comes from the zebrafish mutant, *cloche*, which affects endothelial and blood lineages. [115] As discussed earlier, the VEGF-R2 chimeric mouse shows that only VEGF-R2-positive cells contribute to both lineages. [92] However, in this study the authors were able to show erythropoiesis arising from embryoid bodies of VEGF-R2-null mice. Most intriguing is the evidence that a circulating cell can reendothelialize an impervious Dacron graft and that a circulating mononuclear CD34+ cell can be induced to differentiate into endothelial cells in vivo and ex vivo. [116] [117] In the latter study, circulating CD34+ cells were harvested and injected into animal models of hindlimb ischemia, a procedure which results in substantial neovascularization. [117] The labeled CD34+ cells were detected in the endothelial cells of the neovascularized areas. These studies suggest the presence of a circulating endothelial cell precursor that might be of marrow origin. In contrast, in a study of sex-mismatched bone marrow transplants using in situ hybridization to detect the Y chromosome, it was concluded that marrow endothelial cells were of host derivation.[118] However, if endothelial cells are more resistant to the conditioning regimen due to their low turnover rate, then there would be less need for the donor-derived endothelial cells. Most of the marrow biopsies in this study were done less than a month following transplant, which may be too short a time to detect the few endothelial cells that might have differentiated from transplanted cells. More circumstantial evidence for the existence of a common progenitor is the array of shared cell surface markers (e.g., CD34, CD31) or transcription factors (e.g., Tal1/SCL, Gata-2) between these two cell lineages.[61] [119] [120]

Bone marrow stromal cells secrete cytokines, produce ECM, and are in direct cellular contact with hematopoietic cells, thereby providing a microenvironment suitable for hematopoietic proliferation, differentiation, and self-renewal. [121] A wealth of studies demonstrate the supportive role of endothelium in hematopoiesis. The physical proximity of endothelium and hematopoietic precursors within the marrow and the requirement of blood cells to transit marrow endothelium to reach the circulation is presumptive evidence of an important role of endothelium. Marrow endothelial cells constitutively express high levels of IL-6, stem cell factor (SCF), granulocyte-colony stimulating factor (G-CSF), and granulocyte macrophage (GM)-CSF. [122] Both yolk sac and marrow endothelial cells support long-term proliferation and differentiation of hematopoietic cells in vitro. [122] [123] However, endothelial cells have also been reported to inhibit hematopoiesis. [124] The altered hematopoiesis observed in mice that are deficient in both P- and E-selectin likely reflects a response to infection due to impaired trafficking of neutrophils to tissue rather than a direct involvement of these receptors in hematopoiesis. [125] As already discussed, endothelial VCAM-1 may also be important in trafficking and homing of progenitor cells.[56] In all likelihood, the endothelium, in concert with other stromal cells, provides a finely tuned system to modulate hematopoiesis such that differentiation, proliferation and self-renewal occur in a regulated fashion.

Human endothelial cells have also been reported to express receptors for IL-3, SCF, erythropoietin, and thrombopoietin and show functional responses to IL-3 and erythropoietin.[126] [127] [128] The shared responses to growth factors, combined with the importance of macrophages in angiogenesis and the production of cytokines by monocytes/macrophages, suggest that hematopoietic cells may play a reciprocal role in maintaining the endothelium.

PHYSIOLOGICAL FUNCTIONS OF THE ENDOTHELIUM

The Endothelium as a Barrier

As with other functions, vessel permeability is dependent on the type of vessel and its location. The microvasculature (capillaries and post-capillary venules) act as the exchange vessels of the circulation. There is virtually unimpeded movement of lipophilic and low molecular weight hydrophilic substances between blood and tissue, but the vessels are selectively permeable to macromolecules. This semi-selective barrier is necessary to maintain the fluid balance between intravascular and extravascular compartments, yet antibodies, hormones, cytokines, and other molecules must have access to the interstitial space for the initiation and potentiation of various processes, including inflammation, immune response, and wound repair.

Permeability to Macromolecules

The movement of macromolecules across the vessel wall is governed by: (1) hydrostatic and oncotic pressure gradients; (2) physicochemical properties of the molecule such as size, shape, and charge; (3) properties of the barrier. The barrier of the vessel wall is formed by the cellular components, endothelial cells, and pericytes, as well as by the charge and compactness of the matrix components, the glycocalyx and basement membrane. Macromolecules can either pass directly through the endothelial cell (transcellular path), or between adjacent endothelial

---

cells (paracellular path). Surprisingly, the mechanisms of macromolecular movement remain controversial, and data generated by physiologists, morphologists, and cell biologists have not yet been consolidated in a model that satisfies the findings of the different groups.

Functionally, physiologists have proposed the existence of two sets of pores based on experiments measuring the movement of dextran and other macromolecules: a small pore of radius 35 nm for the transport of water and small hydrophilic molecules, and a large pore of radius 2560 nm for macromolecular transport. [129] [130] [131] [132] Transport into cells may proceed by receptor-mediated systems, e.g., clathrin-coated pits in which the molecules are usually targeted to the lysosome. Alternatively, molecules may be moved across the cell by plasmalemmal vesicles or caveolae, which are abundant in capillary endothelial cells. Caveolae are 50100 nm membrane invaginations that can participate in transcytosis, as well as in the translocation of glycosylphosphatidylinositol-linked proteins into the cytoplasm and in transmembrane signaling.[133] Because of the known leakiness of tumor microvasculature, others have studied these microvessels and identified a structure designated the vesiculo-vacuolar organelle. [64] [134] These organelles are grape-like clusters of interconnecting uncoated vesicles and vacuoles that span the entire thickness of vascular endothelium, thereby providing a potential trans-endothelial connection between the vascular lumen and the extravascular space. [134] Vesiculo-vacuolar organelles are distinguished from clathrin-coated vesicles and capillary caveolae by their larger size and the functional regulation of the channel by diaphragms comprised of a single membrane. Interestingly, their function is enhanced by the injection into normal skin of VEGF which is known to increase the permeability of vessels.[64]

During inflammation, the binding of neutrophils to the endothelium results in the generation of oxidants that can mediate endothelial cell injury and increase permeability.[135] Thrombin, an inflammatory mediator, can increase endothelial permeability by several mechanisms resulting from the activation of its receptor on endothelial cells.[136] [137] [138] First, there is an increase in transcellular vesicular permeability. There is also increased paracellular permeability that results from the phosphorylation of endothelial cell nonmyosin light chains and contractile activity generated by the movement of actin and myosin filaments past each other. The contraction and retraction of endothelial cells are accompanied by the loosening of intercellular junctions and focal integrin contacts with the ECM. Finally, thrombin may also alter the repulsive effect of the negatively charged glycocalyx. Pericyte contractility has also been hypothesized as a mechanism of increasing permeability in inflammatory states.[139]

The Endothelium as a Nonthrombogenic Surface

The mechanisms of hemostasis and thrombosis are addressed in Chapters 100 , 101 , 102 , 103 , 104 . The purpose of this section is to place the endothelium in the appropriate context in these processes. An overview of endothelial cell contributions to the anticoagulant and procoagulant states is presented in Figure 101-2 . Normal unperturbed endothelium presents a nonthrombogenic surface to the circulation by preventing the activation and propagation of coagulation, enhancing fibrinolysis, and inhibiting platetet aggregation. These activities are accomplished by both passive and active processes. Conversely, when injured or under inflammatory conditions, the endothelium may become procoagulant.

Four mechanisms may be utilized by endothelial cells to inhibit coagulation. [140] [141] (1) thrombomodulin on the surface of endothelial cells binds thrombin. This coupling inhibits the coagulant properties of thrombin and also increases its affinity for protein C, which it cleaves and activates. Protein C also binds to the endothelial cell protein C receptor, which may also be essential for protein C activation; [142] (2) protein S, which is thought to be synthesized primarily by the endothelial cell, acts as a cofactor for protein C, but also has anticoagulant properties in its own right. Independent of the presence of activated protein C, free protein S is able to inhibit the prothrombinase and intrinsic tenase complexes and interact directly with factors Va and VIIIa; [140] [143] (3) heparan sulfate proteoglycans are secreted onto the luminal surface of endothelial cells and into the subendothelium. Heparan sulfates are capable of binding and activating antithrombin, thereby accelerating the inactivation of several procoagulant serine proteases including thrombin, factor Xa and factor IXa; (4) tissue factor pathway inhibitor (TFPI) is synthesized in the liver and in endothelial cells, and has been shown to be localized in apical granules of the endothelial cell. The tissue factorfactor VIIafactor Xa complex is inhibited by TFPI.[141] Other proteins such as TFPI-2, annexin V, and protease nexins 1 and 2 may also play an endothelium-dependent anticoagulant role.[140] Although the preceding discussion outlines the

---

major potential endothelial anticoagulant pathways, other factors are likely to be important.

Endothelial cells are the major source of tissue-type plasminogen activator (tPA). [141] [144] Although cultured endothelial cells can secrete urokinase (uPA), the in vivo significance of this finding is not clear. About 40% of tPA is bound to its inhibitor, plasminogen activator inhibitor-1 (PAI-1), also secreted by endothelial cells. Stresses such as exercise, acidosis, hypoxia, shear forces, increased venous pressure, and thrombin will release tPA, [141] [144] and presumably activate plasminogen. Receptors for plasminogen and tPA are present on the endothelial cell surface, allowing for effective localized production of fibrinolytic activity.

When in close proximity to endothelial cells, platelets become unresponsive to agonists. This inhibition of platelet aggregation is accomplished by the secretion of prostacyclin (PGI_2) and nitric oxide (NO), and by the surface expression of an ecto-ADP (adenosine diphosphate)ase recently identified as CD39. [141] [145] Prostacyclin is synthesized mainly by vascular endothelial and smooth muscle cells as a product of arachidonic acid metabolism. It inhibits platelet activation, secretion, and aggregation, and monocyte interactions with endothelial cells. It also causes vascular smooth muscle cell relaxation. Nitric oxide (NO) similarly has a wide range of functions including the inhibition of platelet adhesion, activation, and aggregation. Most of the NO released from endothelial cells is elaborated abluminally where it acts on the smooth muscle cell to cause vasodilation. However, some NO may also enter the lumen and thereby diffuse into platelets. Prostacyclin and NO can act synergistically to reverse platelet aggregation. [146] The released platelet agonist, ADP, can be inactivated by an endothelial membraneassociated ecto-ADPase. Metabolism of ADP by the ecto-ADPase eliminates platelet recruitment and returns the platelets to their resting state.

Although intact endothelium is necessary to maintain blood in a fluid state and inhibit coagulation under normal conditions, when injured the endothelium can rapidly downregulate its anticoagulant functions and become procoagulant, even without overt vascular damage such as with trauma or surgery. Further tissue injury or vascular pathology also leads to exposure of the underlying matrix, which is procoagulant by virtue of its binding to and activation of platelets. Endothelial cells that have been induced to undergo apoptosis in vitro become procoagulant. Apoptotic endothelial cells expose phosphatidylserine on their surface, and downregulate their anticoagulant properties described above. Apoptotic endothelial cells and vascular smooth muscle cells have also been shown to increase thrombin formation in recalcified citrated plasma. [147] [148] Microvascular endothelial cells undergo apoptosis following exposure to plasma from patients with thrombotic thrombocytopenic purpura, which may play a role in the formation of microthrombi seen in this disorder. [149]

Even without endothelial death or vascular injury, perturbation of the vascular lining by inflammatory mediators or altered shear stresses can tip the balance such that the endothelium converts from a nonthrombogenic surface to a procoagulant one. This is due to the downregulation of anticoagulant factors as well as the induction of procoagulant ones. For instance, tumor necrosis factor (TNF) and IL-1 have been shown to downregulate thrombomodulin as well as induce expression of tissue factor on endothelial cells in vitro. [144] [150] Tissue factor, which is not normally expressed by endothelial cells, has been shown to be present in endothelial cells overlying atherosclerotic plaque [151] and can activate the extrinisic pathway of coagulation. Tumor necrosis factor, IL-1, and endotoxin can also increase the expression of PAI-1 in endothelial cells with downregulation or no change in tPA levels, thereby impairing fibrinolysis. In the setting of acute inflammation, there is also increased release of vWF, platelet activating factor, and fibronectin, all of which may potentiate thrombus formation.

Control of Vascular Tone

The control of vascular tone is primarily orchestrated by a balance of endothelium-derived vasodilators (NO, PGI_2, an endothelium-derived hyperpolarizing factor (EDHF) and vasoconstrictors (endothelin-1, superoxide). In addition to inhibiting platelet aggregation, NO and PGI_2 also act as vasodilators. [152] [153] NO is produced by the conversion of L-arginine to L-citrulline by NO synthase (NOS). Three forms of NOS exist: a constitutive NOS in neuronal tissue; an inducible enzyme found in macrophages and other cells that plays a role in NO-induced cytotoxicity; and a constitutively active endothelial form (ecNOS). [51] The inducible form of NOS is also present in endothelial cells and may be responsible for the uncontrolled vasodilation seen in septic shock. [51] Injection into the forearm of L-arginine analogues that inhibit NOS causes substantial vasoconstriction. Conversely, ecNOS-deficient mice are hypertensive, suggesting that NO release is crucial for maintaining a basal vasodilation. [152] [153] The major physiological stimulus for the continuous production of NO in vivo is shear stress. The action of NO on platelets (anti-aggregatory), endothelial cells and smooth muscle cells (relaxation) is due to the activation of guanyl cyclase and the formation of cyclic guanosine 3:5-cyclic monophosphate (cyclic GMP). Whereas NO is quite unstable, the formation of S-nitrosothiols in the presence of oxygen and thiols provides a stable reservoir of NO. [154] Hemoglobin is an avid scavenger of NO, which may account for the vasoconstriction observed with the administration of cell-free, hemoglobin-based red cell substitute. [155] Physiologically, however, S-nitrosohemoglobin acts as a regulator of blood flow. Deoxygenation is accompanied by an allosteric change in S-nitrosohemoglobin that releases the NO group, relaxing blood vessels to bring blood flow into line with local oxygen requirements. [156]

Prostacyclin, on the other hand, does not appear to have as global a role in vasodilation as NO. PGI_2 is synthesized mainly by endothelial cells and acts locally at sites of injury, and may counterbalance the vasoconstriction induced by the platelet-produced arachidonic acid metabolite, thromboxane A_2 (TXA_2). Most PGI_2 is released luminally, where it has an anti-platelet effect. Prostacyclin transduces a cellular signal by increasing the levels of cyclic AMP, whereas TXA_2 signals via the phosphoinositol pathway and lowering of cyclic AMP levels. Synthesis of prostaglandins begins by the action of cyclo-oxygenases (COX1 and COX2) on arachidonic acid. Aspirin inhibits cyclo-oxygenase irreversibly in both platelets and endothelial cells. However, the clinical effect is seen primarily in platelets for two reasons. [51] [153] One reason is that platelets, being non-nucleated, cannot synthesize new cyclo-oxygenase, although endothelial cells can. Therefore, TXA_2 synthesis recovers only when new platelets enter the circulation whereas cyclo-oxygenase production by endothelial cells restores PGI_2 levels within a few hours. The second reason is that platelets encounter orally administered aspirin before it is deacetylated by the liver and diluted by the venous circulation.

There is evidence that endothelial cells release another relaxing factor, EDHF, that acts by increasing the membrane potential of smooth muscle cells. The nature of EDHF is unclear, but it appears to act by effecting potassium efflux. This factor is released in isolated coronary arteries, in the presence of an arginine analogue (NOS-inhibitor) and indomethacin, a COX-inhibitor, suggesting that EDHF, NO, and prostanoids contribute differentially to relaxation in human coronary arteries. [157] Recent findings suggest that EDHF is a cytochrome P450-linked, arachidonate metabolite. [158] [159] [160]

Endothelin-1 (ET-1) is a 21-amino-acid peptide, released preferentially at the abluminal surface of endothelial cells, that exhibits potent vasoconstrictor activity. [161] [162] Of the three known endothelins, only ET-1 is produced by endothelial cells. At least two receptors have been identified (ET-A and ET-B) that bind to

all three endothelins. ET-A is abundantly expressed on smooth muscle cells while ET-B is predominantly expressed on endothelial cells. The vasoconstrictor activity of ET-1 is preferentially mediated by ET-A receptors on smooth muscle cells. Engagement of ET-B on endothelial cells by ET-3 may paradoxically cause a transient vasodilation. There is little evidence that ET-1 plays a role in essential hypertension, but it might contribute to pregnancy-induced hypertension and may also play a role in reperfusion injury following ischemia. [162]

Another seemingly important regulator of vascular tone is the superoxide anion. [152] [163] The source of this free radical may be the endothelium itself or inflammatory cells that have been recruited to sites of injury or inflammation. Interaction of superoxide radicals and NO produces peroxynitrite and reduces the concentration of NO. Peroxynitrite can also oxidize low-density lipoprotein and deleteriously modify other proteins, thereby causing endothelial dysfunction. Increased production of superoxide inhibits synthesis of PGI_2, but not that of TXA_2. [163]

The endothelium also expresses angiotensin-converting enzyme at its surface which converts angiotensin I to angiotensin II, a potent vasoconstrictor. The interaction between endothelin, angiotensin II and alpha-adrenergic agonists in the pathogenesis of hypertension is believed to be complex. [164]

An altered balance of the vasoactive substances described in this section has been proposed to cause endothelial dysfunction and the attendant vascular pathology observed in atherosclerosis, hypertension, and diabetes mellitus. Furthermore, alteration of vascular function in these diseases may then perpetuate the endothelial dysfunction and, consequently, worsen disease.

The Interaction of Blood Elements with the Vessel Wall

Leukocytes

In the absence of any inflammatory stimulus, neutrophils circulate freely and do not interact with the endothelium. In contrast, there is a continuous, low-level physiologic traffic of monocytes and lymphocytes across the vessel wall. Monocytes emigrate from the bloodstream to develop into tissue macrophages that may

exhibit tissue- or organ-specific functions. To maintain immune surveillance of tissue, lymphocytes recirculate between blood and lymphatics, gaining entrance to the latter at the HEV of postcapillary venules in lymphoid tissue.

Studies by intravital microscopy have established a sequence of events involved in leukocyte emigration at extravascular sites of inflammation. [165] Under conditions of flow, leukocytes are first observed to roll along the endothelium of postcapillary venules adjacent to the site of inflammation. Subsequently, some of the rolling leukocytes stick firmly, migrate along the endothelial surface, diapedese between endothelial junctions, and then migrate through subendothelial matrix. These steps in emigrationrolling, firm adhesion, and transendothelial migrationare also involved in lymphocyte emigration at HEV. They result from the interaction of distinct leukocyte and endothelial receptors in an adhesion cascade (Fig. 101-3 ; Chap. 5).[166] [167] [168] Rolling is observed only under flow conditions and is the consequence of shear forces acting on the leukocyte and adhesive interactions between selectin receptors and their glycoconjugate counterstructures. It is initiated primarily by activation of the endothelium by extravascular stimuli such as bacterial-derived products or by endogenous mediators produced by the endothelium or cells in tissue (Table 101-2). Early on, rolling is mediated by P-selectin, which is rapidly translocated from Weibel-Palade bodies to the luminal surface, and possibly also by induced ligand(s) for L-selectin. [169] E-selectin is involved only at later time-points as it is not constitutively expressed, but rather is induced over hours by de novo synthesis.

In order for leukocytes to circulate freely, their integrin receptors must be in a low avidity, i.e., non-binding, state but able to increase avidity rapidly. Once tethered to endothelium by selectin interactions, [170] [171] the leukocyte integrin receptors are activated by endothelial membrane-expressed platelet-activating factor, endothelial membrane-bound chemokines, or locally-secreted chemoattractants. Activation of the leukocyte integrins increases their avidity for their endothelial ligands, which are

Figure 101-3 Leukocyte and endothelial adhesion molecules. Endothelial P-selectin recognizes SLe^x or related sialylated and fucosylated glycoconjugates together with sulfate residues expressed on PSGL-1. Endothelial E-selectin recognizes sialylated and fucosylated glycoconjugates expressed on PSGL-1, L-selectin, and murine ESL-1. Leukocyte L-selectin binds to an uncharacterized ligand on systemic endothelium and to sialylated, sulfated, and fucosylated moieties on GlyCAM-1 and CD34 on peripheral node HEV and MAdCAM-1 on mucosal HEV. Leukocyte $_{L\ 2}$ binds to ICAM-1 and ICAM-2; $_{M\ 2}$ to ICAM-1 and to an as yet unidentified ligand(s). Leukocyte $_{4\ 1}$ interacts with VCAM-1 and $_{4\ 7}$ with MAdCAM-1. The IgSF protein PECAM-1 is expressed on both the leukocyte and the endothelial cell and participates in transendothelial migration. SLe^x, Sialyl Lewis X; PSGL-1, P-selectin glycoprotein ligand; ESL-1, E-selectin ligand; GlyCAM-1, glycosylation-dependent cell adhesion molecule; MAdCAM-1, mucosal addressin cell adhesion molecule; IgSF, immunoglobulin gene superfamily; ICAM-1, intercellular adhesion molecule; VCAM-1, vascular cell adhesion molecule; PECAM-1, platelet-endothelial cell adhesion molecule.

TABLE 101-2 -- Endothelial Cell Activation[a]

	Agonists	Response
Rapid (protein synthesis-independent)	Thrombin, histamine	Synthesis of PAF Secretion of vWF P-selectin, tPA
	Thrombin Oncostatin M	Secretion of TFPI, PGI2 Secretion of P-selectin
Delayed (protein synthesis-dependent)	IL-1, TNF, LPS	Synthesis of ICAM-1, VCAM-1, E-selectin, IL-1, IL-6, IL-8, MCP-1, GM-CSF Synthesis of TF, PAI-1, tPA, uPA Downregulation of TM
	IFN-/, TNF, LT	Synthesis of Class I MHC
	IFN-	Synthesis of ICAM-1, Class II MHC
	IL-4	Synthesis of VCAM-1, P-selectin
	Oncostatin M	Synthesis of E-selectin, VCAM-1, ICAM-1, IL-6
	Thrombin	Synthesis of IL-8, IL-6, E-selectin

ICAM, intercellular adhesion molecule; IFN, interferon; IL, interleukin; LT, lymphotoxin; MCP, monocyte chemoattractant protein; MHC, major histocompatibility complex; PAF, platelet activating factor; PAI, plasminogen activator inhibitor; vWF, von Willebrand factor; TF, tissue factor; TFPI, tissue factor pathway inhibitor; tPA, tissue type plasminogen activator; TM, thrombomodulin; uPA: urokinase type plasminogen activator; VCAM, vascular cell adhesion molecule.

[a] Selected agonists and responses; many other stimuli have been reported to activate.

constitutively expressed (ICAM-1, ICAM-2), further up-regulated (ICAM-1), or induced (VCAM-1) by locally-generated cytokines (Table 101-2). Although the activation-dependent increases in integrin avidity allow shear-resistant firm adhesion, subsequent leukocyte migration over the endothelium requires reversible adhesion due to cyclic modulation of receptor avidity. [172]

Upon encountering an intercellular junction, some of the adherent, migrating leukocytes diapedese between endothelial cells to enter extravascular tissue and then migrate to the site of inflammatory or immune reaction. This process of transendothelial migration utilizes leukocyte integrin interactions with endothelial ligands and, for phagocytes, homophilic binding of PECAM-1.[173] Other leukocyte and endothelial molecules involved in transendothelial migration have not yet been fully characterized. Diapedesis also appears to involve signaling by the leukocyte to the endothelial cell, triggering a disruption of junctional integrity. [174] [175]

Leukocyte recruitment is terminated by several mechanisms. E- and P-selectin are removed from the endothelial cell surface by endocytosis, [176] while L-selectin is cleaved from leukocytes by a membrane protease.[177] Decay of cytokine, chemokine, or chemoattractant generation leads to gradual resolution of endothelial adhesion molecule expression and integrin activation. Locally-generated mediators such as nitric oxide [178] or TGF-[179] also act to inhibit further leukocyte adhesion to endothelium.

Several caveats should be considered with respect to this model of an adhesion cascade. First, selectin-mediated rolling is not a prerequisite for emigration under conditions of reduced flow, as might sometimes occur at sites of inflammation. [180] [181] Second, the model was developed from observations in the systemic microcirculation, where leukocyte emigration occurs in postcapillary venules under relatively low shear forces. Its validity in the pulmonary microcirculation where emigration occurs in the capillaries [182] or in the arterial circulation where shear forces are greater is uncertain. Third, under some conditions leukocytes are able to roll via receptors other than selectins (e.g., VLA-4 or CD44). [183] [184] Finally, a number of other adhesion molecules are involved in leukocyte binding to endothelium and their roles in this cascade remain to be defined.

Although critical for host defense and repair, under some circumstances, leukocyteendothelial interactions may lead to vascular and tissue damage. Activated leukocytes tightly adherent to endothelium may release toxic products that damage endothelium, producing permeability edema or thrombosis. Emigrated leukocytes may similarly damage adjacent tissue. Increased expression of endothelial adhesion molecules occurs in involved tissues in diverse inflammatory and immune disorders.[185] Moreover, blockade of leukocyte adhesion to endothelium by monoclonal antibodies or other antagonists has been demonstrated to reduce vascular and tissue injury in a wide variety of animal models of inflammatory and immune disease. [186] Similar protection is observed in mice with targeted disruption of adhesion molecule genes. Anti-adhesion therapy is now being tested in several clinical trials.

Platelets

Like neutrophils, unactivated platelets do not interact with unperturbed endothelium. Following a vascular injury that produces endothelial denudation or retraction, platelets rapidly adhere to the exposed subendothelium. As discussed in greater detail in Chapters 99 and 100 , at high shear rates this initial adhesion does not require platelet activation and involves platelet glycoprotein (GP)Ib/IX/V binding to vWF in the subendothelial matrix. Platelet activation occurs following adhesion,

leading to platelet spreading mediated by integrin receptors binding to matrix components and aggregation mediated by fibrinogen binding to GPIIb/IIIa.

There is evidence that unactivated platelets can bind directly to activated endothelium via endothelial P-selectin [187] and PECAM-1[188] in vivo or via vWF in vitro.[189] Also, activated platelets have been shown to bind to HEV in vivo via platelet P-selectin [190] and to endothelium in vitro via platelet GPIIb/IIIa.[191] Platelet adhesion to intact endothelium could contribute to thrombus formation in the microcirculation and may provide a link between thrombosis and inflammation.

Red Blood Cells

Only sickled red blood cells have been shown to interact significantly with endothelium. Binding of sickle cells to microvascular endothelium may be an important pathogenic factor in vaso-occlusive events (see Chap. 30). Several adhesive interactions between sickle red cells and endothelium have been described in vitro. [192] Of particular interest is the finding that sickle reticulocytes have abnormally increased expression of VLA-4 ($_{4}{}_{1}$) and CD36. VLA-4 was found to promote sickle reticulocyte adhesion to VCAM-1[193] or fibronectin[194] on activated endothelium. Thrombospondin was shown to serve as a bridge between CD36 on sickle reticulocytes and an endothelial cell receptor, likely $_{v}{}_{3}$.[195] Notably, hydroxyurea therapy, which reduces the clinical severity of sickle cell disease, was found to reduce both VLA-4 and CD36 expression on sickle reticulocytes, providing correlative evidence that these adhesion receptors contribute to the pathophysiology. [196]

Endothelial Cell Activation

Although once viewed as a passive barrier between blood and tissue, it is now evident that the endothelium is a dynamic organ that responds to diverse stimuli. In particular, activation of endothelial cells induces a proinflammatory and prothrombotic phenotype (Table 101-2). Activation responses of endothelium have been categorized as rapid (minutes), protein synthesisindependent

(type I) or delayed (hours to days), protein synthesis-dependent (type II). [197] [198] Histamine and hyperacute xenograft rejection elicit a type I response, while TNF, IL-1, most cytokines, and delayed xenograft rejection induce predominantly a type II activation pattern. [198] Some agents, such as thrombin[199] and oncostatin M,[200] trigger both types of activation.

Chapter 102 - Molecular Basis of Blood Coagulation

Bruce Furie
Barbara C. Furie

INTRODUCTION

Blood coagulation is a host defense system that maintains the integrity of the high-pressure closed circulatory system. After tissue injury, alterations in the capillary bed and laceration of venules and arterioles lead to extravasation of blood into soft tissues or external bleeding. To prevent excessive blood loss, the hemostatic system, which includes platelets, vascular endothelial cells, and plasma coagulation proteins, is called into play. Immediately after tissue injury, a platelet plug is formed through the processes of platelet adhesion and aggregation. Blood coagulation may be considered a mechanism for rapid replacement of an unstable platelet plug with a chemically stable fibrin clot. A series of interdependent enzyme-mediated reactions translates the molecular signals that initiate blood coagulation into a major biologic event, the formation of the fibrin clot.

In vitro the generation of thrombin and the formation of a fibrin clot propagate through two separate pathways, the intrinsic pathway and the extrinsic pathway. [1] [2] To generate a clot via the intrinsic pathway in a test tube, components intrinsic to whole blood are required. To generate a clot via the extrinsic pathway, components intrinsic to whole blood are required along with an activator, tissue factor, that is extrinsic to blood (Table 102-1). Tissue factor, also known as tissue thromboplastin, is a membrane protein that comes in contact with the flowing blood on blood vessel injury.

The intrinsic pathway of blood coagulation includes protein cofactors and enzymes (Fig. 102-1). This pathway is initiated by the activation of factor XII by kallikrein on negatively charged surfaces, including glass in vitro. High-molecular-weight kininogen facilitates this activation. The enzyme form of factor XII, factor XIIa, catalyzes the conversion of factor XI, a proenzyme, to its active enzyme form, factor XIa. In the presence of Ca^{2+} , factor XIa activates the proenzyme factor IX to its enzyme form, factor IXa. Factor IXa binds to the cofactor factor VIIIa bound on membrane surfaces in the presence of calcium ions to generate a complex with enzymatic activity known as tenase, a nickname for the enzymatic activity that acts on factor X. This tenase complex converts the proenzyme factor X to its enzyme form, factor Xa. In a parallel series of interactions, factor Xa binds to the cofactor factor Va bound on membrane surfaces in the presence of calcium ions to generate a complex with enzymatic activity known as prothrombinase. This complex converts the proenzyme prothrombin to its enzyme form, thrombin. Thrombin acts on fibrinogen to generate the fibrin monomer, which rapidly polymerizes to form the fibrin clot. During laboratory analysis of blood clotting, the intrinsic pathway of blood coagulation is evaluated by using the activated partial thromboplastin time (PTT). The clotting of plasma is initiated by the addition of negatively charged particles such as kaolin.

The extrinsic pathway of blood coagulation also includes protein cofactors and enzymes (Fig. 102-1). This pathway is

TABLE 102-1 -- Properties of the Genes, mRNAs, and Gene Products of the Components of the Blood Coagulation Cascade

	Molecular Weight	Gene (kb)	Chromosome	mRNA	Exons (kb)	Plasma Concentration (g/ml)	Function
Prothrombin	72,000	21	11p11q12	2.1	14	100	Protease zymogen
Factor X	56,000	22	13q34	1.5	8	10	Protease zymogen
Factor IX	56,000	34	q2627.3	2.8	8	5	Protease zymogen
Factor VII	50,000	13	13q34	2.4	8	0.5	Protease zymogen
Factor VIII	330,000	185	q28	9.0	26	0.1	Cofactor
Factor V	330,000	7.0	1q2125	7.0	25	10	Cofactor
Factor XI	160,000	23			15	5	Protease zymogen
Factor XII	80,000	12	5	2.4	14	30	Protease zymogen
Fibrinogen	340,000					3,000	Structural
A-chain	64,000		4q26q28		5		
B-chain	56,000		4q26q28		8		
-chain	47,000		4q26q28		9		
Protein C	62,000	11		1.8	8	4	Protease zymogen
Protein S	80,000			2.4		25	Cofactor
von Willebrand factor	225,000 × n[a]	175	12pterp12	8.5	52	10	Adhesion
Tissue factor	45,000	12	1pterp12	2.1	6	0.0	Cofactor/initiator
Factor XIII	320,000					60	Fibrin stabilization

[a] n, number of subunits, where the subunit M_r is 225,000.

Figure 102-1 Blood coagulation cascade. Glycoprotein components of the intrinsic pathway include factors XII, XI, IX, VIII, X, and V, prothrombin, and fibrinogen. Glycoprotein components of the extrinsic pathway, initiated by the action of tissue factor located on cell surfaces, include factors VII, X, and V, prothrombin, and fibrinogen. Cascade reactions culminate in the conversion of fibrinogen to fibrin and the formation of a fibrin clot. Certain reactions, including the activation of factor X and prothrombin, take place on membrane surfaces. Proenzymes, diamonds; procofactors, squares; enzymes and cofactors, circles; macromolecular complexes on membrane surfaces, shaded rectangles. FG, fibrinogen; F, fibrin; PT, prothrombin; T, thrombin; TF, tissue factor; HMWK, high-molecular-weight kininogen. *(Modified from Furie and Furie,[276] with permission.)*

initiated by the formation of a complex between tissue factor on cell surfaces and factor VIIa. Although the mechanism by which a small amount of factor VII is converted to factor VIIa in the absence of ongoing blood clotting is unknown, plasma contains factor VIIa at levels of 0.58.4 ng/ml. [3] When tissue factor is exposed to plasma following injury, this factor VIIa complexes with tissue factor to form an enzyme complex that activates factor X to factor Xa. In turn, factor Xa can feed back to convert more factor VII to factor VIIa,[4] thus accelerating the rate of activation of the extrinsic pathway. Factor VIIa/tissue factor complex, like the tenase complex, converts factor X to its active form, factor Xa, which binds to the cofactor factor V bound on membrane surfaces in the presence of calcium ions to generate the prothrombinase complex. This complex converts prothrombin to thrombin, which converts fibrinogen to fibrin to generate the fibrin clot. During laboratory analysis of blood clotting, the extrinsic pathway of blood coagulation is evaluated by using the prothrombin time. The clotting of plasma is initiated by the addition of exogenous tissue factor.

This scheme of blood clotting (Fig. 102-1) remains invaluable for understanding clot formation in vitro, and specifically for laboratory monitoring of anticoagulation therapy for, and diagnosis of, coagulation disorders. Yet the physiologic pathways relevant to blood coagulation in vivo are clearly different. A scheme of blood coagulation in vivo must consider the following salient features. First, since patients with hereditary factor XII, prekallikrein, or high-molecular-weight kininogen deficiency have a markedly prolonged PTT but no bleeding phenotype, these proteins are not components required to maintain hemostasis in vivo and should not be included in an in vivo model of blood clotting. [5] [6] [7] Second, tissue factor, a normal constituent of the surface of nonvascular cells and of stimulated monocytes and endothelial cells, activates blood coagulation. Third, the tissue factor/factor VIIa complex activates not only factor X but factor XI as well, suggesting a central role for factors VIII and IX in coagulation initiated by the tissue factor pathway. [8] Finally, factor XI deficiency is not invariably associated with a bleeding phenotype; as such, the position and prominence of factor IX in the blood coagulation cascade remain uncertain. Figure 102-2 presents one model of blood coagulation and depicts the pathway of sequential reactions that might lead to clot formation in vivo. [9] The key to the initiation of blood coagulation is tissue factor. The exposure of cell surfaces expressing tissue factor to the plasma proteins leads to the binding of factor VIIa to tissue factor. Either this tissue factor/factor VII complex has low but finite coagulant activity[10] or tissue factor complexed to the activated form of factor VII, factor VIIa, activates factors IX and X. [11] The protease responsible for initial activation of factor VII is unknown, but once clotting is activated, several proteases farther down the pathway can activate factor VII. Factors Xa and VIIa both catalyze the activation of factor VII, so a potential mechanism for acceleration of factor VII activation exists. [12] Furthermore, both thrombin and factor XIa in the presence of negatively charged surfaces catalyze the activation of factor XI. [13] Once factor XIa is generated, an additional mechanism augments the activation of factor IX. Factor IXa in complex with factor VIIIa on membrane surfaces activates factor X. Factor Xa in complex with factor Va on membrane surfaces activates prothrombin. Thrombin cleaves fibrinogen, yielding monomeric fibrin, which then polymerizes to form the fibrin clot.

The blood coagulation cascade proceeds on cell surface membranes. Indeed, only on the membrane surfaces of stimulated cells can the reactions involved in blood clotting proceed efficiently. Phosphatidylserine, a critical component of the cell

Figure 102-2 Physiologic pathways of blood coagulation. Blood coagulation is initiated by tissue factor (TF) expressed on cell surfaces. When plasma comes in contact with tissue factor, factor VIIa in plasma binds to this receptor. The factor VIIa/tissue factor complex activates both factor IX and factor X. The proteolytic activation of factor VII to VIIa, factor XI to XIa, factor VIII to VIIIa, and factor V to Va through feedback mechanisms (e.g., thrombin [T] or factor XIa [FXIa]) greatly accelerates the rate of blood clotting. The process culminates in the generation of fibrin and its polymerization to form a fibrin clot. *(From Furie and Furie, [5] with permission.)*

membrane that is required for assembly of blood clotting proteins on membrane surfaces, is exposed on the external membrane surface following cell activation. Phosphatidylserine is asymmetrically distributed on the phospholipid bilayer of the plasma member. An enzyme known as phospholipid scramblase catalyzes the calcium-dependent redistribution and phosphotidylserine exposure to the outer leaflet. [14] [15] [16] Tissue factor is an integral membrane protein constitutively expressed on the surface of nonvascular cells[17] [18] [19] and expressed on the surface of monocytes and endothelial cells following cell stimulation with certain agonists. This protein binds to factors VII and VIIa, generating the tissue factor/factor VIIa complex on membrane surfaces that activates factor X. [20] In another example of enzyme assembly on membrane surfaces, factors IXa and VIIIa both bind to anionic phospholipid membranes. [21] [22] It is envisioned that these two proteins skate about on the membrane, collide, and form the tenase complex, factor IXa/factor VIIIa. This complex has the enzymatic activity to convert factor X, also bound to the cell membrane, to factor Xa. Similarly, factors Xa and Va bind to anionic phospholipid membranes. [23] These two proteins also skate about on the membrane, collide, and form the prothrombinase complex, factor Xa/factor Va.[24] This complex has

the enzymatic activity to convert prothrombin, also bound to the cell membrane, to thrombin, which is released from the cell surface. In vivo, platelet membranes contribute the critical surface for blood clotting. Activated (but not resting) platelets express a factor VIIIa-binding site. [25] During platelet activation in vitro, small microparticles are released from the platelet membrane that are especially rich in receptors for factors VIIIa and Va. [26] [27]

STRUCTURE OF THE BLOOD COAGULATION PROTEINS

Domain Structure

Each of the blood coagulation proteins contains multiple functional units, derived from common ancestral genes (Fig. 102-3). As a rule these functional units, or domains, are encoded by individual exons. Although the domains are not structurally identical, they have sufficient homology in structure to suggest homology of function as well. These domains are responsible for directing protein trafficking and post-translational processing during biosynthesis and for membrane-binding properties, protein complex formation, and enzyme function of the mature protein. In factor IX, for example, these domains are independently folded but give evidence of significant interdomain interaction. [28]

Signal Peptide

The nascent chains of secreted proteins contain a short domain that permits translocation of the growing polypeptide

Figure 102-3 Structural domains of the proteins involved in hemostasis and related proteins. Domains, identified in the key, include signal peptide, propeptide, Gla domain, epidermal growth factor (EGF) domain, repeat sequences, kringle region, fibronectin (types I and II) domains, aromatic amino acid stack, zymogen activation region, and catalytic domain. Sites of proteolytic cleavage associated with synthesis of mature protein are indicated by thin arrows and those associated with zymogen activation by thick arrows. PT, prothrombin; FIX, factor IX; FX, factor X; FVII, factor VII; PC, protein C; FXI, factor XI; FXII, factor XII; PS, protein S; tPA, tissue plasminogen activator; PUK, prourokinase; MGP, matrix Gla protein; BGP, bone Gla protein; Pmg, plasminogen; T, trypsin. *(Modified from Furie and Furie,[276] with permission.)*

chain into the endoplasmic reticulum. This domain is dominated by hydrophobic amino acids and is usually 1530 residues in length. The blood coagulation proteins found in the plasma are initially synthesized with a signal peptide, which is cleaved within the endoplasmic reticulum by the signal peptidase.

Propeptide/-Carboxyglutamic Acid-Rich Domain

The vitamin K-dependent proteins contain a propeptide domain between the signal peptide and the -carboxyglutamic acid-rich N-terminal region. This propeptide, 18 residues long in factor IX, [29] [30] contains a -carboxylation recognition site that directs -carboxylation of the vitamin K-dependent proteins after synthesis [31] and is sufficient to carboxylate glutamic acid residues regardless of their sequence context. [32] Adjacent to the carboxylation recognition site is the -carboxyglutamic acid-rich region of these proteins. Glutamic acid residues within this region serve as substrates for the vitamin K-dependent -carboxylase. After carboxylation, the propeptide is cleaved from the mature protein in a late post-translational processing step. A single exon in the vitamin K-dependent proteins encodes the propeptide (including the -carboxylation recognition site) and the -carboxyglutamic acid-rich region of 40 residues. The -carboxyglutamic acid domain (Gla domain) of the vitamin K-dependent proteins contains 1012 -carboxyglutamic acid residues and is critical to the Ca^{2+} -binding properties of these proteins. This domain is responsible for promoting the calcium-dependent interaction of these proteins with membrane surfaces, a characteristic essential for the function of these proteins.

The three-dimensional structure of the -carboxyglutamic acid-rich region in bovine prothrombin fragment 1 is disordered in the absence of Ca^{2+} .[33] In the presence of Ca^{2+} the Gla domain assumes a unique structure. [34] Of the ten -carboxyglutamic acid residues, four residues on one side and two residues on the other define a carboxylate surface that chelates five Ca^{2+} organized in a linear cluster that extend from one side of the molecule to the other (Fig. 102-4). The NH_2 -terminal alanine loops back to form an ion pair with Gla 17, Gla 21, and Gla 27. With the exception of Gla 6, all the -carboxyglutamic acid residues are critical for prothrombin function. [35] The mechanism by which this region promotes interaction of the protein with membrane surfaces involves the formation of this unique fold and the expression of a membrane-binding site. The Gla domains of factor VII and factor IX show marked three-dimensional structural homology in their calcium-stabilized conformer, compared to the Gla domain of prothrombin. [36] [37]

Epidermal Growth Factor Domain

The epidermal growth factor (EGF)-like domain is a common motif found in many proteins, including some of the proteins involved in blood coagulation. In the blood clotting proteins it is highly homologous with the EGF precursor. This domain, 4350 amino acid residues in length, contains three disulfide bonds arranged in a characteristic covalent structure. Although the EGF domain in some proteins mediates their interaction with an EGF or EGF-like receptor on cell surfaces, the EGF domains on the blood clotting proteins participate in protein complex formation. A calcium-binding site, present in some of the EGF domains of the vitamin K-dependent proteins, is defined by carboxylate groups on aspartic acid. [38] The structures of the EGF domains of factors IX and X, determined by nuclear magnetic resonance (NMR) spectroscopy, demonstrate marked homology with the three-dimensional structure of EGF. [39] [40] Factors IX, X, and VII contain two adjacent EGF domains (as does protein C, while protein S has four EGF domains). Factor XII contains two nonadjacent EGF domains, while tissue plasminogen

Figure 102-4 Three-dimensional structure of the -carboxyglutamic acid-rich region of prothrombin. This region is responsible for metal binding and membrane-protein interaction. *(Modified from Soriano-Garcia et al.,[34] with permission.)*

activator (t-PA) and prourokinase each have a single EGF domain.

Kringle Domain

Another common motif in proteins is the kringle domain. This region, with a characteristic covalent structure defined by a pattern of three disulfide bonds, is 100 amino acid residues in length. The three-dimensional structure of the prothrombin kringles reveals an oblate ellipsoid, with folding defined by close contacts between the sulfur atoms of two of the disulfide bridges. [33] Internal structures are well conserved among kringles from various proteins, but molecular surface differences relate to differences in function. The kringle domains play a role in protein complex formation. In prothrombin, the second kringle domain interacts with factor Va in the prothrombinase complex. [41] Among the proteins involved in hemostasis, kringles are found in prothrombin, [42] factor XII, [43] plasminogen, [44] prourokinase, [45] and t-PA. [46]

Catalytic Domain

A catalytic domain that is highly homologous with the structure of trypsin and chymotrypsin is common to all the blood clotting enzymes. This domain includes a site for the conversion of an inactive proenzyme to an active enzyme via cleavage of peptide bonds, a regulatory process known as zymogen activation by limited proteolysis. Furthermore, this domain contains the enzymatic machinery for cleavage of peptide bonds, the specific recognition site for protein substrates, and the site for interaction with specific protein inhibitors that regulate enzymatic activity. The blood clotting proteases are serine proteases, a class of enzymes with a common mechanism of enzymatic action that requires the catalytic triad of serine, aspartic acid, and histidine within the active site. The catalytic domain of the blood clotting proteases has an active site and an internal core nearly identical

---

to that of trypsin.[47] The molecular surfaces surrounding the enzyme active site are likely responsible for defining the extended substrate-binding site of the enzyme. Indeed, solution of the crystal structure of human -thrombin has emphasized the structural homology between thrombin and other well-characterized serine proteases while simultaneously providing details of the molecular structure not available from models derived indirectly from other homologous structures. [48] Two patches of positively charged amino acids close to the C-terminal B-chain helix form the presumed heparin-binding site and a secondary fibrinogen-binding site. [49] The interaction of the A and B chains is stabilized by charged residues. A deep canyon-like active site cleft probably contributes significantly to the narrow substrate specificity of thrombin.[48] [49]

Other Domains

Other motifs that appear within the proteins involved in hemostasis include the aromatic amino acid stack domain, the repeat regions observed in factor XI, and the fibronectin type I and type II domains. The functions of these domains are unknown.

Components of the Intrinsic and Extrinsic Pathways

Factor XII

The factor XII gene, located on chromosome 5, contains 14 exons and 13 introns (Fig. 102-5).[43] [50] Exon I encodes the signal peptide, exon II encodes a segment with no structural homology with other proteins, exons III and IV code for a region homologous with the type II fibronectin structure, exons V and VII each encode EGF domains, exon VI encodes a fibronectin finger domain that intervenes between the EGF domains, and exons VIII and IX each encode a kringle domain. The trypsin-like catalytic domain, including the activation region, is encoded by the remaining exons XXIV. The gene organization of the catalytic domains parallels that of urokinase, factor XI, and t-PA. The factor XII mRNA is 2.4 kb in length.[50] [51] The mature, plasma form of factor XII is composed of 596 amino acid residues in a single polypeptide chain.[43] [51]

Factor XII, also known as Hageman factor, is the first component of the intrinsic pathway. As such, it is a component of the contact phase of activation of blood coagulation observed in vitro. This protein does not appear to have a physiologic role in blood coagulation in vivo, because patients lacking this protein do not have a bleeding disorder. The protein circulates in the blood as a single-chain proenzyme of 80,000 molecular weight. [52] [53] Factor XII is a glycoprotein, with carbohydrate attached to Asn 230 and Asn 414. Other glycosylation sites include Thr 280, 286, 309, 310, and 318 and Ser 289. The surface-binding properties of factor XII, specifically the enhancement of the rate of factor XII activation by negatively charged surfaces, may be mediated by the positively charged amino acid sequence His-Lys-Tyr-Lys, a structure common to factor XII and kininogen.[54] The factor XII concentration in plasma is 30 g/ml. Factor XII has a plasma half-life of 2 days. [55]

Factor XI

The gene for factor XI, an intrinsic pathway component, contains 15 exons and 14 intervening sequences (Fig. 102-5). [56] Exon I encodes a 5 untranslated sequence, while exon 2 encodes a signal peptide. Four repeat sequences are each encoded by two exons: repeat 1 by exons III and IV, repeat 2 by exons V and VI, repeat 3 by exons VII and VIII, and repeat 4 by exons IX and X. The trypsin-like domain, responsible for the proteolytic function of the enzyme form of the zymogen, is encoded by exons XIIXV. Factor XI has a molecular weight of 160,000[57] and is composed of two identical chains bound together by disulfide bonds. [58] Factor XI circulates in the blood at a concentration of 5 g/ml. Its biologic half-life is 3 days. [59] [60]

Factor IX

Factor IX plays a critical role in blood coagulation (see Chap. 108). Its gene, adjacent to the factor VIII gene, is located on the X chromosome. Defects in this gene, both major and minor, are the cause of hemophilia B (see Chap. 108). This gene is 34 kb in length, contains eight exons, [61] and has a structure that is highly homologous with the structures of factors VII and X and protein C genes (Fig. 102-5). These genes are sufficiently similar to suggest that they were derived ancestrally from a common related gene. Factor IX is encoded on a 2.8-kb mRNA transcript. The factor IX gene is regulated by a liver-specific cis-activating element that binds to the liver-specific transcription factors CCAAT enhancer-binding protein (C/EBP) and NF-1; the NF-1 binding site is located at 99 to 76 upstream of the transcriptional start site.[62] The EBP-binding site is located close to the transcription initiation site. An androgen-responsive promoter element in the factor IX gene explains the curious phenotype of factor IX Leyden (see Chap. 108).[63]

Figure 102-5 Gene structures among the blood coagulation and regulatory serine proteases. Exons are shown schematically according to scale. Introns (thin lines) are not drawn to scale. *(Modified from Furie and Furie,[276] with permission.)*

The mature protein, with a molecular weight of 56,000, requires vitamin K for its synthesis and contains 12 -carboxyglutamic acid residues. The fully carboxylated form of the protein binds to calcium ions and to membrane surfaces in the presence of calcium ions. Factor IX contains metal-binding sites, defined by -carboxyglutamic acid,[64] and another class of metal-binding site that is a component of the EGF domain.[65] [66] The site within the EGF domain is defined in part by Asp 64, a residue that is partially -hydroxylated. Factor IX is a glycoprotein containing N- and O-linked sugars. A tetrasaccharide is O-linked to Ser 61 through a fucose. [67] Factors IX and IXa bind to phospholipid membranes composed of phosphatidylserine-phosphatidylcholine. [22] [68] This interaction requires both Ca^{2+} and fully carboxylated factor IX.[68] The x-ray structure of porcine factor IXa in the absence of calcium demonstrates the relationship of the two EGF domains and the serine protease domain; however, the Gla domain is partially disordered.[69] The NMR-derived structure of human factor IX Gla domain in the presence of calcium supports, as a first approximation, a model of the Gla domain based upon that of prothrombin. [37] [70]

The expression of phospholipid-binding properties involves two metal-dependent conformational transitions. [68] The calcium-stabilized conformer expresses a phospholipid-binding site that is located at the N-terminus of the protein.[71] An alternative hypothesis, also pointing toward the N-terminus, is also plausible and consistent with existing data.[72] Factors IX and IXa bind to activated platelets but not to resting platelets. [73] [74] However, it is not known whether a receptor is present on the platelet surface, nor is the role played by surface phospholipid known. Factor IXa, but not factor IX, binds to factor VIIIa on the surface of activated platelets. The factor VIIIa-binding site includes regions of the second EGF domain and the serine protease domain.[75] The endothelial cell-binding site of factor IX resides in the Gla domain.[76] Collagen on the surface of endothelial cells defines this factor IX-binding site. [77] [78] However, the biologic role of this site remains uncertain. The factor IX concentration in plasma is 5 g/ml. This protein has a plasma half-life of 24 hours.[79] As with other proteins of this molecular size, it partitions between the intravascular and extravascular space. A comprehensive review of the structure of the factor IX gene and the protein it encodes is presented in Chapter 108 .

Factor VIII

Factor VIII is a critical cofactor required for normal blood clotting (see Chap. 107). Defects in the factor VIII gene that lead to a deficiency in factor VIII are the cause

of hemophilia A. The factor VIII gene is 186 kb in length and is divided into 26 exons (see Fig. 107-1). [80] [81] As such, it is one of the largest genes known. Located on the X chromosome, it is near the locus of the factor IX gene. Factor VIII is synthesized as a single polypeptide chain, including a 19-residue signal peptide; in its mature form it contains 2,332 amino acid residues. [80] [81] Although this factor is synthesized by many cell types, the liver is a major site of synthesis. [82] A molecular weight of 330,000 has been estimated for the glycosylated protein. The protein sequence of factor VIII demonstrates marked sequence homology with factor V, another protein cofactor. [83] Factor VIII circulates in the blood as a heterodimer composed of two polypeptide chains derived from the original single chain. These two chains, including one of relative molecular weight (M_r) 80,000 and one of M_l varying between 90,000 and 200,000, are derived from the COOH-terminus and the NH_2-terminus of the single-chain precursor, respectively. Their interaction is Ca^{2+} dependent. A region of the C2 domain, from residues 2,303 to 2,324, assumes an amphipathic alpha helix that is responsible for the membrane-binding properties of factor VIII. [84] Presumably, six hydrophobic residues on one face of the helix contribute to membrane binding, while two arginines penetrate the hydrophobic plane to interact with phosphate moieties in the phospholipid bilayer. Although membranes including phosphatidyl-L-serine are required for factor VIII interaction, phosphatidylethanolamine enhances membrane binding. [85] [86] In its circulating form, factor VIII is inactive or minimally active as a cofactor in blood coagulation. It circulates in the blood at very low concentration (100 ng/ml) bound to von Willebrand factor (vWF). Its plasma half-life is 812 hours. [87] Factor VIII is converted into its active cofactor form by the proteolytic cleavage of two or more peptide bonds within the protein by thrombin. The structure and function of factor VIII are described in detail in Chapter 107 .

Factor X

The factor X gene, located on the long arm of chromosome 13 adjacent to the factor VII gene, is composed of eight exons and is 22 kb in length (Fig. 102-5).[88] The organization of this gene is identical to that of the factor IX gene. Exon I encodes the signal peptide, exon II the propeptide/-carboxyglutamic acid-rich domain, exon III the short aromatic amino acid stack domain, exons IV and V the two EGF domains, exon VI the activation region, and exons VII and VIII the catalytic domain. The 5 end of the factor X gene is linked to the 3 end of the factor VII gene. [89] A liver-specific promoter element, FXP1-binding site, was located 63 to 42 bp upstream of the factor X gene, while other promoter elements, FXP2 and FXP3, span 215 to 149 and 457 to 351, respectively. [89] After transcription, the factor X mRNA of about 1.5 kb includes a short 3 untranslated region following the stop codon. [90] [91] The polyadenylation signal is located within the 3 end of the coding sequence. Factor X, with a molecular weight of 56,000, is synthesized as a single polypeptide chain. [88] [91] However, factor X as isolated from plasma is composed of two polypeptide chains, a heavy chain with a molecular weight of 38,000 [92] [93] [94] and a light chain with a molecular weight of 18,000. [95] [96] These chains are linked by a single disulfide bond. The Arg-Lys-Arg sequence at residues 139141 in the single polypeptide chain appears very susceptible to intracellular or extracellular proteolysis, yielding the predominant two-chain form. [88] [91] The light chain of factor X includes 11 -carboxyglutamic acid residues at positions 6, 7, 14, 16, 19, 20, 25, 26, 29, 32, and 39 in the human protein. [97] A single -hydroxyaspartic acid residue is located in the first EGF domain at residue 63. Bovine factor X contains both asparagine-linked carbohydrate at Asn 36 and threonine-linked carbohydrate at Thr 300. [98] Like prothrombin, the asparagine-linked sugars contain NeuAc2 3Gal1 3(NeuAc2 6)GlcNAc in the outer chain. The two EGF domains are important for binding to the cofactor, factor Va. The second EGF domain can support factor Va binding but at reduced affinity, [75] suggesting a role for the first EGF domain in this interaction as well. [99]

Factor X is a calcium-binding protein that interacts with membrane surfaces in the presence of calcium. It contains both low- and high-affinity metal-binding sites, [100] occupancy of which leads to conformational changes and the expression of membrane-binding properties. [101] Like the other vitamin K-dependent proteins, factor X binds preferentially to acidic phospholipid surfaces. [102] [103] [104] Bound factor X is an extrinsic membrane protein in that no component of it is embedded within the membrane. The three-dimensional structure of bovine factor X has been determined by x-ray crystallography and demonstrates marked structural homology with trypsin and the other serine proteases involved in blood coagulation. [105] [106] The Gla domain linked to the first EGF domain shows little interaction between the two domains, but the orientation of these domains is altered by the presence of calcium ions. [107] As is the case for factor IX, [108] the N-terminus of the Gla domain of factor X shows little stable structure in the absence of Ca^{2+} . [109]

The plasma concentration of factor X is maintained at 10 g/ml. Its half-life in plasma is 36 hours. [79]

Factor VII

The factor VII gene is 13 kb in length [110] and is located on the long arm of chromosome 13, immediately adjacent to the factor X gene. [111] The coding region is found on nine separate exons (Fig. 102-5). Preprofactor VII is synthesized via two alternative forms. In one form, incorporating exon IB encoding for the signal peptide, factor VII arises from a gene whose gene organization is identical to that of the factor IX gene. In a second form, exon IA directs the coding of the signal peptide instead of exon IB. In this form, preprofactor VII has a polypeptide extension of the NH_2-terminus that elongates the signal peptide/propeptide from 38 to 60 residues. Exon II encodes the propeptide and -carboxyglutamic acid-rich domain, and exon III encodes the short aromatic amino acid stack domain, a segment common to all the vitamin K-dependent proteins. Exons IV and V each encode one of the EGF domains. The catalytic domain is coded by exons VIVIII, with the activation peptide encoded within exon VI. The mRNA for factor VII is about 2.4 kb in length, [112] with a 3 untranslated region of 1.0 kb length and a poly(A) tail located after the stop codon.

Factor VII is a component of the extrinsic pathway of blood coagulation and forms a complex with tissue factor to generate an enzyme complex that activates factor X. Human factor VII, with a molecular weight of 50,000, circulates in plasma as a single-chain zymogen containing 406 amino acid residues. [112] The NH_2-terminal domain includes 11 -carboxyglutamic acid residues at positions 6, 7, 14, 16, 19, 20, 25, 26, 29, 34, and 35 in bovine factor VII. [113] Asp 63 is partially -hydroxylated. Factor VII is a glycoprotein, containing 13% carbohydrate. The structure of the complex of the active site-inhibited factor VIIa and extracellular domain of tissue factor has been determined by x-ray crystallography. [36] Salient general features of this complex include the extensive embracing of extended conformations of one protein by the other. This interaction involves multiple domains and multiple contact sites within each domain. The structure of the calcium-stabilized Gla domain is homologous to that of prothrombin and factor IX.

In contrast to other proenzymes involved in blood coagulation, factor VII circulates in the blood in two forms: the inactive zymogen factor VII and the enzymatic active factor VIIa. [3] Factor VII may be a true zymogen, with no enzymatic activity prior to cleavage. [114] The concentration of factor VIIa is low but sufficient to generate significant factor X-activating activity when the factor VIIa forms a complex with newly exposed tissue factor. The factor Xa formed can activate factor VII to factor VIIa, increasing the amount of factor VIIa available during tissue injury. This model would allow significant amplication of thrombin formation via the extrinsic pathway.

Factor V

Factor V is a plasma glycoprotein with a molecular weight of 330,000. This protein is a critical cofactor that in its activated form facilitates activation of prothrombin by factor Xa. Factor V is a single-chain protein that circulates in the blood in a precursor, inactive cofactor form. The factor V gene, located on chromosome 1 at 1q2125, encodes a 7-kb mRNA, which itself encodes a pre-factor V including a 28-amino acid residue signal peptide and a mature protein composed of 2,196 amino acid residues. [115] [116] The gene contains 25 exons that range in size from 72 to 2,820 bp [117] and resembles the factor VIII gene in organization. The heavy chain region is composed of two domains with notable structural homology, termed the A domain. The light chain region is composed of another A domain and of two homologous C domains. The heavy chain region and light chain region are joined by a connecting region known as the B domain. The A1-A2-B-A3-C1-C2 domain structure is also present in factor VIII. [80] Proteolytic activation of factor V by thrombin leads to the cleavage of three peptide bonds, but a single site adjacent to Arg 1,545 in human factor V is critical for the generation of biologically active factor Va. [118]

Although the liver appears to be the primary site of synthesis of factor V, megakaryocytes also synthesize this protein. In addition to its presence in plasma, factor V is a component of the -granules in megakaryocytes and subsequently in platelets [119] and is secreted on platelet stimulation with specific agonists. Factors V and Va bind to two classes of binding sites on the surface of platelets. [120] However, the higher-affinity binding sites interact specifically with factor Va, and not with factor V. The plasma concentration of factor V is 10 g/ml, and its plasma half-life is 12 hours. [121]

Prothrombin

The prothrombin gene, located on chromosome 11, [122] is 21 kb in length and is composed of 14 exons, each encoding all or part of a functional domain of prothrombin (Fig. 102-5): [123] signal peptide (exon I), propeptide/-carboxyglutamic acid-rich domain (exon II), aromatic amino acid stack domain (exon III), two kringle domains (exons IVVII), the activation region (exons VIII and IX), and the catalytic domain (exons XXIV). The introns vary considerably in size, from 84 bp for the intron between exons VIII and IX to 9,447 bp for that between exons XII and XIII. Although the structure of prothrombin is homologous with those of factors IX, X, and VII and protein C, the prothrombin gene demonstrates only partial homology with the genes of these proteins. Exons IIII are shared by all these proteins, but prothrombin contains

exons IVVII encoding the kringle domains and has a homologous serine protease domain composed of seven exons, in contrast to the two exons found in the factor IX gene family. The prothrombin mRNA is 2.1 kb in length and includes a 5 untranslated region of >150 bp, a 1.8-kb open reading frame, and a 97-bp 3 untranslated region. The prothrombin gene contains a weak promoter before the transcription initiation site and liver-specific enhancer element spanning about 900 bases upstream from the transcription initiation site. This site interacts with hepatic nuclear factor-1 (HNF-1). [124] [125]

Prothrombin is a plasma glycoprotein with a molecular weight of 72,000. [42] [126] [127] On the basis of direct protein sequence analysis and the predicted sequence based on the nucleotide sequence of the cDNA, the complete amino acid sequence of the human protein is known. [123] [126] [127] As with all the blood clotting proteins, prothrombin is synthesized with a hydrophobic signal peptide from residues 43 to 19. After translocation to the rough endoplasmic reticulum, the signal peptide is removed by a signal peptidase. The propeptide, containing the -carboxylation recognition site, [31] includes residues 18 to 1. During protein synthesis, but after -carboxylation, this peptide is removed by an intracellular propeptidase. The mature prothrombin that circulates in the plasma is composed of 579 amino acid residues arranged in a single polypeptide chain. The ten -carboxyglutamic acid residues are located in the Gla domain of human prothrombin at residues 6, 7, 14, 16, 19, 20, 25, 26, 29, and 32. Carbohydrate represents about 10% of the mass of prothrombin. *N*-Asparagine-linked carbohydrate is attached to Asn 78, Asn 100, and Asn 373 in bovine prothrombin, [128] and human prothrombin likely contains carbohydrate at the homologous amino acids. Complex asparagine-linked oligosaccharides include $NeuAc_2$ 3Gal1 3(NeuAc2 6)GlcNAc. The short aromatic amino acid stack domain has significant -helical structure and serves to link the Gla domain to two kringle domains, [33] which are similar to structures found in factor XII, plasminogen, and t-PA and are defined structurally by the pattern of disulfide bonds. The function of these domains is uncertain, but they may be important for protein complex formation with factor Va. The remainder of prothrombin, accounting for approximately one-half the protein structure, represents the

catalytic domain. This region includes the activation domain that is critical for the conversion of zymogen into the active enzyme and the trypsin-like region that possesses the protease activity. Prothrombin has no coagulant activity in its zymogen form and must be converted to thrombin in order to participate in blood coagulation.

The metal-binding properties of prothrombin are conferred by -carboxyglutamic acid residues. [129] Abnormal (des--carboxy) prothrombin, lacking -carboxyglutamic acid, does not bind to Ca^{2+} and does not interact with membrane surfaces in the presence of calcium. [129] [130] Prothrombin binds Ca^{2+} and other metal ions via two classes of metal-binding sites [131] [132] [133] [134] and, on metal binding, undergoes conformational changes leading to expression of membrane-binding properties. [135] [136] [137] Concomitantly, neoantigens are exposed on the metal-stabilized conformers of prothrombin. [138] [139] [140] [141] Prothrombin is an extrinsic membrane-binding protein. In the presence of calcium ions, a surface of the prothrombin/metal complex interacts with phospholipid vesicles; a marked preference for acidic phospholipids, specifically phosphatidylserine, has been demonstrated. The N-terminal third of the protein contains the lipid-binding domain.

The plasma concentration of prothrombin is 100 g/ml, [142] [143] and the plasma half-life of prothrombin is 3 days. [79] [144]

Fibrinogen

Fibrinogen is the most abundant plasma protein involved in blood coagulation. At a plasma concentration of 23 mg/ml, it represents 2% of the total plasma proteins. In addition, platelets contain fibrinogen within their -granules, but they do not synthesize the protein. [145] [146] Variant forms likely arise via post-translational modifications or protein degradation. Fibrinogen, unique among the blood clotting proteins, is encoded by three separate genes, each of which encodes one of the three subunits. These three genes, located on chromosome 4, are clustered on a 50-kb region. [147] The fibrinogen genes are organized with the -chain gene 10 kb upstream of the -chain gene, which in turn is 13 kb upstream of the -chain gene. The -, -, and -chain genes contain nine, five, and eight exons, respectively. The regulation of these genes is coordinated at the transcriptional level by the synchronous production of three separate mRNA species. [148]

Fibrinogen is a structural protein that circulates in the plasma in a functionally inert precursor form. Its conversion to fibrin leads to polymerization of fibrin and to formation of a fibrin clot. Human fibrinogen, with a molecular weight of about 340,000, is composed of three pairs of polypeptide chains: two A-chains, two B-chains, and two -chains. [149] The -, -, and -chains demonstrate significant structural homology within their amino acid sequence, suggesting their evolutionary origin from a common ancestral gene. [150] [151] [152] The A-chain has a molecular weight of 63,500 and contains 610 amino acid residues, the B-chain has a molecular weight of 56,000 and contains 461 amino acid residues, and the -chain has a molecular weight of 47,000 and contains 411 amino acid residues. The A-, B-, and -chains are covalently linked through disulfide bonds. The disulfide bonds near the N-terminal regions of these polypeptide chains link the three chains to each other, as well as linking the two A-chains together and the two -chains together. This region is known as the disulfide knot. Electron micrographs of fibrinogen show a trinodular molecule. [153] X-ray crystal structures of fibrinogen domains have begun to provide insight into the mechanism by which fibrin self-assembles. Crystal structures of fragment D consist of a coiled-coil region and two homologous globular regions. [154] The crystal structure of the C-terminal fragment of the -chain reveals a mechanism for electrostatic steering that guides the alignment of the fibrin monomers during polymerization. [155] The plasma half-life of fibrinogen is 35 days. [156] [157]

Factor XIII

Factor XIII is a zymogen of a cysteine transglutaminase that circulates in the blood. It is composed of two peptide subunits, the -chain (M_r 75,000) and the -chain (M_r 80,000). [158] Factor XIII, with a molecular weight of 320,000, is a tetrameric structure with two -chains and two -chains held together non-covalently. After binding to Ca^{2+}, [159] factor XIII ($_2$ $_2$) is activated to its enzyme form, factor XIIIa ($_2$ $_2$), by thrombin through cleavage of the bond between Arg 37 and Gly 38 in the -chain, thus releasing an activation peptide with a molecular weight of 4,500. Factor XIIIa contains a free sulfhydryl group at the active site on the -chain and functions as a transamidase in cross-linking glutamic acids and lysine residues. The concentration of factor XIII in plasma is 60 g/ml. Platelet factor XIII is composed of only -chains in the form of a dimer, $_2$. Enzymatically, the platelet and plasma form of factor XIIIa are equivalent.

Tissue Factor

Tissue factor is an integral membrane protein with a molecular weight of 45,000 that is located on the plasma membrane of most vascular cells. [160] [161] This protein, a receptor for factor VII, is required for the initiation of blood coagulation through the extrinsic pathway. Factor VII binding to tissue factor is calcium dependent. Tissue factor is a transmembrane protein composed of 263 amino acid residues. [18] [19] Its three-dimensional structure is known. [36] A short hydrophobic domain of 23 amino acids likely represents the membrane-spanning region (Fig. 102-6). The N-terminal domain of 219 amino acid residues is a dominant component of the protein and is oriented extracellularly. A short, 21-residue C-terminal cytoplasmic domain contains palmitate and stearate bound through a thioester bond to a cysteine residue. [162] Although specific glycosylation sites have not been established, tissue factor has multiple potential N- and O-linked sites. Tissue factor is expressed constitutively in most nonvascular cells; in monocytes and endothelial cells, its expression is associated with cell stimulation. [163] [164] [165] The tissue factor gene is 12.4 kb in length and is composed of six exons. [166]

von Willebrand Factor

A multimeric glycoprotein, vWF is present in the plasma and within the -granules of platelets and the Weibel-Palade bodies of endothelial cells (see Chap. 113). The gene for vWF is located on chromosome 12 and is 176 kb in length. [167] The gene includes 52 exons that encode a signal peptide, a large propolypeptide (M_r 80,000), and the mature vWF monomer (M_r 225,000). [168] A 9-kb mRNA encodes a precursor form of the protein, synthesized as a single polypeptide chain containing 2,813 amino acid residues. [168] [169] [170] [171] Pro-vWF undergoes post-translational modification involving initial formation of dimers, which then undergo multimerization via a process that is dependent on the presence of the intact propeptide. [172] [173] The high-molecular-weight vWF multimers vary in size up to about 10 million, the largest forms displaying the most potent biologic activity.

Two critical biologic roles are fulfilled by vWF. First, it can mediate the adhesion of platelets to the injured vascular wall. Adhesion occurs through simultaneous binding of vWf to its receptor, glycoprotein Ib, on platelet surfaces and to collagen in the subendothelium. In addition to being constitutively secreted from endothelial cells, vWF is stored in the Weibel-Palade bodies of endothelial cells and released on stimulation of granule release. [174] As a plasma carrier protein, vWF binds noncovalently to and stabilizes factor VIII and circulates in the blood as a factor VIII/vWF complex. Factor VIII binds stoichiometrically to the vWF subunit. [175] Under physiologic conditions, however, most of the factor VIII-binding sites on mature vWf are unoccupied.

Figure 102-6 Structure of tissue factor. The extracellular domain extends from residues 1 to 229. This region contains three potential glycosylation sites (CHO). A short transmembrane domain is rich in hydrophobic amino acids. The cytoplasmic domain, extending from residues 243 to 263, contains a free sulfhydryl (SH) group, which undergoes esterification to palmitate or stearate.

SYNTHESIS OF THE BLOOD COAGULATION PROTEINS

Biosynthesis of the Vitamin K-Dependent Blood Clotting Proteins

Six of the plasma proteins involved in blood coagulation or the regulation of blood coagulationprothrombin, factors IX, X, and VII, protein C, and protein Srequire vitamin K for their synthesis. These proteins contain between 10 and 12 residues of -carboxyglutamic acid [176] [177] within the first 45 residues of their NH_2 -termini (Fig. 102-7). They represent a unique class of calcium-binding proteins that assemble on membrane surfaces in the presence of Ca^{2+} . These proteins are synthesized in a precursor form, which includes a typical signal peptide and a propeptide that intervenes between the signal sequence and the mature NH_2 -terminus of the protein. Following translocation through the rough endoplasmic reticulum, specific glutamic acid residues in the prozymogen are selectively -carboxylated.

Vitamin K-dependent carboxylation is catalyzed by a membrane-bound -carboxylase located in the endoplasmic reticulum. In the presence of reduced vitamin K, molecular oxygen, carbon dioxide, and the protein precursor substrate, specific glutamic acids adjacent to the -carboxylation recognition site on the propeptide are converted to the corresponding -carboxyglutamic acids. A synthetic peptide whose sequence was based on the -carboxylation recognition site within the propeptide of prothrombin binds to the carboxylase, offering a strategy for purification of the carboxylase by affinity chromatography. [178] A highly purified carboxylase was obtained by this strategy using the propeptide of factor IX. [179] These enzyme preparations catalyze both the formation of -carboxyglutamic acid from glutamic acid and vitamin K epoxide from vitamin K, which indicates the coupling of these two processes (see Chap. 115).[180] The vitamin K-dependent carboxylase is a single-chain protein with a molecular weight of 94,000 that is composed of a single polypeptide chain of 758 amino acids. [179] [180] [181] [182] The carboxylase can be expressed in insect cells otherwise lacking carboxylase activity. [183]

The propeptide within the vitamin K-dependent proteins directs -carboxylation. This region demonstrates sequence homology among proteins that contain -carboxyglutamic acid (Fig. 102-8), [184] [185] an observation that has suggested a role for the propeptide in carboxylation. Site-specific mutagenesis has shown that factor IX species lacking the 18-residue propeptide or containing point mutations at conserved residues, 16 or 10, within the propeptide eliminate -carboxylation. [31] Analogous studies of prothrombin have demonstrated the importance of amino acids at residues 18, 17, 15, and 10 in the propeptide of prothrombin. Deletion mutants of proprotein C lacking residues in the 17 to 12 portion of the propeptide were

Figure 102-7 -Carboxyglutamic acid-rich domains of the vitamin K-dependent proteins. A one-letter amino acid code is employed (denotes -carboxyglutamic acid). Sequences have been aligned to maximize sequence homology.

Figure 102-8 Sequence comparison of the propeptide domains of the vitamin K-dependent blood coagulation proteins. Homologous regions of other vitamin K-dependent proteins are aligned. Residues that demonstrate significant sequence homology are boxed and shaded; regions with conservative amino acid substitutions are boxed. *(Modified from Furie and Furie,[276] with permission.)*

also associated with impaired -carboxylation. [186] These results demonstrate that the propeptide contains a recognition element, termed the -carboxylation recognition site, which designates the vitamin K-dependent proteins for -carboxylation. This propeptide is required for carboxylation. Furthermore, expression of a cDNA construct in which the propeptide is adjacent to a glutamic acid-rich region of thrombin leads to carboxylation of these glutamic acid residues. [32] Thus, the propeptide is sufficient to support carboxylation, and no other components within the substrate are required, except to improve efficiency of carboxylation.

Peptides containing a complete propeptide sequence and carboxylatable glutamic acid residues are efficiently carboxylated, with a K_m of about 3 M. [187] [188] By contrast, peptides without the -carboxylation recognition site or with a truncated site are poor substrates for the carboxylase. Glutamic acid, but not aspartic acid, is a substrate for the carboxylase. Based on the predicted structure of the propeptide of factor X, an 18-residue peptide stimulates the carboxylation of the pentapeptide FLEEL (Phe-Leu-Glu-Glu-Leu) by the partially purified carboxylase by about eightfold. [189]

The propeptide of prothrombin contains the carboxylation recognition site on its N-terminus and the propeptide cleavage site at the C-terminus. This peptide incorporates a ten-residue amphipathic -helix, from residues 3 to 13. [190] This helix serves as a rigid extension to expose the carboxylation recognition site (Fig. 102-9). In contrast to factor IX, profactor IX cannot be activated to its enzymatically active form and does not bind to acidic membranes even though it is fully carboxylated.[191] The propeptide plays three roles in the synthesis of the vitamin K-dependent proteins: (1) via the -carboxylation recognition site, the propeptide signals for carboxylation of adjacent glutamic acid residues; (2) the propeptide inhibits premature zymogen activation and membrane binding during intracellular processing; and (3) the propeptide activates the vitamin K epoxidase activity of the carboxylase. [192]

The propeptide contains a sequence adjacent to the sessile bond that is characteristic of many proproteins and prohormones: Arg-X-Arg/Lys-Arg at residues 4 to 1, where propeptide cleavage occurs between 1 and +1. The propeptidase enzyme responsible for cleavage is probably PACE/furin, [193] a constitutively expressed protease located in the trans-Golgi region that cleaves substrates with adjacent basic amino acid residues. Site-specific mutagenesis of profactor IX has emphasized the importance of Arg 1, the lack of importance of the side chain of residue 3, and the effect of mutation of residue 2 on the efficiency of cleavage. [194]

During synthesis of the vitamin K-dependent proteins, the signal peptide contains a recognition element that directs the partially synthesized protein to the endoplasmic reticulum (Fig. 102-10). With cleavage of the signal peptide, the carboxylation recognition site on the propeptide is expressed. The vitamin K-dependent carboxylase is anchored to this region and modifies all the glutamic acids within a given proximity to the recognition site. After carboxylation, the protein is transported to the Golgi apparatus, where the propeptide undergoes cleavage. Final processing of the protein is completed in the Golgi compartment.

Post-translational -Hydroxylation

An unusual amino acid, *erythro*--hydroxyaspartic acid, is located in the NH_2 -terminal EGF domains of protein C[195] and factors IX, X, and VII. In addition, *erythro*--hydroxyasparagine has

Figure 102-9 Vitamin K-dependent carboxylase. The precursors of the vitamin K-dependent blood clotting proteins, which contain the -carboxylation recognition site (-CRS) within the propeptide, bind to carboxylase through this recognition site. Glutamic acids are converted to -carboxyglutamic acids by carboxylase in the presence of vitamin K, oxygen, and carbon dioxide. *(Modified from Furie and Furie,[276] with permission.)*

Figure 102-10 Biosynthesis of the vitamin K-dependent blood coagulation proteins. Signal recognition particle binds to the signal peptide, thus directing this complex to the endoplasmic reticulum. Signal peptide directs translocation to the luminal aspect of the endoplasmic reticulum. After signal peptide cleavage by signal peptidase, propeptide is expressed. This region, containing the -carboxylation recognition site, binds to the vitamin K-dependent carboxylase. Specific glutamic acids are converted to -carboxyglutamic acids by this enzyme. Propeptide is removed in the trans-Golgi region. *(Modified from Furie and Furie,[276] with permission.)*

been identified in protein S.[196] These amino acids are formed by post-translational hydroxylation of aspartic acid and asparagine. Their function remains unknown, although it has been suggested that they are involved in defining the metal-binding properties of these proteins.

Unlike post-translational -carboxylation, -hydroxylation of factor IX is not directed by the propeptide, nor does this process require vitamin K or concomitant -carboxylation. -Hydroxylation occurs in domains homologous to the EGF precursor in certain vitamin K-dependent proteins,[196] as well as in proteins outside this family, including the complement proteins Clr and Cls, thrombomodulin, uromodulin, and the low-density lipoprotein receptor.[196] [197] [198] A consensus sequence encompassing the -hydroxylated aspartic acid and asparagine residues within a number of EGF domains has been noted by Stenflo et al:[196]

EGF domains that lack the consensus sequence do not contain this post-translational modification. The hydroxylation is catalyzed by aspartyl -hydroxylase, an enzyme that requires 2-ketoglutarate and Fe^{2+}.[199] This reaction is blocked by agents that inhibit 2-ketoglutarate-dependent dioxygenases.[200]

von Willebrand Factor Multimerization

vWF is synthesized as a single polypeptide chain containing a signal peptide, a large propolypeptide (M_r 80,000) and the mature vWF (M_r 225,000). During synthesis, the mature vWF forms a dimer, which multimerizes to the high-molecular-weight, biologically active forms critical for cellular adhesion. Synthesis of vWF takes place in endothelial cells and megakaryocytes. In endothelial cells vWF is secreted via a constitutive pathway involving mainly dimeric forms. In addition, the regulated pathway involves storage of vWF in Weibel-Palade bodies, within which vWF undergoes multimerization and subsequently cleavage of the propolypeptide. Endothelial cells degranulate under specific stimuli, leading to the secretion of vWF. The propolypeptide is required for multimerization[172] [173] and is further required for directing vWF to the Weibel-Palade bodies.[201]

ACTIVATION OF BLOOD COAGULATION

Mechanism of Extrinsic Activation

Activation of blood clotting through the extrinsic pathway likely plays a dominant physiologic role in hemostasis. Tissue factor, a cellular receptor for factors VII and VIIa, is present on most cell surfaces. The expression of tissue factor activity is constitutive on most nonvascular cells and is inducible via de novo synthesis in cells within the blood or on the blood vessel wall, including monocytes and endothelial cells. On tissue injury and laceration of blood vessels, nonvascular cells become exposed to blood, leading immediately to the formation of a complex of tissue factor on the cell surface with factor VIIa from the blood. The formation of this complex initiates the tissue factor pathway, culminating in the generation of thrombin and in the formation of a fibrin clot:

Through its extracellular domain, tissue factor forms a catalytic complex with factor VIIa in the presence of Ca^{2+} .[20] [161] Low amounts (10100 pM) of factor VIIa are present in normal plasma.[3] With tissue factor as a cofactor, factor VIIa can autocatalyze

Figure 102-11 Factor VII activation. The zymogen, factor VII, is composed of a single polypeptide chain. Activation of factor VII to factor VIIa involves cleavage of the bond between Arg 152 and Ile 153 by factor Xa or factor VIIa. Light (L) chain and heavy (H) chains are linked by a disulfide bond.

the activation of factor VII to factor VIIa.[202] [203] Deletion of the membrane-anchoring region of tissue factor abolishes autoactivation of factor VII but not cofactor function in the activation of factor X or factor IX. [204] The tissue factor/factor VIIa complex acts on factor IX and on factor X, leading to the generation of factor IXa and factor Xa, respectively. Factor Xa is able to feed back to convert more factor VII to factor VIIa, thereby amplifying the initiation of clotting. [4] Activation of factor VII involves cleavage of the Arg 152-Ile 153 bond, leading to a form of factor VIIa composed of a light chain (M_r 20,000) and a heavy chain (M_r 30,000) linked by a disulfide bond (Fig. 102-11).[205] [206] [207] This reaction is greatly enhanced by the presence of tissue factor and phospholipid vesicles. [11] [208] [209] Activation of factor VII is associated with the expression of the catalytic triad within the heavy chain, His 41, Ser 192, and Asn 90, common to the active site of all serine proteases. Although the potential for factor Xa-mediated and factor VIIa-mediated amplification of this pathway is apparent, the nature of the protease that generates constitutive factor VIIa in plasma is unknown.

Activation of Factor IX

The activation of factor IX proceeds either via the tissue factor pathway or through the intrinsic pathway with factor XIa:

Factor IX can be activated through the extrinsic pathway. [210] The factor VIIa/tissue factor complex activates both factor IX and factor X in reactions that require Ca^{2+} . Although the kinetics of factor IX activation by factor XIa and by factor VIIa/tissue factor differ, both enzymes cleave the same peptide bonds and generate the same structural form of factor IXa.

The activation of factor IX by factor XIa, in contrast to the activation of the other vitamin K-dependent blood clotting proteins or the activation of factor IX by factor VIIa tissue factor (which occur on membrane surfaces), takes place in the solution phase. Membrane surfaces, including those of artificial phospholipid

Figure 102-12 Factor IX activation. The zymogen, factor IX, is composed of a single polypeptide chain. Activation of factor IX to factor IXa involves cleavage of two peptide bonds. Factor IXa contains a light (L) chain and a heavy (H) chain linked by a disulfide bond. An activation peptide (AP) is released during the activation process.

vesicles or platelets, do not accelerate the generation of factor IXa. The reaction has an absolute requirement for Ca^{2+} .[211] Factor IX is activated by the cleavage of two internal peptide bonds, the Arg 145-Ala 146 bond and the Arg 180-Val 181 bond (Fig. 102-12).[212] [213] A factor IXa light chain (M_r 18,000), from residues 1145, and a factor IXa heavy chain (M_r 27,000), from residues 181416, are generated by the proteolytic activation. These chains remain covalently attached through a single disulfide bond. An activation peptide, from residues 146180, is cleaved from factor IX during activation.

Like factor IX, factor IXa binds to phospholipid vesicles in the presence of calcium ions and binds to calcium and other metal ions. Activation of factor IX to factor IXa leads to the expression of a factor VIII-binding site and active enzyme site with full coagulant activity. Cleavage of Arg 180-Val 181 is required for at least partial expression of the factor VIII-binding site; the cleavage of Arg 145-Ala 146 in addition to Arg 180-Val 181 leads to full enzymatic and cofactor binding activity.

Activation of Factor X

Factor X, at the confluence of the intrinsic pathway and the extrinsic pathway, may be activated by the factor IXa/factor VIIIa complex (tenase complex) or by the factor VIIa/tissue factor complex.

The tenase complex, composed of factor IXa and factor VIIIa, requires factor VIII in its active cofactor form, factor VIIIa. Factor VIII expresses either no or minimal cofactor activity but is converted to factor VIIIa by the cleavage of two or possibly three peptide bonds (Fig. 102-13).[214] Factor VIII, a heterodimer composed of a heavy chain that varies in molecular weight from 90,000 to 200,000 and a light chain with a molecular weight of 76,000, is a substrate for thrombin, an enzyme that cleaves at least four peptide bonds within factor VIII. The cleavage of peptide bonds at Arg 372373 and at Arg 1,6861,689 is required

Figure 102-13 Activation of factor VIII, an inactive cofactor composed of a single polypeptide chain. Factor VIII is converted to its active cofactor form, factor VIIIa, by the cleavage of two, and possibly three, peptide bonds to generate a heavy chain and a light chain noncovalently linked in the presence of Ca^{2+} .

Figure 102-14 Factor X activation. Factor X is composed of two chains, a heavy (H) chain and a light (L) chain, linked by a disulfide bond. Activation of factor X to factor Xa requires cleavage of a single peptide bond on the heavy chain. AP, activation peptide.

for factor VIII activation.[214] The resulting factor VIIIa contains polypeptide chains of 50,000 molecular weight (derived from the heavy chain), of 43,000 molecular weight, and 73,000 molecular weight (derived from the light chain) (see Chap. 105). [215] Factors VIII and VIIIa bind tightly to phospholipid vesicles and to activated platelets.[25] [216]

Factor IXa binds to factor VIIIa that is bound to phospholipid membranes and activated platelets. The formation of this enzyme complex is required for activation of factor X on a physiologically relevant time scale. [217] Alternatively, factor VIIa in complex with tissue factor on cell surfaces can activate factor X on a physiologically relevant time scale. The formation of this complex requires Ca^{2+} .

Factor X, a zymogen with no coagulant activity, is converted to its active enzyme form, factor Xa, by cleavage of a single polypeptide bond between Arg 51 and Ile 52 in the heavy chain (Fig. 102-14). This cleavage is catalyzed either by the complex of factor IXa and factor VIIIa on membrane surfaces in the presence of Ca^{2+} or by the complex of factor VIIa and tissue factor on membrane surfaces in the presence of Ca^{2+} .[218] [219] An activator without physiologic relevance, the coagulant protein of Russells viper venom is often used for clinical laboratory measurements in a test known as the Stypven or RVV time. [220] The activation peptide remains associated with factor Xa[221] but, with the exception of the C-terminal amino acids, does not contribute to the initial formation of a complex with tenase. [222] Although zymogen activation results in a major functional change in the protein, only subtle structural changes in factor X are associated with the development of enzymatic activity. [223] The expression of enzymatic activity involves the catalytic triad common to all serine proteasesHis 93, Asp 138, and Ser 233in the heavy chain of bovine factor X.

Factor Xa is inhibited by specific plasma protease inhibitors, including antithrombin III and $_2$ -macroglobulin.[224] These inhibitors are probably scavengers in that they neutralize the potent coagulant activity of any factor Xa that flows past the site of tissue injury.

The tissue factor pathway is regulated by a protease inhibitor, tissue factor pathway inhibitor (TFPI). [225] [226] [227] [228] The gene for this protein is located on chromosome 2 and includes 9 exons.[229] [230] This inhibitor, with a molecular weight of 34,000, contains three tandem Kunitz-type protease inhibitor domains. [231] TFPI binds factor Xa directly and inhibits factor VIIa-tissue factor activity in a reaction that appears to involve the formation of a factor Xa/TFPI/factor VIIa/tissue factor complex. [232] The generation of this complex down-regulates the activity of the tissue factor pathway.

Generation of Thrombin: Assembly of the Prothrombinase Complex

The conversion of prothrombin to thrombin is mediated by the enzyme action of factor Xa and the cofactor factor Va in a complex formed on membrane surfaces. The factor Xa/factor Va complex that is formed on membranes in the presence of Ca^{2+} is known as the prothrombinase complex, since it serves to act on prothrombin as substrate (Fig. 102-15).

The factor Xa/factor Va/membrane complex has many structural and functional parallels with the factor IXa/factor VIIIa/

Figure 102-15 Model for the macromolecular complex associated with zymogen activation. A central feature of the proteins involved in blood coagulation is their assembly on membrane surfaces. Interaction of Ca^{2+} with the -carboxyglutamic acids on vitamin K-dependent proteins leads to the exposure of a membrane-binding site on these proteins. Assembly of these proteins on membranes in a geometry defined by the protein cofactor facilitates enzyme-substrate interaction. The protein cofactor likely plays an important regulatory role in this complex. Factor Xa, enzyme (L, light chain; H, heavy chain); prothrombin (PT), substrate; factor Va, cofactor; , Ca^{2+} ; , -carboxyglutamic acid; lipid-binding sites in black. *(Modified from Furie and Furie,[276] with permission.)*

Figure 102-16 Activation of factor V, an inactive cofactor composed of a single polypeptide chain. Factor V is converted to its active cofactor form, factor Va, by the cleavage of two or possibly three peptide bonds to generate a heavy chain and a light chain noncovalently linked in the presence of calcium ions.

membrane complex. Factors V and Va are extrinsic membrane-binding proteins. The interaction of these factor V forms with membranes is independent of Ca^{2+} or other metal ions. Factor V binds with high affinity to phospholipid vesicles rich in phosphatidylserine, [233] [234] [235] [236] to activated platelets,[120] [237] and to microparticles derived from activated platelets.[238] [239]

Factor V circulates in the blood as an inactive cofactor or as a cofactor with low intrinsic activity. It is converted to its active cofactor form, factor Va, by the hydrolysis of three peptide bonds, Arg 709-Ser 710, Arg 1,018-Thr 1,019, and Arg 1,545-Ser 1,546, by thrombin or factor Xa (Fig. 102-16).[240] [241] [242] [243] These cleavages generate a heavy chain (M_r 110,000) and a light chain (M_r 78,000) that are linked noncovalently in the presence of Ca^{2+} .

In the presence of Ca^{2+} , a complex of factors Xa and Va forms on phospholipid vesicles. The formation of the prothrombinase complex involves three steps: (1) the binding of factor Va to membrane surfaces, (2) the binding of factor Xa to membrane surfaces, and (3) the interaction of membrane-bound factors Va and Xa. [244] Although factor Xa can activate prothrombin directly in the absence of Ca^{2+} , factor Va, and membrane surfaces, the rate of activation is very slow and irrelevant on a physiologic time scale. By contrast, the rate of prothrombin activation by the prothrombinase complex is about 300,000 times as high as the rate of activation by factor Xa.[244]

Although phospholipid vesicles serve as a model system for study of prothrombinase complex formation on platelets, the details of formation of the complex on the two surfaces may vary. Factor Va binds to specific sites on the platelet surface, defining the formation of the prothrombinase complex. Factor Va appears to be the factor Xa receptor on platelets.[245] [246] Factor Xa binds to platelets, leading to the expression of prothrombinase activity.[247] Furthermore, factor Va binds to endothelial cells, monocytes, and lymphocytes, facilitating assembly of the prothrombinase complex.[248] [249] [250] [251]

Prothrombin is converted to thrombin by the prothrombinase complex. Although multiple fragments can be generated by the action of prothrombinase on prothrombin, two or possibly

Figure 102-17 Activation of prothrombin, which is composed of a single polypeptide chain. Its activation to thrombin involves cleavage of two or possibly three peptide bonds. Thrombin, the active enzyme, is composed of two chains, the A chain and the B chain, linked by a disulfide bond.

three peptide bonds are necessarily cleaved in generating thrombin, a two-chain enzyme with a molecular weight of 38,000 (Fig. 102-17).[252] [253] [254] [255] Cleavage of the Arg 271-Thr 272 or Arg 286-Thr 287 bond in the presence of plasma proteins yields fragment 1 2 (M_r 43,000) or fragment 1 2 3 (M_r 45,000), respectively, both derived from the NH_2 -terminus of human prothrombin.[256] [257] With these cleavages prethrombin 2 (M_r 38,000) or prethrombin 2 with a 13-residue NH_2 -terminal extension is generated. Cleavage of the Arg 322-IIe 323 bond in prothrombin generates meizothrombin and in prethrombin 2 generates both the A chain (M_r 5,000) and the B chain (M_r 32,000) of thrombin, linked by a single disulfide bond. In contrast to thrombin, meizothrombin has enzymatic activity toward small substrates but does not convert fibrinogen to fibrin.[258] The charge relay system, common to the trypsin-like serine proteases, is located at His 365, Asp 419, and Ser 527.

Effector cell protease receptor-1 (EPR-1), a receptor for factor X with a molecular weight of 65,000, is widely distributed on cells and recognizes a portion of the EGF domain exposed upon zymogen activation of factor X.[259] This receptor is exposed on the platelet surface only upon platelet activation, and participates in prothrombinase assembly on cell surfaces.[260]

Thrombin is inhibited by antithrombin III. This inhibition is greatly accelerated by heparin (see Chap. 104).

Conversion of Fibrinogen to Fibrin

Fibrinogen circulates as a plasma protein in a biologically inactive form. It is converted to fibrin as a consequence of the cleavage of peptide bonds in both the A- and the B-chain by the enzyme thrombin (Fig. 102-18). Thrombin is specific for the Arg 16-Gly 17 bond in the A-chain. Cleavage of this bond releases fibrinopeptide A, a peptide containing 16 amino acid residues from the A-chain, thereby generating a new amino terminus

Figure 102-18 Conversion of fibrinogen to fibrin monomer. Fibrinogen is composed of three chains, the A-, B-, and -chains, arranged as a heterodimer, $A_{\ 2}B_{2\ 2}$. The conversion of fibrinogen to fibrin, $_{2\ 2\ 2}$, requires the cleavage of peptide bonds to release fibrinopeptide A and fibrinopeptide B.

on the -chain. Thrombin is also specific for the Arg 14-Gly 15 bond in the B-chain, cleavage of which releases fibrinopeptide B, a 14-amino acid peptide, from the B-chain, thereby generating a new amino terminus on the -chain. Thus, the covalent structure of fibrinogen and fibrin are identical except for the removal of two fibrinopeptide A and two fibrinopeptide B fragments from fibrinogen.

The fibrin monomer, on generation, homopolymerizes to form long strands known as protofibrils (Fig. 102-19). Both fibrinogen and fibrin are characterized by a trinodal domain structure, with a linear D-E-D domain organization. After removal of the fibrinopeptides, binding sites within the central E domain of the fibrin monomer bind to sites on the D domain of the -chain of another fibrin monomer.[261] This yields a half-staggered noncovalent complex between two monomeric units.[262] Addition of a third monomer in a half-staggered orientation facilitates the end-on-end interaction of the D domains of two adjacent monomers. Through these two intermolecular interactions, E domain-D domain and D domain-D domain, two-stranded protofibrils are formed. Only after the protofibrils have become sufficiently long is their lateral associationa necessary event in the formation of thick fibrin fibrilsobserved.

The polymerized form of fibrin contains fibrin monomers that are noncovalently bound to each other. As such, the fibrin strands are unstable. Through the action of factor XIIIa, the - and -chains of adjacent fibrin strands are covalently cross-linked to yield a form of fibrin that is not easily disrupted. Factor XIIIa, a transglutaminase, catalyzes the condensation of lysine residues on one chain and glutamic acid residues on a second chain.[263] Factor XIII, an inactive precursor, is a plasma protein that is converted to its active form, factor XIIIa, by the proteolytic action of thrombin.

Although many details of blood coagulation remain unclear, there has been considerable definition of the structure and function of participating components and of the special role that cell membranes play in complex formation. The rapid generation of thrombin, with concomitant platelet activation and fibrin clot formation, is localized to the region of tissue injury.

Contact Phase of Blood Coagulation: Activation of Factors XII and XI

Patients with factor XII, prekallikrein, or high-molecular-weight kininogen deficiency have no bleeding phenotype despite prolonged PTTs. These proteins are not required for hemostasis (i.e., the rapid generation of fibrin clot). However, these proteins may play a role in fibrinolysis and in fibrin formation during inflammation and wound healing.

Prekallikrein, with a molecular weight of 100,000, is in part bound to high-molecular-weight kininogen in plasma. It is converted to kallikrein, the active enzyme form of the protein, by factor XIIa. Kallikrein, a serine protease, is composed of two subunits, a heavy chain of 52,000 and a light chain of about 35,000. The active site resides on the light chain, whereas the heavy chain binds to high-molecular-weight kininogen.[264] In plasma, kallikrein is inactivated by $_2$ -macroglobulin and by C1 inhibitor.[265] [266]

High-molecular-weight kininogen, with a molecular weight of 120,000, is a plasma protein that participates in contact activation. High-molecular-weight kininogen accelerates the rate of surface-dependent activation of factor XII[267] and the rate of prekallikrein activation by activation products derived from factor XIIa.[268]

Factor XII, a zymogen of 80,000 molecular weight, is composed of 596 amino acids in its circulating form.[43] [50] [51] It is activated to factor XIIa by plasma kallikrein (Fig. 102-20A).[269] [270] [271]

This reaction is greatly accelerated by the presence of high-molecular-weight kininogen and by contact with negatively charged surfaces such as glass or collagen.[272] [273] The activation of factor XII to generate factor XIIa involves cleavage of the peptide bond between Arg 353 and Val 354. A heavy chain (M_r 50,000) composed of 353 amino acid residues binds to negatively charged surfaces and is derived from the NH_2 -terminus of factor XII. This chain contains the EGF domains, the kringle

domain, and the fibronectin type I and type II domains. A light chain (M_r 30,000) composed of 243 amino acid residues contains the catalytic domain, which is common to serine proteases. The catalytic triad includes His 393, Asp 442, and Ser 544. The light chains and heavy chain are linked by disulfide bonds. Factor XIIa functions to convert factor XI to its activated form, factor XIa, and to convert prekallikrein to kallikrein (Fig. 102-20B).

Factor XI is composed of two identical polypeptide chains, each of 80,000 molecular weight, connected by a disulfide bond. Factor XI is converted to its enzymatic form, factor XIa, by proteolytic cleavage of the Arg 369-Ile 370 bond in each chain (Fig. 102-20B).

Figure 102-19 Formation of fibrin strands. **(A)** Fibrin forms **(B)** a staggered dimer. **(C)** The addition of another fibrin monomer end-on-end yields a trimer. **(D)** Continued addition of fibrin monomer generates the fibrin strands.

Figure 102-20 Contact phase of blood coagulation. **(A)** Factor XII, a zymogen composed of a single polypeptide chain, is converted to its active form, factor XIIa, by the cleavage of a single peptide bond. Kallikrein catalyzes this reaction, and the rate of the reaction is greatly accelerated by high-molecular-weight kininogen and by contact with negatively charged surfaces. The light chain of factor XIIa contains the enzyme-active site. **(B)** Factor XI, composed of a homodimer formed by two identical subunits, is converted to factor XIa by the enzyme factor XIIa. Each subunit is cleaved to yield a heavy chain and a light chain; the latter contains the enzyme-active site.

The heavy chain (M_r 50,000), derived from the amino terminus, and the light chain (M_r 30,000) remain attached through a disulfide bond. Recent data suggest that thrombin is the physiologically relevant activator of factor XI. [13] The catalytic domain of factor XIa resides on the light chain; the catalytic triad common to all serine proteases includes His 44, Asp 93, and Ser 188.

Factors XI and XIa bind to platelets. [274] [275] It remains uncertain whether the factor XI-platelet interaction has a physiologic role and whether factor XIa on platelets activates factor IX in the solid phase.

Chapter 103 - Molecular and Cellular Basis of Fibrinolysis

H. Roger Lijnen
Désiré Collen

OVERVIEW OF THE FIBRINOLYTIC SYSTEM

The fibrinolytic system in mammalian blood plays an important role in the dissolution of blood clots and in the maintenance of a patent vascular system. The fibrinolytic system (Fig. 1031) comprises an inactive proenzyme, plasminogen, that can be converted to the active enzyme, plasmin, that degrades fibrin into soluble fibrin degradation products. Two immunologically distinct physiologic plasminogen activators have been identified in blood: tissue-type plasminogen activator (t-PA) and urokinase-type plasminogen activator (u-PA). Inhibition of the fibrinolytic system may occur either at the level of the plasminogen activators, by specific plasminogen activator inhibitors (PAI-1 and PAI-2), or at the level of plasmin, mainly by $_2$ -antiplasmin. Some physicochemical properties of the main components of the fibrinolytic system are summarized in Table 1031 . Tissue-type plasminogen activatormediated plasminogen activation is primarily involved in the dissolution of fibrin in the circulation,[1] whereas u-PA binds to a specific cellular receptor (u-PAR) resulting in enhanced activation of cell-bound plasminogen. The main role of u-PA is the induction of pericellular proteolysis during tissue remodeling and repair, macrophage function, ovulation, embryo implantation, and tumor invasion. [2] A u-PARindependent function of u-PA in fibrin clearance [3] and in arterial neointima formation[4] has been demonstrated.

Regulation and control of the fibrinolytic system is mediated by specific molecular interactions among its main components, and by controlled synthesis and release of plasminogen activators and plasminogen activator inhibitors, primarily from endothelial cells. Disorders of the fibrinolytic system may result either from impaired activation (thrombotic complications) or from excessive activation (bleeding tendency). [5] [6] [7] [8]

PROTEIN STRUCTURE OF THE MAIN COMPONENTS

The enzymes of the fibrinolytic system are serine proteases i.e., their active site consists of a catalytic triad composed of the amino acids serine, aspartic acid, and histidine. This active site is located in the COOH-terminal serine protease domain, while the NH_2 -terminal regions contain one or more functional domains, such as the finger domain (homologous to the fingers in fibronectin), the epidermal growth factor-like domain and kringle domains. The inhibitors of the fibrinolytic system are grouped into the serpin (serine proteinase inhibitor) superfamily. Serpins have in their COOH-terminal region a specific reactive site peptide bond which is cleaved by their target enzyme, resulting in the release of a peptide from the inhibitor and formation

Figure 103-1 Schematic representation of the fibrinolytic system. t-PA, tissue-type plasminogen activator; u-PA, urokinase-type plasminogen activator; PAI-1 and PAI-2, plasminogen activator inhibitor-1 and -2; $_2$ -AP, $_2$ -antiplasmin.

of an inactive enzyme-inhibitor complex. The reactive site of the serpins has a basic amino acid residue (arginine or lysine) in the P1 position (Arg-X or Lys-X) (Table 1031).

Human plasminogen is a 92 kD single chain glycoprotein, consisting of 791 amino acids; it contains 24 disulfide bridges and five homologous kringles (Fig. 1032).[9] [10] Native plasminogen has NH_2 -terminal glutamic acid (Glu-plasminogen) but is easily converted by limited plasmic digestion to modified forms with NH_2 -terminal lysine, valine, or methionine, commonly designated Lys-plasminogen. The plasminogen kringles contain lysine binding sites that mediate the specific binding of plasminogen to fibrin and the interaction of plasmin with $_2$ -antiplasmin; they play a crucial role in the regulation of fibrinolysis. [11] Nuclear magnetic resonance spectroscopy studies indicate that the first kringle is a compact globular structure built around a core of hydrophobic aromatic amino acids, whereas chemical modification studies have revealed that specific arginine residues are involved in fibrin binding. [12] Kringle 4 of plasminogen mediates its binding to tetranectin. [13]

Tissue-type plasminogen activator (t-PA) is a 70 kD serine protease, originally isolated as a single polypeptide chain of 527 amino acids (Fig. 1033).[14] However, native t-PA contains an NH_2 -terminal extension of three amino acids (Gly-Ala-Arg-). [15] Tissue-type plasminogen activator is converted by plasmin to a two-chain form by hydrolysis of the Arg^{275} Ile^{276} peptide bond. The NH_2 -terminal region is composed of several domains

TABLE 103-1 -- Some Properties of the Main Components of the Fibrinolytic System

	M_r	Carbohydrate Content (%)	Number of Amino Acids	Catalytic Triad	Reactive Site	Plasma Concentration (g/ml)
Plasminogen	92,000	2	791			200
Plasmin	85,000	2	±715	His^{603} ,Asp^{646} ,Ser^{741}

with homologies to other proteins: a finger domain including residues 450, an epidermal growth factor (EGF) domain consisting of residues 5087, and two kringles including residues 87176 and 176262. The region constituted by residues 276527 represents the serine protease part with the catalytic site, composed of His^{322} , Asp^{371} , and Ser^{478} .[14] These distinct domains in t-PA are involved in several functions of the enzyme, including its binding to fibrin, fibrin-specific plasminogen activation, rapid clearance in vivo and binding to endothelial cell receptors. Binding of t-PA to fibrin is mediated via the finger and the

asterisk. *(Adapted from Pennica et al.,[14] with permission.)*

second kringle domains.[16] Physicochemical characterization of t-PA suggests that the molecule is ellipsoidal and relatively compact, [17] with the individual domains folded within the molecule yielding a globular structure, stabilized by strong interactions between the proteinase domain and the finger domain or EGF domain. [18] Nuclear magnetic resonance studies of the structure of the finger domain of t-PA support this model. [19] The t-PA molecule comprises three potential N-glycosylation sites, at Asn[117] , Asn^{184} , and Asn^{448} . Tissue-type plasminogen activator preparations usually contain a mixture of variant I (with all three glycosylation sites) and variant II (lacking carbohydrate at Asn ^{184}).[14] In contrast to the single-chain precursor form of most serine proteases, single-chain t-PA is enzymatically active. On the basis of conformational similarities between single-chain and two-chain t-PA, the activity of single-chain t-PA may involve an equilibrium between an active and a zymogen conformation. The structure is shifted to the active conformation upon substrate binding. [20] Alternatively, amino acid Lys[156] was shown to contribute directly to the enzymatic activity of the single-chain molecule, by forming a salt bridge with Asp ^{194} that selectively stabilizes the active conformation. [21]

Single chain urokinase-type plasminogen activator (scu-PA) is a 54 kD glycoprotein containing 411 amino acids (Fig. 1034). [22] Upon proteolytic cleavage of the Lys^{158} Ile^{159} peptide bond, the molecule is converted to a two-chain derivative (tcu-PA). The catalytic triad is located in the COOH-terminal polypeptide chain and is composed of Asp^{255} , His^{204} , and Ser^{356} . The NH_2 -terminal chain contains an epidermal growth factor domain (residues 549) and one kringle domain. A low Mr tcu-PA (33 kD) can be generated with plasmin by hydrolysis of the Lys [135] Lys [136] peptide bond following previous cleavage of the Lys ^{158} Ile^{159} bond.

Urokinase-type plasminogen activator receptor (u-PAR), the specific cell surface receptor for u-PA, is a heterogeneously glycosylated protein of 5060 kD, synthesized as a 313-amino-acid polypeptide, anchored to the plasma membrane by a glycosyl phosphatidylinositol (GPI) moiety that is attached at amino acids 282, 283, or 284. The u-PAR molecule is composed of three related structural domains, of which the NH_2 -terminal domain is involved in binding u-PA;[23] it binds all forms of u-PA containing an intact growth factor domain.

Binding of scu-PA to u-PAR on the cell surface appears to be crucial for the activity of u-PA under physiological conditions. The binding results in enhanced plasmin generation, due to effects on both the activation of plasminogen and on the feedback activation of scu-PA to tcu-PA by generated plasmin. Both of these effects are critically dependent on the cellular binding of plasminogen. Cell-associated plasmin is protected from rapid inhibition by $_2$ -antiplasmin, which further favors activation of receptor-bound scu-PA.[23]

Alpha$_2$ -antiplasmin is a 70 kD single chain glycoprotein containing about 13% carbohydrate. The molecule consists of 464 amino acids and contains two disulfide bridges (Fig. 1035). [24] [25] Alpha$_2$ -antiplasmin is a serpin with reactive site peptide bond Arg ^{376} Met^{377} . Its concentration in human plasma is about 70 g/ml (about 1 M). Alpha$_2$ -antiplasmin is synthesized primarily in a plasminogen-binding form that becomes partially converted in circulating blood to an inactive form that lacks a 26-residue peptide from the COOH-terminal end.[26] The inhibitor is cross-linked to the fibrin chain when blood is clotted in the presence of calcium ions and factor XIIIa; Gln[14] is involved in this cross-linking. [27]

Plasminogen activator inhibitor-1 (PAI-1) is a 52 kD single chain glycoprotein consisting of 379 amino acids; it is a serpin

Figure 103-4 Schematic representation of the primary structure of single chain urokinase-type plasminogen activator. The arrow indicates the cleavage site for plasmin. The active site residues are indicated with an asterisk. *(Adapted from Holmes et al.,[22] with permission.)*

with reactive site peptide bond Arg ^{346} Met^{347} .[28] PAI-1 is stabilized by binding to S-protein or vitronectin; [29] the PAI-1 binding site on vitronectin comprises residues Lys^{348} to Arg^{370} . [30] PAI-1 also binds to heparin through positively charged amino acids in the region between residues 65 to 88. [31]

Plasminogen activator inhibitor-2 (PAI-2) exists in two different forms with comparable kinetic properties; a 47 kD intracellular nonglycosylated form with pI 5.0 and a 60 kD secreted glycosylated form with pI 4.4.[32] PAI-2 is a serpin,[33] containing 393 amino acids with reactive site Arg ^{358} Thr^{359} . The function of intracellular PAI-2 is unclear because its main target enzyme (u-PA) occurs extracellularly. It may constitute

Figure 103-5 Schematic representation of the primary structure of $_2$ -antiplasmin. *(Adapted from Holmes et al.,[24] with permission.)*

a storage pool from which PAI-2 can be secreted upon cell injury. [34]

GENE STRUCTURE OF THE MAIN COMPONENTS

The human plasminogen gene was mapped to the long arm of chromosome 6 at band q26 or q27[35] (Table 1032). It spans 52.5 kb of DNA and consists of 19 exons.[36] Each of the five kringles is encoded by two separate exons with a single intron in the middle of each structure. The gene is closely related to that of apolipoprotein (a).[37]

The human *t-PA* gene has been localized on chromosome 8 (bands 8.p.12q.11.2)[38] and more than 36 kb of its sequence have been determined.[39] It consists of 14 exons, and the intronexon organization suggests that the assembly is an example of the exon shuffling principle whereby the distinct structural domains are encoded by a single exon or by adjacent exons.[40] The

TABLE 103-2 -- Some Characteristics of the Genes of the Main Components of the Fibrinolytic System

	Gene Length (kb)	mRNA (kb)	Exons (number)	Chromosomal Location
Plasminogen	52.5	2.7	19	6
t-PA	36.6	2.7	14	8
u-PA	6.4	2.4	11	10
u-PAR	23	1.4	7	19
$_2$ -Antiplasmin	16	2.2	10	18
PAI-1	12.2	2.4;3.2	9	7
PAI-2	16.5	1.9	8	18

t-PA, tissue-type plasminogen activator; u-PA, urokinase-type plasminogen activator; u-PAR, u-PA receptor; PAI-1, plasminogen activator inhibitor-1; PAI-2, plasminogen activator inhibitor-2.

proximal promoter sequences in the human *t-PA* gene contain typical TATA and CAAT boxes and several potential recognition sequences for transcription factors have been identified.[41] [42] A consensus sequence of a cyclic adenosine monophosphate (cAMP)-responsive element (CRE) and a sequence homologous with the consensus sequence of the AP-2 binding site were recently identified, which may have a cooperative effect on constitutive *t-PA* gene expression.[43]

The human *u-PA* gene is 6.4 kb long and is located on chromosome 10.[38] It contains 11 exons and the intronexon organization of the gene closely resembles that of the *t-PA* gene.[44] However, exons III, VIII, and IX of the *t-PA* gene are totally, and exon IV partially, missing in the *u-PA* gene; this accounts for the absence of a finger domain and a second kringle in u-PA. Exon II codes for a signal peptide consisting of 20 amino acids; exons III and IV code for the growth factor domain and exons V and VI for the kringle region. The 5-region of exon VII, which codes for the peptide connecting the light and the heavy chain, is 39 bp longer than the corresponding exon X of the *t-PA* gene. The 3-region of exon VII and exons VIII to XI code for the heavy chain.

The human *u-PAR* gene is located on chromosome 19 bands q13.1q13.2.[45] It consists of 7 exons spread over 23 kb of genomic DNA. The organization of the exons reflects the pattern of triplicated homologous domains observed in the mature protein. Each protein domain is coded for by a pair of exons, with the intron break within each pair always between the 5th and 6th cysteine residue. The urokinase binding domain is encoded by exons 2 and 3.[46] Besides the 1.4 kb mRNA encoding a protein of 313 amino acids (*u-PAR1*) and a signal peptide, a variant form of human *u-PAR* mRNA has been reported (*u-PAR2*) arising by alternatively splicing in the middle of the third domain.[47] The deduced amino acid sequence of this variant consists of a signal peptide and 259 amino acids, of which the 230 residue NH_2 -terminal sequence is identical to that of *u-PAR1*, whereas the 29 residue COOH-terminal sequence is unique. The variant form, *u-PAR2*, contains the u-PA-binding domain, but lacks the GPI anchor and may be a soluble secreted protein.[47] A soluble form of *u-PAR* has been detected in ascitic fluid from patients with ovarian cancer and also in human plasma.[48] [49]

The human $_2$-*antiplasmin* gene is located on chromosome 18, bands p11.1q11.2.[50] It contains 10 exons covering approximately 16 kb of DNA.[51] The NH_2 -terminal region of the protein, comprising the fibrin cross-linking site, is encoded by exon IV, whereas both the reactive site and the plasminogen-binding site in the COOH-terminal region are encoded by exon X.

The *PAI-1* gene has been mapped to chromosome 7, bands q21.3q22.[52] It is approximately 12.2 kb in length and consists of nine exons. As a result of alternative polyadenylation, two mRNA species of 3.2 and 2.4 kb occur. The *PAI-2* gene is located on chromosome 18 q2123. It spans 16.5 kb and contains 8 exons; a consensus sequence TATAAAA is found 22 bp 5 of the proposed transcription initiation site. The structure of the gene is quite different from that of *PAI-1*, but is similar to that of the chicken ovalbumin gene.[53]

MECHANISM OF ACTIVATION OF PLASMINOGEN TO PLASMIN

All plasminogen activators convert plasminogen to plasmin by cleavage of a single Arg ^{561} Val^{562} peptide bond, using the 791 amino acid numbering system. The two-chain plasmin molecule is composed of a heavy chain containing the five kringles (NH_2 -terminal part of plasminogen) and a light chain (COOH-terminal part) containing the catalytic triad, composed of His ^{603} , Asp^{646} , and Ser^{741} . [9] [10] Activation of Glu-plasminogen in human plasma probably occurs by direct cleavage of the Arg^{561} Val^{562} peptide bond without generation of Lys-plasminogen intermediates. [54]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

MECHANISM OF INHIBITION OF PLASMIN BY $_2$ -ANTIPLASMIN

Alpha$_2$ -antiplasmin forms an inactive 1:1 stoichiometric complex with plasmin. The inhibition of plasmin (P) by $_2$ -antiplasmin (A) can be represented by two consecutive reactions: a fast, second order reaction producing a reversible inactive complex (PA), which is followed by a slower first-order transition resulting in an irreversible inactive complex (PA). This model can be represented by:

The second order rate constant of the inhibition is very high (k_1 = 2 to 4 × 10^7 M^1 s^1), but this high inhibition rate depends upon the presence of free lysine binding sites and a free active site in the plasmin molecule and upon the availability of a site complementary to the lysine binding site (plasminogen binding site) and of the reactive site peptide bond in the inhibitor (Fig. 1035). The half-life of plasmin molecules generated at the fibrin surface, which have both their lysine binding sites and active site occupied, is two to three orders of magnitude longer than that of free plasmin. [55]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

MECHANISM OF ACTION OF TISSUE-TYPE PLASMINOGEN ACTIVATOR

In the Presence of Fibrin

Tissue-type plasminogen activator is a poor enzyme in the absence of fibrin, but the presence of fibrin strikingly enhances the activation rate of plasminogen. [56] During fibrinolysis, fibrinogen and fibrin itself are continuously modified by cleavage with thrombin or plasmin, yielding a diversity of reaction products. [57] Thrombin-catalyzed formation of desA-fibrin monomer, and desA-fibrin polymerization are essential for stimulation of plasminogen activation by t-PA. Optimal stimulation is only obtained after early plasmin-cleavage in the COOH-terminal A-chain and the NH_2 -terminal B-chain of fibrin, yielding fragment X-polymer. [57] Kinetic data support a mechanism in which fibrin provides a surface to which t-PA and plasminogen adsorb in a sequential and ordered way yielding a cyclic ternary complex. [56] Formation of this complex results in an enhanced affinity of t-PA for plasminogen (Michaelis constant K_m of 0.16 M as compared to 65 M without fibrin), yielding an up to three orders of magnitude higher catalytic efficiency for plasminogen activation (Fig. 1036). In agreement with this mechanism, the increase in fibrin stimulation after formation of fibrin X-polymers is associated with an enhanced binding of t-PA and plasminogen, which is mediated in part by COOH-terminal lysine residues generated by plasmin cleavage. Interaction of these COOH-terminal lysines with lysine binding sites on t-PA and plasminogen may allow an improved alignment as well as allosteric changes of the t-PA and plasminogen moieties, thus enhancing the rate of plasminogen activation. [57]

Lipoprotein (a) (Lp(a)) competes with plasminogen for binding to fibrin, as a result of binding of Lp(a) to fibrin via its lysine-binding domains. [58] [59] [60] Binding of Lp(a) to fibrin is enhanced by partial proteolytic degradation of the fibrin surface. [58] A functional consequence of the competition between Lp(a) and plasminogen for binding to fibrin is that the fibrin-dependent enhancement of plasminogen activation by t-PA may be reduced,

Figure 103-6 Schematic representation of the molecular interactions regulating the fibrin-specific activation of the fibrinolytic system by tissue-type plasminogen activator. t-PA in circulating plasma in the absence of fibrin has a low affinity for its substrate plasminogen (Km = 65 M), and no efficient plasminogen activation occurs. t-PA binds specifically to fibrin and the bimolecular t-PA/fibrin complex has a high affinity for plasminogen (Km = 0.16 M). Plasminogen binds to the binary t-PA/fibrin complex and is activated to plasmin at the fibrin surface. In loco generated plasmin is protected from rapid inactivation by $_2$ -antiplasmin.

[59] [60] although kinetic studies suggest only a limited effect. [61] However, the inhibition constant of Lp(a) for the activation of plasminogen by t-PA is of the same order as the physiologic plasma concentration of Lp(a), suggesting that elevated levels of Lp(a) might indeed impair physiologic fibrinolysis.

A Thrombin Activatable Fibrinolysis Inhibitor (TAFI), which is activated by the thrombin-thrombomodulin complex, has recently been characterized. TAFI is a carboxypeptidase B-like enzyme that inhibits fibrinolysis by downregulating the cofactor functions of partially degraded fibrin. This effect is most likely mediated by removal of newly exposed COOH-terminal lysine residues that are generated upon plasmin cleavage of fibrin. [62]

At the Cell Surface

A striking analogy exists between the role of fibrin and that of cell surfaces in plasminogen activation. [63] Many cell types bind plasminogen activators and plasminogen, resulting in enhanced plasminogen activation [64] [65] [66] [67] and protection of bound plasmin from inhibition by $_2$ -antiplasmin. [68] [69]

Binding of plasminogen to cultured human umbilical vein endothelial cells (HUVEC) was reported with a K_D of 310 nM, and approximately 10^6 binding sites per cell. [65] Other studies report that most cells bind plasminogen via its lysine binding sites with a high capacity (>10^7 sites per cell) but a relatively low affinity (dissociation constant of approximately 1 M). Gangliosides, [70] as well as a class of membrane proteins with COOH-terminal lysine residues such as -enolase, [71] play an important role in binding of plasminogen to cells. The catalytic efficiency of t-PA for activation of cell bound plasminogen is about 10-fold higher than in solution, possibly as a result of conversion of the plasminogen conformation to the more readily activatable Lys-plasminogen-like structure. [72] Lp(a) competes with plasminogen for binding to endothelial cells, potentially resulting in downregulated activation of cell surface bound plasminogen by t-PA. Thus, Lp(a) may also play a role in the regulation of fibrinolysis at the endothelial cell surface. [73] Alternatively, it was shown that vascular cells have the capacity to regulate pericellular fibrinolysis by modulating the expression of plasminogen receptors; enhanced receptor occupancy results in enhanced plasminogen activation by t-PA. [74]

Specific, saturable and reversible binding of t-PA to HUVEC was also demonstrated. [64] [75] A high affinity binding site (K_D of 29 pM) with a low number of binding sites (3,700 per cell) and a lower affinity binding site (K_D of 18 nM) with a high number of binding sites (800,000 per cell) have been identified. A 40 kD membrane protein (related to annexin II) was proposed as the functional t-PA receptor. [76] Cell surface bound t-PA retains its enzymatic activity and is protected from inhibition by PAI-1. Assembly of plasminogen and plasminogen activators at the endothelial cell surface thus provides a focal point for plasmin generation and may play an important role in maintaining blood fluidity and nonthrombogenicity.

Cellular receptors may also play a role in the rapid clearance of t-PA from the circulation. Circulating t-PA (half-life of 56 min in man) may interact with several receptor systems in the liver. Liver endothelial cells have a mannose receptor which recognizes the high mannose-type carbohydrate antenna on kringle 1, and liver parenchymal cells contain a calcium-dependent receptor which interacts with the finger and/or EGFdomains of t-PA. [77] Parenchymal cells also contain a high affinity receptor for the uptake and degradation of t-PA/PAI-1 complexes, which also binds free t-PA albeit with lower affinity; this receptor, termed low density lipoprotein receptor-related protein (LRP) is identical to the $_2$ -macroglobulin receptor. [78]

MECHANISM OF ACTION OF UROKINASE-TYPE PLASMINOGEN ACTIVATOR

In the Presence of Fibrin

In contrast to tcu-PA, scu-PA displays very low activity toward low molecular weight chromogenic substrates. Scu-PA appears to have some intrinsic plasminogen activating potential, which represents less than 0.5% of the catalytic efficiency of tcu-PA. [79] [80] Other investigators, however, have claimed that scu-PA has no measurable intrinsic amidolytic or plasminogen activator activities. [81] The occurrence of a transition state of scu-PA with a higher catalytic efficiency for native plasminogen than tcu-PA has also been postulated. [82] In plasma, in the absence of fibrin, scu-PA is stable and does not activate plasminogen; in the presence of a fibrin clot, scu-PA, but not tcu-PA, induces fibrin-specific clot lysis. [79] Scu-PA does not bind to a significant extent to fibrin, although in the presence of Zn^{2+} ions some binding may occur. [83] An intrinsic activity of scu-PA toward fibrin-bound plasminogen may contribute to its fibrin-specificity. In addition, plasma $_2$ -antiplasmin prevents conversion of scu-PA to tcu-PA outside the clot and thus preserves fibrin-specificity. [84] Fibrin fragment E-2 selectively promotes the activation of plasminogen by scu-PA, mainly by enhancing the catalytic rate constant of the activation. [85] Scu-PA is an inefficient activator of plasminogen bound to internal lysine residues on intact fibrin, but has a higher activity toward plasminogen bound to newly generated COOH-terminal lysine residues on partially degraded fibrin. [86] Thus, the fibrin-specificity of scu-PA does not require its

Figure 103-7 Plasminogen activation by u-PA at the cell surface. Urokinase-type plasminogen activator (u-PA) bound to its cellular receptor (u-PAR) efficiently converts plasminogen (Plg) bound to its cellular receptor(s) (PlgR) to plasmin (Pli), which is protected from rapid inhibition by $_2$ -antiplasmin ($_2$ -AP). Plasmin converts u-PAR-bound scu-PA to tcu-PA, resulting in enhanced plasminogen activation. Receptor bound tcu-PA, but not scu-PA is inhibited by PAI-1 and PAI-2.

conversion to tcu-PA, but is mediated by enhanced binding of plasminogen to partially digested fibrin. [87]

At the Cell Surface

The binding of scu-PA to u-PAR on the cell surface was claimed to be crucial for its activity under physiological conditions. Binding results in a strongly enhanced plasmin generation, due to effects on both the activation of plasminogen [88] and on the feedback activation of scu-PA to tcu-PA by generated plasmin. [89] Both of these effects are also critically dependent on the cellular binding of plasminogen. Cell-associated plasmin is protected from rapid inhibition by $_2$ -antiplasmin, which further favors the activation of receptor-bound scu-PA. [88] This system can be efficiently inhibited by both PAI-1 and PAI-2 [90] (Fig. 1037). The mechanisms underlying these stimulatory effects are not completely elucidated. A model based on u-PAR-dependent complex formation has been proposed, which would allow initiation of plasminogen activation by the low intrinsic activity of scu-PA. [91] However, the observation that direct anchorage of u-PA to the cell surface (using a GPI-anchored u-PA mutant) leads to a potentiation of plasmin generation equivalent to that observed in the presence of u-PAR, suggests that u-PAR only functions to localize u-PA at the cell-surface. [92] Furthermore, a u-PAR-independent function of u-PA has been demonstrated in fibrin clearance [3] and in arterial neointima formation. [4]

MECHANISMS OF INHIBITION OF PLASMINOGEN ACTIVATORS

Multiple mechanisms are involved in the rapid inhibition of t-PA in human plasma. PAI-1 is a specific rapid-reacting inhibitor of t-PA, which is present at a low concentration in normal plasma, but at higher concentrations in many clinical conditions. [93] In addition, t-PA is inhibited slowly by $_2$ -antiplasmin, $_1$ -antitrypsin and C1-inhibitor.[94] The main mechanism of removal of t-PA from the blood, however, is by clearance via the liver. In healthy volunteers and in patients with acute myocardial infarction, the initial half-life of t-PA is 4 to 6 min. [95] [96]

In human plasma, tcu-PA is also slowly inhibited by several proteinase inhibitors [97] including $_2$ -macroglobulin, $_1$ -antitrypsin, antithrombin III, $_2$ -antiplasmin, and plasminogen activator inhibitor-3 (PAI-3, which is identical to activated protein C inhibitor). More specific and rapid inhibition occurs by PAI-1 and PAI-2. In contrast to tcu-PA, scu-PA is not inhibited by plasma proteinase inhibitors. The main mechanism of removal of u-PA from the blood is by hepatic clearance. [98] [99] Rapid clearance does not involve carbohydrate receptors and is not mediated via the NH_2 -terminal region of the molecule.[99] In patients with acute myocardial infarction, scu-PA shows a biphasic disappearance rate with an initial half-life in plasma (post-infusion) of about 4 min. [100]

PAI-1 reacts with single-chain and two-chain t-PA and with tcu-PA, but not with scu-PA.[101] The second order rate constant for the inhibition of single chain t-PA by PAI-1 is about 10^7 M^1 s^1 , and inhibition of two-chain t-PA and tcu-PA is somewhat faster. PAI-1 inhibits its target proteinases by formation of a 1:1 stoichiometric reversible complex, followed by covalent binding between the hydroxyl group of the active site serine residue of the proteinase and the carboxyl group of the P1 residue at the reactive center (bait region) of the serpin. Highly positively charged regions in t-PA (residues 296304) [102] and in u-PA (residues 179184)[103] are involved in the rapid interaction. A molecular form of intact PAI-1 has been isolated that does not form stable complexes with t-PA but is cleaved at the P1-P1 peptide bond (substrate PAI-1).[104] By point mutations in the reactive site loop, PAI-1 could also be converted from an inhibitor into a substrate. [105] Examination of the structure of the cleaved substrate variant using X-rays shows that it has a new -strand (s4A) formed by insertion of the NH_2 -terminal portion of the reactive site loop into -sheet A subsequent to cleavage.[106] Thus, inhibitory PAI-1 may not only convert to latent PAI-1, which can be reactivated, but also to substrate PAI-1, which may be irreversibly degraded by target proteinases, including t-PA, u-PA, and thrombin. [104] PAI activity is very rapidly cleared from the circulation via the liver; a half-life of 7 min in the rabbit has been reported.[107]

PAI-2 inhibits tcu-PA with a second order rate constant (k_1) of 9×10^5 M^1 s^1 , which is about 10-fold slower than PAI-1. PAI-2 also efficiently inhibits two-chain t-PA (k_1 of 2×10^5 M^1 s^1), less efficiently single-chain t-PA (k_1 of 9×10^3 M^1 s^1) and it does not inhibit scu-PA.[101]

SYNTHESIS AND SECRETION OF PLASMINOGEN ACTIVATORS

The synthesis and secretion of t-PA, u-PA, and PAI-1, mainly by endothelial cells, is highly regulated, although some mediators influence the production of plasminogen activators and plasminogen activator inhibitors in parallel.

Vascular endothelial cells synthesize and secrete t-PA into the circulating blood. [108] Human endothelial cells grown under arterial shear stress synthesize more t-PA.[109] Stimulation of vascular endothelium by venous occlusion, infusion of DDAVP or epinephrine, and physical exercise results in a rapid release (within minutes) of t-PA.[110] This response is too rapid to represent increased synthesis and may reflect release from cellular storage pools, although such a storage pool has not been conclusively identified. Agents, such as thrombin, that stimulate the release of t-PA from endothelial cells, also stimulate the secretion of PAI-1. [111] [112] Dexamethasone increases t-PA antigen levels in hepatoma cells moderately but increases PAI-1 antigen levels to a greater extent, resulting in inhibition of t-PA activity.[113]

A variety of agents have been shown to increase the synthesis of t-PA by cultured endothelial cells, including thrombin, [111] [112] histamine,[112] butyrate,[114] phorbol myristate acetate (PMA), [115] basic fibroblast growth factor,[116] activated protein C,[117] butanol and alcohol derivatives, [118] and retinoids.[115] However, only histamine, butyrate, or a combination of cAMP with protein kinase C agonists exclusively stimulate t-PA synthesis without affecting PAI-1 synthesis.

The mechanisms involved in the stimulatory effect of these

various agents on t-PA synthesis appear to be different. A functional retinoic acid response element (RARE), which consists of a direct repeat of the GGTCA motif spaced by five nucleotides (DR5), has been localized 7.3 kb upstream for the transcription start site of the human t-PA gene. This element mediates the direct regulation by retinoic acid in human fibrosarcoma, endothelial, and neuroblastoma cells. [120] Vasoactive substances, such as histamine and thrombin, bind to specific receptors and activate phospholipase C, which acts on phosphatidyl-inositol biphosphate to produce diacylglycerol. Diacylglycerol activates membrane-bound protein kinase C, which plays an important role in the regulation of t-PA synthesis. This is suggested by the findings that direct activation of protein kinase C by phorbol esters induces t-PA synthesis, whereas suppression of protein kinase C impairs the increase in t-PA synthesis by histamine and by PMA. [121] The increase of t-PA induced by histamine, thrombin, and PMA in endothelial cells is paralleled by increased levels of mRNA, as a result of enhanced transcription of the *t-PA* gene.[122] Overexpression of t-PA in endothelial cells using a retroviral expression vector did not alter the morphology, attachment, proliferation, migration, or invasion in in vitro systems. Potentially such *t-PA* transduced cells could increase local fibrinolysis and may be useful for in vivo therapeutic interventions. [123] Plasmin inhibits the biosynthesis of t-PA antigen by human umbilical vein endothelial cells in a dose-dependent manner, possibly through the signal transduction pathway involving one or more protein kinases.[124]

Whereas the synthesis of t-PA occurs mainly in endothelial cells, immunocytochemical staining of tissues indicates that many cells of different origin (i.e., fibroblasts, epithelial cells, pneumocytes, etc.) produce u-PA. [125] The scu-PA concentration in human plasma ranges between 2 and 20 ng/ml.

SYNTHESIS AND SECRETION OF PLASMINOGEN ACTIVATOR INHIBITORS

PAI-1 mRNA has been demonstrated in a large variety of tissues, suggesting that common cells in these tissues, such as endothelial or smooth muscle cells, may be the site of production.[126] PAI-1 is found in plasma, platelets, placenta, and in the extracellular matrix. Except for platelets, which contain essentially inactive PAI-1, PAI-1 is not stored within cells, but is rapidly and constitutively secreted after synthesis. For unknown reasons PAI-1 exhibits a circadian variation; its plasma concentration is highest in the morning and lowest in the late afternoon and evening, whereas t-PA exhibits an opposite diurnal variation.

Synthesis and secretion of PAI-1 can be modulated by various agonists such as hormones, growth factors, endotoxin, cytokines, and phorbolesters. [126] [127] Although posttranscriptional regulation of *PAI-1* mRNA levels has been suggested,[128] [129] [130] most studies on the regulation of PAI-1 expression demonstrated an effect at the transcriptional level. [131] [132] [133] [134] [135] Alterations in mRNA stability may also contribute to increased PAI-1 levels in some cells. [126] In endothelial cells *PAI-1* gene expression is stimulated by lipopolysaccharide, [129] [136] [137] [138] [139] interleukin 1 (IL-1), [138] [139] [140] tumor necrosis factor-, [129] [141] [142] transforming growth factor ,[143] basic fibroblast growth factor, [143] phorbol esters, [135] [144] [145] [146] thrombin, [111] [112] [147] very low density lipoprotein, [148] Lp(a), [149] insulin, [134] or proinsulin. [150] Studies on the mechanism of the induction by phorbol esters suggest that it is mediated by two regulatory DNA sequences in the proximal promotor of the *PAI-1* gene which were called Box A (65 to 50) and Box B (82 to 65). [151] Recently, the DNA encoding a novel transcription factor which selectively interacts with Box B and which is also involved in basal expression of PAI-1 was characterized. This factor has conserved helicase and RING finger domains, and was called helicase-like transcription factor. [152]

In endothelial cells juxtaposed to thrombi, in smooth muscle cells adjacent to the neointima, and in macrophages, *PAI-1* mRNA is increased and PAI-1 protein is detectable. This augmented arterial wall expression of PAI-1 induced by thrombosis may shift the local balance between fibrinolysis and thrombosis towards the latter. [153] Only a few studies have reported a downregulation of PAI-1 synthesis in endothelial cells, either by forskolin or by endothelial cell growth factor combined with heparin. [144] [154] [155]

PAI-2 has been identified in human placenta and in pregnancy plasma; it is also secreted by leukocytes and by fibrosarcoma cells. Secretion of PAI-2 is regulated by endotoxin and by phorbol esters which stimulate the gene transcription of PAI-2. [101] [156]

CONCLUSIONS

Fibrinolysis is regulated by specific molecular interactions between its main components. Activation of plasminogen by t-PA is enhanced in the presence of fibrin or at the endothelial cell surface. Inhibition occurs at the level of the plasminogen activators or at the level of plasmin. Fibrinolysis may also be regulated as a result of increased or decreased synthesis and/or secretion of t-PA and of PAI-1 from the vessel wall. Assembly of fibrinolytic components at the surface of many cell types via binding to specific receptors provides a mechansim for generation of localized cell-associated proteolytic activity. The physiological importance of the fibrinolytic system is demostrated by the association between abnormal fibrinolysis and a tendency toward bleeding or thrombosis.

Chapter 104 - Regulatory Mechanisms in Hemostasis: Natural Anticoagulants

Charles T. Esmon

INTRODUCTION

Understanding hemostasis requires consideration of the mechanisms that regulate this process and thereby serve to localize the clotting response to the immediate area of injury. This chapter has three main goals: to examine the molecular mechanisms by which the natural anticoagulant complexes function to regulate coagulation, to examine how the expression of the anticoagulant complexes may be altered in response to mediators, and to review current understanding of the physiologic ramifications of these systems.

Current information suggests that there are three major natural anticoagulant mechanisms directed at the control of coagulation responses per se: the heparin-antithrombin III (AT III) system,[1] [2] [3] the protein C anticoagulant pathway,[4] [5] [6] and the tissue factor pathway inhibitor, [7] formerly referred to as lipoprotein-associated coagulation inhibitor and the extrinsic pathway inhibitor. [8] These pathways appear to complement each other and to work in concert to exert a potent in vivo anticoagulant response. Defects in these pathways, particularly the protein C pathway, are more commonly associated with familial thrombophilia than any other mechanisms.

INHIBITION OF THE VITAMIN K-DEPENDENT PROTEASES OF THE COAGULATION CASCADE: THE ANTITHROMBIN III/HEPARIN MECHANISMS

Antithrombin III is a glycoprotein inhibitor that functions by neutralizing coagulation proteases, indicated below by the letter E for enzyme, by forming a 1:1 complex between the enzyme and AT III:

This reaction probably accounts for the major mechanism of inhibition of thrombin and factors Xa and XIa, [3] but the reaction is slow in the absence of heparin. Factor VIIa is not inhibited effectively by AT III with heparin unless the factor VIIa is complexed to tissue factor. [9] [10] Heparin accelerates inhibition of the coagulation proteases about 1,000-fold.[11] As a result, AT III must be present[12] for heparin to function as an effective anticoagulant. With thrombin, optimal rates of inactivation require the simultaneous interaction of heparin with AT III and thrombin. [13] [14] Heparin acts as a bridge between thrombin and AT III, thereby concentrating the reactants and accelerating the reaction. In addition, the interaction of heparin with AT III alters the conformation

Figure 104-1 Thrombin inhibition by AT III in the presence of heparan molecules on the endothelial cell surface. The binding of AT III to the heparan results in a conformational change in the AT III that results in rapid inactivation of thrombin. Both thrombin and antithrombin bind to the heparan. After complex formation with AT III, the complex rapidly dissociates from the heparan.

of the inhibitor, which makes the protease trap more accessible to thrombin and the other coagulation factors. [3] [15] Relative to thrombin, the interaction of heparin with factor Xa plays a much less important role in accelerating inactivation. [3] [11] This difference in the nature of the reactions has led to a new class of antithrombotic agents, the low-molecular-weight heparins. The low-molecular-weight heparins retain most of their ability to inactivate factor Xa, but because of their lower molecular weight, they are less effective in forming the bridge between thrombin and AT III and hence have reduced activity toward thrombin. As the size of the heparin fractions become smaller, the ratio of activity toward factor Xa versus thrombin increases. The pharmacologic ramifications of this remain to be fully explored, but this property would be anticipated to increase the half-life of thrombin relative to factor Xa as compared with high-molecular-weight heparins.

Little naturally occurring heparin is found in the blood. The vascular endothelium, and the microvascular endothelium in particular, is rich, however, in anticoagulantly active heparin-like proteoglycans. [3] Most of the heparin-like proteoglycans are on the abluminal side of the endothelium. [16] It has been proposed that these proteoglycans accelerate inhibition of some of the coagulation proteases. [16] [17] Whether the low concentration of heparin-like proteoglycans on the luminal surface is responsible for the acceleration of thrombin clearance or the larger pool of abluminal proteoglycan can interact with thrombin remains unclear. [16] A model of the mechanisms by which these proteoglycans may function is illustrated in Figure 1041 . Proteoglycans are endothelial cell-associated proteins with heparin/heparan side chains bearing the critical carbohydrate sequences required for AT III recognition. Both thrombin and AT III bind to sulfated carbohydrates and are brought into close proximity to each other. AT III undergoes a conformational change required for rapid inactivation of thrombin. Little evidence exists that thrombin alters its structure on binding, but thrombin interaction with heparin is clearly important. [13] [14] Heparin functions catalytically, facilitating the rapid dissociation of the thrombin/AT III complex from the proteoglycan.[14] This critical step is responsible for re-exposure of the heparin sites for binding with other thrombin and AT III molecules.

One important feature of heparin as an anticoagulant is that the molecules are heterogeneous, both structurally and functionally. Less than one-third of the heparin in commercial preparations is catalytically active in accelerating AT III-dependent inhibition of thrombin, and <10% of the naturally occurring heparin-like proteoglycans are anticoagulantly functional[16] (see Chap. 122). The critical structure responsible for the inhibition of thrombin by AT III is a specific sequence of sulfated sugars corresponding to iduronic acid-N-acetylglucosamine-6-OSO_3 -glucuronic acid-N-sulfated glucosamine-6-OSO_3 -iduronic acid-2-OSO_3 -N-sulfated glucosamine-6-OSO_3 -iduronic acid-2-OSO_3 -glucuronic acid-6-OSO_3 .[3]

The function of other forms of nonanticoagulantly active forms of heparin in commercial heparin preparations is unresolved. Some functions of heparin, such as its potential role in blocking angiogenesis, [20] are distinct from its role as an anticoagulant.

INHIBITION OF THE EXTRINSIC PATHWAY OF COAGULATION

The AT III/heparin complex accounts for inhibition of all the vitamin K-dependent proteases, except factor VIIa. Although it has long been recognized that the factor VIIa/tissue factor complex is inhibited by serum, factor VIIa alone is remarkably stable both in serum and in vivo. [7] An inhibitor of the extrinsic pathway has been described, recently renamed as tissue factor pathway inhibitor (TFPI). The available evidence suggests a remarkable and novel mechanism of action. TFPI forms a complex with factor Xa, thereby inhibiting factor Xa activity. [21] How, then, does this serve as the mechanism for inhibition of the tissue factor/factor VIIa complex? Insight into the mechanism comes from structure/function analysis. Structure/function studies, outlined below, indicate that the factor Xa/TFPI complex interacts with the membrane, raising the local concentration of the TFPI and facilitating the inhibition of the factor VIIa/tissue factor complex (Fig. 1042). The supporting evidence for this model consists of the following observations. Binding of factor Xa to TFPI is Ca^{2+} independent and does not require the Gla domain of factor Xa. [21] Both Ca^{2+} and the Gla domain are required for factor Xa-dependent inhibition of factor VIIa. Furthermore, once TFPI inhibits the tissue factor/factor VIIa/factor Xa

Figure 104-2 Inhibition of factor VIIa by tissue factor pathway inhibitor (TFPI). In this model, the binding of TFPI to factor Xa results in a conformational change in the TFPI that facilitates the inhibition of factor VIIa, which is complexed to tissue factor (TF).

Figure 104-3 (A) Formation and function of activated protein C under basal conditions. A small thrombus containing platelets and fibrin is illustrated on the lining of a small vessel. Thrombin (Th) originating on the surface of the thrombus is carried in a capillary bed by blood flow. On the endothelial cells in the capillaries, thrombin binds to thrombomodulin. The thrombin/thrombomodulin complex rapidly converts protein C (PC) to activated protein C (APC). The APC subsequently functions as an anticoagulant by enzymatically degrading clotting factors Va and VIIIa on membrane surfaces. Protein S (S) is required for these inhibitory steps to occur. Approximately 60% of the protein S is complexed to C4b-binding protein (C4BP) and is not functionally active. C4b-BP also binds serum amyloid P (SAP). APC is inhibited in plasma by protein C inhibitor, which is also known as plasminogen activator inhibitor-3, and by $_1$ -antitrypsin. *(From Esmon,* [5] *with permission, adapted from Esmon.* [157] *)* **(B)** Inflammation-induced changes in the coagulation system. During inflammation, the thrombomodulin available on the endothelial surface is decreased. This results in decreased activated protein C formation. Tissue factor (TF) is expressed on the cell surface, resulting in increased factor Xa formation, leading to more thrombin formation on the platelet surface. Binding of leukocytes to the endothelial cell surface is increased by the appearance of endothelial leukocyte adhesion molecules (E- or P-selectin) and the bound leukocytes then contribute to local vascular damage. In the plasma, inflammation results in increased levels of C4b-BP. This increase shifts the protein S to the complexed, inactive form; farther down, it regulates the protein C system. These inflammation-induced changes promote thrombus formation.

complex, the addition of chelating agents frees factor VIIa from inhibition and dissociates TFPI. [7] [22] Thus, the TFPI/factor Xa complex forms first, and this complex combines with the membrane-bound factor VIIa/tissue factor complex. The precise role played by factor Xa in factor VIIa inactivation remains unclear. Although the model shows the initial event of factor Xa/TFPI interaction as a solution phase reaction, the possibility exists that the reaction can occur on the membrane surface as well.

Some potential insights into the molecular basis for the capacity of the inhibitor to neutralize two proteases simultaneously can be derived from an analysis of the structure of TFPI. This protein has been cloned and a cDNA coding for TFPI characterized. [8] The inhibitor has three tandem repeated domains with strong homology to other basic protease inhibitors of the Kunitz type (i.e., the same class as pancreatic-trypsin inhibitor). [7] [8] Factor Xa reacts with the second domain and factor VIIa binds to the first domain. Binding of factor Xa at one site may alter the conformation of the inhibitor at a second site, thereby baiting the trap for factor VIIa. Alternatively, factor Xa may concentrate the inhibitor at the membrane surface, forcing the equilibrium toward factor VIIa neutralization.

One potential advantage of this mechanism is that the inhibition of factor VIIa may be delayed temporally until factor Xa is formed, ensuring that some product can be made when tissue factor is exposed to the blood. This may contribute significantly to the fine-tuning of the regulatory mechanisms.

The importance of this inhibitor is illustrated by the observation that gene deletion in mice results in embryonic lethality, probably due to inadequate control of the coagulation reactions and subsequent thrombosis. [23]

INHIBITION OF THE REGULATORY PROTEINS (COFACTORS) OF THE BLOOD COAGULATION SYSTEM: THE PROTEIN C ANTICOAGULANT PATHWAY

The third major regulatory mechanism involves the protein C anticoagulant pathway. This pathway differs from the other pathways by the nature of the target molecules that it inhibits. Unlike the TFPI and AT III mechanisms directed at the inhibition of the protease components of the coagulation cascade, activated protein C inhibits two of the nonproteolytic regulatory proteins (cofactors) of the blood coagulation cascade, factor Va and factor VIIIa. The components of the pathway are illustrated schematically in Figure 1043A (which depicts normal physiologic conditions) and in Figure 1043B (which depicts this pathway after an inflammatory insult).

In this model, thrombin forms at a wound site and excess thrombin moves downstream to bind to thrombomodulin on endothelial cells. On endothelial cells in larger vessels,[24] an endothelial protein C receptor (EPCR) binds to protein C and augments protein C activation by increasing the affinity of the activation complex for protein C (Fig. 1044).[25] The thrombin/thrombomodulin complex activates protein C[26] catalytically, and activated protein C rapidly dissociates from cells in the microcirculation expressing only the thrombin/thrombomodulin complex, but more slowly from endothelium of larger vessels because EPCR binds both protein C and activated protein C. When bound to EPCR, activated protein C loses anticoagulant activity and cannot inactivate factor Va, but retains the capacity to be inhibited by proteinase inhibitors.[27] Presumably, the complex between EPCR and activated protein C catalyzes cleavage of new plasma or cellular substrates that are yet to be identified. These may be involved in the anti-inflammatory activities associated with activated protein C (see later). For activated protein C to function effectively, it must interact with protein S bound to cell surfaces.[28] [29] [30] This interaction facilitates activated protein C binding to platelet [31] and endothelial cell surfaces, [32] although

Figure 104-4 A model of the function of the endothelial cell protein C receptor in protein C activation. Protein C can bind directly to the protein C receptor (EPCR) whether or not thrombomodulin (TM) is present. The complex of protein C (PC) with EPCR is activated more effectively by the thrombin (T)-TM complex than free protein C. The activated protein C (APC) that is formed does not inactivate factor Va and presumably cleaves an alternative, as yet to be identified, substrate. Once the APC dissociated from EPCR it can bind to protein S (S) and inactivate factor Va. *(Modified from Stearns-Kurosawa et al.,[25] with permission. Copyright 1996 National Academy of Sciences USA.)*

other cell types may be involved as well.[33] [34] The cell surface-bound complex can then inactivate the target proteins, factors Va and VIIIa.[35] The procofactors factors VIII and V seem relatively resistant to the action of activated protein C.[36] [37] Protein S circulates in the blood in at least two forms: (1) as the free protein, and (2) noncovalently associated with a large, multisubunit regulatory protein of the complement system, C4b-binding protein (C4b-BP).[38] [39] Only the free form of protein S functions as an active inhibitor in this pathway.[40] [41] Recently, protein S has also been proposed to inhibit prothrombin activation directly, probably by binding to factor Va or factor Xa, or both.[42] The relative importance of this direct inhibition versus the cofactor function for activated protein C is unknown, but it seems likely that the cofactor function predominates. In addition to protein S, Dahlbäck et al. [43] have identified patients whose plasma is normal in protein S, but fails to respond to addition of activated protein C. The abnormality in this plasma is due to a mutation at one of the factor Va cleavage sites (Arg 506) [44] (see Genetics of Factor V below). Factor V, the precursor of factor Va, accelerates the inactivation of factor VIIIa, [45] suggesting an even more complex regulatory mechanism than illustrated in Figure 1043A . In the presence of activated protein C, the rate-limiting steps in coagulation appear to be the formation of adequate factor Va or factor VIIIa, or both, to amplify the original coagulation stimulus. Evidence for this concept comes from the observation that prior activation of factor V to factor Va in plasma almost totally abolishes the anticoagulant activity of activated protein C. This finding is consistent with the observation that factor Va interacts with activated protein C on activated platelets with high affinity, but the catalytic rate of inactivation is relatively slow.[46] Once activated protein C is formed, the enzyme has a half-life in the circulation of approximately 15 minutes,[47] [48] in contrast to a thrombin half-life of 1020 seconds.[49] Inhibition involves two major inhibitors: a protein C inhibitor [50] and $_1$ -antitrypsin.[51] Both are relatively slow reacting. Of the two, only the protein C inhibitor activity is enhanced by heparin. Recent studies have demonstrated that both inhibitors function in vivo.[48]

Protein C, protein S, thrombomodulin, and the endothelial cell protein C receptor all interact with the membrane surface, but the mechanisms are distinct (Fig. 1045). For protein C and protein S, membrane association requires -carboxyglutamic acid residues and Ca^{2+} . Because these proteins require vitamin K for their biosynthesis, the proteins synthesized in the presence of vitamin K antagonists or in the absence of vitamin K

Figure 104-5 Schematic representation of protein C, protein S, thrombomodulin, and the endothelial cell protein C receptor. The disulfide bonds in thrombomodulin are predicted by homology. The -carboxyglutamic acid residues in protein C and protein S are indicated by small Y-shaped symbols. *(From Esmon,[5] with permission.)*

are inactive.[52] [53] Their binding to membrane surfaces is largely Ca^{2+} dependent and requires negatively charged phospholipids.[54] Thrombomodulin is an integral membrane protein and does not dissociate from the cell surface. Proteolytic modification of thrombomodulin with elastase yields a soluble protein that retains the capacity to accelerate thrombin-dependent protein C activation [55] that may be structurally similar to the soluble form of thrombomodulin described.[56] [57] The protein C receptor is also an integral membrane protein.[58] Neither thrombomodulin nor EPCR requires Ca^{2+} or negatively charged phospholipid to remain membrane bound.

Examination of the structures of protein C, protein S, and thrombomodulin shows a remarkable number of tightly knotted structures.[59] [60] [61] [62] [63] [64] These have the disulfide bond patterns characteristic of the epidermal growth factor (EGF) precursors. In thrombomodulin, this domain is all that is required for thrombin binding and for the activation of protein C.[65] [66] [67] In fact, the major thrombin binding site is located in an 80-residue stretch defined almost exclusively by the last two EGF-like regions (Fig. 1045C). Ca^{2+} is required for protein C activation. There are three classes of Ca^{2+} binding sites in protein C: (1) those involving Gla residues, (2) the site in the first EGF domain, and (3) a site in the protease domain. The Ca^{2+} dependence for activation of protein C by soluble thrombin/thrombomodulin complexes is not mediated through the Gla domain, but rather through a single Ca^{2+} -binding site in protein C[68] [69] [70] that is located in the protease domain.[71] [72] Occupancy of this site changes the conformation of protein C, so that it is not activated effectively by thrombin alone, but rather is a substrate for the thrombin/thrombomodulin complex.[73] [74] A schematic representation of how substrate recognition is defined is presented in Figure 1046 . On the membrane surface the Gla domain is important for interaction with phospholipids[75] and the protein C receptor.[76] Optimal interaction with membranes also appears to involve the Ca^{2+} binding site in the EGF domain of protein C.[69] The -hydroxy aspartic acid residue in protein C[77] and the three hydroxylated aspartic acid and asparagines in protein S[78] are located within the EGF domains. The role of these hydroxylated residues is unknown, but they appear to be located near the Ca^{2+} -binding site. Substitution of the aspartic acid with glutamic acid interferes with normal Ca^{2+} binding.[63] This observation, coupled with their known role as metal-binding residues in bacterial proteins, [79] suggested that they are involved in Ca^{2+} binding, but recent two-dimensional nuclear magnetic resonance structural studies indicate that these side chain modifications are not directly involved in ligating the Ca^{2+} .[80] The hydroxylated residues could be involved with metal-dependent recognition of other proteins. Activated protein C also

contains a monovalent ion-binding site that accelerates cleavage of synthetic substrates. [81]

Bovine thrombomodulin has also been shown to contain a -hydroxy aspartic acid residue. [82] The role in thrombomodulin function remains unknown.

The COOH-terminal regions of protein C, and protein S, demonstrate little structural similarity. In protein C, this region contains the serine protease domain that has extensive sequence

Figure 104-6 A plausible mechanism for thrombomodulin function. Thrombin (T) can interact with protein C (PC) in the absence of Ca^{2+} (upper left). In the presence of Ca^{2+}, a conformational change in protein C occurs that prevents the interaction with thrombin (upper right). A conformational change occurs in the enzymatic active site of thrombin when thrombin binds to thrombomodulin. This change prevents cleavage of protein C by thrombin in the absence of Ca^{2+} (lower left). However, the change in the binding site of thrombin induced by thrombomodulin results in the binding of the Ca^{2+} -stabilized conformation of protein C (lower right) and the subsequent formation of activated protein C. TM, thrombomodulin. *(From Johnson et al., [65] with permission.)*

homology to trypsin.[83] In activated protein C, the protease domain is covalently linked to the EGF and Gla domains by a single disulfide bridge. [83] [84] Protein C circulates both as a single-chain and two-chain molecule with a ratio of about 1:3. [85] [86] There are also two subforms, referred to as and , with the latter appearing somewhat smaller and differing specifically in the heavy chain. The different forms differ in carbohydrate content.

In contrast to protein C, protein S is a single-chain molecule. Consistent with the proposed model as a binding protein (Fig. 1043), the COOH-terminal domain has no similarity with proteases. Some sequence similarities have been noted with steroid-binding proteins. [87] The role of this domain remains uncertain, but evidence suggests that the domain is involved in C4b-BP interaction, [88] although this concept would appear to be inconsistent with site-specific mutations in this region of protein S that do not influence C4b-BP binding. [89]

In thrombomodulin, the role of the NH_2 -terminal domain is also obscure. Limited sequence similarities to some lectins has led to the hypothesis that it may be involved in carbohydrate binding, but no direct evidence for this function exists. This domain is not critical to protein C activation, leaving open the possibility that this receptor may participate in more than one control mechanism. Consistent with this possibility, thrombomodulin gene deletion in mice results in embryonic lethality prior to development of the cardiovascular system.[90]

Endothelial protein C receptor has a very short cytosolic tail, the single transmembrane spanning domain and two extracellular domains. [56] EPCR is homologous to the major histocompatibility class 1 molecules. Molecular modeling based on this homology suggests that the extracellular region forms a relatively compact structure without obvious domains.

CONTROL MECHANISMS IN PROTEIN C ACTIVATION

Protein C activation can be controlled by a number of different mechanisms. When thrombin binds to thrombomodulin, several coagulation reactions, including fibrin generation and platelet activation, are inhibited. [91] [92] [93] [94] [95] Bound thrombin reacts with AT III more rapidly than does free thrombin, [93] an acceleration that depends on the presence of a sulfated galactosaminoglycan (chondroitin sulfate) on the thrombomodulin molecule. [96] Thrombin bound to thrombomodulin is also inhibited rapidly by the protein C inhibitor, [97] but this rapid inactivation does not require the chondroitin sulfate moiety on thrombomodulin. The rapid inactivation of thrombomodulin-bound thrombin ensures the termination of protein C activation shortly after thrombin generation has ceased. Thus, the two processes are very tightly coupled. Thrombomodulin appears to work in concert with vascular heparins to augment thrombin inhibition. The relative importance of the role of thrombomodulin and vascular heparin-like molecules in thrombin inhibition by proteinase inhibitors is uncertain and may vary within different organs. For instance, thrombomodulin is difficult to detect in the microcirculation of the human brain, [98] although low levels are present. [99]

Thrombin can also be cleared by internalization when bound to thrombomodulin, [100] but the extent of the observed internalization varies and its importance is controversial. [101] This internalization is much slower than the rate of thrombin inhibition, raising the question of the role of this process in regulation. The thrombin/AT III complex dissociates readily from thrombomodulin, so that neither thrombin nor thrombin/ antithrombin clearance via internalization is likely to contribute significantly to overall clearance of either species from the circulation. [96]

INFLAMMATORY MEDIATORS, THROMBOMODULIN, AND THE HEMOSTATIC BALANCE

Under most circumstances, the blood clotting process is under very tight control, and the in vivo regulatory mechanisms adequately limit the extent of clotting in response to injury. Inflammatory events, such as occur in gram-negative bacterial sepsis, can shift this balance in favor of the clotting response at the expense of the natural anticoagulant mechanisms. A prime target for this modulation appears to be the protein C anticoagulant pathway. A hypothetical depiction of the vasculature following an inflammatory insult is presented in Figure 1043B . As compared with the normal vasculature, inflammatory mediators depress thrombomodulin and EPCR,[58] thereby inhibiting protein C activation. [102] [103] [104] [105] As a result, more free thrombin is formed. The levels of C4b-BP are elevated;[106] this leads to a shift toward the C4b-BP/protein S complex. Because this complex is not active in supporting activated protein C anticoagulant activity, [40] [41] the limited amounts of activated protein C that are formed are not fully functional. Thus, there is a major decrease in the anticoagulant activity of this system.

Not only is the anticoagulant pathway down-regulated, but several procoagulant events ensue essentially simultaneously. Tissue factor synthesis and cell surface expression[107] are initiated, leading to the activation of factors X and IX. This occurs not only on the endothelium (Fig. 1043B), but on the macrophage/monocytes as well. Leukocytes are also bound to the cell surface. [108] Because these cells release both proteases and active oxygen species, this may contribute to vascular injury. In particular, recent studies have shown that human thrombomodulin is especially sensitive to oxidant damage due to oxidation at Met 388. [109]

Formation of tissue factor and the down-regulation of the

protein C pathway is predicted to lead to factor Xa formation and to increased stability of the factor Xa/factor Va complex on the platelet surfaces.

These observations raise the question of why inflammatory stimuli do not lead to even more severe injury. Available evidence suggests that TFPI remains fully active.[7] Little evidence has been presented that vascular heparin-like substances are down-regulated by these stimuli.

WHERE DO ANTICOAGULANT FACTORS FUNCTION? COORDINATED CONTROL OF A COMPLEX PROCESS

As pointed out by Busch et al.,[110] the vasculature presents an unusual feature. As blood moves from the large vessels to the capillaries, the surface area of endothelium in contact with each milliliter of blood rises dramatically. For endothelial cell surface-bound receptors, this translates directly into an increase in the concentration of the regulatory receptor. Thrombomodulin is present at approximately 100,000 copies per endothelial cell. The concentration of thrombomodulin in a vessel about the size of a coronary artery is 0.10.2 nM. Rapid clotting with thrombin occurs at concentrations of 10 nM. Thus, the concentration of regulatory proteins is insufficient to control the process. By contrast, in the microcirculation the concentration of thrombomodulin is 500 nM. Because the interaction with thrombomodulin is governed by a K_d of 0.5 nM,[111] virtually no free thrombin would exist in the microcirculation. This assumes that the concentration of the receptor is invariant throughout the vasculature. Certainly, thrombomodulin is present in capillaries, and the available evidence suggests that the concentration per cell is approximately constant.[112] [113] If one makes the same assumptions for other regulatory mechanisms of the endothelium, it would appear that the microcirculation may be a major site for the function of vascular heparins, prostacyclin, and plasminogen activator, as well as thrombomodulin.

The heparin and protein C systems do not work in isolation, but rather orchestrate a coordinated control over coagulation events (see Fig. 1041). AT III inhibits many factors in the presence of heparin, but the inactivation of platelet-bound factor Xa/factor Va complex is relatively resistant to the action of heparin and AT III. [114] This complex is also relatively resistant to inactivation by activated protein C. [29] [115] Protein S, however, is capable of at least partially overcoming this protection. [46] Thus, activated protein C may be required for factor Xa clearance by the AT III/heparin system. No comparable interplay has yet been elucidated between TFPI and these two anticoagulant systems.

POTENTIAL ROLE OF PROTEIN C IN PREVENTION OF THROMBOSIS AND DISSEMINATED INTRAVASCULAR COAGULATION

Clinical manifestations of impaired functions of the protein C system provide important clues that it is a major inhibitor of coagulation in the microcirculation. Homozygous protein C deficiency is usually manifested by neonatal purpura fulminans that results from microvascular thrombosis. This has been effectively treated with protein C concentrate,[116] establishing an unambiguous link between the deficiency state and the evolution of the skin lesions. A second clinical manifestation of protein C deficiency appears to be warfarin-induced skin necrosis. Skin lesions appear shortly after the onset of oral anticoagulant treatment at times when protein C levels are much lower than all the vitamin K-dependent proteins except factor VII.[52] The incidence of warfarin-induced skin necrosis is increased in heterozygous protein C-deficient individuals and some patients with protein S deficiency.[117] [118] [119] [120] [121] [122] Progression of the lesion can be halted by treatment with protein C concentrate,[120] [121] [122] further linking inhibition of protein C function during oral anticoagulant therapy to the skin necrosis. The basis for localization to the skin is unknown, but the skin is an inflammatory organ, perhaps linking the down-regulation of the protein C system due to inflammation in the skin to the necrotic lesions. Like the purpura fulminans commonly seen in homozygous protein C-deficient infants, warfarin skin necrosis involves microvascular thrombosis. Both observations are consistent with the fact that protein C activation occurs largely in the microcirculation.

Another setting in which skin necrosis can occur is in gram-negative sepsis. Because the protein C system seems to be a major target of inflammatory mediators with respect to the coagulation system, activated protein C might offer protection from gram-negative sepsis. In a baboon model of *Escherichia coli* sepsis, activated protein C blocked both the fibrinogen consumption and the organ damage that ultimately lead to death.[123] Although high levels of activated protein C were required, this approach holds promise as an adjunct therapy for disseminated intravascular coagulation. Despite the bacterial challenge to vascular integrity, no overt bleeding complications were observed with activated protein C treatment of the shock process.

Protein C is also consumed in patients during septic shock.[124] Some of these patients develop severe purpura lesions resembling those of homozygous protein C-deficient infants. It follows that protein C might effectively prevent these lesions from progressing. Based on limited clinical data, protein C may be effective in treating patients with very low protein C levels and septic shock.[125] [126] [127]

Activated protein C has also been studied for its ability to inhibit fibrinogen accretion on preformed jugular vein thrombi in dogs and rhesus monkeys.[128] Fibrin deposition was decreased approximately 4-fold in dogs and 10-fold in rhesus monkeys relative to a control. Despite the obvious influence on thrombus growth, bleeding at surgical sites was not significantly increased.

Activated protein C has also been tested in a baboon model of platelet-dependent thrombosis,[129] entailing examination of platelet deposition on prosthetic vascular grafts. Under the conditions used, infusion of activated protein C reduced platelet deposition by 70%. Thus, in this model, activated protein C was an effective antithrombotic agent and did not alter primary hemostasis. Because activated protein C is generated in response to thrombin/thrombomodulin interaction, it follows that systemic infusion of thrombin, which would lead to protein C activation, might actually retard platelet and fibrin formation on the vascular grafts. Indeed, infusion of thrombin into baboons at 1 or 2 U/kg/min reduced the platelet or fibrin deposition on the graft in a dose-dependent fashion.[130]

Ischemia is another potential setting in which protein C may play a role in preventing injury. Model studies in dogs and pigs demonstrate the rapid activation of protein C in ischemic areas in the heart following ligation of the coronary artery. Blocking this activation impairs recovery of coronary function.[131] Taken together, studies on protein C in the coronary circulation suggest that it might be important in preventing or limiting platelet deposition at sites of arterial injury and, if occlusion should occur, it could play important functions in keeping the coronary microcirculation patent.

Some of these activities are probably due to anti-inflammatory functions of activated protein C. The exact mechanisms by which the activated protein C may express anti-inflammatory activity is uncertain, but treatment of monocytes with activated protein C has been observed to dampen monocyte activation and secretion of the inflammatory cytokine, tumor necrosis factor-alpha.[132]

THE FUNCTION OF THE THROMBIN/ THROMBOMODULIN COMPLEX IN REGULATING FIBRINOLYSIS

Recently, a plasma procarboxypeptidase B, referred to as the thrombin activatable fibrinolysis inhibitor or TAFI has been identified. Thrombin can activate this protein slowly, but thrombomodulin enhances the activation of TAFI and protein C to similar degrees. [133] Once activated, TAFI can remove carboxy terminal Arg or Lys residues. When this occurs on fibrin, it renders the fibrin resistant to lysis. Carboxy terminal Arg residues are also critical to the activity of many potent mediators like complement C5a, an anaphylotoxin. What physiologic role TAFI plays in regulation remains somewhat unclear. It is known that during inflammation infusion of soluble thrombomodulin minimizes fibrin deposition and inflammatory organ injury, [134] [135] [136] [137] [138] [139] [140] suggesting that anticoagulant and anti-inflammatory effects of thrombomodulin are dominant in vivo.

GENETICS OF PROTEIN C

Recent advances in genetics have facilitated the analysis of the molecular basis of protein C deficiency. The protein C cDNA and genomic clones have been sequenced.[141] [142] [143] Heterozygous protein C-deficient patients usually have few clinical symptoms. In some families, however, the protein C deficiency clearly correlates with an increased risk of thrombosis. [144] [145] The genetic basis of these pedigrees has been determined and summarized in a comprehensive review. [144] More than 130 different pedigrees of families with protein C deficiency have now been characterized at the level of mutations within the gene. Of 134 apparently unrelated probands characterized, 99 had low expression levels and 18 had dysfunctional molecules with near-normal antigen levels. Single base-pair substitutions are the most common finding, with 67 different base-pair substitutions now characterized. Three mutations in the promoter have been detected. Deletions within the protein C gene appear to be relatively rare. The available mutations have not provided any striking insights into protein C function, and it is difficult to determine from the limited number of available sequences and patients whether certain mutations carry a greater risk of thrombosis than others.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

GENETICS OF PROTEIN S

The protein S gene has been sequenced and characterized, [146] [147] [148] revealing a complex gene containing 15 exons. The molecular basis of protein S-deficient patients has been determined in only a relatively few instances. This is in part because of the existence of a pseudogene for protein S that complicates the analysis. Furthermore, although protein S is clearly important for the anticoagulant pathway to function in vivo, the ability of protein S to stimulate anticoagulant activity in vitro in purified systems is modest, usually about two- to threefold. Finally, in at least some of the patients with low free protein S, the defect may lie in the C4b-BP. For these reasons, too few patients have been characterized to allow any clear picture of the molecular basis of protein S deficiency to emerge. The approaches to protein S gene analysis have been described by Schmeidel et al., [149] and a summary of all known genetic abnormalities has been published recently. [150]

GENETICS OF THROMBOMODULIN

The multiple functions of thrombomodulin suggest that deficiencies of the protein might be associated with thrombosis. Recently, clinical studies have suggested that a C/T dimorphism at position 1,418 resulting in Ala 455-Val substitution in the 6th EGF domain in thrombomodulin may be related to risk of premature myocardial infarction. Specifically, the frequency of the C allelle was significantly higher in the Swedish population surviving premature myocardial infarction. [151] Preliminary studies from this group indicate that mutations in the thrombomodulin gene may be present in about 5% of the patients with venous thrombosis. [151] The mutations were observed at many sites throughout the thrombomodulin gene. Analysis of the thrombomodulin gene mutations is simplified to some extent by the fact that the gene lacks introns.[62]

A recent study has examined mutations in the promoter region of thrombomodulin. Mutations in the 5 regulatory region of the thrombomodulin gene were observed in 5 of 100 patients with myocardial infarctions, compared to 1 in 100 in the control group. [152] This small study suggests that mutations in thrombomodulin expression are likely to contribute to arterial thrombosis.

GENETICS OF THE ENDOTHELIAL CELL PROTEIN C RECEPTOR

No information is known about abnormalities in this gene or the relationship between these possible abnormalities and human disease. It is known that like thrombomodulin, plasma levels of soluble EPCR rise dramatically in disease states associated with vascular injury such as lupus erythematosus. [153]

GENETICS OF FACTOR V AS THEY APPLY TO NATURAL ANTICOAGULANT MECHANISMS

Factor Va is a major target of activated protein C anticoagulant activity. To understand the genetics, one must appreciate some of the complications in factor Va inactivation. Factor Va consists of two subunits formed by activation of single-chain factor V. Factor Va is inactivated by proteolytic cleavage at Arg residues 306 and 506.[154] Both of these sites are located on the larger subunit, the heavy chain. Another cleavage at Arg 679 occurs but its physiologic significance is uncertain. Cleavage of Arg 506 is the most rapid and results in loss of most of the factor V activity in plasma assays. In purified systems, this form of factor Va retains some activity. Complete inactivation requires cleavage at Arg 306, and this is potently facilitated by membrane surfaces.

A common dimorphism exists in Caucasians in which Arg 506 is replaced by Gln because of a single base change (G to A) at position 1,691. This renders factor Va insensitive to cleavage at residue 506 and as a result, factor Va activity is about 10 times more stable in the presence of activated protein C. [155] This trait is usually referred to as factor V Leiden or APC resistance. Estimates suggest that the variant may be found in approximately 5% of the Caucasian population and is present with much higher frequency in patients with venous thrombosis, with estimates ranging from 2060% of these patients. [155]

The factor V Leiden trait is usually associated with venous thrombosis, but recent data suggest that the Leiden trait is a risk factor for myocardial infarction in patients who smoke.[156]

SUMMARY

Current information indicates that protein C, protein S, and thrombomodulin are potent inhibitors of the blood coagulation process. The system is down-regulated by inflammatory mediators. Total deficiencies of protein C and S are associated with severe thrombotic complications. Presumably, the down-regulation of the protein C pathway by inflammatory agents decreases the capacity of the system to redirect thrombin from a procoagulant enzyme into the initiator of a potent anticoagulant.

Chapter 105 - Clinical Evaluation of Hemorrhagic Disorders: The Bleeding History and Differential Diagnosis of Purpura

Barry S. Coller
Paul I. Schneiderman

INTRODUCTION

The initial evaluation of patients with hemorrhagic problems involves obtaining a detailed history of bleeding symptoms and analyzing any current hemorrhagic lesions, which are most often on the skin. This chapter focuses on the bleeding history and the differential diagnosis of purpuric skin lesions that may reflect an underlying hemorrhagic or nonhemorrhagic disorder.

THE BLEEDING HISTORY

The bleeding history forms the basis of the diagnosis and therapy of hemorrhagic disorders. In order to maximize its value, several basic principles of eliciting and interpreting this information deserve emphasis:

1. Many normal, healthy people consider their bleeding and bruising excessive. For example, using standardized, self-administered questionnaires, Miller et al. [1] found that 23% of the normal population had positive bleeding histories, and Wahlberg et al. [2] reported that a remarkable 65% of healthy women and 35% of healthy men answered Yes to the question: Do you suffer from a bleeding disorder? (Table 105-1). [2]
2. Patients with profound coagulation disorders invariably have dramatically abnormal bleeding histories, although surprisingly they may not volunteer the information unless specifically questioned.

3. Patients with mild to moderate abnormalities may not admit to having excessive bleeding symptoms or may not recognize subtle symptoms as abnormal, even though they are at risk of developing excessive bleeding if exposed to severe hemostatic challenges. In a study by Miller et al., [1] 35% of patients with heterozygous von Willebrand disease had negative bleeding histories, and in a study by Wahlberg et al., [2] approximately 54% of the men and 38% of the women with either von Willebrand disease or a platelet function defect failed to identify themselves as suffering from a bleeding disorder (Table 105-1). Identification of the group of patients with milder defects, and distinguishing them from the normal population, requires considerable skill and experience. In fact, given the low frequency of hemorrhagic disorders in the population and the high false-positive rate in the normal population, the task is truly formidable. For example, if one uses the values of 65% for the sensitivity of the bleeding history and 77% for its specificity derived from the study of Miller et al., [1] and assumes a prevalence of 10 patients with von Willebrand disease in a population of 100,000, [3] the predictive accuracy of a positive history is a dismal 0.03%. Thus, in a population of 100,000 people, there would be seven patients with von Willebrand disease with positive histories (65% of 10) to be differentiated from the 22,998 normal individuals with positive histories (23% of 99,990).
4. A search for objective confirmation of subjective symptoms provides important information in assessing the severity of the patients disorder. This is especially important when obtaining a bleeding history because some patients are extremely sensitive to even minor hemorrhagic problems, whereas others ignore major ones. Specific objective indicators are discussed later with each group of symptoms, but overall indicators include: (1) visits to other physicians for bleeding problems, along with any laboratory data obtained; (2) previous need for transfusion of whole blood, packed red blood cells, plasma, platelets, or coagulation factor concentrates; and (3) a history of documented anemia and/or physician-prescribed iron therapy.
5. A medication history is incomplete without specific questions concerning aspirin and other medications available without prescription that may affect platelet function, because patients may not recognize these agents as medications. Similarly, it is important to inquire about vitamin tablets that may contain vitamin K in patients taking oral anticoagulants.
6. Although self-administered questionnaires with Yes or No answers facilitate data collection and statistical analysis, obtaining the maximal amount of useful information requires a dialogue between patient and physician. This allows the physician to assess whether the patient truly understands what is being asked, to refine the questions in response to the initial answers, and to follow up on potentially important data that are revealed only as the discussion proceeds. In short, good history taking is not a passive process in which boxes are checked off in response to bland and ambiguous questions, but rather an extremely active process consisting of initial data gathering, hypothesis development, construction of questions to test the hypothesis, additional data gathering, and new hypothesis development. Moreover, it is an exhilarating endeavor in which the physician must meld his or her knowledge of science, medicine, and human behavior into a series of pointed questions that the patient can understand and respond to.
7. A constellation of hemorrhagic symptoms, rather than any single symptom, is most helpful in suggesting the etiology of the disorder. Thus, spontaneous hemarthroses and muscle hemorrhages are highly suggestive of severe hemophilia, whereas epistaxis, gingival bleeding, and menorrhagia are more commonly found in patients with thrombocytopenia, platelet disorders, or von Willebrand disease.
8. Excessive bruising and bleeding may be a manifestation of diseases of the blood vessel rather than diseases of coagulation or platelets. In patients with impressive bleeding histories, but no abnormalities in coagulation or platelets, the clinician must have a high index of suspicion for hereditary hemorrhagic telangiectasias, Cushing disease, scurvy, Ehlers-Danlos syndrome, and other systemic disorders. In patients whose hemorrhagic symptoms are confined to the skin, consideration must be given to a wide range of dermatologic disorders.
9. The diagnostic value of any single hemorrhagic symptom

varies according to the disorder. In studies of hemophilia carriers by Wahlberg et al. [4] and of patients with von Willebrand disease or platelet function abnormalities,[2] the individual questions were ranked on the basis of their ability to discriminate between patients and normals. Results from the hemophilia carrier study are shown in Table 105-2 . Because the patterns of hemorrhage differ in different hemorrhagic disorders, the diagnostic value of any given question will differ as well. For example, in the study on patients with von Willebrand disease and platelet disorders, [2] long bleeding after tooth extractions (Table 105-1) was a more powerful discriminator than it was in the study on hemophilia carriers [4] (Table 105-2).

10. A dietary history is important in patients taking oral anticoagulants because the patients intake of vitamin K will affect the response to the medication. In order to maintain a constant level of anticoagulation, the dietary intake of vitamin K must remain constant. [5] The absolute amount of vitamin K intake is less important, so it is reasonable to permit the patient free choice of diet with the proviso that, once selected, it remain reasonably constant. [6] If the patient wishes to change diets, it is important to monitor the level of anticoagulation more carefully. Patients should also be instructed that food additives, such as fish oils, may contain vitamin K. Patients who are not taking food by mouth are at particularly high risk of developing vitamin K deficiency, especially if they are also taking broad-spectrum antibiotics, since the latter decrease the vitamin K contribution from bacteria in the gastrointestinal tract. [7] [8] This combination of decreased oral intake and antibiotic therapy is quite common in patients with bowel disorders during the preoperative and postoperative periods. It is vital to recognize this scenario because vitamin K is required on a daily basis despite its fat solubility, and significant depression of coagulation factors can occur within only a few days.
11. Potentially confounding pharmacological and medical influences should be considered in evaluating the history. For example, because pregnancy and birth control pills can increase von Willebrand factor in some patients with the mild to moderate forms of the disease, this should be considered in assessing the bleeding history. The decrease in von Willebrand factor soon after delivery often leads to prolonged postpartum hemorrhage. Similarly, because the stress of surgery or pregnancy can lead to thrombocytopenia in type 2B von Willebrand diseases, bleeding may be especially severe at these times. [9] [10]
12. Assessing excessive bleeding in the newborn is especially difficult. For example, some neonates with Glanzmann thrombasthenia have only minimal symptoms at birth, and the symptoms of von Willebrand disease may be masked by an increase in von Willebrand factor as a result of the stress involved in the delivery. Similarly, a significant number of hemophilic neonates do not have hemorrhagic symptoms in the first weeks of life. Large cephalhematomas may be a result of birth trauma, but if they continue to progress after delivery, hemophilia or a vitamin K-dependent factor deficiency should be considered. Prolonged bleeding from the umbilical cord stump should raise the possibility of factor XIII deficiency or a fibrinogen abnormality (quantitative or qualitative).

TABLE 105-1 -- Self-administered Questionnaire for the Diagnosis of Hemorrhagic Disorders

Questions	Males		Females	
	Normals (N = 23)	Patients[a] (N = 24)	Normals (N = 20)	Patientsa[a] (N = 21)
Do you suffer from a bleeding disorder?	35[b]	46	65	62
Bleeding from the gums?	52	67	50	67
Long bleeding after tooth extraction?	4	21	10	24
Skin bleeding?	0	13	15	10
Long bleeding from small wounds?	13	25	10	10
Tendency to bruises?	22	25	55	62
Spontaneous bruises?	0	4	40	48
Nose bleeding?	57	63	85	57
Blood coughed up or vomited?	9	13	5	10
Metrorrhagia?			55	42
Muscle bleeding?	4	13	15	0
Blood in the urine?	0	8	10	10
Joint bleeding?	0	0	0	10
Blood in the stool?	13	8	5	10
Treated with vitamin K?	0	4	10	19
Treated with plasma or blood transfusion?	0	4	0	0

Adapted from Wahlberg et al.,[2] with permission.

[a] The patient group consisted of 16 individuals with von Willebrand disease, 27 individuals with a variety of qualitative platelet abnormalities (including aspirin-like defects (N = 9), isolated abnormal collagen-induced aggregation (N = 12), and isolated abnormal arachidonic acid-induced aggregation (N = 6), and 2 patients with antithrombin III deficiency.
[b] Percentage of normal patients compared with patients with von Willebrand disease, platelet abnormalities, or antithrombin III deficiency answering yes to indicated questons. Subjects were given a choice of yes, no, and dont know. The percentage answering no and dont know varied considerably from question to question.

TABLE 105-2 -- Discriminant Capacity of Questions in Distinguishing Between Normal Persons and Hemophilia Carriers

Questions	Sensitivity[a]	Specificity[b]	Difference Between Carriers and Noncarriers (*P*)
Tendency to bruises?	50	77	< 0.025
Metrorrhagia	44	81	< 0.025
Abnormal bleeding at delivery	38	97	< 0.005
Abnormal bleeding at operation	35	92	< 0.005
Tendency to nosebleeding?	32	87	< 0.05
Long bleeding after tooth extraction?	15	98	n.s.
Blood in the urine?	11	98	n.s.
Long bleeding from small wounds	8	96	n.s.
Blood in the stool?	3	100	n.s.

N.s., not significant.

[b] Percentage of negative responses among normals.

Documenting the History

Table 105-3 shows a bleeding history form based on the one in use at the State University of New York at Stony Brook and Mount Sinai Medical Center, New York. It is not self-administered by the patient, but rather is filled out by the physician during discussions with the patient. The use of the form ensures that the major symptoms are elicited and recorded in a standardized manner. The form itself is then made a part of the patients permanent record.

Epistaxis

Bleeding from the nose is one of the most common manifestations of platelet disorders and von Willebrand disease; it is also the most common symptom of hereditary hemorrhagic telangiectasias. However, it is important to note that a large fraction of the normal population has experienced one or more nosebleeds. Thus, when a group of normal subjects was presented with the question, Nose bleeding? on a self-administered questionnaire, 57% of the men and 85% of the women answered Yes (see Table 105-1). To obtain more meaningful data, it is important to inquire about the frequency of nosebleeds and whether the nose bleeding occurs spontaneously or only with trauma. The latter may not always be appreciated because some individuals habitually and subconsciously traumatize their mucous membranes when manually removing crusted secretions from the nose. If the bleeding is confined to a single nostril, it is more likely the result of a localized vascular abnormality than a systemic coagulopathy. In northern locales, nosebleeding from nonhematologic etiologies is more likely to occur in the dry winter months, especially if forced air heating systems that dry out the mucous membranes are used. It is also important to ascertain the effects of aging on epistaxis because many individuals with no discernible abnormalities will have childhood epistaxis that disappears after puberty, whereas patients with hereditary hemorrhagic telangiectasias usually suffer increasingly severe epistaxis with the onset of adulthood, middle age, and old age. The length of time for the bleeding to stop will give valuable insight into the severity of the episodes. Objective information can be obtained by inquiring whether the epistaxis was severe enough to require evaluation by a physician, and if so, whether packing, cautery, or transfusions were necessary to control the bleeding.

Gingival Hemorrhage

Bleeding from the gums is another very common symptom of platelet disorders and von Willebrand disease. In addition, it is often the first sign of hemostatic compromise in patients who

24. Family history of bleeding

Based on Coller and Hultin, unpublished data.

develop thrombocytopenia after chemotherapy. Interestingly, patients with long-standing disorders may not recognize that their gingival bleeding is excessive because they assume that everyone has gum bleeding every day. In fact, occasional, but not perennial, gum bleeding is very common among the normal population, with 52% of normal males and 50% of normal females answering Yes to the question, Bleeding from the gums? It is therefore important to establish how frequently the patients gum bleeding occurs and whether it is spontaneous, since the vast majority of normal persons will only experience gum bleeding after the trauma of tooth brushing. If spontaneous gum bleeding occurs during the night, patients may notice blood-tinged stains on their pillow cases. Daily gum bleeding with tooth brushing may or may not be abnormal, depending on whether the patient has gingival disease and whether a hard bristle or soft bristle tooth brush is used. Because routine tooth scaling performed by dental workers to remove plaque is a significant hemostatic challenge, it is useful to inquire whether the patient was told that he or she bled excessively after this procedure. In addition, some patients may have oral mucous membrane bleeding in the form of blood blisters as another manifestation of a hemorrhagic diathesis, most commonly due to severe thrombocytopenia; such blisters have a predilection to form at sites of tooth irregularities that may traumatize the inner surface of the cheek.

Skin Hemorrhage

Petechial lesions characteristically appear as crops or showers of lesions in dependent portions of the vasculature. However, the integrity of the microvasculature is dependent on a variety of vascular and extravascular factors, so it is not surprising that patients with similar platelet or coagulation disorders show considerable variability in the appearance of petechial lesions. When infants cry, they increase the pressure in the veins draining the face (as discussed later in this chapter) and this may be sufficient provocation to bring out petechial lesions in patients with platelet disorders such as Glanzmann thrombasthenia.

Bruising is one of the most difficult symptoms to evaluate because patients vary greatly in their recognition and response to the symptom. Thus, patients who always bruise excessively, even without trauma, may assume this is normal because they have experienced it all their lives, whereas normal individuals who bruise only rarely may grow inordinately concerned about a single large bruise associated with trauma. Bruising is more common in women than men. For example, 22% of normal men and 55% of normal women responded affirmatively to the question, Tendency to bruises? and none of the normal men but 40% of the normal women indicated that they had spontaneous bruises. It is necessary, therefore, to try to more clearly define the nature of the bruising in order to determine whether it is likely to be part of a hemorrhagic diathesis.

The dermatologic literature recognizes the female easy bruising syndrome (purpura simplex, discussed later in this chapter) as one in which women have excessive bruising in relationship to their menstrual cycle, although the point in the cycle when the bruising is excessive may vary from woman to woman. This diagnosis should be considered only after excluding other etiologies. If there are no underlying hematologic or nonhematologic causes, it is appropriate to reassure the patient that she is unlikely to be at risk of excessive hemorrhage, even with more severe hemostatic challenges such as surgery. It is inappropriate, however, to tell the patient that there is nothing wrong with her, because this can be misinterpreted to mean that the physician thinks the patient inappropriately sought medical attention for a trivial matter. These patients clearly do have an abnormality that can be quite frightening, even though at present the defect cannot be identified biochemically.

It is important to try to establish whether the patients hemorrhagic response is excessive when measured against the inciting trauma. Thus, spontaneous bruising is most likely to be pathologic, and the patient should be asked specifically whether bruises appear even without any recognized antecedent trauma. Unfortunately, patients vary significantly in appreciating when they have been traumatized. For example, mothers of children who are old enough to be physically active, but still young enough to be held in the mothers arms, often focus on other matters while holding the child and do not realize that they are being repeatedly kicked. Similarly, normal toddlers and youngsters who are physically active commonly have bruises on their legs and arms.

The location of a bruise may offer indirect evidence of its relationship to trauma. The vast majority of traumatic events occur on exposed sites on the arms and legs. Therefore, if the patient suffers repeated bruises on unexposed sites on the trunk or back, these are more likely to be either spontaneous or in response to minimal trauma. The size of the bruise may also give some indication of the extent of bruising. It is best to provide patients with size standards that they can understand, such as dime-sized, silver-dollar-sized, or as large as your palm. When assessing bruise size, it is important to remember that bruises often spread during the resolution phase. With severe bruises there may be hemorrhage into the bruise, resulting in very dark discoloration and the appearance of a raised knot in the center of the bruise; such bruises tend to be particularly painful.

The color of the bruise may also be quite significant. Fresh bruises associated with hemorrhagic phenomena tend to be dark purple, black-and-blue marks that evolve into shades of yellow-green as they resolve. By contrast, patients with senile purpura or Cushing syndrome commonly have bruises that are much redder in appearance. Because easy bruising may be the presenting symptom of Cushing syndrome, it is important to have a high index of suspicion for this disorder in younger patients whose bruises simulate the appearance of senile purpura.

Another color variant worth distinguishing is the jet black central area and violaceous-erythematous surrounding area characteristic of coumadin-induced skin necrosis (discussed later in this chapter). This thrombotic disorder, associated in some cases with protein C deficiency, tends to be most apparent in fatty tissues such as the breasts; it can be mistaken for a hemorrhagic abnormality because of the bruiselike quality of the lesion and the association with oral anticoagulant use.

Bruises usually take 10 days to 2 weeks to resolve, depending on the extent of the bruise. When patients indicate that their bruises take months to resolve or that they have required casting of a limb in order for the bruising to stop, consideration should be given to the poorly understood entity of psychogenic purpura (discussed later in this chapter).

Tooth Extractions

Bleeding in response to tooth extraction can provide extremely important information. The hemostatic challenge varies with the type of tooth removed; molar extractions are usually the severest tests of hemostasis. Objective information can be obtained about the duration and extent of bleeding by asking about the need to reconsult the dentist for packing, suturing, or even transfusion of blood products. A deep injection given to achieve anesthesia of the lower jaw by nerve block constitutes another important hemostatic challenge; hemorrhage from such an injection that extends down into the neck is especially important to note, since it may compromise the airway.

Bleeding from Minor Cuts

In our society, shaving nicks are the most common minor cuts suffered, and patients with platelet disorders or von Willebrand

disease usually bleed excessively from them. If a patient uses an electric razor or a depilatory instead of a razor blade, it is worthwhile asking whether a razor blade was ever used and, if so, why the switch was made. Although it may be difficult to obtain objective information about bleeding after razor nicks, it may be helpful to ask whether the patient delays leaving home in the morning because of persistent oozing from these wounds or whether the patient leaves home with small pieces of tissue paper still attached to the bleeding wounds. It is also useful to instruct patients that direct pressure for 5 minutes is usually much more effective than tissue paper, since rebleeding is very common when the paper is removed. Patients with purpura secondary to amyloidosis (discussed later in this chapter) may paradoxically choose to switch from an electric razor to a blade razor because the pressure of the electric razor causes more purpura than razor nicks.

Hemoptysis

Hemoptysis is virtually never the presenting symptom of a bleeding disorder and is rare even with serious bleeding disorders. Thus, a comprehensive search for an anatomic abnormality or an underlying infectious or neoplastic disease is required, even if the patient has a systemic coagulopathy. Patients with bleeding diatheses may, however, have blood-tinged sputum in association with acute respiratory tract infections. Occasionally, a patient with an upper respiratory tract infection associated with a postnasal drip may also complain of hemoptysis, even though the true source of blood is in the upper airway.

Bleeding from Major Trauma

In the absence of previous surgery, the extent of bleeding in response to major trauma furnishes the most reliable information about future hemostatic risk. In order to assess the appropriateness of the bleeding, the details of the injury must be determined. The need for sutures and/or transfusions to stop the bleeding provides objective information. Excessive bleeding due to thrombocytopenia or platelet dysfunction tends to occur immediately, whereas excessive bleeding due to coagulation abnormalities may be delayed. It is especially important to know whether aspirin or other antiplatelet agents were taken at the time of injury to alleviate pain.

Hematemesis

Like hemoptysis, hematemesis is virtually never the presenting symptom of a hemostatic disorder, and thus a search for an anatomic basis is mandatory. Hemostatic defects may, however, contribute significantly to the problem, as in patients with liver disease and esophageal varices, or patients with gastritis secondary to aspirin ingestion.

Hematuria

Urinary tract bleeding is also virtually never the first symptom of a hemostatic disorder and thus a full investigation to define an anatomic defect is required. Hemostatic defects may, however, exacerbate hematuria caused by other disorders; thus, patients with urinary tract infections that might ordinarily produce microscopic hematuria, may have gross hematuria. Normal subjects may also develop gross hematuria with urinary tract infections. Because women are much more likely to contract such infections, it may explain why none of the normal men but 10% of the normal women complained of blood in their urine in the study by Wahlberg et al. (see Table 105-1).[2] Even among patients with platelet disorders and von Willebrand disease, however, only 8% of the men and 10% of the women complained of hematuria (see Table 105-1).[2]

Hematochezia

Hemorrhoids are the most common cause of hematochezia, but more serious, less common, causes need to be excluded. In Wahlberg et al.s study, 13% of normal men and 5% of normal women complained of blood in the stool (see Table 105-1). [2] Although a systemic coagulopathy may exacerbate hematochezia, one should not ascribe the bleeding to the coagulopathy itself without extensive evaluation. von Willebrand disease, platelet abnormalities, and both inherited and acquired forms of angiodysplasia may all be associated with severe recurrent episodes of hematochezia and often the search for discrete bleeding sites is frustrating and inconclusive. Associations between von Willebrand disease and both angiodysplasia and hereditary hemorrhagic telangiectasias have been reported, [11] but it is possible that having von Willebrand disease merely makes it more likely that the vascular disorder will be diagnosed because the hemorrhage is more severe.

Melena

It is important to make certain that the patient understands precisely what is meant by the term melena, because many patients will answer Yes to a question about black stools when, on further questioning, it is clear that their stools are really dark brown. The black rubber tubing of a stethoscope is a good visual prompt for making this clear. Objective evidence of gastrointestinal hemorrhage can be obtained by explicitly asking whether the patients stool ever tested positive for occult blood and whether the patient ever underwent endoscopy. Like other sources of gastrointestinal bleeding, melena is virtually never the presenting symptom of an inherited hemostatic defect. Recurrent episodes of melena, like hematochezia, do occur, however, in patients with serious hemorrhagic abnormalities or angiodysplasia and on occasion may even be lethal. Objective data on previous hospitalizations, the results of endoscopic studies, and the need for blood replacement should also be obtained.

Central Nervous System Bleeding

Severe thrombocytopenia (<5,000 platelets/l) is associated with central nervous system hemorrhage, with both diffuse petechial lesions and gross hemorrhagic strokes. Hemophilia is also associated with spontaneous central nervous system hemorrhage, and it greatly increases the risk of serious hemorrhagic stroke with even minimal head trauma. It is of interest that spontaneous central nervous system hemorrhage is exceedingly rare in Glanzmann thrombasthenia. [12]

Venipuncture Site Bleeding

Patients with diffuse intravascular coagulation, hyperfibrinolysis, thrombocytopenia, or qualitative platelet disorders characteristically bleed for a long time after venipunctures, whereas patients with coagulation disorders do not. Delayed bleeding, however, may occur in the latter group.

Ophthalmologic Bleeding

Subconjunctival hemorrhages are associated with both platelet and coagulation abnormalities, especially in children when crying leads to increased venous pressure. Severe thrombocytopenia may lead to retinal hemorrhage if not effectively treated for several days to weeks. Orbital hemorrhage is more commonly associated with hemophilia than with platelet disorders.

Menses

Menorrhagia has been defined as loss of more than 80 ml of blood per cycle. [13] [14] Assessing the severity of menstrual flow

---

based on the patients subjective estimation or the number of sanitary napkins or tampons used is generally unreliable because women vary greatly in their perception of excessive bleeding and their hygienic practices. [15] It is usually more helpful to establish the number of days of heavy flow and the total number of days for an average menstrual period; if the former is greater than 3 and/or the latter is greater than 6 or 7, it is likely that the menstrual bleeding is excessive. It may also help to ascertain whether the bleeding is heavy enough to require especially large sanitary napkins or to require curtailment of ordinary activities. Objective data would include whether a physician (1) prescribed birth control pills to control the bleeding, (2) told the patient she was anemic, (3) prescribed iron, (4) performed a dilation and curettage (D&C) to assess the bleeding, (5) was forced by circumstances to perform an emergency hysterectomy to secure hemostasis, and/or (6) performed elective hysterectomy or radiation sterilization of the uterus as preventive measures. When menorrhagia is confirmed by direct measurement of menstrual blood loss, it is a valuable predictor of hemostatic disorders; in one study, six of 30 women with confirmed menorrhagia were thought to have mild von Willebrand disease, one

had a low value of factor X, two had elevated D-dimer levels, and five others had prolonged bleeding times thought to reflect platelet disorders. [13]

Childbirth

A detailed history of bleeding with each pregnancy should be obtained, including objective data regarding the need for transfusions, D& C, iron therapy, and/or hysterectomy. It is useful to ask specifically whether the patients doctor commented on the bleeding being excessive at delivery, even if none of the objective criteria were met. A history of recurrent spontaneous abortion may be part of the antiphospholipid antibody syndrome (discussed later in this chapter), which may include a lupus-like anticoagulant, anticardiolipin antibodies, and/or a false-positive serologic test for syphilis. The suspicion of this syndrome should be even greater if the recurrent spontaneous abortions occur after the first trimester. Recurrent spontaneous abortions have also been reported in association with abnormalities of fibrinogen,[16] presumably due to abnormal stability of placental attachment.

Hemarthroses

Joint bleeding is the hallmark of the hemophilias and is extremely rare in all other hemostatic defects except severe von Willebrand disease. Because joint bleeding is usually not associated with discoloration, patients may not understand that their symptoms are caused by hemorrhage. It is important, therefore, to inquire specifically about pain, swelling, and limitation of motion rather than merely asking about bleeding into the joints.

Operations

The details of each surgical procedure should be recorded, including any statements made by the surgeon about the extent of bleeding. In general, excessive bleeding resulting from coagulation abnormalities may be delayed in time for hours to a day or so, whereas excessive bleeding due to platelet disorders or thrombocytopenia usually occurs immediately. Emphasis should be placed on ascertaining whether any blood products were administered. Specific questioning about tonsillectomy and appendectomy may be required because some patients forget about these operations, especially if they were performed many years before. The hospital records should be secured because they may contain important clinical and laboratory data that the patient never knew or forgot. When hospital records are unavailable, it may help to ask how long the patient was hospitalized, since delayed discharge may have been due to excessive bleeding.

Circumcision

Congenital bleeding disorders, in particular the hemophilias, may cause excessive bleeding at circumcision as their first manifestation. Delayed bleeding from the umbilical cord stump or after circumcision is said to be particularly suggestive of factor XIII deficiency, but factor VIII or factor IX deficiency can also produce these symptoms.

Telangiectasias

Patients may manifest a wide range of telangiectatic lesions, ranging from pinpoint erythematous dots that blanch when compressed, to classic cherry angiomata ranging in size to up to several centimeters (see Differential Diagnosis). The vast majority of the otherwise normal population will demonstrate an increase in skin telangiectasias with aging associated with the development of papular cherry angiomata. The latter may have a distinctive blue appearance if present in the deeper layers of the skin. Patients with hereditary hemorrhagic telangiectasias usually have progressively more severe disease as they age. In fact, it is not at all clear what constitutes the minimal criteria for hereditary hemorrhagic telangiectasias; some otherwise normal persons with no clinical manifestations in their early years may develop easy bruising in association with skin telangiectasias in their later years. The classic hallmarks of hereditary hemorrhagic telangiectasias include epistaxis and tongue telangiectasias, but lesions may be present in virtually every organ, manifesting as space-occupying lesions, sources of bleeding, or sources of arteriovenous shunting. On physical examination, the lesions may be much more subtle than the florid examples found in most textbooks; a very careful search of the integument is necessary, focusing on the face, chest, shoulders, legs, and under the nails. Lesions are also commonly found on the vermilion border of the lips and under the tongue, even when the tip of the tongue is not involved. It is important to distinguish the lesions of hereditary hemorrhagic telangiectasias from the spider telangiectasias associated with liver disease. The latter have a more splotchy appearance, are concentrated on the shoulders, chest, and face, and have a more serpiginous quality.

Connective Tissue

If Ehlers-Danlos syndrome is considered in the differential diagnosis, it is useful to inquire specifically as to whether the patient was double-jointed as a child or had unusually distensible skin. More obvious abnormalities such as lens dislocations should be apparent. Questions regarding common skin manifestations of Cushing syndrome should also be posed, including rounded faces, purple striae, truncal obesity, or fat deposition in the back of the neck. Old photographs of the patient may be extremely helpful in deciding whether facial changes are new. The full differential diagnosis of disorders affecting the integrity of the blood vessel and supporting tissues is discussed in the following section.

Wound Healing

Although abnormal wound healing is not a common problem in hemostatic disorders, defects have been reported in association with factor XIII deficiency and fibrinogen abnormalities. Patients with Ehlers-Danlos syndrome and Cushing disease also have abnormal wound healing.

Medications

The dosage of each prescription and nonprescription drug taken by the patient should be recorded. Specific questions should cover aspirin and other antiplatelet agents, birth control pills, vitamins, and food supplements, because these may not be viewed as medications by the patient. Iron therapy in the past should also be noted since it may provide information on previous episodes of anemia due to blood loss.

Family History

A pedigree going back at least one or two generations should be recorded, with emphasis on hemorrhagic and/or thrombotic manifestations for each member. A specific question regarding parental consanguinity should be included since patients may not realize that this is important information. Details about the cause of death for each deceased individual should also be obtained.

Summary

Obtaining the details of the bleeding history requires insight into the mechanisms and manifestations of the different hemorrhagic disorders as well as an understanding of the patients perceptions of symptoms. Whenever possible, objective data should be obtained to provide a more comprehensive and credible picture. Although obtaining a complete bleeding history may seem tedious, it is well worth the effort, since the patients previous responses to hemostatic challenges are much better predictors of the patients likelihood of bleeding excessively in the future than are the patients routine laboratory values. In fact, in one study, routine screening assays of coagulation and platelets failed to detect any clinically significant abnormalities in more than 100 preoperative patients with normal bleeding histories. [9] Although the clinical value of routine laboratory tests for screening for coagulation abnormalities is still in dispute, this study certainly highlights the central role of the bleeding history in evaluating hemostatic risk.

DIFFERENTIAL DIAGNOSIS OF HEMORRHAGIC DERMATOLOGIC LESIONS

Skin hemorrhage is defined as the indiscriminate extravasation of blood cells out of the vasculature and into the skin, subcutaneous tissue, or both. The amount of blood leaking from the vessel determines the size of the lesion, with minute amounts producing pinpoint red lesions <2 mm in size (petechiae), and larger amounts producing purpuric lesions (2 mm-1 cm) or frank ecchymoses (>1 cm).[10] Despite these precise definitions, conventional usage often groups purpuric lesions and ecchymoses under the term *purpura*, and this general group of disorders, including petechiae, is often referred to as the purpuras. All these lesions can be readily differentiated from simple erythema and telangiectasias, in which the blood remains confined within the vasculature, because these latter lesions will blanch if direct pressure is applied to them. This can be easily demonstrated using a glass slide or the tip of a ballpoint pen with the penpoint in the retracted position. True purpura may demonstrate partial blanching with these maneuvers, but a nonblanchable component will remain. The color of the lesion depends on the size and location of the hemorrhage, as well as the time since the extravasation occurred. Initially, superficial lesions are bright red or deep red, and deeper lesions have a more purple appearance. With time, the lesions evolve into deep purple, brown, orange, or blue-green discolorations.

The general mechanisms by which extravasation of blood from the vasculature can occur are depicted schematically in Figure 105-1 . The integrity of the blood vessel depends on (1) the competence of the hemostatic mechanism to combat the basal level of ongoing vascular trauma, (2) the strength of the blood vessel itself and its surrounding tissues, and (3) the transmural pressure gradient tending to drive blood out of the vessel. Even if all these systems are functioning normally, however, serious trauma of diverse etiologies may be sufficient to cause hemorrhagic extravasation.

A classification of disorders producing skin hemorrhage is given in Table 105-4 .[16] [17] It is organized primarily according to etiology, but a division is made between lesions that are palpable and those that are not palpable because palpability can be readily determined at the bedside and thus has important practical significance in developing a differential diagnosis. Although the specific mechanism(s) producing palpability is still poorly understood, one hypothesis is that a lesion becomes palpable when a generalized increase in vascular permeability secondary to an inflammatory process results in marked extravasation of plasma proteins with the development of extravascular coagulation leading to fibrin deposition. Support for such a mechanism comes from studies showing that the palpable induration accompanying delayed hypersensitivity reactions can be diminished by administration of oral anticoagulants.[18] Alternatively, palpability may be secondary to extensive cellular infiltration as in certain inflammatory or malignant disorders.

Purpuric lesions secondary to hemostatic defects were described in the previous section. Among the nonhemostatic defects, we will first consider those producing nonpalpable lesions.

Nonpalpable Purpura

Increased Transmural Pressure

Acute

The clinical picture of minute petechiae of the face, especially the eyelids (Plate 105-1), neck, and upper chest may be seen after prolonged Valsalva maneuvers, coughing, vomiting, childbirth, or weight lifting.[19] [20] A similar syndrome can be found in newborns with umbilical cord strangulation. Lesions on the lower extremities, especially in the elderly, may be caused by acute venous stasis due to tight clothing or stockings. Occasionally, such dependent purpura may be palpable (Plate 105-2), even in the absence of microscopic inflammation.

Chronic

Chronic venous stasis of the lower extremity, resulting from either venous valvular incompetence or chronic use of tight-fitting garments, can convert subclinical insults of diverse etiologies into frank purpura. Thus, it is common, but not universal, for the first signs of petechiae resulting from hemostatic defects to appear at the ankles. Moreover, other common cutaneous disorders, such as drug rashes, contact dermatitis,[21] and sunburn often progress to become petechial and purpuric over the lower extremities after the first 24 hours. Chronic venous stasis accompanied by recurrent episodes of extravasation of red blood cells leads to the development of purpuric and yellow brown macules, with the latter resulting from the persistent presence of hemosiderin.

High Altitude

An increase in cutaneous petechiae has been noted in mountain climbers ascending higher than 3,800 m above sea level.[22] In this case, the mechanism for purpura may be an increase in transmural pressure due to reduced extravascular pressure rather than increased intravascular pressure.

Figure 105-1 Mechanism of nonpalpable purpura.

Decreased Mechanical Integrity of Microcirculation and Supporting Tissue

Senile Purpura

Chronic solar damage and decreased collagen, elastin, and ground substance resulting from aging may result in characteristic red to purple purpuric patches on the exterior surfaces of the forearms and hands (Plate 105-3). The skin accompanying solar purpura is particularly thin and lacks elasticity, making it highly susceptible to tears induced by shearing forces.[23] Owing to the decreased healing capacity that accompanies aging, the purpuric changes may take months to resolve. Interestingly, the syndromes of premature aging such as progeria, Werner syndrome, and acrogeria may all give rise to acral purpuric changes identical to those of senile purpura.[24]

Corticosteroid Excess

The patches of purpura in Cushing syndrome are classically described as appearing on the extensor surfaces of the forearms, but they may appear on both the flexor

and extensor aspects of both the upper and lower extremities. As with senile purpura, the lesions have a very characteristic bright red appearance, and the skin is fragile.[10] Shear stress is often the immediate cause of the purpura, and the patches may last for weeks to months. The use of potent fluorinated topical corticosteroids, either alone or with occlusive dressings, may result in cutaneous atrophy and purpura. Microscopically, there is a loss of dermal connective tissue with thinning of the epidermis.

Vitamin C Deficiency (Scurvy)

Follicular keratosis and perifollicular purpura with entrapped corkscrew hairs are the characteristic findings of vitamin C deficiency (Plate 105-4). Larger ecchymoses on the legs and mucous membranes are seen in more severe cases and may be produced by mild or inapparent trauma. Petechial lesions and hemorrhagic gingivitis or stomatitis may also occur.

Ehlers-Danlos Syndrome

Easy bruising is one of the most prominent features of Ehlers-Danlos syndrome types IV and V, but bruising may also be seen in the more common types I to III. Milder forms of Ehlers-Danlos syndrome that do not meet the diagnostic criteria for the more classic forms have been described, and mild to moderate bruising may be seen in these patients.[25] In evaluating patients for this heterogenous group of connective tissue disorders, it is important to assess the elasticity of the skin, the extensibility of the joints, and the presence of associated abnormalities such as high-arched palate and pectus excavatum.

Amyloid Infiltration of Blood Vessels

Cutaneous manifestations may be prominent in primary systemic amyloidosis associated with either mild plasmacytosis or multiple myeloma. Histologic examination demonstrates extensive infiltration of blood vessel walls with amyloid, resulting in increased vascular fragility. As a result, minimal trauma can produce hemorrhagic lesions ("pinch purpura"), and petechiae occur readily when there is an increase in transmural pressure

TABLE 105-4 -- Differential Diagnosis of Purpura

[a]May also have a papable purpuric component.
[b]May also have a nonpalpable purpuric component.
[c]May also have a purpuric component, either nonpalpable or palpable.

(e.g., after a Valsalva maneuver or after proctoscopy), especially when the amyloidosis involves the eyelids and face. Many different cutaneous lesions can occur, including brown- to tan-colored translucent papules, plaques, nodules, and bullae; these may all become hemorrhagic, either spontaneously or with minimal trauma. An enlarged tongue with peripheral indentations secondary to pressure from the adjacent teeth (scalloped tongue) is also frequently seen in patients demonstrating cutaneous amyloid lesions, whereas alopecia and nail changes are less common manifestations.

Colloid Milium

Colloid milium is a cutaneous disorder characterized clinically by translucent yellow papules and plaques, and histologically by the deposition of upper dermal amorphous eosinophilic material (similar in appearance to amyloid). Lesions of colloid milium may also become purpuric after minimal trauma. [26]

Female Easy Bruising Syndrome

The female predominance and the frequent association with phases of the menstrual cycle suggest that the female easy bruising syndrome (purpura simplex) is caused by hormonal effects on the blood vessel and/or its surrounding tissues. [10] Concomitant use of nonsteroidal anti-inflammatory drugs (NSAIDs) may inhibit platelet function and contribute to the severity of the symptoms. Patients complain of frequent purpuric and ecchymotic lesions with minimal trauma. As discussed in the section on history taking, patients with this entity do not appear to be at increased risk of hemorrhage from more severe hemostatic challenges such as surgery.

Administration of Lorenzos Oil

Purpura from a defect in vessel wall function has been seen in a patient receiving Lorenzos oil (glycerol trioleate and glycerol trierucate). [27]

Trauma to Blood Vessels

Physical

Any form of injury, if severe enough, can damage blood vessels sufficiently to cause skin hemorrhage. It is thus important to

know in detail the extent of the injury before deciding whether the skin hemorrhage is consistent with the magnitude of the trauma. [19] Traumatic lesions usually have well-defined margins. Depending on the etiology (e.g., occupational, accidental, recreational), the pattern may be annular or circumferential (e.g., baseball injury), linear or loop-shaped (e.g., child beating), or subungal (e.g., running shoe injury) (Fig. 105-2). The lesions associated with child abuse often include both cutaneous purpura and petechiae of the bulbar and palpebral conjunctivae, the latter reflecting strangulation, smothering, or both. [28] [29] Patients with factitial, or self-inflicted, purpura usually have medium- to large-sized lesions on the lower extremities, but other sites may be involved as well. They characteristically express indifference to the bruises. Purpura also occurs after use of the 585 nm pulsed dye laser. [30]

Ultraviolet Radiation

Acute, severe sunburn can have a petechial component if the damage is severe enough. Patients have been described who developed petechial eruptions on the legs and trunk after only brief exposures to natural sunlight (solar purpura). It was hypothesized that their skin is particularly sensitive to long-wave ultraviolet light. [31] [32]

Infections

Bacterial, viral, rickettsial, protozoal, and parasitic infections may all produce purpura as a primary clinical manifestation. [33] [34] The pathogenesis of infectious purpura is often complex, and may include direct vascular invasion by the organism, diffuse intravascular coagulation, immune complex vasculitis, septic emboli, and/or direct toxic effects on the vasculature. Although characteristic patterns of purpura have been described for the different agents, overlap between the patterns is quite common.

One particular pattern is papular-purpuric gloves and socks syndrome. This disorder may be seen in association with parvovirus B19, measles virus, [35] cytomegalovirus, or Coxsackie B6 infections. [36]

Gram-negative sepsis with *Pseudomonas* sp., *Klebsiella* sp., or *Escherichia coli* produces characteristic lesions of ecthyma gangrenosum, which begin as plaquelike areas of edema and erythema with subsequent nodule formation surmounted by irregular purpura (Plate 105-5). The central area of purpura is often bullous, and is surrounded by concentric areas of normal skin and a thin band of erythema. Erosions and ulceration may occur. Lesions may be single or multiple, and the palms and

soles may occasionally be involved.

Meningococcemia initially produces erythematous papules, but these soon evolve into stellate purple to slate-gray purpuric lesions (Plate 105-6). The combination of purulent meningitis and petechiae strongly suggests that *Neisseria meningitides* is the etiologic agent. [37] Acrocyanosis and symmetric peripheral gangrene

Figure 105-2 "Tennis toe" subungual hemorrhage.

may ensue and are thought to be due to disseminated intravascular coagulation (DIC). The purpura of meningococcemia may be due to direct vascular invasion by the organism or an endotoxin-induced Shwartzman reaction. In chronic intermittent meningococcemia an immune complex dermatitis may develop, characterized by hemorrhagic papulovesicles over the joints.

The classic rash of scarlet fever characteristically features linear purpuric lines in the skin folds (Pastias lines). Streptococcal pharyngitis has been reported to produce perioral, neck, and truncal petechiae in 2% of patients.

Bacterial sepsis, including acute and subacute bacterial endocarditis due to gram-positive or gram-negative organisms, may cause purpuric macules, papules, hemorrhagic bullae, erosions, and/or ulcers (Plate 105-7). The first manifestations of pneumococcal sepsis in asplenic patients may be facial petechiae and purpura, accompanied by acral cyanosis or livedo reticularis. [38] [39] Although splinter hemorrhages of the nails occur in subacute bacterial endocarditis, they may also be seen in normal individuals following trauma, or in patients with trichinosis, peptic ulceration, hypertension, malignancies, severe rheumatoid arthritis, and a number of dermatologic conditions; thus, the specificity of splinter hemorrhages as a sign of endocarditis is quite limited. [40] [41]

Rickettsial infections, including Rocky Mountain spotted fever (Plate 105-8) and epidemic typhus, typically produce an array of cutaneous changes ranging from urticarial macules to petechiae, ecchymoses, and areas of hemorrhagic necrosis. Although the characteristic lesion of Lyme borreliosis is a non-purpuric annular expanding plaque (erythema migrans), the central aspect of this lesion may contain a purpuric macule, papule, or a hemorrhagic bulla.

Patients with either disseminated fungal infections (e.g., cryptococcoses, zygomycosis, candidemia, alternariosis, histoplasmosis) [42] [43] or locally invasive fungal diseases (e.g., mucomycosis) may have necrosis, purpura, and/or petechiae early in the course of the illness. [44] Viral infections may have primary purpuric eruptions as their presenting manifestations. Human parvovirus B19 infection has been described as demonstrating a petechial or confluent purpuric rash on the buttocks, axilla, and/or chest. [45]

Purpura may be the initial manifestation of parasitic infections, especially in the immunocompromised host. Migration of filariform larvae of *Strongyloides stercoralis* typically produces rapidly progressive abdominal thumbprint linear and reticulated purpura on a background of petechiae; the periumbilical region is usually most severely affected. [3] [46] Disseminated *Pneumoncystis carinii* infections in patients with AIDS may demonstrate purpuric papules and nodules that resemble the lesions of Kaposi sarcoma (discussed later in this chapter). [47]

Embolic

Atheroemboli with prominent cholesterol crystals, usually originating from atherosclerotic lesions in the aorta, produce a constellation of cutaneous findings, including acral petechiae and purpura, livedo reticularis, nodules, unilateral peripheral ulcers, and bilateral cyanosis and gangrene. [48] Distal pulses are present and occasionally the emboli can actually be seen in the retinal circulation as refractile interruptions in the column of arterial blood. The syndrome is seen most frequently in older men on anticoagulation or after vascular repair procedures. A high predilection for the pancreas makes elevations of serum amylase a common accompanying laboratory finding. Since this syndrome is often undiagnosed, it is important to have a high index of suspicion, especially in older men with livedo reticularis.

Fat embolism may occur 2 to 3 days after severe trauma. The initial findings include upper extremity, thoracic, and/or conjunctival

petechiae. The full syndrome consists of hyperthermia, respiratory distress, retinal fat emboli, neurologic symptoms, and pulmonary infiltrates. [49] [50]

Allergic and/or Inflammatory

In serum sickness, morbilliform or urticarial eruptions are the most common manifestations. Linear or serpiginous bands of erythema along the sides of the hands and feet may be seen at the margins of the palmar or plantar surfaces. [45] If the patients are thrombocytopenic, purpura usually appears within these linear bands. The eruption often heralds the onset of the syndrome. Immunologic evaluation of biopsy material often demonstrates immunoglobulin and complement deposits.

The pigmented purpuric eruptions, [47] [51] [52] [53] including Schamberg disease, Majocchi disease, and others, are a poorly understood group of disorders characterized by petechiae and purpura on a background of light to dark brown or orange hyperpigmentation (Plates 105-9 , 105-10 , and 105-11); telangiectasias may or may not be present. Occasionally scaling, lichenification, and atrophy are seen. These eruptions characteristically involve the lower extremities, but they may also be seen on either the arms or trunk, or both; on occasion, they may even be found on the palms and soles. [54] They are not associated with any systemic manifestations. There is a great deal of clinical overlap between these disorders, and an individual patient may demonstrate features of more than one pigmented purpuric eruption. Histologically, extravasation of red blood cells, hemosiderin deposits within macrophages, and a perivascular lymphohistiocytic infiltrate with endothelial cell swelling are seen. The pathogenesis of these disorders is not established, but suggested mechanisms include increased capillary fragility with rupture of capillaries in the papillary dermis, aneurysmal dilation of the microvasculature, and abnormal cellular immune responses to an unknown antigen. [55] Recently, cutaneous T-cell lymphoma was reported to produce lesions simulating those found with the pigmented purpuric eruptions [56] and the differential diagnosis of these disorders should include this possibility.

Pyoderma Gangrenosum

Pyoderma gangrenosum is a destructive, necrotizing ulceration of the skin presenting as a nodule, pustule, or hemorrhagic bulla. The lesions occur on the calves, thighs, buttocks, and face. Pyoderma gangrenosum occurs in association with inflammatory bowel disease, rheumatoid arthritis, gammopathies, blood dyscrasias, leukemia, and lymphoma. A superficial hemorrhagic bullous form occurs with acute leukemia or other myeloproliferative disorders.

Contact Dermatitis

Allergic or irritant contact dermatitis to clothing, rubber, woolen garments, elastic, benzoyl peroxide, dyes, balsam of Peru, [57] Emla[58] or detergent whiteners may result in purpuric eruptions that may simulate the pigmented purpuric eruptions. [59]

Neoplastic

Infiltration of the skin in the histiocytosis X group of disorders can result in the development of a papular and crusted dermatitis of the scalp and intertriginous areas (Plates 10512 and 10513). These lesions can have both petechial and purpuric features. As indicated previously, cutaneous T-cell lymphoma may produce cutaneous lesions similar to those seen in the pigmented purpuric eruptions. Similarly, skin infiltrations in patients with leukemias, lymphomas, and plasma cell disorders can produce red to purple papules that may simulate purpura. [60]

Drug-Related

Petechial and purpuric reactions can be observed after administration of a variety of drugs, including aspirin, alclofenac, allopurinol, atropine, belladonna, bismuth, carbamazepine, carbimazol, carbromal, chloral hydrate, chlordiazepoxide, cimetidine, desipramine, disopytramide, doxepin, fenbufen, gold salts, indomethacin, iodides, isoniazide, meclofenamate sodium, mefenamic acid, menthol, mercury, morphine, naproxen, nitrofurantoin, penicillamine, penicillin, phenacetin, phenytoin, piperazine, piroxicam, pyrazolon derivatives, quinine, quinidine, sulfonamides, sulindac, thiouracils, and tolmetin. [61] The mechanism for at least some of these reactions is presumed to be allergic hypersensitivity.

Metabolic

Relapsing diffuse petechiae on the trunk and extremities were observed in four infants with ethylmalonic aciduria, a metabolic disorder associated with acral cyanosis, chronic diarrhea, and progressive central nervous system dysfunction. [62]

Thrombotic

Diffuse (disseminated) intravascular coagulation (DIC) may result from a variety of different insults, many of which have the common denominator of producing hypotension (see Chap. 117). Because endothelial cells are active metabolically, hypotension can produce widespread ischemia and endothelial cell damage. This damage can expose subendothelial surfaces, which in turn can initiate an uncontrolled thrombotic response that ultimately selectively depletes coagulation factors and platelets. Alternative mechanisms for initiating the process involve the effects of endotoxin and other mediators such as interleukin 1 (IL-1) and tumor necrosis factor (TNF) on increasing endothelial cell and monocyte procoagulant activity. This is achieved, at least in part, by an induction of tissue factor expression, an increase in tissue plasminogen activator inhibitor-1 (PAI-1) synthesis, and a decrease in the production of thrombomodulin and tissue plasminogen activator. [63] [64] Because there is a potential for both thrombotic and hemorrhagic manifestations, it is not surprising that the skin manifestations are diverse. The most common skin findings of diffuse intravascular coagulation are acral cyanosis (Plate 105-14) with variably associated petechial, purpuric, and ecchymotic lesions (Fig. 105-3). The competence of the fibrinolytic system to digest deposited fibrin determines the extent of tissue compromise. In the most severe cases, hemorrhagic gangrene of fingers and toes can occur. [33] The presence of peripheral gangrene may be an important consideration in the often difficult decision as to whether heparin is indicated in treating the syndrome.

Coumarin Necrosis

This process affects 0.010.1% of all patients receiving coumarin and appears from day 2 to day 14 (usually days 36) of coumarin therapy. [65] Patients who are deficient in protein C appear to be at high risk because the disorder is thought to result from a temporary imbalance in the reduction of the procoagulant vitamin K factors and the anticoagulant vitamin K factors. [66] [67] [68] [69] Coumarin necrosis begins suddenly as painful erythematous patches (Plate 105-15) that become edematous and rapidly progress to irregularly hemorrhagic and necrotic plaques, nodules, and bullae; eventually large tumid indurations and infarcts occur [70] with eschar formation and sloughing (Plate 105-16). [71] This syndrome appears to be more common in women than men and the lesions often develop in the skin overlying fatty areas, such as the buttocks, thighs, and breasts. Men can also be affected, and more acral lesions can occur, as witnessed by the reports of penile involvement. [65] Lesions may be symmetric and widely distributed; on occasion, they may be severe enough to require surgical intervention. [72] Histologically, fibrin and platelet thrombi are observed in the dermal and subcutaneous vasculature. In one study, TNF was identified in the lesions and endothelial cell adhesion molecules were upregulated. [73] The lesions

Figure 105-3 Disseminated intravascular coagulation.

of coumarin necrosis can be differentiated from hemorrhagic lesions caused by excessive coumarin administration by the presence of the nearly black eschar in the center of the necrotic zone and by histologic examination. Ancillary differentiating points in favor of coumarin necrosis include the female sex predilection, the absence of an excessively prolonged prothrombin time, and the relationship to the onset of therapy. The management of this disorder and its prevention are discussed in Chapter 121 .

Protein C or Protein S Deficiency

Congenital, homozygous protein C deficiency has been reported to produce diffuse purpuric and ecchymotic skin lesions suggestive of chronic DIC and purpura fulminans. Widespread venous thrombosis usually accompanies the skin lesions. Fortunately, both the skin lesions and venous thrombosis respond rapidly to therapy with plasma. Long-term therapy may require the careful introduction of oral anticoagulants. [74] Replacement therapy with protein C concentrate has been successful. [75] Cutaneous necrosis similar to coumarin necrosis has also been reported in a patient with acquired protein C deficiency due to the development of an immunoglobulin inhibitor. [76] Post-infectious purpura fulminans has also been reported in association with production of anti-protein S IgG and IgM antibodies. [77] [78]

Purpura Fulminans

Purpura fulminans defines a syndrome of DIC manifested by massive widespread ecchymoses, especially on the upper and lower extremities, abdomen, thighs, and buttocks (Plate 105-17). [79] [80] It may be triggered by any of the infectious agents discussed previously [33] [81] or may occur without antecedent infections. Homozygous protein C deficiency can produce essentially the same pattern in the neonate. [69] [82] In addition, resistance to activated protein C caused by a single point mutation of factor V (factor V Leiden) has been shown to result in neonatal purpura fulminans. [83] Clinically, the syndrome of purpura fulminans is most often characterized by symmetric, hemorrhagic necrosis and bulla formation. The lesions enlarge with time and progress to gangrene, often with autoamputation of the digits. Associated symptoms and signs include prostration, fever, and edema of the extremities; death is not uncommon. Histopathology reveals hemorrhagic necrosis of the dermis with thromboses of the capillaries and small blood vessels. Fibrinoid necrosis of vessel walls and perivascular granulocytic infiltrates have been described.

Paroxysmal Nocturnal Hemoglobinuria

Occasional patients with paroxysmal noctural hemoglobinuria develop erythematous patches with dusky centers that may enlarge to form painful plaques of erythema with central necrosis. [84] Hemorrhagic bullae, ulcerations, petechiae, ecchymoses, palpable purpura, and eschar formation may also develop. Histologically, intravascular thrombi are seen in the absence of vasculitis.

Phospholipid Antibody Syndrome

The phospholipid antibody syndrome is characterized by the variable presence of antibodies to phospholipid-protein complexes [including cardiolipin-containing complexes and those used in coagulation assays (lupus anticoagulant)], in association with a tendency to thrombosis, thrombocytopenia, and fetal wastage (see Chaps. 120 and 129). Cutaneous manifestations are present in only a minority of patients, but they may include widespread cutaneous necrosis with thrombi within the microvasculature (similar to that seen in purpura fulminans), livedo reticularis, leg ulcers, painful skin nodules, subungual splinter hemorrhages, and acral red-to-purple macules. [85]

Unknown Origin

Psychogenic Purpura

Psychogenic purpura is the term given to a poorly understood disorder of severe, recurrent ecchymoses affecting women almost exclusively (Plate 105-18). [86] [87] [88] [89] Patients usually experience pain before or at the time the bruise appears, and the bruising is often so extensive that the patient loses the use of the limb during the healing process. In the most severe cases, the patient can become bedridden. In desperation, physicians sometimes cast the affected limb(s), and this usually succeeds in facilitating healing, but at the price of muscle atrophy. Attempts to identify the etiology have been unsuccessful. Early studies implicated allergic reactions

to blood cells or DNA, but these hypotheses are no longer fully accepted. Localized neurogenic release of fibrinolytic activity in the skin has been proposed as a mechanism to link the psychological and dermal components of the syndrome.[90] Psychological profiles of patients with this disorder have demonstrated widespread abnormalities,[87] [91] raising the possibility of self-inflicted trauma, a view supported by the healing that usually accompanies casting. It is far from certain,

however, that this is the cause in all cases, so it is best to continue to classify the etiology as unknown.

Palpable Purpura

Dysproteinemias

Cryoglobulinemia

Cryoglobulins represent cold-precipitable proteins found in plasma or serum. Single-component cryoglobulins may be IgG, IgM, or IgA. [92] These cryoproteins may be idiopathic in origin or may occur with Waldenström macroglobulinemia, myeloma, lymphoma, or benign paraproteinemias. Mixed cryoglobulins are usually composed of a rheumatoid factor IgM complexed with a monoclonal or polyclonal IgG; less frequently, IgG or IgA antibodies may have anti-IgG activity. Mixed cryoglobulins may be seen as an idiopathic phenomenon or in association with a wide variety of subacute and chronic disorders, most particularly hepatitis C. The immune complex is composed of hepatitis C virus (HCV), anti-HCV, and IgA-type rheumatoid factor.[93] Clinical lesions of cryoglobulinemia include the intermittent appearance of acral hemorrhagic necrosis (Fig. 105-4), palpable purpura, livedo reticularis, subungual hemorrhage (Plate 105-19), urticaria, leg ulcerations, Raynaud phenomenon, and erythema multiforme-like lesions.[94] [95] [96] Weakness and arthralgias are prominent noncutaneous symptoms. Monoclonal cryoglobulins may crystallize and result in livedo reticularis with purpuric necrosis, destructive arthropathy, and malignant hypertension (cryocrystalglobulinemia). [97] [98]

Cryofibrinogenemia indicates the presence in the blood of an abnormal cold-precipitable protein indistinguishable from fibrinogen or fibrin. Cutaneous manifestations include sensitivity to cold, purpura, livedo reticularis, cyanosis, ulcerations, erythema, hematoma, urticaria, gangrene, acral blisters, and Raynaud phenomenon. [99] Essential (primary) cryofibrinogenemia occurs in association with DIC. Secondary cryofibrinogenemia may occur with neoplastic, thromboembolic, or infectious disorders.

Hyperglobulinemic Purpura of Waldenström

Macular and papular, discrete or confluent purpuric lesions with hemosiderin staining are the classic cutaneous findings of benign hyperglobulinemic purpura (Plate 105-20), a syndrome that most often occurs on the legs of women between 20 and 40 years of age.[53] [100] Precipitating factors include increased hydrostatic pressure, hyperviscosity, and low temperatures.[101] [102] The polyclonal increase in globulins (mostly IgG 1) can be associated with Sjögren syndrome, systemic lupus erythematosus

Figure 105-4 Cryoglobulins.

(SLE), polymyositis, rheumatoid arthritis, myeloma, thymoma, sarcoid, or multiple sclerosis. Lesions may be recurrent and the eruption must be differentiated from the pigmented purpuric eruptions. Histologically, acute inflammatory cells, red blood cells, and arteriolar necrosis predominate. There is also a decrease in IgG_2.[103] Many patients have antibodies to Ro/SSA.[104] Circulating complexes containing IgG anti-IgG and/or IgA anti-IgG have been detected. [94]

Cutaneous Vasculitis

Patients with collagen vascular diseases as well as those with systemic large- and small-vessel vasculitis (including hypocomplementemic vasculitis, polyarteritis nodosa, microscopic polyarteritis, Wegener granulomatosis, Behçet disease, Churg-Strauss angiitis, rheumatoid vasculitis, or relapsing polychondritis) may have an array of vasculitic purpuric lesions, including petechiae, papules, ecchymoses, hemorrhagic bullae, splinter hemorrhages, and periungual hemorrhages [94] [105] [106] [107] [108] [109] [110] (Plates 105-21 and 105-22). Nonpurpuric cutaneous lesions may also be present, including ulcers, subcutaneous nodules, livedo reticularis, erythema, erythematous plaques, and telangiectasias.

Drugs and infections are common causes of small vessel vasculitis. Bacterial infections with staphylococci, streptococci, mycobacterium leprae, and others are often associated with vasculitic lesions. Viruses causing vasculitis include HIV, hepatitis B, and hepatitis C. The tetrad of necrotizing vasculitis, chronic hepatitis C infection, hypo-complementemia, and cryoglobulinemia is a late manifestation of hepatitis C infection. [111]

Alpha-1 antitrypsin deficiency has been described in association with manifestations of systemic vasculitis, including cutaneous involvement resembling that oberved in microscopic polyarteritis, Wegener granulomatosis, and Henoch-Schönlein purpura. [112]

Paraneoplastic vasculitis[113] [114] [115] describes a syndrome of petechiae, palpable purpura, urticaria, maculopapular lesions, leg ulcers, and/or erythema multiforme seen in association with hairy cell leukemia and other lympho- and myeloproliferative disorders. Intense pruritus or dysesthesias are prominent symptoms. [116] In some cases, the cutaneous lesions may precede the diagnosis of the malignancy or signal the recurrence of the malignancy. Carcinomas of the breast, lung, colon, cervix, prostate, and kidney have all been reported in association with cutaneous vasculitis. [115] [117]

Henoch-Schönlein purpura is a leukocytoclastic vasculitis that usually affects children. [99] [118] [119] Palpable purpuric lesions, abdominal pain, and arthritis of the knees and ankles are common findings, but other organs may be involved as well. Acute and chronic renal disease is an important, associated finding. Renal involvement in adults is more common but the prognosis in children and adults is the same.[120] There is no sex predilection, but there is a seasonal increase during the winter months. Several precipitating factors have been implicated, including infections, environmental chemicals, toxins, insect bites, physical trauma, complement component C2 deficiency, familial Mediterranean fever[121] and malignancies. The genetic predisposition for development of Henoch-Schönlein purpura may be an increased frequency of DQA1* 0301 as well as complement 4 (C4) gene deletion.[122] Clinical presentations include the explosive onset over the legs and buttocks of urticarial papules and plaques, with or without purpura (Plate 105-23), palpable purpura, or hemorrhagic vesicles or bullae; larger stellate, reticulate, and necrotic lesions may also occur (Plate 105-24). Occasionally, ecchymotic lesions resembling child abuse may be present, but unlike the latter, the lesions of Henoch-Schönlein purpura are usually strikingly symmetrical. Henoch-Schönlein purpura is thought to be an immune complex disease, with 50% of patients producing IgA rheumatoid factor.[123] IgA-containing immune

complexes have been detected, especially during the early phases of the syndrome. [123] [124] [125] Increased levels of von Willebrand factor, an indicator of endothelial cell damage, decreased levels of factor XIII, and increased excretion of TNF were found in a significant number of patients with Henoch-Schönlein purpura. [126]

Acute hemorrhagic edema of infancy occurs in children between the ages of 4 months and 2 years who demonstrate fever, tender iris-like or medallion-like large purpuric cutaneous lesions, and edema.[98] The lesions occur on the cheeks, eyelids, ears, extremities, and genitalia, and must be differentiated from the cutaneous findings of child abuse, Sweet syndrome, Kawasaki disease, septic emboli, drug eruption, meningococcemia, and hemorrhagic erythema multiforme.

Approximately 10% of adults with leukocytoclastic vasculitis have been reported to demonstrate livedoid superficial plaques, with multifocal areas of hemorrhage or necrosis, and reticulate margins connecting adjacent lesions. [127] These lesions contain IgA and C3 deposits in the blood vessel walls. Smooth-margined purpuric papules with uniform hemorrhage may also show IgA, but more frequently demonstrate IgG or IgM vascular deposits.

Long-distance walkers may also develop purpuric lesions of leukocytoclastic vasculitis on the lower legs. [128]

Primary Cutaneous Diseases

Insect bites (especially blackfly bites), dermatitis herpetiformis, pityriasis rosea, and other primary cutaneous disorders may present with purpuric papules and vesicles mimicking septic and vasculitic lesions.

Nonpurpuric Disorders Simulating Purpura

Disorders with Telangiectasias

Cherry angiomas are the common papular, brightly erythematous lesions seen on the trunk and extremities of middle-aged and older men and women. The lesions are progressive with age and may produce easy bruising because they tend to bleed excessively with trauma. Pinpoint or smaller cherry angiomas may be present in large numbers and may mimic a petechial eruption. Differentiating this very common disorder from hereditary hemorrhagic telangiectasias may be difficult, and these lesions may, in fact, be part of the continuum of that disorder.

Hereditary hemorrhagic telangiectasia (HHT) is an autosomal dominant disorder with an estimated frequency of 1 in 50,000 manifested by widespread dermal, mucosal, and visceral telangiectasias. [129] One form of the disorder, characterized by a high frequency of pulmonary arteriovenous malformations, has been identified as being due to abnormalities in the endothelial protein endoglin on chromosome 9, which appears to mediate the response of endothelial cells to members of the transforming growth factor (TGF-) family. A number of the mutations involve the production of truncated forms of the receptor, opening up the possibility of a dominant negative mechanism to explain the autosomal dominant inheritance pattern. [130] Another form of the disease has been linked to a region of chromosome 3 containing the TGF- II receptor and a third form has been linked to the activin receptor-like kinase 1 gene on chromosome 12, which is a cell surface receptor for the TGF- superfamily of ligands. [131] [132] Clinically, venous lakes and papular, punctate, mat-like, and linear telangiectasias appear on all areas of the skin and mucous membranes, with a predominance of lesions under the tongue and on the face, lips (Plate 105-25), perioral region, tongue, nasal mucosa, fingertips, toes, and trunk. [133] Epistaxis is a nearly universal finding in this disorder, with symptoms almost always becoming worse with age. Thus the severity of the disorder can often be gauged by the age at which the nosebleeds begin, with the most severely affected patients developing recurrent epistaxis during childhood. Cutaneous changes usually begin at puberty and progress throughout life. Bleeding can occur in virtually every organ, with gastrointestinal, oral, and urogenital sites most common. In the gastrointestinal tract, the stomach and duodenum are more common sites of bleeding than the colon. Hepatic and splenic arteriovenous fistulae, as well as intracranial, aortic, and splenic aneurysms may occur; pulmonary arteriovenous fistulae are associated with oxygen desaturation, hemoptysis, hemothorax, brain abscess, and cerebral ischemia resulting from paradoxical emboli. The vessels of hereditary hemorrhagic telangiectasia show a discontinuous endothelium and an incomplete smooth muscle cell layer. The surrounding stroma lacks elastin. Thus, the bleeding tendencies are thought to be due to mechanical fragility of the abnormal vessels.

Therapy for HHT remains problematic with laser treatment for cutaneous lesions; split-thickness skin grafting, embolization, or hormonal therapy (estrogen or estrogens + progesterone) for epistaxis; pulmonary resection or embolization for pulmonary arteriovenous malformations; and hormonal therapy and laser coagulation for gastrointestinal lesions. [129] The antifibrinolytic agent epsilon amino caproic acid has been reported to be beneficial in controlling hemorrhage [134] but negative results have also been reported. [135]

Telangiectasias from chronic actinic damage (Plate 105-26), and telangiectatic mats seen in scleroderma (CREST syndrome) (Plate 105-27) may be easily confused with the lesions of hereditary hemorrhagic telangiectasia. Angiokeratoma corporis diffusum, ataxia telangiectasia, and spider telangiectasias from chronic liver disease must also be differentiated. Spider telangiectasias have a central, prominent, easily blanchable feeding vessel with several smaller telangiectasias emanating from this central vessel. Spider telangiectasias seen in patients with chronic liver disease are distributed from the head to the nipple line, and correlate with the risk of bleeding from esophageal varices. [136]

Kaposi Sarcoma and Other Vascular Sarcomas

The epidemic form of Kaposi sarcoma found among patients infected with the HIV virus is easily confused with purpuric (Plate 105-28) and ecchymotic (Plate 105-29) lesions, as well as some of the pigmented purpuric eruptions [137] (Plate 105-30). Oral lesions of epidemic Kaposi sarcoma may also mimic petechiae and purpura (Plate 105-31). Similarly, angiosarcoma may present as a purple to brown plaque resembling purpura (Plate 105-32).

Fabry Disease

Fabry disease (angiokeratoma corporis diffusum) is an X-linked inherited disorder of glycolipid metabolism with deficiency of the enzyme ceramide trihexosidase. [138] Accumulation of glycolipid throughout the body leads to cutaneous, renal, ophthalmologic, cardiac, and central nervous system manifestations. Angiokeratoma corporis diffusum lesions are pinpoint-sized to 4-mm-deep red, blue, or black macules or papules (Plate 105-33). These nonblanchable lesions are distributed over the trunk, extremities, and genitalia. In mild cases, lesions are localized to the thighs, scrotum, or periumbilical region. Grouping of lesions may occur. Superficial corneal dystrophy and varicosities of the bulbar conjunctivum are commonly seen (Plate 105-34).

Neonatal Extramedullary Hematopoiesis

Infants with congenital toxoplasmosis, rubella, or cytomegalovirus infections may have these dark red, blue, or blue-gray

macules and/or papules at birth or within the first 48 hours of life. [139] The lesions are most commonly found on the scalp, neck, and trunk but may be widely distributed. These lesions fade into tan- or copper-colored macules by 8 weeks of age.

Angioma Serpiginosum

Angioma serpiginosum is a vascular nevoid lesion showing pinpoint vascular ectasias on a background of erythema. [10] The lesion is partially blanchable and is not petechial. Capillary microscopy demonstrates punctate dilated capillaries. This lesion is usually seen on the legs and buttocks of women, but it may occur anywhere and may expand in childhood and regress with age.

Chapter 106 - Laboratory Evaluation of Hemostatic Disorders

Samuel A. Santoro
Charles S. Eby

INTRODUCTION

Once the presence of a bleeding disorder has been established or a high level of suspicion is generated by either the history or physical examination, or both (see Chap. 105), laboratory tests are used to establish the diagnosis. Familiarity with, and rational application of, a few laboratory procedures will enable one to place the defect in one of several broad categories. More specialized tests are subsequently necessary to establish a definitive diagnosis.

For diagnostic purposes, the hemostatic system may be somewhat simplistically divided into two parts: the plasma coagulation factors and platelets. An abnormality in either portion may give rise to a bleeding disorder. Although the history and physical examination may provide clues as to which portion of the hemostatic system is defective, the information is not definitive. Therefore, when faced with a bleeding disorder, the first task is to establish whether the disorder is due to either impairment of the reactions leading to thrombin generation and fibrin clot formation or to inadequate numbers or function of platelets. This is accomplished by performing a prothrombin time (PT), an activated partial thromboplastin time (PTT), a platelet count, and a bleeding time.

SCREENING TESTS OF PLASMA COAGULATION FACTORS

The PT and PTT are used to assess the function of the plasma coagulation factors, with the notable exception of factor XIII. For diagnostic purposes, it is useful to divide the plasma coagulation reactions into the extrinsic, intrinsic, and common pathways, although recent data from several laboratories have indicated the existence of several interconnections between these pathways. These pathways are diagrammed schematically in Figure 1061 . The extrinsic system includes the reactions of tissue factor and factor VII that lead to the conversion of factor X to factor Xa. The intrinsic system is composed of factors VIII, IX, XI, and XII, prekallikrein, and high-molecular-weight kininogen. The common pathway includes factors V and X, prothrombin, fibrinogen, and factor XIII.

Prothrombin Time

A PT is performed by adding a crude preparation of tissue factor (commonly an extract of brain) or recombinant tissue factor reconstituted with phospholipids to citrate-anticoagulated plasma, recalcifying the plasma, and measuring the clotting

Figure 106-1 Reactions of coagulation. HMWK, high-molecular-weight kininogen; TF, tissue factor; T, thrombin; PT, prothrombin; FG, fibrinogen; F, fibrin clot (not cross-linked).

time.[1] It is standard practice to add both thromboplastin (tissue factor preparation) and Ca^{2+} in a single step. It should be apparent from Figure 1061 that abnormalities of factors VII, V, and X, prothrombin, or fibrinogen may result in prolongation of the PT. The test may be prolonged due to either a deficiency of one or more of the involved factors or to the presence of an inhibitor. The PT is also the most frequently used method to monitor the anticoagulant effect of warfarin, which causes a decrease in the activity of vitamin K-dependent factors VII, IX, and X and prothrombin. Warfarin dosage is typically adjusted to achieve a desired patient/mean normal PT ratio expressed as the International Normalized Ratio (INR) (see Chap. 121).

Commercially available thromboplastins vary in the animal source and method of preparation, resulting in differing sensitivities to factor deficiencies. [2] Although differences in instrumentation, methodology, and control plasmas also contribute to inter- and intralaboratory variability, the lack of a standard thromboplastin is thought to be the most important factor.[3] The World Health Organization has established a reference thromboplastin derived from human brain that has been used to calibrate secondary standards, available to manufacturers and laboratories for the evaluation of thromboplastin reagents. [2] The sensitivity of a thromboplastin is described by the International Sensitivity Index (ISI). Most commercial thromboplastins derived from animal sources are less sensitive to factor deficiencies than is the reference standard (ISI = 1.0) and have ISIs of 1.22.8.[4] Some authorities and panels have advocated routine reporting of PTs, especially for anticoagulant monitoring, as an INR.[5] [6] [7] The INR converts the PT patient/PT mean normal ratio to the value expected if the test had been performed with the reference thromboplastin and is given by $INR = (PT\ patient/PT\ mean\ normal)^{ISI}$. Advocates argue that use of the INR would reduce interlaboratory variation in reported PT ratios and permit the adoption of more uniform and consistent monitoring of oral anticoagulation based on INR target ranges. The use of recombinant human tissue factor is a potential alternative to the many animal thromboplastins currently in use. [8] [9] When compared with the World Health Organization standard thromboplastin, the ISI of recombinant human tissue factor was 0.961.12, with a comparable degree of precision.[9] Although the ISI is derived from analysis of plasmas from patients on chronic, stable oral anticoagulation therapy, the INR may also be superior to the PT ratio for monitoring the initiation phase of warfarin therapy. [10] When compared to the PT ratio, less variation was encountered with the INR when different thromboplastins were used to monitor the induction phase of warfarin therapy. Enthusiasm for the INR approach has been somewhat tempered by recognition that the apparent ISI of a thromboplastin used on an automated coagulation analyzer may differ from that obtained by the manual tilt-tube method used for calibration. [3] [11] [12] Instrument-specific ISI values for thromboplastins may be required to overcome this difficulty.

The use of sensitive thromboplastins or of the INR, or both, is not without drawbacks. Mild deficiencies of extrinsic or common pathway coagulation factors that represent a negligible bleeding risk do not prolong the PT when an insensitive (ISI >2) thromboplastin is used. If, however, the PT ratio is converted to the INR, or if a sensitive thromboplastin is used, more patients, especially those with acquired vitamin K deficiency or liver disease, will be identified with an abnormal coagulation test and will be at risk of receiving unnecessary plasma infusions or for having invasive procedures delayed or canceled. Thus, clinical judgment must be brought to bear in interpreting the INR within a particular clinical context.

Activated Partial Thromboplastin Time

The PTT is performed by the addition of a surface activating agent, such as kaolin, silica, or ellagic acid, and phospholipid to citrate-anticoagulated plasma. [1] After incubation for a period sufficient to provide for the optimal activation of the contact factors, the plasma is recalcified and the clotting time measured. The name of the test emanates from the phospholipid reagents being originally derived from a lipid-enriched extract of complete thromboplastin, hence the term partial thromboplastin. The PTT is dependent on factors of both the intrinsic and common pathways (Fig. 1061). The PTT may be prolonged due to a deficiency of one or more of these factors or to the presence of inhibitors that affect their function. Although it is commonly stated that decreases in factor levels to approximately 30% of normal are required to prolong the PTT, in practice the variability is considerable in the sensitivity of different commercially available PTT reagents to the various factors. In our experience, the levels vary from 2540%. Because detection of a fibrin clot does not require covalent cross-linking of the fibrin, neither the PT nor the PTT will detect even severe deficiencies of factor XIII.

Recently developed portable instruments offer the potential for rapid determination of the PT and PTT at the bedside or in an outpatient setting. [13] [14] [15] [16] [17] [18] [19] Blood from a finger stick is applied to an opening on a disposable card. The blood flows by capillary action through an enclosed channel that contains either lyophilized thromboplastin (PT) or phospholipid and surface activator (PTT), where coagulation begins. The card is inserted into a portable laser photometer, which measures the time until blood flow stops due to clot formation. The instruments convert the clotting time to a comparable PT or PTT result. Early studies indicate that these methods correlate well with traditional laboratory methods, exhibit acceptable precision, and are easily performed by health care workers and patients. One recent randomized prospective study has suggested that the use of these instruments in the cardiothoracic operating room facilitated rapid correct diagnosis in bleeding patients and resulted in a significant reduction in blood product use. [20]

Platelet Count

The platelet count is performed to detect thrombocytopenia, which is usually defined as a platelet count of $<150 \times 10^9$ /L. The procedure is now almost always performed as part of an automated blood cell profile. Currently used instruments are quite reliable, even down to platelet counts approaching 25×10^9 /L, and are

much less susceptible to the artifacts that plagued earlier generations of platelet counters. [21] [22] Nevertheless, the finding of thrombocytopenia, especially unexpected thrombocytopenia, should be confirmed by a review of the peripheral blood smear and platelet size histogram obtained from automated blood cell counters. Abnormalities of platelet size, the presence of red blood cell fragments, or evidence of pseudothrombocytopenia [23] [24] [25] [26] [27] may provide clues with which to direct the further evaluation of the patient.

Bleeding Time

The bleeding time is the screening test for platelet function. [28] [29] [30] The test is not, as its name might imply, a global test of the hemostatic system. The test is not significantly prolonged in most disorders that result in prolongation of the PT or PTT (e.g., deficiencies of factors VIII, IX, or VII). The bleeding time is prolonged not only due to functional defects of platelets, but also to deficiencies or functional abnormalities of plasma proteins such as von Willebrand factor (vWF), which are required for normal interactions of platelets with the vessel wall. The bleeding time may also be prolonged in severe hypofibrinogenemia.

The procedure is usually performed with a disposable template device that produces one or two standardized incisions on the volar aspect of the forearm. A sphygmomanometer around the arm is inflated to 40 mmHg to standardize venous pressure. The time required for bleeding to cease is determined by carefully blotting the blood emerging from the wounds with filter paper at 30-second intervals.

The test is influenced by a number of factors, including the

depth, location, and direction of the incisions; skin thickness; and skill of the technologist performing the test, in addition to platelet function. [31] [32] The bleeding time may be prolonged by some of the many medications known to inhibit platelet function (see Chap. 131). Knowledge of the platelet count is essential for accurate interpretation of the bleeding time. The test is independent of platelet count down to approximately 100×10^9 /L and is prolonged as the platelet count falls from 100×10^9 /L to 10×10^9 /L.[28] [33] Because of this, a bleeding time is generally indicated only when the platelet count is $>100 \times 10^9$ /L. In the presence of thrombocytopenia, a prolonged bleeding time must be interpreted with caution.

Analysis of the performance of the bleeding time indicates that the test functions poorly as a screening test in the general population and is a poor predictor of surgical bleeding and of the response to hemostatic therapy. [34] [35] [36] The sensitivity, specificity, and predictive value of the test have not been established. Nevertheless, we concur with Tripletts conclusion that the bleeding time can be a valuable laboratory test that can yield important diagnostic information when used in a selected patient population with suggestive or positive bleeding histories. [29]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

FURTHER EVALUATION OF ABNORMAL SCREENING TESTS

The initial battery of four tests establishes whether the patient has a quantitative disorder of platelets, a defect in platelet function, or an abnormality within either the intrinsic or extrinsic pathways of coagulation, or both.

Evaluation of Prolonged PT and/or PTT

Several tests can be performed to ensure that the prolongation of the PTT is not due to the presence of heparin in the specimen. The thrombin time is a useful test for this purpose because it is very sensitive to the presence of heparin (see following discussion). Once it is clearly established that the PT or PTT, or both, is prolonged, the task is to determine whether the prolongation is caused by factor deficiency or by the presence of an inhibitor. [37] This is usually accomplished by repeating the determinations after mixing equal volumes of the patients plasma with plasma derived from a pool of normal donors. Because factor levels of 50% of normal are sufficient to produce a normal PT and PTT, this procedure will result in correction of the abnormality if it is caused by the deficiency of one or more factors. If an inhibitory antibody is present, the mixing procedure will result in little or no correction of the abnormality. Two caveats must be borne in mind. First, relatively low-titer, low-avidity inhibitors producing only modest prolongations of the PT or PTT, or both, may be difficult to detect with the 1:1 mixing procedure. Some authorities have advocated performing inhibitor assays on other than 1:1 mixtures, in an effort to detect weaker inhibitors. In our experience, this procedure has not proved satisfactory and, as often as not, has produced ambiguous results.

INITIAL LABORATORY EVALUATION OF A BLEEDING PATIENT

Second, some classes of inhibitors seen in patients with severe factor VIII deficiency react slowly with factor VIII in the normal plasma on mixing and may not be detected if the mixture is assayed immediately. [38] The latter situation is addressed by assaying the mixture after an incubation of 0.52 hours, as well as immediately after mixing.

A series of 100 consecutive patients referred for consultation because of a prolonged PTT demonstrated that in 50% of patients the problem was indicative of a hemostatic defect. [39] Of the hemostatically compromised patients, 81% gave an abnormal hemostatic history. A laboratory approach to evaluating acquired and inherited prolongations of the PT or PTT, or both, is presented in algorithm form. This approach is discussed in greater detail in the following sections.

Inhibitors

Factor VIII inhibitors and lupus anticoagulants are the most frequently encountered inhibitors of coagulation. Factor IX inhibitors are encountered much less often; other inhibitors are seen only rarely. A detailed discussion of circulating anticoagulants is presented in Chapter 116 . One of the several approaches described following should be used to establish the presence of the lupus anticoagulant. Assays of specific coagulation factors are used to document the specificity of inhibitors against individual factors.

Quantitation of the level of factor VIII inhibitors may have therapeutic implications. [38] Two common approaches have evolved. In the Bethesda assay, patient plasma or dilutions of patient plasma and normal plasma are incubated for 2 hours at 37°C, after which the residual factor VIII activity is measured. [40] [41] One Bethesda unit/ml is the concentration that will neutralize 50% of the added factor VIII during the 2-hour incubation. In the new Oxford assay, the preliminary incubation requires 4 hours. One new Oxford unit/ml is defined as the concentration of inhibitor that will neutralize 50% of the added factor VIII (from a lyophilized concentrate) in 4 hours. [41] [42]

Lupus Anticoagulants

The so-called lupus-type anticoagulant is by far the inhibitor most likely to be encountered [43] (see Chap. 116 for a more extensive discussion). Only about one-third of these anticoagulants occur in patients with lupus erythematosus. A review of the literature indicates that this anticoagulant is present in approximately 25% of patients with systemic lupus erythematosus (SLE), if the analysis is restricted to series composed of consecutive or otherwise unselected patients. The lupus anticoagulant is paradoxically associated with an increased occurrence of thrombosis, recurrent fetal loss, and thrombocytopenia. [44] When these complications are encountered in a lupus anticoagulant-positive patient without SLE, the term primary antiphospholipid syndrome has been applied. [45]

The lupus anticoagulants react with anionic phospholipids and may therefore give rise to either a prolonged PTT (common) or prolonged PT (less common), or both. Several different laboratory procedures have been proposed as tests for the lupus anticoagulant. These have included tests based on the PTT, the PT performed with dilute thromboplastin (the tissue thromboplastin inhibition test), the dilute Russells viper venom time (activation of factor X by venom and subsequent thrombin generation) performed with limiting concentrations of venom and phospholipid, the kaolin clotting time, the plasma clotting time, and platelet or phospholipid neutralization procedures. [46] [47] No single test for the detection of lupus anticoagulants has proved entirely satisfactory or gained widespread acceptance. The sensitivity and specificity have not been adequately established for any of these procedures. [48] Problems include patient-to-patient variability due to the heterogeneity of these antibodies, as well as variation in the sensitivity of reagents to inhibitory activity. [49] [50] Minimal guidelines have been proposed. [51] These include the demonstration that (1) an abnormality of phospholipid-dependent coagulation reactions is present; (2) the abnormality is due to the presence of an inhibitor, rather than to factor deficiency; and (3) the inhibitor is directed at phospholipid rather than specific coagulation factors.

At our laboratory we use the following approach, which is consistent with the above criteria. A dilute Russells viper venom time is performed. If the initial screening test is prolonged, the test is repeated after mixing the patients plasma with an equal volume of normal pooled plasma to exclude factor deficiency as a cause of the prolongation and to demonstrate the presence of an inhibitor. Finally, the lipid dependence is established by the ability of hexagonal phase phosphatidylethanolamine to neutralize the effect of the anticoagulant.

Another test used to detect antiphospholipid immunoglobulins is the anticardiolipin antibody (ACA) assay. This test entails incubating patient serum with solid-phase

cardiolipin. Following incubation and washing, bound immunoglobulin is detected using appropriate antisera (e.g., antihuman IgG, IgM, and IgA). Progress has been made toward standardization of the ACA through the use of similar methodology and the availability of antiphospholipid immunoglobulin standards. [52] It must be borne in mind that not all ACAs exhibit lupus anticoagulant activity, nor do all lupus anticoagulants give positive results in ACA assays.

Factor Deficiency

If the prolonged PT or PTT normalizes after mixing the patients plasma with normal plasma, a deficiency of one or more of the involved factors is indicated. [37] [53] Clinical considerations, such as the presence of liver disease, may give clues to the existence of multiple factor deficiencies. If only the PT is prolonged, a deficiency of factor VII is present. If only the PTT is prolonged, a deficiency of factors VIII, IX, XI, and XII, high-molecular-weight kininogen, and/or prekallikrein should be suspected. The history and physical examination may again provide valuable clues. Deficiencies of factors VIII and IX are associated with significant bleeding disorders that conform to classic sex distribution and inheritance patterns (see Chap. 109). Factor XI deficiency is variably associated with a bleeding diathesis (see Chap. 111). Even severe deficiencies of factor XII, prekallikrein, or high-molecular-weight kininogen are asymptomatic despite the fact that the PTT may be markedly prolonged.

If both the PT and the PTT are prolonged, the patient has either a deficiency of multiple factors affecting both the intrinsic and extrinsic pathways and/or the common pathway or has a selective deficiency of factor V or X, prothrombin, or fibrinogen. In this setting, a concentration of fibrinogen adequate for clot formation should be ensured before other specific factor assays are performed. Fibrinogen levels must fall to 6080 mg/dl before hypofibrinogenemia can be accepted as the sole explanation for the prolonged PT and PTT. If hypofibrinogenemia is not the cause of the abnormal PT and PTT, specific assays for factors V and X and prothrombin should be performed.

Factors V, VII, and X and prothrombin are usually assayed by determining the ability of dilutions of the patient plasma to correct the PT of a plasma congenitally deficient in the factor to be assayed. The degree of correction is compared to that produced by equivalent dilutions of normal pooled plasma. Factors VIII, IX, XI, and XII are determined in a similar manner, except that the specific factor assays are based on the PTT.

Fibrinogen Determinations

A number of procedures for the determination of fibrinogen have been devised. These include chemical determinations of

thrombin-clottable protein, salt precipitation techniques, and immunochemical approaches such as radial immunodiffusion and nephelometry. More common, however, are assays based on the original method described by Clauss, [54] which is the basis for several assays available in kit form for routine use in clinical laboratories. These procedures involve an initial (typically 10-fold) dilution of the plasma sample to ensure that fibrinogen is rate limiting for clotting and for the subsequent measurement of a clotting time initiated by the addition of a large excess of thrombin to the sample. The length of the clotting time is inversely related to the fibrinogen concentration. Because this type of assay measures the time to formation of a detectable clot, inhibitors of fibrin polymerization, such as fibrinogen/fibrin degradation products (FDPs) produced by plasmin, which are present in patients with disseminated intravascular coagulation (DIC) or in those undergoing fibrinolytic therapy, may result in an underestimation of the actual fibrinogen concentration. Immunologic assays of fibrinogen may measure both fibrinogen and FDPs. A dysfibrinogenemia will typically result in a substantially lower value for fibrinogen concentration when determined by the Clauss technique than by immunologic assays. However, it should be noted that antigenic and functional determinations of fibrinogen tend to be somewhat discordant even in normal subjects, with the ratio of antigenic/functional fibrinogen ranging from 1.121.65. [55] [56] Congenital hypofibrinogenemia will result in low concentrations of fibrinogen by all techniques; congenital afibrinogenemia will result in virtually undetectable levels by all techniques (see Chap. 112). In contrast to the thrombin time on which it is based, determination of fibrinogen by the Clauss technique is not susceptible to interference by commonly encountered concentrations of heparin.

Thrombin Time

The thrombin clotting time has also been used to establish the presence of adequate levels of fibrinogen. We recommend, however, that one of the simple fibrinogen assays that yields quantitative information about the fibrinogen concentration be used instead for this purpose. The thrombin time is performed by measuring the clotting time after the addition of excess thrombin to undiluted plasma. [1] The test may be prolonged as a result of hypofibrinogenemia or dysfibrinogenemia; the presence of FDPs, heparin, or an antibody to thrombin; and in amyloidosis. [57] [58] Prolongation of the thrombin time due to hyperfibrinogenemia has also been described. [59] The relative sensitivity of the thrombin time to these factors depends on the precise configuration of the assay. [53] Correction of a prolonged thrombin time on the addition of protamine sulfate or of a commercially available ion-exchange resin (Heparsorb) is a presumptive test for the presence of heparin or a heparin-like anticoagulant.

Evaluation of Thrombocytopenia

Thrombocytopenia is commonly defined as a platelet count of $<150 \times 10^9$ /L. Thrombocytopenia is a laboratory finding indicative of an underlying disease process, but does not constitute the diagnosis. A number of different conditions may give rise to the finding of thrombocytopenia. The evaluation of thrombocytopenia is treated in detail in Chapters 126 , 128 , and 129 .

von Willebrand Disease

von Willebrand disease (vWD) is the most likely cause of an inherited prolongation of the bleeding time. It is now believed by some to be the most common of the inherited disorders of hemostasis. [60] [61] [62] The prevalence of this disorder was recently estimated at 0.8% in a population of children in northern Italy. [62] The disorder arises as a consequence of quantitative (types 1 and 3) or qualitative (type 2) abnormalities of the vWF protein. A recently revised classification scheme [63] is presented in Table 1061 . vWD is considered in detail elsewhere (see Chaps. 113 and 114). Although a prolonged bleeding time is the hallmark of vWD, this laboratory finding is not specific for vWD. Thus, the diagnosis is definitively established by means of additional laboratory tests. [64] These usually include measurements of the amount of vWF protein present in plasma, the functional activity of the vWF, and the procoagulant activity of the associated factor VIII molecule. Analysis of the multimeric structure and factor VIII binding capacity of vWF is useful in some settings, as described in the following sections.

The vWF protein is quantitated by immunochemical procedures. Rocket immunoelectrophoresis (electroimmunoassay) remains the most commonly used procedure, although other approaches, including enzyme-linked immunosorbent assays, are increasingly used. [1] [65] In most patients with vWD, the antigenic level of the von Willebrand protein will be reduced. However, in patients with type 2 disorders, antigenic levels of the protein may be close to, or within, the reference range.

Pregnancy, ingestion of oral contraceptives, or liver disease may elevate the plasma level of vWF and factor VIII coagulant activity, complicating the diagnosis. A recent study demonstrated that levels of vWF are a function of the ABO blood group. [66] Persons with blood group O had significantly lower levels of vWF (75 U/dl) than were found in group A (106 Udl), group B (117 U/dl), or group AB (123 U/dl) subjects.

The functional activity of vWF is assessed by measuring the ristocetin cofactor activity of the patients plasma. This assay determines the ability of vWF in the plasma to agglutinate a standardized suspension of fixed normal platelets in the presence of ristocetin from either the rate or extent of platelet agglutination. [1] [67] [68] Agglutination is usually measured in a platelet aggregometer, although other approaches have been devised. This activity is usually decreased in plasma from patients with vWD, even in those with type 2B or platelet-type pseudo-vWD in which enhanced platelet agglutination/aggregation is observed when low concentrations of ristocetin are added to the patients own platelet-rich plasma. Even in type 1 disorders, determination of ristocetin cofactor activity by the semiquantitative procedure described above appears to have a greater diagnostic sensitivity than the more qualitative determination of ristocetin-induced platelet aggregation in platelet-rich plasma. [69] This is attributable to the lower concentrations of vWF actually present in the ristocetin cofactor assays.

This functional assay tests only the ristocetin-dependent interaction of vWF with the platelet membrane GPIb/IX complex. Clinically useful tests of the interactions of vWF with the platelet membrane IIb/IIIa complex or with components of the extracellular matrix have not been devised. Defects in these interactions may, at least theoretically, also contribute to bleeding disorders.

TABLE 106-1 -- **Revised Classification of von Willebrand Disease**

Type 1Partial quantitative deficiency of vWF with normal structure and function
Type 2Qualitative abnormalities of vWF
Type 2ADecreased platelet-dependent function with loss of high-molecular-weight multimers
Type 2BIncreased affinity of vWF for platelet membrane glycoprotein IbIX complex
Type 2MDecreased platelet-dependent function but with retention of high-molecular-weight multimers
Type 2NMarkedly decreased affinity of vWF for factor VIII resulting in an autosomal mimic of hemophilia A
Type 3Essentially complete deficiency of vWF

Factor VIII procoagulant activity is also typically, but not universally, decreased in vWD. This activity is commonly measured in an assay based on the ability of various dilutions of patient plasma to correct the clotting time of authentic factor VIII-deficient plasma in a PTT-based assay. Although factor VIII levels are commonly reduced in vWD, the level may not be sufficiently low so as to prolong the PTT. Thus, a PTT within the normal range does not permit exclusion of the diagnosis of vWD.

In contrast to the type 1 forms of vWD, in which a generalized decrease in all multimeric forms of vWF occurs, the type 2A and 2B forms of the disease manifest a selective deficiency of the higher molecular-weight forms. The deficiency may have a number of causes, including impaired biosynthesis, enhanced proteolysis, or selective adsorption of the high-molecular-weight forms onto platelets. [61] Because the higher molecular-weight forms account for most of the ristocetin cofactor activity in plasma, a discrepancy between the amount of ristocetin cofactor activity present and the level of vWF antigen should lead to the suspicion of the presence of a qualitative type 2 disorder. Two approaches have been used to confirm this suspicion.

In crossed immunoelectrophoresis, the plasma sample is electrophoresed through agarose in the first dimension to separate the vWF multimers by size and then electrophoresed in the second dimension into agarose containing antibody to vWF. An immunoprecipitate forms, the shape of which is indicative of the distribution of vWF multimers. [70] Today this approach has largely been replaced by sodium dodecyl sulfate agarose gel electrophoresis.

Sodium dodecyl sulfate agarose gel electrophoresis provides a higher resolution analysis of the multimer distribution and is usually available in clinical coagulation reference laboratories. [71] Following electrophoretic separation in agarose in the presence of sodium dodecyl sulfate, the vWF multimers are detected with either ^{125}I-labeled antibodies or enzyme-linked antibodies to vWF. The discrimination of several types of vWD by this technique is illustrated in Figure 1062 .

Figure 106-2 Sodium dodecyl sulfate agarose gel electrophoretic analysis of the multimeric composition of plasma vWF from a normal subject (NP) and patients with types 1, 2A, 2B, and 3 vWD. Note the absence of high-molecular-weight multimers in the 2A and 2B disorders and the absence of all forms of vWF in the type 3 disorder. (Photo and analysis courtesy of Marlies R. Ledford, University of Miami Coagulation Reference Laboratory.)

Establishing the existence of a type 2 disorder is no longer an academic exercise. Because deamino- D-arginine vasopressin (DDAVP) is now considered front-line therapy for type 1 vWD but appears to be less effective in some of the type 2 disorders and can induce thrombocytopenia in some of the type 2B patients, this distinction has taken on important therapeutic implications. [60] [61]

Although ristocetin-induced platelet aggregation of the patients own platelet-rich plasma is not recommended as a front-line test for the diagnosis of vWD, it is useful in sorting out type 2 forms of the disease. Platelets in type 2B disease exhibit enhanced platelet aggregation to low concentrations of ristocetin when platelet-rich plasma is examined, even though the ristocetin cofactor activity of the patients plasma may be diminished. [72] This is attributed to an exceptionally high avidity of the abnormal vWF for the platelet, resulting in its adsorption from plasma. A similar phenomenon is observed in platelet-type pseudo-vWD, except that the defect resides in the patients platelets rather than in the vWF molecule. [73] [74] [75]

Type 2N is a qualitative form of vWD with a recessive mode of inheritance. [76] Mutations have been identified in the amino-terminal factor VIII binding domain of vWF that decrease affinity for factor VIII and consequently lead to lower plasma factor VIII activity. [77] vWF antigen, ristocetin cofactor activity, and multimeric patterns are normal in vWD 2N. Inheritance is homozygous or compound heterozygous, producing a laboratory profile similar to that observed in hemophilia A. Distinguishing type 2N vWD from hemophilia A has implications for both genetic counseling and patient management. However, many reference laboratories do not offer a factor VIII binding assay of vWF, most likely due to the lack of commercially available diagnostic reagents. As a result, vWD 2N is probably underdiagnosed. [78] [79]

In trying to establish the diagnosis of vWD, one must be aware that all the laboratory parameters may fluctuate significantly over time. [80] On some occasions, all four major parametersbleeding time, vWF antigen, vWF activity, and factor VIII activitymay be within the normal range. In the presence of a strong clinical suspicion, repeated testing is warranted to establish the diagnosis.

Platelet Function Testing

A prolonged bleeding time in the presence of a relatively normal platelet count may be due to an inherited defect in platelet function, but less frequently than to vWD. The inherited defects of platelet function include abnormalities or deficiencies of membrane glycoproteins; deficiencies of secretory granules or their contents, or both; and defects in the enzymatic machinery required for secretion. Hereditary disorders of platelet function are considered in Chapter 130 . Acquired defects due to associated disease states, such as uremia, multiple myeloma, myeloproliferative disorders, various inhibitory antibodies, or the presence of medications must also be considered. Acquired disorders of platelet function are discussed in Chapter 131 .

Review of the peripheral blood smear may provide a clue to the nature of the platelet function defect. In gray platelet syndrome (-granule deficiency), the characteristic purplish staining of platelets is absent, leaving them with a gray, washed-out appearance. Giant platelets are present in Bernard-Soulier syndrome and in a variety of other inherited disorders associated with thrombocytopenia. If the smear is prepared from fresh blood in the absence of anticoagulant, platelet aggregates are readily apparent in normal individuals. The aggregates are not detectable in Glanzmanns thrombasthenia. None of these observations can be considered definitive. Additional studies are required to establish the diagnosis.

Platelet aggregation studies are the mainstay of platelet function

Figure 106-3 (Figure Not Available) Platelet aggregation patterns in platelet disorders. Representative aggregation patterns in response to ADP, epinephrine (EPI), collagen (COLL), arachidonic acid (ARACH), and ristocetin (RISTO) are shown for a normal subject and for patients with a storage pool defect (SPD), Glanzmanns thrombasthenia (GT), and Bernard-Soulier syndrome (BSS). The characteristic abnormality in patients with release defects is an absent second wave of aggregation with ADP and epinephrine, an absent or greatly diminished aggregation with collagen, and a normal or variably reduced arachidonate aggregation. In Glanzmanns thrombasthenia, the characteristic abnormality is absent aggregation with all agents, except ristocetin. In Bernard-Soulier syndrome, the characteristic abnormality is absent aggregation with ristocetin and a reduced response to collagen, but aggregation with ADP, epinephrine, and arachidonate is normal. *(From White et al., [103] with permission.)*

testing in the laboratory. [81] [82] [83] Platelet aggregation is monitored by the increase in light transmission through a suspension of platelet-rich plasma as aggregation occurs. Collagen, adenosine diphosphate (ADP), epinephrine, arachidonic acid, and ristocetin are commonly used agonists in the clinical laboratory. Studies of platelet aggregation are usually performed in concert with studies of platelet secretion. The secretion of granule contents is usually monitored by following the agonist-induced release of ^{14}C-serotonin from platelet-dense granules or of adenosine triphosphate release by a chemiluminescence procedure. These rather sophisticated evaluations are obviously beyond the scope of most clinical laboratories but are usually available in referral centers.

Platelet aggregation patterns observed in some of the more common, classical inherited abnormalities are shown in Figure 1063 (Figure Not Available) . As more has been learned about platelet function defects and more disorders described, it has become clear that simple examination of the results of the usual set of platelet function studies in many cases does not permit a diagnosis at the molecular level. Although some disorders, such as Glanzmanns thrombasthenia (defect in GPIIb/IIIa) or Bernard-Soulier syndrome (defect in GPIb), give rise to unambiguous findings, defects such as storage pool deficiency, cyclo-oxygenase deficiency, or thromboxane synthase deficiency, may give rise to virtually identical patterns of aggregation with the commonly used agonists. More detailed studies, including analysis of platelet membrane proteins, electron microscopic examination of the platelets, analysis of granule contents, or the analysis of arachidonic acid metabolites, may be required for a definitive diagnosis.

Although ristocetin-induced platelet aggregation may be ab-normal both in vWD and in Bernard-Soulier syndrome, plasma ristocetin cofactor activity is normal in the latter disorder but is usually decreased in vWD. Furthermore, the defect in ristocetin-induced platelet aggregation observed in vWD can be corrected by the addition of normal plasma to the patients platelet-rich plasma. The defect in Bernard-Soulier syndrome is not corrected by normal plasma because it is due to a deficiency of the platelet membrane GPIb/IX complex. Careful attention to detail is required to obtain reproducible platelet function studies. Results are influenced by choice of anticoagulant, pH, time of storage, rate of stirring, and platelet count, as well as numerous drugs. [82] [83]

Several other tests, more common in years past, are less often used today. These include assays of platelet factor 3 activity, clot retraction, and glass bead retention. These procedures lack the diagnostic specificity of the approach to platelet function testing outlined above and are not commonly performed in most diagnostic coagulation laboratories.

The development and characterization of monoclonal antibodies reactive with platelet surface-adhesive receptors have resulted in new approaches to the investigation of platelet function disorders. Assays for the diagnosis of Bernard-Soulier syndrome (GPIb deficiency) and Glanzmanns thrombasthenia (GPIIb/IIIa complex deficiency) have been developed using antibodies directed against GPIb and IIb/IIIa, respectively. [84] [85] The availability of a panel of antibodies that can recognize the resting, activated, and ligand-occupied forms of the GPIIb/IIIa complex has been exploited in a flow cytometric approach to assess not only the presence, but also the functional activity, of the complex. [86] Although not yet in widespread use, it is likely that such assays will play an increasing role in the evaluation of platelet function in the near future.

New instruments for the rapid, in vitro assessment of platelet function using specimens of anticoagulated whole blood may soon be available for clinical use. [87] Although capable of discriminating between hemostatically normal individuals and those with well-characterized, congenital or acquired disorders of primary hemostasis, it would be inappropriate to advocate the use of these devices for screening to predict surgical bleeding risk until the application can be supported by the results of rigorous clinical trials.

Factor XIII Deficiency

When no abnormalities of the four screening tests are found despite suspicion of an underlying bleeding disorder, a deficiency of factor XIII (fibrin stabilizing factor), must be considered. Plasma factor XIII is composed of two -chains and two -chains; platelet factor XIII consists of two -chains. In the presence of Ca^{2+} , cleavage by thrombin of factor XIII -chains produces an active transglutaminase. Factor XIIIa covalently cross-links fibrin molecules, leading to clot stabilization. [88] Clinical bleeding due to factor XIII deficiency occurs at levels <2% of normal and is a rare congenital (homozygous recessive inheritance) or acquired deficiency. [88] [89] [90]

Most laboratories use a simple qualitative assay to detect a deficiency of fibrin-stabilizing activity based on the ability of 5 M urea or 1% monochloracetic acid to dissolve fibrin clots that have not been cross-linked. Normally cross-linked clots are resistant to solubilization by these agents. This is an insensitive test with a threshold for clot lysis of <2% factor XIII activity. It is below this level, however, that clinical manifestations of factor XIII deficiency occur.

More quantitative assays of factor XIII transglutaminase activity have been devised. [91] [92] These tests are more sensitive and rapid than the clot lysis assay; they can also be automated. However, they are not in widespread use because screening for factor XIII deficiency is rarely clinically indicated. Factor XIII - and subunits can be quantitated by immunologic methods using commercial polyclonal antisera. The determinations may be helpful in characterizing an inherited deficiency. [90]

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation results from the poorly regulated activation of coagulation and fibrinolysis systems in response to an underlying illness or injury that, in most cases, is clinically apparent. The generation of thrombin and plasmin predisposes the patient to both thrombotic and hemorrhagic complications. DIC syndrome is considered in detail in Chapter 117 .

Detection of diffuse fibrin deposition in the microvasculature would be definitive for the diagnosis of DIC, but obtaining such direct evidence is impractical. Red blood cell fragmentation on a peripheral blood smear signifying microangiopathic hemolysis is indirect morphologic evidence of DIC. However, this finding lacks sufficient sensitivity and specificity to be considered a reliable screening procedure for DIC.

A common approach to the laboratory investigation of DIC is to use a battery of relatively simple, rapid procedures to document the activation of both coagulation and fibrinolytic systems.[53] [93] [94] [95] [96] Interpretation of the test results can be difficult, however, because none of these tests is specific for DIC. In general, screening tests are more sensitive in the setting of acute fulminant DIC than in clinical conditions associated with chronic compensated DIC.

Thrombocytopenia occurs as a result of thrombin generation, platelet activation, and microvascular thrombus formation. Thus, the platelet count is commonly depressed in DIC and is a component of most laboratory DIC profiles. Unfortunately, thrombocytopenia is associated with several of the predisposing conditions for DIC (i.e., liver disease, leukemia, sepsis), even in the absence of DIC. Acquired platelet function defects can also be a complication of DIC, adding to the hemorrhagic risk.

The PTT and PT are frequently prolonged in DIC [94] [95] [96] due to the consumption of fibrinogen and other coagulation factors, as well as to the presence of FDPs that interfere with fibrin polymerization. Fibrinogen concentration is frequently decreased but may remain within normal limits in the chronic or compensated low-grade forms of DIC. Because fibrinogen may be markedly elevated initially in patients with sepsis, neoplasia, or other inflammatory disorders, the concentration of fibrinogen may not fall below the reference range, at least early during the course of DIC, despite substantial decreases. Because of the presence of FDPs, the concentration of fibrinogen as determined by assays based on the thrombin clotting time of diluted plasma samples (Clauss-type assays) will be lower than those determined by immunologic techniques. The thrombin clotting time may also be prolonged due both to the decrease in fibrinogen and to the presence of FDPs. Frequently, the results of the first DIC panel are normal or inconclusive. Repetition of the test battery may disclose changes over time (e.g., decreased platelets or fibrinogen) consistent with DIC.

When these screening tests are positive in an appropriate clinical setting, the diagnosis of DIC is usually confirmed by measurement of the concentration of FDPs. This determination is most commonly performed on a plasma sample collected in the presence of plasmin inhibitors to prevent in vitro fibrinogenolysis. The specimen is subsequently clotted in the laboratory with thrombin. The resulting serum sample is assayed for the presence of fibrinogen fragments D and E and sometimes other fibrinogen-related antigens by a latex agglutination procedure using particles coated with antibodies directed against the fibrinogen-related antigens. Obviously, the assay detects degradation products originating from either fibrinogen or fibrin because the antigens are expressed on both. It should also be apparent that samples that clot poorly, for example, due to the presence of a high concentration of heparin or low concentration of fibrinogen, may result in artifactually elevated levels of FDPs.

Several monoclonal antibodies directed against the fibrin-specific degradation product, D-dimer, have been used in latex agglutination assays similar to those described above. Comparisons of the D-dimer and FDP assays have led to different conclusions. Carr et al. [97] believe that the D-dimer assay is more specific but less sensitive than the FDP assay, and they recommend using the D-dimer to confirm a positive FDP result. However, Wilde et al. [98] and Boisclair et al. [99] concluded that both assays were 100% sensitive in patients fulfilling their clinical criteria for DIC. Finally, Greenberg et al. [100] reported considerable discordance between the results of the two tests in patients suspected of having DIC. Critical evaluation of these studies is hampered by variability in patient selection and by the inconsistent use of

immunoblotting as the gold standard for detection of FDP. Neither the D-dimer nor the FDP assay distinguishes between pathologic and physiologic fibrinolysis and may be elevated due to recent trauma, surgery, and thrombotic events. One advantage of the D-dimer assay is the convenience of performing the test on plasma, instead of having to perform the extra step of preparing serum, because fibrinogen and fibrin do not cross-react with the D-dimer monoclonal antibody. In addition to the semiquantitative latex agglutination methods, quantitative and automated assays have been introduced for both the D-dimer and FDP tests.[101] [102] No compelling data have been found to support the use of both tests in the laboratory evaluation of a patient with suspected DIC. Cost, convenience, and test volume are appropriate factors to consider when deciding which test and method to implement.

Bleeding due to hyperfibrinogenolysis without thrombin generation is a rare complication of various acute and chronic conditions. Typical laboratory findings are normal platelet count, decreased fibrinogen and plasminogen levels, and shortened euglobulin lysis time. Because fibrinogen degradation is increased, FDP levels are elevated. However, because fibrin degradation is not increased, D-dimer levels are not increased.

A number of more sophisticated laboratory determinations have been useful in examining and defining the pathophysiology of DIC. These include decreased plasma concentrations of antithrombin III, $_2$ -antiplasmin, factors V and VIII, and protein C. However, these determinations are not commonly used clinically

to establish the diagnosis of DIC.[53] [93] Concentrations of fibrinopeptides A and B increase in DIC, directly reflecting the action of thrombin on fibrinogen. Elevated levels of the fibrinopeptides are not, however, specific for DIC. The role of this determination in the clinical evaluation of suspected DIC has not been established. The unavailability of the results of most of the above tests in a sufficiently short time interval represents a major impediment to their use in the evaluation of DIC.

Paracoagulation tests such as the protamine sulfate precipitation test or the ethanol gelatin test, which detect qualitatively the presence of circulating complexes of fibrinogen, fibrin monomer, and the higher molecular-weight degradation products, lack sufficient sensitivity and specificity and are not recommended for routine use in the evaluation of suspected DIC.

Chapter 107 - Structure, Biology, and Genetics of Factor VIII

Randal J. Kaufman
Stylianos E. Antonarakis

INTRODUCTION

Hemophilia A, a bleeding disorder resulting from a deficiency in factor VIII, was documented more than 1,700 years ago in the Talmud. [1] The genetics of hemophilia A was described during the early 1800s [2] and transfusion of whole blood was shown to treat a hemophilia-associated bleeding episode successfully by 1840. [3] The presence of factor VIII in plasma was demonstrated in 1911 [4] and in 1937 Patek and Taylor described its role in hemostasis. [5] In the early 1980s factor VIII was purified from human plasma [6] and subsequently the factor VIII gene was cloned. [7] [8] These developments have dramatically increased our understanding of the structure and function of factor VIII in blood coagulation and have provided a recombinant-derived source of factor VIII that is free of human plasma-borne viruses. [9] [10]

The relationship between hemophilia A and von Willebrand disease (vWD) was confused for many years because the autosomally inherited vWD is associated with factor VIII deficiency, although the hereditary factor VIII deficiency of hemophilia A is

an X-linked disease. Early preparations of antihemophilic factor were demonstrated not only to correct the clotting time of hemophilic plasma, but also to restore platelet adhesion and aggregation defects in the plasma from patients with vWD. It is now known that factor VIII and von Willebrand factor (vWF) are two separate proteins that exist as a complex in plasma and that are under separate genetic control. These proteins have distinct biochemical and immunologic properties and have unique and essential physiologic functions. Factor VIII is an X-linked gene product that accelerates the activation of factor X by factor IXa in the presence of calcium and phospholipid. vWF is an autosomal gene product that is essential for platelet adhesion to subendothelium and for ristocetin-induced platelet agglutination. Because vWF and factor VIII are found in the plasma as a complex and vWF stabilizes factor VIII and regulates its activity, the activities of these two proteins are intimately intertwined. Based on the greater understanding of factor VIII and vWF, in 1985 the Subcommittee on Factor VIII and vWF of the International Committee on Thrombosis and Haemostasis formulated nomenclature guidelines. [11] Factor VIII protein is designated VIII; factor VIII antigen is designated VIII:Ag; factor VIII procoagulant activity is designated VIII:C; von Willebrand factor is designated vWF; and von Willebrand factor antigen is designated vWF:Ag.

FACTOR VIII FUNCTION

The physiologic response to blood vessel injury is the sequential activation of plasma proteases within the blood coagulation cascade, leading to the localized generation of thrombin and the conversion of fibrinogen to fibrin. Thrombin generation requires the interaction of proteases, protein cofactors, and substrate zymogens that assemble on a phospholipid surface or the cell surface. Factor VIII is proteolytically activated by factor Xa or thrombin to yield factor VIIIa. Factor VIIIa serves as a cofactor for factor IXa-mediated activation of factor X. Subsequently factor Xa acts in the presence of activated factor V, negatively charged phospholipids, and calcium to convert prothrombin to its active enzymatic form thrombin.

The mechanism by which factor VIIIa functions in the factor Xa-generating complex is poorly understood. Factor VIII has no enzymatic activity of its own but acts as a cofactor to increase the V_{max} of factor X activation by factor IXa by 10,000-fold in the presence of negatively charged phospholipids and calcium. [12] The mechanism by which the homologous cofactor, factor V,[13] [14] functions in the prothrombin-generating complex has been more extensively studied. Prothrombinase assembly on the surface of phospholipid vesicles requires initial protein-phospholipid rather than protein-protein interactions. The rate-limiting step is the binding of factor Xa and factor Va to separate sites on the phospholipid surface. The proteins then react rapidly by restricted diffusion on the two-dimensional surface of the phospholipid vesicle to form the prothrombinase complex.[15] [16] The association of factor Va with factor Xa on a phospholipid surface induces an allosteric conformational change in the active site of factor Xa to position the active site at a proper distance above the membrane for optimal prothrombinase activity. [15] The mechanism by which factor VIIIa accelerates the proteolysis of factor X by factor IXa also involves the interaction of factor VIIIa and factor IXa on a phospholipid surface to facilitate a conformational change in the enzyme that favors catalysis.[17]

The reported specific activity of pure factor VIII ranges from 2,300 U/mg [6] to 8,000 U/mg.[18] The definition of factor VIII activity is complicated because thrombin converts the cofactor into a much more active form. However, for standardization, 1 U of factor VIII is defined as that amount of activity in 1 ml of normal pooled human plasma measured in a factor VIII assay using factor VIII-deficient plasma.[19] For greater convenience and precision, factor VIII activity can be measured by its ability to promote activation of factor X in the presence of factor IXa, phospholipid, and calcium ions. Factor Xa is measured directly by monitoring cleavage of a synthetic chromogenic substrate.[20] Factor VIII antigen can be measured using factor VIII-specific antibodies in specific immunoassays. [21]

Characterization of factor VIII was hampered by its low concentration in plasma, its heterogeneity in size, and its exquisite sensitivity to degradation. Significant advances in our understanding of factor VIII resulted from the use of immunoaffinity chromatography for the successful purification of factor VIII from porcine [22] and human[6] [23] plasma, and from the cloning of the human factor VIII gene and elucidation of the primary structure of factor VIII. [7] [8]

FACTOR VIII PROTEIN STRUCTURE

The deduced primary amino acid sequence of human factor VIII determined from the cloned cDNA demonstrated that factor VIII is encoded by a precursor protein of 2,351 amino acid residues from which a 19-amino acid signal peptide is cleaved on translocation into the endoplasmic reticulum (ER). Plasma factor VIII is a heterodimer processed from a larger precursor polypeptide. It consists of a COOH-terminal-derived light chain of 80,000 molecular weight (MW) in a metal ion-dependent association with an NH_2 -terminal-derived heavy chain fragment of 90,000 to 200,000 MW. [7] [24] In the plasma this complex is stabilized by association through hydrophilic and hydrophobic interactions with a 50-fold excess of vWF. The amino acid sequence revealed an organization of three structural domains that occur in the order A1:A2:B:A3:C1:C2, as shown in Fig. 107-1 .[7] [24] The A1 (amino acid residues 1329) and A2 (380711) domains of factor VIII occur in the heavy chain and the A3 (16492019) domain occurs in the light chain. The A domains have 30% identity to each other and to the triplicated A domains of ceruloplasmin and factor V and to the single A domain of ferroxidase. [7] [25] [26] The residues implicated for copper binding in ceruloplasmin are conserved in the first and third A domains of factor VIII, suggesting the A domains of factor VIII may be involved in metal ion binding. Copper ions were detected in purified preparations of factor V [27] and factor VIII,[28] and most data support that a single molecule of reduced copper (CuI) resides within a type-1 copper ion-binding site (composed of ligands His265Cys310His315Met320) in the factor VIII A1 domain.[29] Mutagenesis of the single cysteine at residue 310 to a serine, a mutation that would destroy copper ion binding to the type-1 site in the A1 domain, destroyed factor VIII activity and yielded secreted heavy and light chains that were not associated. [29] The C1 (residues 20202172) and C2 (residues 21732332) domains occur in the COOH-terminus of the factor VIII light chain and exhibit homology to milk fat globule protein and to A, C, and D chains of discoidin 1, all proteins that are capable of binding glycoconjugates and negatively charged phospholipids. [30] [31] The B domain is encoded by a single large exon of 3,100 nucleotides, has no known homology to other proteins, and contains 18 of the 25 potential asparagine (N)-linked glycosylation sites within factor VIII. Comparison to the cloned factor V cDNA and gene revealed a high degree of amino acid conservation between the A and C domains with no detectable homology within the B domains,[25] although both B domains are encoded by large single exons. The domain organization and homologies between factors V and VIII suggests that these genes evolved from a primordial ferroxidase gene by triplication of the A domain, insertion of the B domain, and addition of the two C domains. After duplication of the primordial cofactor gene, the factor V and factor VIII genes likely evolved by extensive divergence of amino acid residues within the B domain while amino acid residues within the A and C domains were conserved.

Figure 107-1 Domain structure and processing of factor VIII. The structural domains of factor VIII are depicted in the top line: (1) a triplicated A domain of 330 amino acids; (2) a unique B domain of 980 amino acids; and (3) a duplicated C domain of 150 amino acids. The hatched areas represent highly acidic regions. The location of free cysteine residues and disulfide bonds (brackets below line), potential asparagine-linked glycosylation sites, and sites of tyrosine sulfation are shown. Within the Golgi compartment in the cell, factor VIII is cleaved within the B domain to generate a 200-kDa peptide and the 80-kDa light chain polypeptide. The thrombin (IIa), activated protein C (APC), and factor Xa (Xa) cleavage sites are shown. Factor Xa also cleaves at all the thrombin cleavage sites. The two cleavages required for thrombin activation (**) and the sites of proteolytic inactivation by APC (*) are also shown.

In addition to the A, B, and C domains, there are three acidic amino acid-rich regions in the factor VIII molecule at the junction of the A1/A2 (residues 331372), A2/B (residues 700 740), and B/A3 (residues 16491689) domains and are juxtaposed to sites of thrombin cleavage (Fig. 107-1). All these acidic regions also contain the post-translationally modified amino acid, tyrosine sulfate, at residues 364, 718, 719, 721, 1664, and 1680. [32] The murine factor VIII cDNA is 8493% identical to the A and C domains of human factor VIII, whereas the acidic regions and B domain are only 4270% identical. [33] However, all thrombin cleavage sites and sulfated tyrosine residues are conserved. The murine factor VIII B domain has conserved 19 potential N-linked glycosylation sites, although in different positions than in the human sequence, suggesting that glycosylation in the B domain is important for factor VIII expression and function.

BIOSYNTHESIS AND METABOLISM OF FACTOR VIII

The natural cell type that produces factor VIII has not been definitively identified. However, evidence obtained from liver transplantation in factor VIII-deficient dogs [34] [35] [36] and several hemophiliac patients[37] [38] strongly implicates that the liver and the reticuloendothelial system are primary sites of factor VIII synthesis. In addition, immunochemical localization by light microscopic[39] or electron microscopic[40] examination detected the factor VIII antigen in hepatocytes. However, RNA hybridization analysis has detected factor VIII mRNA in hepatocytes and in many other cells and tissues, with the spleen being the most abundant source. [41] To date there are no known established cell lines that express factor VIII. Thus, it has not been possible to study the biosynthesis of factor VIII in its natural host cell. However, the expression of factor VIII in mammalian cells transfected with the factor VIII gene allowed analysis of the biosynthesis and processing of this glycoprotein.[42]

Factor VIII Secretion

Analysis of the expression of factor VIII in Chinese hamster ovary cells provided insights into a proposed biosynthetic pathway (Fig. 107-2). On synthesis, factor VIII is translocated into the lumen of the ER where the signal peptide is cleaved. In the ER, addition of high mannose-containing core oligosaccharides to multiple asparagine residues within the factor VIII molecule occurs. A significant portion of the factor VIII in the ER is bound to resident proteins of the ER that include the glucose-regulated protein of 78,000 MW (GRP78), also known as immunoglobulin-binding protein, or BiP, [43] [44] and two lectin-binding proteins calnexin and calreticulin.[45] [46] Factor VIII undergoes cycles of binding and release from these protein chaperones and binding correlates with retention within the secretory pathway (Fig. 107-2). BiP expression is induced by glucose deprivation, inhibition of N-linked glycosylation, or the presence of malfolded protein within the ER. [47] [48] In addition, high-level factor VIII expression can also induce transcription of the BiP gene. [49] The level of BiP in the cell inversely correlates with the efficiency of factor VIII secretion.[50] [51] BiP exhibits a peptide-dependent adenosine triphosphatase activity. [52] Factor VIII dissociation from BiP and secretion requires an unusually high level of intracellular adenosine triphosphate. [53] Because factor VIII interacts with BiP, and factor V does not, a primary BiP-binding site was mapped by analysis of the secretion of factor VIII and factor V chimeric proteins. This study identified a hydrophobic pocket within the factor VIII A1 domain that occurs within the type-1 copper ion binding site. [54] Hydrophobic residues are preferred sites of BiP binding. [55] Mutation of a single phenylalanine at residue 309 to serine within the hydrophobic pocket, the residue adjacent to cysteine 310 that is part of the copper ion binding site, increased the secretion efficiency of factor VIII several fold and this correlated with a reduced requirement for adenosine triphosphate for secretion. [54] These studies suggest that BiP may provide a role in copper ion binding to factor VIII.

A significant portion of factor VIII within the ER never transits to the Golgi compartment, but rather is degraded within the cell (Fig. 107-2). Proteolysis of intracellular factor VIII is inhibited by lactacystin, a microbiotic that specifically modifies the active site of the proteasome, although secretion of factor VIII is not improved. [45] These results indicate that factor VIII within the ER is directed to the cytosolic 26S proteasomal machinery for degradation. The portion of factor VIII that is secretion competent transits to the Golgi apparatus, where the majority of factor VIII is processed at two sites within the B domain after residues 1313 and 1648 to generate the heavy chains (90,000200,000 MW) and the light chain (80,000 MW). Also within the Golgi apparatus, factor VIII is further processed by (1) modification of the asparagine-linked high mannose-containing oligosaccharides to complex types, (2) addition of carbohydrate to multiple serine and threonine residues within the B domain, and (3) addition of sulfate to six tyrosine residues within the heavy and the light chains. [56]

Stabilization of Factor VIII by vWF

Numerous in vivo observations support that the level of factor VIII and vWF in plasma is maintained at a fairly constant

Figure 107-2 Synthesis, processing, and secretion of factor VIII in mammalian cells. The factor VIII primary translation product is translocated into the lumen of the ER where asparagine-linked glycosylation occurs. A fraction of factor VIII binds tightly to the glucose-regulated protein of 78 kDa (GRP78 or BiP) and is probably destined for degradation. A proportion of the molecules transit to the Golgi apparatus where complex modification of carbohydrate on asparagine-linked sites, addition of carbohydrate to serine and threonine residues, sulfation of tyrosine residues, and cleavage of the protein to the mature heavy and light chains occur. The presence of vWF in the medium promotes stable secretion of factor VIII. In the absence of vWF, the individual chains are secreted and degraded. The A (crosshatched), B (solid), and C (dotted) domains are indicated. The acidic regions where tyrosine sulfation occurs adjacent to the A domains are shown (solid). *(From Kaufman et al.,[42] with permission.)*

ratio of 1:50. For example, patients with type 1 vWD who have a 50% reduction in vWF have a corresponding 50% reduction in factor VIII. Autosomally inherited factor VIII deficiency results from missense mutations in the first 91 amino acids of mature vWF, called vWD type Normandy or type 2N, that reduces its ability to bind and stabilize factor VIII in plasma.[57] [58] Infusion of vWF into vWF-deficient patients elicits an immediate rise in circulating levels of factor VIII. In addition, increase in the plasma concentration of vWF following infusion with 1-desamino-8-D-arginine vasopressin (DDAVP) elicits an increase in the plasma level of factor VIII. [59] It is established that vWF stabilizes factor VIII in plasma. Factor VIII and vWF are cleared with a half-life of 12 hours on infusion of the factor VIII1/vWF complex into patients with hemophilia.[60] [61] [62] Infusion of factor VIII into factor VIII-deficient patients also exhibits clearance kinetics similar to that of factor VIII/vWF complex, presumably due to rapid binding of the factor VIII to plasma vWF. [63] By contrast, infusion of factor VIII into patients with severe vWD results in rapid clearance with a half-life of 2.4 hours.[60] [64] Therefore, preparations of factor VIII that contain minimal amounts of vWF are ineffective in the treatment of patients with severe vWD. [65] These studies establish the stabilizing influence of vWF for factor VIII in the circulation. However, it is not known whether vWF also regulates factor VIII synthesis or secretion.

In vitro studies demonstrate that vWF can alter intracellular transport and secretion of factor VIII from the cell. vWF promotes the association of the light and heavy chains of factor VIII and results in stable accumulation of factor VIII activity in the conditioned medium of factor VIII-producing cultured mammalian cells. [42] [66] In the absence of vWF in the conditioned medium, the factor VIII heavy and light chains are secreted into the medium as dissociated chains that are subsequently degraded. In vitro reconstitution experiments demonstrated that vWF can directly promote reassembly of isolated heavy and light chains of factor VIII, [66] [67] suggesting a possible role of vWF in facilitating factor VIII assembly. The effect of vWF in promoting factor VIII heavy and light chain assembly and stable secretion in cell culture systems may reflect the role of vWF in regulating levels of factor VIII activity in vivo. [60] [61] [62] [63] [64] The immediate rise in vWF and factor VIII observed after administration of DDAVP suggests the existence of a pool of factor VIII/vWF complex that is DDAVP releasable. [68] Recently, DNA transfection experiments demonstrated that vWF co-expressed with factor VIII in endothelial cells can direct factor VIII into intracellular storage granules (Weibel-Palade bodies) that are released on stimulation,[69] demonstrating the potential for a factor VIII/vWF complex to be released from the cell on stimulation. However, at present there are no known natural cell types that express both factor VIII and vWF.

INTERACTIONS OF FACTOR VIII WITH COMPONENTS OF HEMOSTASIS

Binding to vWF

In addition to increasing factor VIII survival, vWF plays a critical role in directly regulating factor VIII activity. [70] vWF prevents factor VIII binding to phospholipids [3] [71] [72] and activated platelets.[73] vWF inhibits factor VIII from activation by factor Xa, [74] from inactivation by activated protein C(APC) [74A] [74B] but does not interfere with activation by thrombin.[75] [76] It is likely that vWF mediates its inhibitory effects by preventing factor VIII interaction with phospholipids, a reaction required for both factor Xa and APC-mediated cleavage of factor VIII. It is proposed that vWF binding to platelet receptor GP1b brings factor VIII to the vicinity of platelets adhering to damaged endothelium.[73]

The affinity and stoichiometry of the factor VIII-vWF interaction has been extensively studied. [70] Binding assays that immobilize vWF onto plastic have yielded stoichiometries of one molecule of factor VIII:50100 monomers of vWF. [77] [78] In contrast, gel filtration, ultracentrifugation, and immobilization of vWF on colloidal gold or agarose microspheres yield stoichiometries close to 1:1. [78] [79] [80] [81] It appears that immobilization of vWF onto plastic alters the conformation to prevent most of the sites from being occupied. To date, these in vitro studies have not identified the mechanism by which the stoichiometry in plasma is maintained at 1:50. [63] In contrast, the dissociation constant for the vWF-factor VIII interaction is similar for all the methods described (range, 0.20.4 nM). Binding occurs within seconds. [70] [82]

The interaction of factor VIII with vWF is mediated by a major factor VIII binding site that resides within the first 272 amino acids of the mature vWF molecule [83] [84] [85] with residues 7896 and residues around 53 providing crucial roles. [85] [86] Type N vWD results from specific missense mutations within this region of vWF that cause a deficiency in factor VIII due to decreased factor VIII binding. [58] The vWF propeptide serves an essential role in multimerization of vWF, [87] a process that leads to expression of a high affinity factor VIII binding site. [78] Expression of propeptide-deleted vWF does not produce multimeric vWF, but rather produces dimeric vWF through COOH-terminal disulfide bonds. This dimeric form of vWF binds factor VIII with a sixfold reduced affinity. [78] Co-expression of the vWF propeptide promotes generation of a high affinity factor VIII binding site. However, within native pro-vWF, the propeptide needs to be cleaved to expose the factor VIII binding site. [78]

The vWF binding site on factor VIII requires both the NH_2-terminal and COOH-terminal ends of the factor VIII light chain. A vWF binding site on factor VIII was localized by monoclonal antibody inhibition to residues 16731684. [88] [89] This region is composed of a high density of acidic amino acids located at the NH_2-terminus of the factor VIII light chain and is removed by thrombin cleavage at residue 1689 (Fig. 107-1). Deletion of the acidic region in the NH_2-terminus of the light chain by site-directed mutagenesis yielded a molecule that bound vWF with a 10-fold reduced affinity, although the mutant protein had a specific activity similar to wild-type factor VIII.[73] [90] These results demonstrate that the acidic region between residues 1649 and 1689 of the light chain is critical for appropriate interaction with vWF but is not required for cofactor function of factor VIII. Recently, it was demonstrated that antibodies that interact with residues 22482312 within the factor VIII C2 domain can inhibit factor VIII binding to vWF and to phosphatidylserine. [91] This observation is consistent with the presence of a phospholipid-binding region between residues 2303 and 2332 within the C2 domain[123] and that phospholipid and vWF compete for binding to factor VIII. [71] [72] [81] It is proposed that a high affinity vWF binding site requires interactions at both the NH_2-terminal and COOH-terminal region of the factor VIII light chain. [93] [94] However, an anti-factor light chain antibody that interacts with a C2-domain epitope between residues 2248 and 2285 was able to increase vWF binding to a factor VIII molecule that had deleted the acidic region at the NH_2-terminus of the factor VIII light chain.[90] This indicates that the acidic region may not directly contact vWF, but may be required to induce a conformation at the COOH-terminus of the light chain that is capable of high affinity vWF interaction.

Factor VIII is post-translationally modified by sulfation on tyrosine residues 346, 718, 719, 721, 1664, and 1680. [32] Inhibition of tyrosine sulfation by treatment of factor VIII-expressing cells with sodium chlorate did not affect factor VIII secretion but reduced the specific activity of the factor VIII by fivefold, indicating that this modification is required for full cofactor activity. [32] The importance of this post-translational modification was also studied by the conservative mutation of tyrosine residues to phenylalanine residues to block sulfation. Tyrosine to phenylalanine mutations at residues 346 and 1664 reduced the rate of thrombin cleavage and activation.[95] Tyrosine to phenylalanine mutation at residue 1680 reduced interaction with vWF by fivefold. [95] [96] In addition, a patient with the 1680 tyrosine to phenylalanine mutation had a fivefold reduction in factor VIII antigen and activity, likely due to a defect in vWF binding. [97] These experiments show that post-translational sulfation of tyrosine residues affects factor VIII procoagulant activity and interaction with vWF.

Factor VIII Molecular Interactions in the Factor Xase Complex

Due to the lability of thrombin-activated human factor VIIIa, most binding studies have been performed with intact factor VIII. Because it is known that factor VIII activation influences the activity of factor IXa, [17] it must be considered that changes occur in binding affinities or sites of interactions on factor VIII activation. The interaction of factor VIIIa on the influence of factor IXa conformation was studied using fluorescently labeled factor IXa. These studies demonstrated that the A2 domain of factor VIIIa is required to induce a maximal conformational change in factor IXa. [17] [98] Peptide inhibition studies showed that a factor IXa binding site is localized to factor VIII residues 558 to 565 within the A2 domain. [99] [100] Monoclonal antibody inhibition experiments indicate that factor IXa binding site also exists between residues 1770 and 1840 of the factor VIII light chain, [101] and this site was further localized to residues 18111818 using synthetic peptides. [102] It is suggested that the higher affinity binding site on the factor VIII light chain interacts with the first epidermal growth factor (EGF)-like domain in factor IXa, and the weaker factor IXa interaction site within the A2 domain might induce a conformational change within the factor IXa active site. [100] [103]

The binding of substrate factor X to factor VIII has been studied by fluorescence anisotropy, solid-phase binding assays, cross-linking, and functional assays. [9] [104] The findings demonstrate that a factor X interactive site is contained within the acidic region at the COOH-terminus of the A1 subunit. The activation of factor VIII does not appear to be required for exposure of the factor X binding site. The interaction is sensitive to high ionic strength, is calcium dependent, and has a dissociation constant that is approximately several micromolars.[104]

Factor VIII Interaction with Phospholipids

Phospholipids interact with substrates, enzymes, and cofactors to play a critical role in the assembly and functional activity of the coagulation protease complexes. Negatively charged phospholipids are required for factor VIIIa-mediated enhancement of the activation of factor X. [12] [105] [106] In vivo the negatively charged phospholipids are likely provided by activated platelets and damaged endothelial cells. Factor VIII and factor V bind phosphatidylserine

---

by both hydrophobic and electrostatic interactions. [107] [108] [109] [110] [111] [112] [113] However, factor V does not efficiently compete with the binding of factor VIII to phospholipid vesicles composed of 15% phosphatidyl-L-serine. [105] Under equilibrium conditions, factor VIII can bind phospholipid vesicles containing 1525% phosphatidylserine with an apparent Kd of 24 nM. [81] [105] [114] Saturation occurs at 170385 moles of phospholipid per mole of factor VIII, [105] although the process

involves both rapid and slow interactions. [115] Factor VIII binding to phospholipid involves stereoselective recognition of the O-phospho- L-serine moiety of phosphatidylserine. [81] Factor V displays a similar affinity to phospholipids but has a lower requirement for phosphatidylserine. Because the composition of phosphatidylserine exposed on the platelet membrane surface can increase from 2% to 13% after stimulation, [116] the increase in phosphatidylserine content could account for the ability for factor VIII to specifically bind the surface of thrombin-activated platelets.

Addition of negatively charged phospholipids to the factor VIII/vWF complex dissociates factor VIII from vWF. [71] [72] Thrombin-treated factor VIII does not bind vWF with high affinity, [117] [118] [119] but it does retain phospholipid-binding properties. [72] The phospholipid-binding domain within factor VIII is localized to the light chain, [120] [121] and antibody inhibition studies suggest that the phospholipid binding site likely occurs in the C2 domain. [122] Peptides corresponding to the COOH-terminus of factor VIII (residues 23032332) inhibit the interaction of factor VIII with phospholipid. [123] Deletion analysis also suggests a phospholipid-binding domain resides in the factor V C2 domain. [124] In contrast, a proteolytic fragment of the factor V A3 domain inhibits factor V binding to phospholipid, [125] suggesting a phospholipid-binding site resides in the NH_2 -terminal end of the factor Va light chain. Thus, at present it is unclear whether the phospholipid-binding sites of factors V and VIII occur at the same positions within the proteins.

REGULATION OF FACTOR VIII ACTIVITY

Activation of Factor VIII

On treatment of intact factor VIII with thrombin or factor Xa, there is a rapid 30-fold increase and subsequent first-order decay of procoagulant activity. However, the maximal activation by thrombin is greater than that observed with factor Xa.[126] The activation coincides with proteolysis of both the heavy and light chains of factor VIII as depicted in Figure 107-1 . Cleavage within the heavy chain after arginine residue 740 generates a 90,000-MW polypeptide that is subsequently cleaved after arginine residue 372 to generate polypeptides of 50,000 MW and 43,000 MW. [127] Concomitantly, the 80,000-MW light chain is cleaved after arginine residue 1689 to generate a 73,000-MW polypeptide.[127] Each of these cleavage sites is bordered by a region rich in acidic amino acids that also contain the post-translationally modified amino acid tyrosine-sulfate.[32] The tyrosine-sulfate residues enhance thrombin cleavage at adjacent sites but do not affect factor Xa cleavage. [95] Factor V also contains tyrosine sulfate adjacent to thrombin cleavage sites and this modification also facilitates thrombin activation without affecting factor Xa activation. [128] These observations suggest that thrombin selectively utilizes tyrosine sulfate residues to facilitate interaction or cleavage. Most data support that thrombin anion-binding exosites I and II are involved in recognition of factor VIII and factor V. For example, thrombin activation of factor VIII is inhibited by either heparin, a molecule that interacts with anion-binding exosite II, or hirugen, a peptide that contains tyrosine sulfate and binds the anion-binding exosite I of thrombin. [129] [130]

Numerous studies correlated the appearance of 90,000-, 50,000-, 43,000-, and 73,000-MW polypeptides with peak factor VIII activity. [127] [131] [132] Mutagenesis studies showed that cleavages after residues 740 and 1648 were not required for cofactor activity. [133] In contrast, mutation at either arginine 372 or arginine 1689 yielded molecules that were not cleaved by thrombin at the mutated site and were not susceptible to thrombin activation. [133] [134] The importance of cleavage at residues 372 and 1689 for activation of factor VIII was also elucidated by the identification of hemophilia A patients having missense mutations that prevent cleavage at either residue 372 or residue 1689.[135] [136] These findings indicate that activation requires cleavage at both residues 372 and 1689, but does not appear to require a specific sequential order for cleavage at these sites. Cleavage at 1689 releases factor VIII from the inhibitory influence of vWF. [137] However, cleavage 1689 appears to additionally increase the activity of factor VIII in the absence of vWF. [138]

The B domain, delimited by amino acid residues 740 and 1648, is cleaved from factor VIII during activation. Comparison of the deduced amino acid sequence of porcine, murine, and human factor VIII showed a striking divergence within the B domains, whereas the bordering A2 and A3 domains exhibit 8085% homology. [24] [33] Factor VIII molecules constructed to lack most or all of the B domain have specific activities, thrombin cleavage products (except for the B domain), and thrombin activation coefficients similar to the wild-type molecule. [139] [140] The B-domain deletion molecules exhibit no detectable difference in vWF binding, survival in plasma, and ability to normalize the cuticle bleeding time after infusion into a factor VIII-deficient dog compared to the wild-type factor VIII. [76] By these analyses, removal of the B domain did not affect in vitro or in vivo procoagulant activity. In addition, B domain-deleted factor VIII has recently been used in clinical studies to demonstrate correction of bleeding episodes associated with hemophilia A. [141] One notable difference between wild-type and B domain-deleted factor VIII is that the B domain-deleted molecule is expressed at 510-fold higher levels, exhibits a reduced association with BiP in the ER, and is secreted more efficiently. [44] [76] This suggests that the B domain may regulate factor VIII biosynthesis. It is also possible that the B domain may have procoagulant, anticoagulant, or vasoactive properties heretofore unknown. For example, a portion of the B domains of factor V and factor VIII can serve as a substrate for transglutaminase activity of factor XIII. [142] [143]

Inactivation of Factor VIII

The activity of thrombin-activated factor VIII requires all polypeptides of the heterotrimer composed of the 50,000-, 43,000-, and 73,000-MW species. [144] [145] [146] The 50,000-MW A1 domain is in a Cu(I) ion-dependent association with the 73,000-MW light chain. The 43,000-MW A2 domain polypeptide is associated with the A domain by electrostatic interactions that likely involve residues 336 to 372 at the COOH-terminus of the 50,000-MW fragment. [147] [148] A detailed characterization of thrombin-activated factor VIIIa was hampered due to its marked instability that results from reversible dissociation of the 43,000-MW A2 domain polypeptide that occurs at physiologic pH.[147] [149] [150] Once activated by thrombin, the factor VIIIa heterotrimer can be stabilized by the addition of factor X and phospholipid. [151] The specific activity of porcine factor VIII is approximately fivefold greater than human factor VIIIa, and this correlates with a lower dissociation rate constant of the A2 domain polypeptide from the thrombin-activated heterotrimer.[150] [152] Covalent attachment of the A2 domain to the light chain yielded a factor VIII molecule that was stable after thrombin activation.[90] These results demonstrate the significance of A2 domain dissociation in the inactivation of factor VIII.

Factor VIII and activated factor VIII are also inactivated by proteolytic cleavage. Cleavage after arginine 336 is mediated by factor Xa, [127] factor IXa,[98] [153] APC,[127] [154] and also thrombin[32] in the presence of anionic phospholipids and correlates with inactivation of factor VIII. Additionally, APC cleaves the heavy chain

after residue 562,[155] and this cleavage at least partially inactivates factor VIII. [156] Finally, factor IXa and factor Xa cleave the light chain after residue 1719 and 1721, respectively,[127] [153] and at least cleavage at 1721 does not appear to significantly reduce factor VIII activity. [157] Factor X binding can prevent factor IXa-and APC-mediated cleavage at Arg 336,[104] and it is proposed that this may provide a mechanism to sustain maximal factor Xase activity until substrate becomes limiting.

Recently, APC resistance was shown to be one of the major causes of hereditary thrombophilia as a consequence of an arginine to glutamine mutation in the APC cleavage site in factor V at residue 506. [159] [160] [161] The APC-resistant phenotype was first reported as a poor anticoagulant response to APC in an activated partial thromboplastin time assay (called the APC resistance ratio). [159] It is possible that APC-resistant mutations in factor VIII may also lead to hereditary thrombophilia. Analysis of mutant factor VIII protein demonstrated that cleavage at either arginine 336 or arginine 562 only partially inactivated factor VIII and that resistance to cleavage at both arginine 336 or arginine 562 was necessary to detect a poor anticoagulant response in an activated partial thromboplastin time assay. [156] These results show that a single mutation in either factor APC cleavage site to yield cleavage resistance would not be detected as a poor anticoagulant response in vitro. In addition, a search did not identify any mutations at arginine 336 and 562 in factor VIII in 125 patients with venous thrombosis. [162] The sum of these studies indicates that it is unlikely mutations in factor VIII APC cleavage sites result in thrombophilia.

Modulation of Factor VIII Activity by Biologic Membranes

Procoagulant activity is profoundly affected by the presence of cellular surfaces. On platelet activation by thrombin, the platelet surface exhibits procoagulant activity. This activity results from the exposure of negatively charged phospholipids and possibly also of specific receptors for the coagulation factors. Negatively charged phospholipids are usually confined to the inner leaflet of cellular membranes [163] [164] and are exposed on cellular lysis at sites of injury. Unactivated platelets exhibit binding sites for factor Va and Xa.[165] [166] [167] Platelet activation is associated with exposure of factor VIII and factor IXa binding sites. [168] [169] [170] [171] There are approximately 400 factor VIII sites per activated platelet and factor V cannot compete with factor VIII binding. [168] The specificity in binding of factor VIII suggests that a specific protein receptor for factor VIII is involved. In addition, the kinetics of thrombin generation mediated by the prothrombinase complex on pure phospholipid surfaces compared to activated platelets suggests that a specific saturable receptor exists for prothrombinase and probably also for the factor Xa-generating enzyme

complex.[172] Platelet binding is mediated by the factor VIII light chain and is inhibited by the presence of vWF. A factor VIII mutant protein that cannot bind vWF with high affinity retains its ability to bind platelets. [73] Thus the vWF binding site and the platelet binding site appear to be distinct within the factor VIII molecule.

The present understanding of the mechanism by which factor VIII functions is presented in Figure 107-3 . The two chains of factor VIII are associated in a monovalent Cu(I)-dependent manner. vWF interacts with the NH_2 -terminus and the COOH-terminus of the light chain. The mechanism by which initial activation of factor VIII occurs is unknown, but evidence suggests that the extrinsic pathway may be the most significant physiologic initiator of factor VIIIa generation. [173] Patients deficient in factor VII have low levels of factor Xa compared with patients with deficiencies in factor VIII. [174] In addition, infusion of VIIa into a chimpanzee increases the level of circulating factor Xa.[175] These results indicate that the primary mechanism of factor Xa generation in vivo is via the extrinsic pathway. Because patients deficient in factor VIII or factor IX do have a bleeding diathesis, there is a need for the intrinsic pathway for hemostasis in vivo (Chap. 102). Two possible mechanisms could explain the need for factors VIII and IX in vivo. First, because factor Xa generation via the tissue factor pathway can bind tissue factor pathway inhibitor and subsequently inhibit the factor VIIa tissue factor complex, only small amounts of factor Xa can be generated before further extrinsic factor X activation is inhibited. [173] [176] Because tissue factor pathway inhibitor does not inhibit the intrinsic formation of factor IXa or its activity, the intrinsic route is required to amplify the response. Alternatively, because the extrinsic pathway can activate factor IX in vitro, [177] this pathway may primarily activate factor IX as opposed to factor X in vivo. Either mechanism could explain the need for factors VIII and IX for effective hemostasis.

Molecular Modeling of Factor VIII

Our knowledge of the structural requirements for factor VIII activity have dramatically increased since the original isolation of factor VIII protein from human plasma and identification of the factor VIII gene. The three-dimensional x-ray structure is now available for factor IXa [178] (Chap. 108). In addition, a molecular model of the A domains of factor VIII, based on the crystal structure of the homologous plasma protein ceruloplasmin, [179] was recently proposed.[180] Although this model comprises only the A domains and lacks the acidic regions and the B and C domains and does not consider what changes occur on activation of factor VIII to factor VIIIa, the three-dimensional model

Figure 107-3 Model for thrombin activation and inactivation of factor VIII. Factor VIII is depicted as two chains in a copper ion (CuI)-dependent association. vWF is illustrated to promote association of the light and heavy chains of factor VIII. Thrombin cleavage at residues 336 and 1689 releases the activated species from the vWF complex. Inactivation may occur through a dissociation of the A2 subunit or by a specific proteolytic event.

is a good basis for further functional studies. The model indicates that the factor IXa-binding sites in the A2 and A3 domains are in close proximity and are exposed at the same side of the molecule. With information obtained from analysis of gene defects in hemophilia A, mutagenesis studies to identify critical regions for factor VIII function, and from biochemical analyses to identify interacting regions between factor VIII and factor IXa and factor X, it should be possible to refine this model to elucidate the basis of the mechanism of action of factor VIII.

HEMOPHILIA A

The gene for factor VIII is on the human X chromosome and therefore hemophilia A is a classic example of X-linked recessive inheritance. It occurs almost exclusively in males for they have only one X chromosome; females with one abnormal copy of the factor VIII gene are carriers because the other X chromosome contains a normal copy of the gene. The frequency of the disorder is 1/5,00010,000 male births and there is no particular ethnic group that has unusually lower or higher incidence of the disease. The severity and frequency of bleeding in the patients correlates with the factor VIII activity in plasma. [181] [182]

About 5060% of patients have severe hemophilia A with factor VIII activity <2% of normal; these patients have frequent spontaneous bleeding into joints, muscles, and internal organs. Moderately severe hemophilia A occurs in about 2530% of patients; the factor VIII activity is 25% of normal and there is bleeding after minor trauma. Mild hemophilia, which occurs in 1520% of patients, is associated with factor VIII activity of 530% and there is bleeding only after significant trauma or surgery. Individuals with factor VIII activity >30% do not have symptoms of hemophilia A. Of particular interest for the understanding of function of factor VIII is a category of patients who have considerable amount of factor VIII protein in their plasma (at least 30% of normal) but the protein is nonfunctional. Approximately 5% of patients belong to this category, termed cross-reacting material (CRM) positive. [183] CRM reduced is another category in which the factor VIII antigen and activity are reduced to approximately the same level.

Before the introduction of modern treatment, severe hemophilia A was a genetically lethal disease in which affected males produced few offspring. Therefore, nearly one-third of the mutant alleles would be lost in each generation. In 1935, Haldane predicted that to maintain a constant frequency in the population about one-third of cases would be the result of novel mutations. The prediction was proven to be correct because a large number of different mutations have been found in the factor VIII gene and many patients have been identified who carry a de novo mutation not present in the X chromosome of their mothers. One notable exception to the Haldane prediction, however, is the case of the common inversion of factor VIII.

FACTOR VIII GENE STRUCTURE AND LOCATION

The factor VIII gene is 186 kb long (approximately 0.1% of the DNA of the X chromosome) and contains 26 exons. The nucleotide sequences of the exons, intron-exon boundaries, and 5 and 3 untranslated regions have been determined. [8] [24] [184] The exon length varies from 69 to 262 nucleotides except for exon 14, which is 3,106 nucleotides, and the last exon 26, which has 1,958 nucleotides (Fig. 107-4). There are some large intervening

Figure 107-4 Schematic representation of chromosomal localization and structure of the factor VIII gene. The gene is located about 1,000 kb from the Xqter (panel B). It is 186 kb long and contains 26 exons (panel C). In the large intron 22 there are two nested genes, the intronless F8A and F8B, which utilize the exon 23 of factor VIII gene as its second exon (panel D). There are three copies of the F8A-F8B sequences on Xq28 as shown by the gray boxes of panel B. See text for further discussion of the gene structure.

sequences such as IVS22, which is 32 kb, and IVS1, IVS6, IVS13, IVS14, and IVS25, which are 1423 kb long.

The normal factor VIII mRNA is approximately 9 kb, of which the coding sequence is 7,053 nucleotides. There is a CpG island within IVS22, which is associated with two additional transcripts. One transcript of 1.8 kb is produced abundantly in a wide variety of cells. The orientation of this transcript is opposite to that of factor VIII and contains no intervening sequence.[185] This 1,739-nt long cDNA has been termed factor VIII-associated gene A (F8A) and is conserved in the mouse. [186] The second transcript of 2.5 kb is transcribed in the same direction as factor VIII and after a short exon that may encode for eight amino acids, it utilizes exons 2326 of the factor VIII gene.[187] This gene has been termed factor VIII-associated gene B (F8B). The two transcripts F8A and F8B originate within 122 bases from each other. The sequences of F8A and F8B along with few kilobases of surrounding DNA are also present in two other areas of the X chromosome approximately 400 kb telomeric to factor VIII gene.[185] [188] The function of these transcripts and their potential protein products are unknown.

The promoter (5 flanking) region of factor VIII has been studied by transient transfection studies in liver-derived cell lines, DNase I footprinting, electrophoretic mobility shift assays with nuclear extracts and purified transcription factors, and mutation analysis. DNase footprinting showed the presence of more than 12 protein-binding sites distributed up to 1 kb upstream of the transcription start site. A region up to 300 nucleotides contains all the necessary elements for maximal promoter activity.[189] [190] Mutation analysis suggested that the putative TATA box is not essential for factor VIII promoter activity. Liver-enriched transcription factors such as HNF1, NFkB, C/EBPa, and C/EBPb interact with the factor VIII promoter region.[189]

The factor VIII gene maps on the long arm of the X chromosome, in the most distal band Xq28. Haldane and Smith[191] reported linkage of hemophilia A with color blindness and Boyer and Graham[192] demonstrated close linkage of hemophilia A with polymorphisms at the glucose-6-phosphate dehydrogenase (G6PD) locus. Additional studies confirmed the close linkage of factor VIII with G6PD. [193] Patterson et al.[194] showed that G6PD and factor VIII genes lie within 500 kb of each other. Pulsed field gel electrophoresis and physical mapping of Xq28 using yeast artificial chromosomes suggested that the factor VIII gene mapped distal to G6PD. [188] [195] The order of these loci and the direction of transcription is Xcen-G6PD-3F8-5F8-Xqter. [188] [196] The distance from factor VIII gene to the Xq telomere is approximately 1 Mb.

FACTOR VIII GENE DEFECTS

Since the cloning of the factor VIII gene, the DNA of >2,500 patients with hemophilia A has been examined for molecular defects. Initially, restriction endonuclease analysis and Southern blot, cloning, and sequencing were the methods used. The introduction of polymerase chain reaction (PCR) amplification from genomic DNA or from RNA (reverse transcriptase-PCR, RT-PCR) had revolutionized the mutation detection protocols. Several screening methods for recognition of mutations have been used, namely, denaturing gradient gel electrophoresis, single-stranded conformational analysis, RNA cleavage analysis, and subsequently direct sequencing of PCR product. A database of mutations in the factor VIII gene has been published [197] [198] and is constantly updated. A Web site of factor VIII mutations has been created (http://146.179.66.63/usr/www/WebPages/main.dir/main.htm and reference [199]). Figure 107-5 depicts the different kinds of mutations found in patients with hemophilia A from the studies of references [200] [201] [202] as updated after the identification of the common inversion by Lakich et al. [203] These studies have been selected because almost all mutations have been identified in a given sample.

Figure 107-5 Factor VIII gene defects in two samples of patients with severe and mild to moderate hemophilia.

Gross DNA Rearrangements

Common Partial Inversion of Factor VIII

The efforts to characterize all mutations in the factor VIII gene in a defined sample of patients with hemophilia A revealed a surprising and unexpected finding. After scanning all the exons of factor VIII gene using denaturing gradient gel electrophoresis, Higuchi and coworkers found that the causative mutation in about 90% of patients with mild to moderate hemophilia A.[200] However, when severely affected patients were similarly extensively studied, the causative mutation was only found in about 50%.[201] The cause of the remaining 50% of severe hemophilia A remained elusive. Subsequently Naylor et al., using RT-PCR of illegitimate transcription of the factor VIII gene, found that in about 40% of severely affected patients no RT-PCR amplification was possible between exons 22 and 23 of the gene. [204] Lakich et al. [203] and Naylor et al.[205] found that these patients have a partial inversion of the factor VIII gene (the gene up to and including exon 22 is inverted). The inversion is due to homologous recombination between the region that includes the F8A gene in intron 22 and one of the two other homologous regions located more than 400 kb 5 (telomeric) to the factor VIII gene[203] (Fig. 107-6). The regions of homology are each 9.5 kb long and there is >98% nucleotide sequence identity among them. [206] Depending on which extragenic copy of gene A is involved in the crossing-over event, two main types of inversions are recognized. Type 1 inversion affects the distal copy, whereas type 2 inversion affects the proximal copy.[203] In addition, a rare Southern blot pattern, type 3, is thought to result from an inversion occuring in individuals carrying more than two extragenic copies of gene A. The inversions originate almost exclusively in male meiosis. [207] Because the mutation occurs very rarely in female germ cells, nearly all mothers of patients with inversions are carriers of factor VIII deficiency. A recent consortium analysis of 2,093 patients with severe hemophilia A revealed an inversion of factor VIII in 890 or 43%. [208] Inversion type 1 accounts for 83% and type 2 for 16% of the inversion cases; the type 3 patterns were observed in only 1% of the cases. The discovery of this mutation is of considerable clinical significance because it accounts for about 25% of all patients with hemophilia A and >40% of those with severe disease.

Large Deletions

In 5% of the patients with hemophilia A there are large (>100 nucleotides) deletions in the factor VIII gene. [209] The mutation database contains 89 different deletions (see reference [210] and http://146.179.66.63/usr/www/WebPages/main.dir/main.htm).

Figure 107-6 Factor VIII gene inversions in hemophilia A. Due to intrachromosomal crossing-over between the homologous regions A1, A2, and A3, there is an inversion of factor VIII sequences encompassing exons 122. The various types of inversion (types 1, 2, 3A, and 3B) are shown. These inversions are easily recognizable (bottom of the figure) after Southern blot analysis using part of the homologous regions as a probe.

In the majority of these defects the deletion breakpoints have not been precisely characterized. Southern blot analysis indicated that there were not many patients with the same breakpoints suggesting that factor VIII gene does not contain sequences that are prone to become deletion breakpoints. Deletions almost always produce severe hemophilia A; however, a deletion of exon 22 and another deletion of exons 2324 were associated with moderate disease probably because of in-frame joining (after mRNA splicing) of exons 21 and 23 in one case and exons 22 and 25 in the other, to produce proteins lacking 52 and 98 amino acids, respectively.[210] [211] Few deletion breakpoints have been characterized at the nucleotide sequence level. The majority of the breakpoints examined do not occur in repetitive elements such as Alu sequences. There is usually two to four nucleotide homology at the junction point and the deletion mechanism is probably via nonhomologous recombination.[212] A total of 27 of the 73 patients (37%) with deletions for which data were available have developed factor VIII inhibitors after treatment.

Insertion of Retrotransposons

De novo insertion of LINE repetitive elements in the human genome was first reported in the factor VIII gene in two patients with severe de novo hemophilia A. [213] In one patient a 3.8-kb portion of a LINE element was inserted in exon 14 of factor VIII. The inserted DNA had a poly (A) tail, produced a target site duplication, and was inserted in a relatively adenine-rich sequence of exon 14 (Fig. 107-7). The de novo insertion in the second case was a 2.1-kb portion of a LINE element. It occurred in a different site of exon 14 and had all the characteristics of retrotransposition. LINE elements compose about 5% of the human genome and there are approximately 10^5 copies.[214] The full length of the element is 6.5 kb and most of the copies in the human genome are partial and defective. The consensus sequence of LINE element contains two open reading frames, the second of which predicts a protein with amino acid homology to viral reverse transcriptase. About 3,000 LINE copies are full length and are potential transposable elements. Only a few of these, perhaps those with open reading frames, can produce a new insertion through an RNA intermediate. They are probably transcribed into DNA and then reinserted as double-stranded DNA into a new genomic site. [215] The full length active LINE element responsible for the insertion in the first hemophilia A patient was cloned and characterized. It maps on chromosome 22 and probably encodes for a peptide that has reverse transcriptase activity. [216] [217] A third LINE element insertion in intron 10 has also been observed but since it did not co-segregate with the hemophilia A phenotype it represents a recently established private polymorphism. [218] Insertions of LINE or other retrotransposons are not common because there are only two such examples in more than 1,000 patients studied. There are about a dozen additional reports for LINE and Alu insertions in other genes. [215]

Duplications

Duplications of parts of human genes are very rare causes of mutations. There are two such lesions described in the factor VIII gene. In one there was a duplication of 23 kb of IVS22 inserted between exons 23 and 25. [219] This rearrangement found

Figure 107-7 Schematic representation of insertions of LINE retrotrans-posons in exon 14 of factor VIII gene. Color boxes represent the LINE elements and the arrows within the boxes point toward the 3 end of the sequence. The numbers on the LINE boxes represent the corresponding nucleotides of the consensus LINE sequence. Numbers in the sequences flanking the inserted LINE elements denote the corresponding nucleotides of the factor VIII cDNA. The target site duplication is bracketed. *(From Kazazian et al.,[213] with permission.)*

in two female siblings was apparently unstable and led to deletion of exons 2325 in the male offspring of one of the females. In the second case there was an in-frame duplication of exon 13 in a patient with mild hemophilia A. [220]

Chromosomal Rearrangement Breakpoints Involving the Factor VIII Gene

A complex de novo translocation of chromosomes X and 17 [46,X,t(X;17)] has been reported in a female patient with severe hemophilia A. [196] The normal X, always late replicating, contained a normal factor VIII gene. The der(17) contained a deleted factor VIII gene that lacked exons 115; exons 1626 were present in another autosome. One of the breakpoints of the complex rearrangement was therefore between exons 15 and 16 of the factor VIII gene.

Point Mutations and Small (<100 bp) Deletion/Insertions

Nucleotide substitutions and insertion/deletions of up to 100 nucleotides are discussed under point mutations.

Small Deletion/Insertions

Small deletions or insertions in the coding region of factor VIII gene that result in frameshifts and cause severe hemophilia A have been reported in 86 unrelated patients[197] [198] [199] (http://146.179.66.63/usr/www/WebPages/main.dir/main.htm). The database contains 63 small deletions (186 nucleotides) among 572 independent point mutations recorded (11%). There are 23 small insertions (110 nucleotides) (4% of the total point mutations). More than one-third of the small deletions (24 of 63) and half of the insertions (13 of 23) were found as expected in the large exon 14. The majority of the small deletions/insertions occur in DNA regions of short direct repeats. Almost all of the mutations that result in translation frameshifts cause severe hemophilia A. An exception was observed in a family with moderately severe hemophilia A and a deletion of a single nucleotide T within an A_8TA_2 sequence of exon 14. The severity of the clinical phenotype did not correspond to that expected of a frameshift mutation. A small amount of functional factor VIII protein was detected in the patients plasma. Analysis of DNA and RNA molecules from normal and affected individuals and in vitro transcription/translation suggested a partial correction of the molecular defect, because of: (1) DNA replication/RNA transcription errors resulting in restoration of the reading frame or (2) ribosomal frameshifting resulting in the production of normal factor VIII polypeptide and, thus, in a milder than expected hemophilia A. All of these mechanisms probably were promoted by the longer run of adenines, A_{10} instead of A_8TA_2 , after the delT. [221]

Nonsense Mutations

There are 115 independent nonsense mutations in 48 different codons that are included in the point mutation database comprising 20.1% of the total number of point mutations (references [197] [198] [199] and http://146.179.66.63/usr/www/WebPages/ main.dir/main.htm). This percentage is perhaps biased because many investigators have used restriction digestion analysis with Taq I that recognizes CG to TG mutations and in particular CGA to TGA (Arg to Stop) substitutions. [222] In two samples of 52 severe hemophilia A patients[200] [202] in which all point mutations have been characterized, the number of nonsense codons were 7, that is 13.5% of the total severe mutations or 29% of the severe point mutations.

CpG Dinucleotide Hypermutability

The study of point mutations in factor VIII uncovered two general lessons concerning human mutations. The first was the discovery of a mutation hotspot at CpG dinucleotides in which there is a common substitution CG to TG if the mutation occurs in the sense strand or CG to CA if the mutation occurs in the antisense strand.[222] The mutations probably occur because, in mammalian DNA, the majority of CpG dinucleotides are methylated by methyltransferase; the subsequent spontaneous deamination

of the 5-methylcytosine produces a TpG dinucleotide. The mutation usually occurs in tissues in which the gene is not expressed. [223] There are 276 independent mutations in 46 sites that conform to the CG to TG rule in the point mutation database (48%). This high proportion of CpG mutations is probably due to the deliberate screening by restriction analysis or oligonucleotide hybridization. In 35 sites recurrent mutation at CpG dinucleotides appears to have occurred. An unbiased estimate of the frequency of CG to TG mutation may be obtained from studies in which all point mutations have been characterized in a given sample of patients. [200] [201] [202] [224] In these selected studies a total of 84 point mutations have been characterized and 32 were of the CG to TG rule (38%). It has been estimated that in the factor VIII gene CG to TG or CA mutations are 1020 times more frequent than mutations of CG to any other dinucleotide. [225] The mutation hotspot has subsequently been observed in a wide variety of other human genes related to disease phenotypes.

Exon Skipping Due to Nonsense Mutations

An important observation concerning the pathophysiology of nonsense mutations has been made in the factor VIII gene and independently in the fibrillin and OAT genes using RT-PCR for mutation detection. [202] [226] In some cases a nonsense codon mutation can lead to abnormal RNA processing where the exon containing the mutation is skipped. In one case of Glu 1987 to Stop mutation in exon 19, all detectable mRNA lacked the sequences of this exon. In the second case of Arg 2116 to Stop mutation of exon 22 there was about 50% of mRNA without the sequences of exon 22 while the remaining 50% of mRNA was of normal size. The junctions of exons 1820 and 2123 do not result in translational frameshift. The mechanism, significance, and frequency of the exon skipping due to nonsense mutations are presently unknown.

Missense Mutations

The study of missense mutations is important for understanding the function of the protein and the pathophysiology of the disease. A total of 191 mutations in 457 unrelated patients leading to amino acid substitutions have been included in the database and the majority of them are schematically presented in Figure 107-8 (references [197] [198] [199] and http://146.179.66.63/usr/www/WebPages/main.dir/main.htm). These mutations are spread throughout the different domains of the gene except for exon 14 that encodes for domain B, which is devoid of amino acid substitutions that cause hemophilia A. Despite the wealth

Figure 107-8 Missense mutations in the factor VIII protein. The structural domains of the protein are shown and the amino acid substitutions are depicted using the one letter code for amino acids. For example E11V indicates a Glu to Val substitution at amino acid residue 11; similarly R282H/L/C indicates that Arg 282 is substituted by His, Leu, or Cys in different patients (bold).

of amino acid substitutions found, the mode of action of the majority of these mutations in producing reduced factor VIII activity in plasma is unknown. However, several mutations have been identified that alter thrombin cleavage sites, the vWF binding site, or otherwise introduce or destroy N-linked glycosylation sites.

Mutations at Thrombin Cleavage Sites

There are natural mutations in patients with CRM-positive hemophilia A that affect the thrombin cleavage needed for activation of the molecule. Mutations arginine 372 histidine and arginine 372 cysteine have been shown in vitro to abolish the normal cleavage by thrombin in the heavy chain. [135] [227] [228] The Serine 373 leucine mutation has also been shown to abolish normal cleavage by thrombin. [229] By inference it seems highly likely that Serine 373 proline would have the same effect, although this has not yet been tested directly. Mutations arginine 1689 cysteine and arginine 1689 histidine abolish thrombin cleavage at the light chain. [200] [204] These mutations also lead to CRM-positive hemophilia A in which there is normal amount of nonfunctional factor VIII in plasma.

Mutations at the vWF Binding Site

There are two sulfated tyrosine residues tyrosine 1664 and tyrosine 1680 in the region of factor VIII between amino acids lysine 1673 and glutamic acid 1684 in which a vWF binding site has been localized. A natural mutation tyrosine 1680 phenylalanine has been observed in patients with moderate, CRM-reduced hemophilia A. [97] Site-directed mutagenesis of tyrosine 1680 phenylalanine results in a molecule that has lost high affinity binding to vWF presumably because the phenylalanine residue cannot be sulfated. [95] [96]

Mutations at N-Glycosylation Sites

Two other CRM-positive mutations produce severe hemophilia A by creating new N-glycosylation sites in the protein. [230] The first isoleucine 566 threonine creates a new such site at asparagine 564 (Asn-Gln-Ile to Asn-Gln-Thr) in the A2 domain of the heavy chain. The second new site is in the A3 domain of the light chain; the mutation is methionine 1772 threonine, changing Asn-Ile-Met to Asn-Ile-Thr. In both cases factor VIII is present at normal levels in plasma, but it is completely inactive. When the plasma of either patient is deglycosylated, factor VIII activity is restored to a significant degree. Inhibition assays using synthetic peptides corresponding to factor VIII residues 558565 previously shown to be a factor IXa interaction site provided support that the defect in the isoleucine 566 threonine mutant factor VIII molecule is caused by steric hindrance for the interaction with factor IXa. [231] Furthermore, the isoleucine 566 threonine mutant in transiently transfected COS1 cells had a reduced mobility probably because of the additional N-glycosylation site. [231] The significance of a serine 577 proline mutation that in theory eliminates a potential N-glycosylation site at asparagine 575 is unknown.

Study of Mutations in CRM-Positive and CRM-Reduced Patients

The elucidation of mutations in this group of patients is very instructive in understanding the importance of specific amino acid residues. A small number of such mutations have been described. [198] [199] [232] Many of the CRM-positive mutations occur in the A2 domain, which consists of 228 amino acids or about 10% of the coding region of factor VIII; this region must then be important in procoagulant activity. A few of the CRM-positive mutations have been biochemically studied. The defect in the serine 558 phenylalanine factor VIII molecule has been shown to result by steric hindrance for interaction with factor IXa. [231] The majority of mutations, however, are CRM negative and probably affect the folding or stability of the protein. Because these mutations result in absence of secreted factor VIII and the in vitro functional studies depend on the analysis of the protein produced in eukaryotic cells after transfection with factor VIII cDNA, the mechanisms of action of these mutants will be difficult to elucidate. In the case of the deletion of phenylalanine 652, the secretion of the mutant factor VIII was defective and the protein was degraded within the transiently transfected COS1 cells. [231] Cases with two different mutations in the same amino acid are also of interest (Fig. 107-8). The mutations arginine 2307 leucine and arginine 2307 glutamine exhibit defective intracellular transport and secretion of apparently biologically active factor VIII molecule. [233]

Splicing Errors

Only 25 potential splicing errors have been found (references [197] [198] [199] and http:146.179.66.63/usr/www/WebPages/main.dir/main.htm). Despite the presence of 50 splice junctions in the factor VIII gene, splicing mutants do not account for a sizeable fraction of hemophilia A patients. There are 5 mutations in the invariant AG of the acceptor splice site in introns 1, 4, 5, and 6 and 14 associated as expected with severe disease. There are 4 mutations in the donor splice site consensus (nt-1 of IVS 14, nt +3 of IVS 6, nt +5 of IVS 12 and nt +3 of IVS19) and two in cryptic splice sites. No formal proof that the mutations cause abnormal splicing has been obtained.

Promoter Mutations

No examples of mutations in the 5 untranslated region of factor VIII gene have been reported to date. If such mutations do occur they are probably infrequent because two laboratories failed to find any nucleotide substitutions in 530 nucleotides of the 5 flanking region of factor VIII in 227 patients with hemophilia A. [97]

FACTOR VIII INHIBITORS

One of the major limitations with present factor VIII replacement therapy is the development of inhibitory antibodies to factor VIII (Chap. 110) in 1020% of patients with severe hemophilia A. [234] [235] The etiology of inhibitor development is unknown and host related factors are poorly understood. [236] Studies attempting to relate inhibitor development with HLA haplotypes have had little success. The antifactor VIII antibody response recruits all subclasses of antifactor VIII antibodies, but the IgG4 isotype is somewhat overrepresented.[237] [238] Epitope mapping has shown specificities against the heavy or light chain or both in different patients. [237] [239] Studies established that the most common factor VIII epitopes that induce inhibitory antibodies are localized to the A2 domain (residues 373740), the C2 domain (residues 21732332), and possibly the A3 domain of factor VIII.[238] [240] [241] [242] [243] Because a limited number of antigenic regions have been identified, it may be possible to engineer factor VIII to be less immunogenic through recombinant DNA technology. For example, Lollar and coworkers prepared human and porcine factor VIII chimeric molecules that had residues between 484 and 508 in human factor VIII replaced by the respective porcine residues. The resultant factor VIII displayed less reactivity to antifactor VIII inhibitory antibodies. [244]

The analysis of many factor VIII mutations and their association with inhibitor development may uncover some rules, if such exist, concerning the contribution of the nature of the mutations to inhibitor formation. In the recent consortium analysis of >900 patients with factor VIII inversions, 130 of 642 patients studied had developed inhibitors (20%); in the control population of severe hemophilia A patients without inversions, 131 of 821 patients had developed inhibitors (16%). [208] These results are

not statistically different, suggesting that factor VIII inversions are not a predisposing factor for inhibitor development.

The majority of the reported inhibitor cases have nonsense mutations, deletions, or inversions in their factor VIII gene. There are, however, 10 missense mutations reported in the database that are associated with low levels of inhibitors. These may create local structural modifications with new immunogenic epitopes. Among the nonsense mutations, arginine 1941 is associated with inhibitors in 8 of 11 cases; arginine 2147 in 3 of 8, arginine 2209 in 6 of 16, lysine 1827 in 2 of 2, and arginine 1696 in 2 of 2 cases. Other nonsense mutations, however (e.g., 8 cases with arginine 336 or 9 cases with arginine 2116), are never associated with inhibitors. In these cases, exon skipping may provide a protein merely lacking 2050 amino acids (exon skipping has been detected for mutation of arginine 2116, [202] in which inhibitors have never been observed). Gross deletions of the factor VIII gene result in two- to threefold increased incidence of inhibitors than for patients without detectable deletions.[197] [245] However, no clear picture has emerged as to the correlation between the size or the breakpoints of the deletions and the development of inhibitors.

CARRIER AND ANTENATAL DIAGNOSIS

The cloning of factor VIII gene, the discovery of DNA polymorphic markers within and closely linked to the gene, and the elucidation of molecular defects in many patients with hemophilia A have changed dramatically the practice of diagnosis of carriers and affected fetuses. The discovery of the common partial inversion of the factor VIII gene[203] provided a means of diagnosis using Southern blot analysis. This defect accounts for approximately 45% of severe hemophilia A. The diagnosis of the exact molecular defect in the remainder of the families is still not practical even in sophisticated laboratories. Because of the enormous variety of the remaining mutations, DNA diagnosis is almost always limited to indirect detection using linked DNA polymorphisms. Figure 107-9 shows the location and informativeness of DNA polymorphisms within factor VIII gene. Families requesting carrier or prenatal diagnosis (after the initial screening for the detection of the inversion) are usually asked to supply blood samples on a number of family members for linkage analysis. The affected factor VIII gene is marked within the family using polymorphic markers both within[245] [246] [247] [248] and outside[249] [250] the gene (Fig. 107-10). Short sequence repeats have been found in two introns.[251] [252] Nearly all families are informative, but 2030% for extragenic polymorphisms only. In those families the chance of error is 25% depending on the polymorphism

Figure 107-9 DNA polymorphisms within the factor VIII gene. Arrows denote the location of the polymorphisms. Percent numbers represent the observed heterozygosity of each polymorphic system in female individuals. The Msp I site in intron 22 is only polymorphic in Japanese (J). There are two polymorphic (CA)n repeats identified in introns 13 and 22.

Figure 107-10 Example of DNA diagnosis in hemophilia A. The DNA analysis is shown below the pedigree. Direct analysis shows an abnormal DNA fragment in affected individual III-2 (this fragment is due to amplification of a small rearrangement). This analysis shows that individual II-2 and her daughters III-3 and III-4 are carriers, individual III-1 is not a carrier, and the parents of II-2 do not have the abnormal fragment and, therefore, the mutation occurred de novo in one X chromosome of their germ cells. The fetus IV-1 does not have the abnormal factor VIII allele and therefore he is not affected. Indirect analysis was performed using a highly informative intragenic polymorphism that shows five different alleles in the DNA of the members of the pedigree. Affected individual III-2 has allele 1 that marks his abnormal factor VIII gene. This allele 1 was inherited from his grandfather I-1 and, therefore, the de novo mutation should have occurred in his germ cells. Note that without the results of the direct DNA analysis in this pedigree, the DNA polymorphisms were not sufficient in identifying carriers.

used. When an intragenic polymorphism is used, the chance of error is negligible (<1%).

The indirect detection of mutant genes is not feasible when only one male offspring is available and the carrier status of the mother is unknown. In these cases direct detection of molecular defect should be used. However, the large number of different molecular defects, the considerable size of the gene, and the sophistication of the mutation detection methodology make direct diagnosis not available to all families. The situation has

dramatically changed with the simple test to recognize the common partial inversion of factor VIII, which accounts for about 45% of cases of severe hemophilia A. Few laboratories will then deal with the remaining molecular defects. It seems that the method of choice is the RT-PCR amplification of illegitimate transcripts and their analysis using chemical cleavage or another mutation screening method. Further technical improvements are needed to make the analysis faster and less costly. The availability of high-density oligonucleotide arrays. [253] for the factor VIII gene will permit the rapid detection of the molecular defects in the majority of patients.

COMBINED DEFICIENCY OF FACTORS V AND VIII

Combined factors V and VIII deficiency is an autosomal recessive disease that was described in 1954 by Oeri et al. [254] To date, a total of 89 patients in 58 families have been reported, where 24 of the families are from the Mediterranean region. Patients with this disorder exhibit factor V and factor VIII antigen levels in the range of 530% that correlates with the activity measurements. Bleeding is similar to that observed in other coagulation factor deficiencies. The levels of all other plasma proteins that have been measured appear normal in these patients, including those of the homologous copper ion binding protein ceruloplasmin. Although there have been several reports of individuals who simultaneously inherited mutations in both the factor VIII and factor V gene, [255] this is rare (approximately $1/10^{10}$).

It was originally proposed that combined deficiency of factors V and VIII resulted from a loss of protein C inhibitor. [256] However, subsequent studies failed to confirm deficiency of protein C inhibitor in these patients. [257] [258] [259] Recently, homozygosity mapping, a method originally described by Lander and Botstein [260] and positional cloning approaches were used to identify the defective gene. [261] [262] Analysis from 14 affected individuals from nine unrelated families identified that the factor V and VIII deficiency gene mapped to the long arm of chromosome 18. Positional cloning approaches identified that the gene responsible for the defect is ERGIC-53. [263] Haplotype analysis among these families suggested that two independent founders gave rise to two mutations in all of the original nine unrelated families studied. Subsequent studies have identified five different mutations in ERGIC-53 in 17 of 25 families analyzed with combined factor V and VIII deficiency. At present the genetic defect has not been identified in the remaining families.

ERGIC-53 encodes a 53,000-MW transmembrane protein of the ER-Golgi intermediate compartment (hence, ERGIC-53) that has mannose-binding capability and that cycles between the ER and the Golgi compartment.[264] [265] Analysis of lymphocytes from patients with factors V and VIII deficiency demonstrated a complete lack of ERGIC-53 protein.[263] Although ERGIC-53 has the properties expected for a protein that may facilitate protein transport from the ER to the Golgi compartment, the elucidation of its absence in combined factor V and VIII deficiency suggests the selective loss of factors V and VIII in the plasma is due to defective intracellular transport and secretion unique to these two coagulation factors. Both of these proteins contain an unusually heavily glycosylated B domain, suggesting that ERGIC-53 may interact with the B domain to facilitate their intracellular transport and secretion.

THE FUTURE FOR HEMOPHILIA A THERAPY

Animal Models for Hemophilia A

To evaluate improved therapeutic regimens for hemophilia A and to study the role of factor VIII in vivo, animal models of hemophilia A have been studied. Dogs have been diagnosed with hemophilia A, and several colonies have been established. Bleeding tests have been established in these dogs, the most frequently used being the cuticle bleeding test.[266] A German shepherd dog model among others has been used for several studies[267] [268] that includes testing of recombinant-derived factor VIII and B domain-deleted factor VIII.[76] [269]

More recently, a mouse with severe factor VIII deficiency was made by targeted disruption of the murine factor VIII gene.[270] Exons 16 or 17 of the cloned murine factor VIII genomic DNA were interrupted by the insertion of a neomycin-resistant gene cassette and mouse embryonic stem cell lines containing the neomycin gene insertions after homologous recombination were produced. These ES cell lines were used to produce male mice with targeted disruption of the factor VIII gene. The two strains of resulting affected mice have <1% factor VIII activity and bleeding after minor trauma, a phenotype similar to that observed in severe hemophilia A in humans.[270] Affected mice do not, however, bleed spontaneously. Heterozygous females show factor VIII levels that are 50% of normal. Affected females were also produced; when bred with affected males, these animals survived pregnancy and delivery. RT-PCR of liver mRNA indicated that the factor VIII deficiency in the exon 16 knockout mice is due to truncated protein, whereas in exon 17 knockout mice it is due to either truncated or partially deleted protein.[271] Assay of cryoprecipitate from the plasma of affected mice using two antimouse factor VIII monoclonal antibodies failed to detect any factor VIII. The mice with hemophilia A provide an excellent animal model for gene therapy experiments and the study of factor VIII inhibitors.

Chapter 108 - Biochemistry of Factor IX and Molecular Biology of Hemophilia B

Robert Flaumenhaft
Bruce Furie

INTRODUCTION

Factor IX is a plasma protein with a molecular weight of 56,000 whose synthesis by the liver requires vitamin K. Factor IX participates in an intermediate phase of the blood coagulation pathway (see Chap. 102). It can be activated by factor XIa or factor VIIa complexed with tissue factor. In complex with factor VIIIa on membrane surfaces, factor IXa then activates factor X. The critical importance of factor IX is emphasized by the phenotype of hemophilia B, a hereditary disease characterized by factor IX deficiency.

In 1952 factor IX was discovered, distinct from factor VIII, in that after mixing of plasmas from two unrelated patients with hemophilia, the clotting time of the mixed plasma was corrected.[1] [2] Hemophilia B, or Christmas disease, is an X-linked disorder defined by the hereditary decrease in factor IX activity. The molecular defect causing factor IX deficiency in the index patient has been shown to be a point mutation causing a change from Cys 206 to serine in the catalytic domain. [3] Hemophilia B accounts for about 12% of the total cases of hemophilia. The disease is variable in phenotype, and the degree of bleeding severity usually correlates with the level of factor IX activity present in the patients plasma. As anticipated from the variable phenotypes of hemophilia B and the similarity of phenotypes within each particular family, hemophilia B is caused by a variety of genetic defects. It is estimated that one-third of cases of hemophilia B arise from spontaneous mutations.

GENE STRUCTURE AND REGULATION

The factor IX gene is located on the tip of the long arm of the X chromosome at Xq27.1,[4] close to the factor VIII gene. The gene is 34 kb in size and contains seven introns that range in size from 188 nucleotides to almost 10 kb. The mRNA is composed of a 205-bp 5 untranslated region (UTR), a 1,383-bp preprofactor IX region that encodes for a 461-amino acid precursor protein, and a 1,392-bp 3 UTR.[5] [6] [7] The protein is encoded by all eight exons (Fig. 108-1). The factor IX gene was derived ancestrally from a precursor of the prothrombin gene.[8] The genes for factor VII, factor X, and protein C share common splice junctions with the gene for factor IX, demonstrating the close relationship of the vitamin K-dependent proteins (see Fig. 102-5).

The regulation of the factor IX gene is mediated by elements in the 5 UTR, intron sequences, and the 3 UTR. The 5 proximal region extending to 270 contains the minimal promoter sequence required for maximal factor IX expression.[9] [10] Multiple promoters exist within this region, including a CAAT box at 238 and a TATA box at 181.[11] [12] A transcription start site has been defined at approximately 176.[9] Multiple negative regulatory elements (silencers) that suppress gene expression exist upstream of 416. One such silencer consists of a promoter (766 to 417) oriented in the reverse direction of the factor IX promoter activity.[12] Experiments using transgenic mice indicate that the introns of factor IX are required for its expression in vivo.[13] Furthermore, expression vectors that include the first intron of the factor IX gene produce 7- to 9-fold higher levels of mRNA than vectors lacking this sequence.[14] The 3 UTR contains polyadenylation signal sequences that are important in normal gene expression. A 653-bp deletion of this region has been found in a mild form of hemophilia B.[15]

Factor IX Leyden is a form of hemophilia B characterized by a severe bleeding disorder during childhood; factor IX activity and antigen levels are <1%.[16] With the onset of puberty or with the administration of androgen therapy,[17] the factor IX levels rise to 3060% of normal, and the hemophilia phenotype disappears (Fig. 108-2). Analysis of the factor IX genes from patients with various pedigrees with the factor IX Leyden phenotype demonstrated 11 unique point mutations clustered in an area from 40 to +20.[11] This clustering of mutations has led to the identification of binding sites for various transcription factors within the 5 regulatory region.[11] [18] Included in this region are binding sites for (1) the CCAAT/enhancer-binding protein (C/EBP) between +4 and +19,[19] (2) hepatic nuclear factor-4 (HNF-4) between 19 and 27,[20] [21] and (3) unidentified proteins between 16 to 3, 15 to +3, and +15 to +36.[9] [22] C/EBP is thought to interact with D-binding protein, a transcription factor whose expression is increased in adulthood.[23] Binding sites immediately upstream of the cluster of factor IX Leyden mutations have been found for nuclear factor-1 between 77 and 99,[11] for Ets factor GA-binding protein (GABP/) between 195 to 220,[24] and for an unidentified protein that binds

Figure 108-1 Structure of the factor IX gene and encoded factor IX domains. The factor IX gene includes eight exons and seven introns. Exons 18 are represented as solid bars and designated with roman numerals IVIII.

Figure 108-2 Factor IX Leyden. Changes in the plasma factor IX level as a function of age. *(From Briet et al.,[17] with permission.)*

between 67 and 49.[11] A transgenic mouse with a mutation at +13 in the factor IX promoter shows age-dependent, male-specific expression of factor IX.[25] In normal individuals, factor IX levels increase modestly after puberty.[26]

SYNTHESIS OF FACTOR IX

Factor IX is synthesized in the hepatocyte as a precursor protein; it then undergoes a series of intracellular post-translational modifications and is secreted as a zymogen (Fig. 108-3). The coding sequence of the factor IX gene encodes two peptides that are removed prior to secretion of the mature factor IX into the blood: a 28-residue signal peptide that directs the nascent peptide chain to the endoplasmic reticulum and an 18-residue propeptide between the signal peptide and the mature N-terminus of factor IX.[7] The signal peptide is cleaved cotranslationally by the signal peptidase. The propeptide contains the -carboxylation recognition site that directs -carboxylation of the adjacent glutamic acid residues in the -carboxyglutamic acid (Gla) domain of mature factor IX. [27] This recognition element is defined by amino acids 18, 17, 16, 14, and 10 toward the N-terminus of this region. [28] The vitamin K-dependent carboxylase binds to the -carboxylation recognition site within the propeptide. [27] [28] [29] [30] The carboxylation reaction, catalyzed by the carboxylase, requires a reduced form of vitamin K (vitamin KH_2), molecular oxygen, carbon dioxide, and the factor IX precursor, uncarboxylated profactor IX, containing glutamic acid residues. [31] The carboxylase is an enzyme with a molecular weight of 94,000 that is sufficient to carboxylate a precursor substrate in the presence of the necessary cofactors. [32] [33] [34] [35] The carboxylase is a membrane protein, and its catalytic activity resides on the luminal side of the rough endoplasmic reticulum. [36] [37] Multiple glutamic acids are carboxylated within a single precursor upon interaction with the carboxylase.[38] The carboxylglutamic acid residues that are formed play a critical role in calcium binding.

In addition, aspartic acid 64 undergoes -hydroxylation in the rough endoplasmic reticulum. From the cDNA sequences of factor IX, [6] [7] factor X,[39] protein C,[40] [41] protein S,[42] and factor VII,[43] it is apparent that specific aspartic acid residues in precursor forms of these proteins undergo -hydroxylation post-translationally. Stenflo et al.[44] have suggested that a consensus sequence consisting of Cys-X-Asp/Asn-X-X-X-Phe/Tyr-X-Cys-X-Cys signals this event. Factor IX contains about 0.4 mol of -hydroxyaspartic acid per mol of factor IX.[45] [46] This modified amino acid is formed from aspartic acid by a post-translational process catalyzed by an -ketoglutarate-dependent dioxygenase, [47] aspartyl -hydroxylase, which has been purified [48] and cloned.[49] Mutants lacking Asp 64 have decreased calcium binding, which suggests that -hydroxyaspartic acid might be involved in calcium binding. However, detailed studies using nuclear magnetic resonance spectroscopy failed to show a significant difference in calcium binding between -hydroxylated and non--hydroxylated factor IX epidermal growth factor (EGF)-like domains. [50] Furthermore, recombinant factor IX expressed in the presence of dipyridyl, o-phenanthroline, or pyridine 2,4-dicarboxylate, which are inhibitors of 2-ketoglutarate-dependent dioxygenases, retains full activity. [51] These data are consistent with the hypothesis that Asp 64 is required for full functional activity, but -hydroxylation is not.

Bovine and human factor IX are glycoproteins that contain about 17% carbohydrate by weight. The first EGF-like domain is glycosylated at two O-linked glycosylation sites. Xyl(1 3) Glu1 O-Ser and Xyl(1 3) Xyl(1 3) Glc1 O-Ser

Figure 108-3 Biosynthesis of factor IX. Factor IX is synthesized in the liver in a precursor form. The signal peptide is responsible for translocation of the nascent peptide chain to the endoplasmic reticulum. Profactor IX undergoes post-translational processing, including -carboxylation, glycosylation, -hydroxylation, disulfide bond formation, and finally propeptide cleavage. -Carboxylation requires molecular oxygen, reduced vitamin K, and carbon dioxide in the presence of the vitamin K-dependent -carboxylase.

saccharides are glycosidically linked to Ser 53. [52] A tetrasaccharride NeuAc(2 6) Gal(1 4) GluNAc(1 3) Fuc1 O-Ser is linked to Ser 61. [53] [54] [55] A second heavily glycosylated portion of factor IX is the activation peptide (Ala 146-Arg 180). It is glycosylated at two N-linked and two O-linked glycosylation sites. [56] Asn 157 and Asn 167 are fully glycosylated. Thr 159 and Thr 169 are partially glycosylated.

Profactor IX, including the propeptide and factor IX sequence, undergoes carboxylation in the endoplasmic reticulum. Profactor IX, even in its fully carboxylated form, and in contradistinction to factor IX, is not capable of binding to membrane surfaces. [57] Presumably, this property prevents factor IX from being hung up inside the cell, where high levels of calcium ions within the endoplasmic reticulum could support factor IX-membrane interaction. Profactor IX undergoes additional post-translational processing, including disulfide bond formation and glycosylation, characteristic of other secreted plasma proteins. The propeptide is cleaved as a late processing event.[7] [58] [59] Furin or a furin-like converting enzyme cleaves peptide bonds at a site adjacent to the sequence RXRR, where X can be any amino acid and R is arginine.[60] Bristol and colleagues[61] used site-directed mutagenesis to define a hierarchy of the efficiency of cleavage given different paired amino acids at the P1 and P2 positions: Lys-Arg > Arg-Arg Thr-Arg > Arg-Lys > Lys-Lys >> Lys-Thr. -Carboxylation precedes propeptide cleavage. [62]

The carboxy-terminus of factor IX may contribute to its intracellular trafficking. Mutant factor IX with substitutions in amino acids 403415 are degraded and secreted only at low levels when expressed in a hepatoma cell line. [63] Addition of proteosome inhibitors to this system leads to recovery of factor IX secretion. [63] Consistent with these observations, naturally occurring mutations in the carboxy-terminus of factor IX lead to hemophilia B with severely depressed antigen levels in the plasma.[64]

STRUCTURE OF FACTOR IX

Human factor IX is a single-chain glycoprotein composed of 415 amino acids (Fig. 108-4). [6] [7] [65] It has a molecular weight of 56,000.[66] [67] The structure of porcine factor IX has been determined by x-ray crystallography. [58] The protein resembles a tulip with the N-terminal Gla domain composing the bulb, the two EGF domains the stalk, and the catalytic domain the flower (Fig. 108-5A).[68]

Propeptide

The propeptide directs -carboxylation of profactor IX and then is cleaved to yield factor IX. The propeptide includes an amphipathic -helix with a hydrophobic face and hydrophilic face.[69] The carboxylation recognition site is located proximal to this helix. This recognition site binds the N-terminal third of the carboxylase. [70] [71] Mutations in the propeptide have been documented as the cause of some forms of hemophilia B. Diuguid et al. [58] determined the size of the propeptide of factor IX by analysis of a mutant factor IX, factor IX Cambridge. This mutant has an 18-residue N-terminal extension due to the mutation of Arg 1 to a serine, precluding propeptide cleavage by a propeptidase with trypsin-like specificity. Concurrently, Bentley et al. [59] evaluated factor IX Oxford 3, a mutant factor IX in which Arg 4 is mutated to glutamine; this mutation also prevents propeptide cleavage.[59] Similar mutations have been described, each characterized by the complete absence of factor IX activity and the presence of the 18-residue propeptide extension. [72] [73] [74] [75] Of the several proteins studied, [58] [72] [76] [77] there is a partial defect in -carboxylation of factor IX. Because of the failure of propeptide cleavage, these profactor IX mutants cannot bind to phospholipid vesicles, nor can they be activated by factor XIa. In fact, the propeptide prevents binding of profactor IX to membranes even if the profactor IX is fully carboxylated. [57] These data and the marked sequence homology of this domain in Gla-containing proteins led to the proposal of a role for the propeptide in designating protein precursors containing this specific propeptide for subsequent -carboxylation. [78] Using site-specific mutagenesis and an heterologous mammalian expression system, Jorgensen et al.[27] and Rabiet et al. [46] demonstrated that factor IX lacking the 18-residue propeptide was not carboxylated in vivo. Similarly, point mutations at 16 (Phe Ala) or 10 (Ala Glu), both positions highly conserved in the propeptides of the vitamin K-dependent proteins, inhibited -carboxylation. These results demonstrated that the propeptide contains a recognition element, designated the -carboxylation recognition site, that signals for the -carboxylation of the vitamin K-dependent proteins during hepatic biosynthesis. This region is sufficient to support -carboxylation of an adjacent but unrelated glutamic acid-rich substrates. [79]

-Carboxyglutamic Acid Domain

The NH_2 -terminal Gla domain of human factor IX includes 12 Gla residues, located at positions 7, 8, 15, 17, 20, 21, 26, 27, 30, 33, 36, and 40. [80] [81] The Gla domain defines some of the critical calcium-binding sites of the protein and is required for the interaction of factor IX with membrane surfaces in the presence of calcium ions.[82] Naturally occurring point mutations of glutamic acid residues destined to be -carboxylated include Glu 7, Glu 8, Glu 17, Glu 21, Glu 27, Glu 30, and Glu 33; patients with these mutations have moderate to severe hemophilia, an observation emphasizing the functional importance of these residues. [64] In contrast, factor IX that lacks Glas 36 and 40, Gla residues that are not found in other vitamin K-dependent blood coagulation proteins, maintains full function. [83] In the absence of calcium, the Gla domain consists of three well-defined structural elements linked by a flexible polypeptide backbone. [84] The three structural elements are a short amino terminal loop (residues 69), a hexapeptide loop formed by disulfide binding of cysteines at residues 18 and 23, and a carboxyl-terminal -helix (residues 3746). [85] The hexapeptide loop is essential for factor IX function, as evidenced by the fact that factor IX Zutphen (Cys 18 Arg) cannot form the Ca $^{2+}$ -dependent conformation and results in severe hemophilia.[85] When bound with calcium, the Gla domain folds in a manner that exposes an amino-terminal region, which may represent the phospholipid-binding site in factor IX (Fig. 108-5B).[86] This amino-terminal region is well structured in the Ca $^{2+}$ -bound form of factor IX (which binds membranes) but is unstructured in the Mg^{2+} -bound form of factor IX (which does not bind membranes). [87]

Epidermal Growth Factor-like Domains

The Gla domain is linked to two adjacent EGF domains by a short domain rich in aromatic amino acids. The EGF domains, each characterized by a segment of 53 amino acids and a pattern of disulfide-bonded cysteine residues, have distinct functions. The structure of the first EGF domain has been determined by two-dimensional NMR spectroscopy and x-ray crystallography. [88] [89] It consists primarily of a two-stranded beta sheet. Astermark et al., using both inhibitory peptides[90] and cross-linking experiments,[91] have suggested that the first EGF domain participates in the interaction between factor X and factor IXa in the tenase complex. A naturally occurring mutant, factor IX London-6 (Asp 64 Gly), results in mild hemophilia B. [92] Experiments using mutant factor IX in which Asp 64 has been mutated suggest that the binding of calcium to this domain enhances the enzymatic activity of factor IXa and its assembly into

Figure 108-4 Amino acid sequence of factor IX. The preprofactor IX sequence includes the signal peptide, propeptide, -carboxyglutamic acid domain, aromatic amino acid stack domain, two EGF domains, and the serine protease domain. Amino acids are designated by the one-letter code. , -carboxyglutamic acid; , -hydroxyaspartic acid.

the factor IXa-VIII complex.[93] In addition, deletion and chimeric mutants of the first EGF-like domain have been constructed that lead to defective activation by factor VIIa/tissue factor with normal activation by factor XIa.[94] Factor IX Alabama, which results from a point mutation in the first EGF domain (Asp 47 Gly), [95] binds normally to phospholipid vesicles[96] because the Gla domain is intact. However, the activation of factor X by factor IXa Alabama is not enhanced by factor VIIIa, [97] and its affinity for calcium is reduced.[98] Other naturally occurring mutations within this domain, including Gln 50, Cys 51, Cys 56, and Gly 60, lead to a severe hemophilia phenotype, but the basis for this defective factor IX function is not known.

The second EGF domain is required for the interaction between factor IXa and factor VIIIa in the tenase complex. [99] It appears that this second EGF domain contains contact residues that interact with factor VIIIa, but not directly with the substrate factor X. Some point mutations within this domain have only a moderate effect on

function. However, moderate to severe hemophilia is associated with mutations of Asn 92, Gly 93, Arg 94, Cys 95, Cys 99, Cys 111, Gly 114, Asn 120, Cys 124, and Ala 127.[64]

Serine Protease Domain

The C-terminal portion of factor IX demonstrates marked sequence homology with zymogens of serine proteases, such as trypsin and chymotrypsin. This region is almost 250 amino acids long and contains, in latent form, the enzyme active site of factor IXa. The mechanism of enzyme activation involves limited proteolysis. The cleavage of two peptide bonds in factor IX leads to the generation of the enzyme factor IXa. The enzyme active site is common to all serine protease and contains the enzymatic machinery for the hydrolysis of peptide bonds. Superimposed on this structure is an extended substrate-binding site, surrounding the active site, that defines the high substrate specificity of factor IXa for protein substrates. [10C]

CALCIUM-BINDING PROPERTIES

Factor IX binds to metal ions. As with the other vitamin K-dependent proteins, there are two classes of metal-binding sites: high affinity and lower affinity. [100] Occupation of these two classes of metal-binding sites leads to two sequential conformational changes in these proteins. [102] [103] The first conformational change can be induced by calcium, magnesium, and many other divalent cations; the second conformational change is induced only by calcium ions. Fab fragments of conformation-specific antibodies, directed against factor IX after it has undergone the conformational transition that is calcium ion selective, block the binding of factor IX to phospholipid vesicles and the activation of factor IX by factor XIa. The binding of other conformation-dependent probes and the rate of conversion by factor XIa are increased in the presence of magnesium but remain dependent on calcium. These finding suggests that the conformer achieved only in the presence of calcium is necessary for the expression of a phospholipid-binding site and for the binding of factor IX by factor XIa (Fig. 108-6).[104]

The binding of calcium to the Gla-rich domain involves formation of an internal calcium-binding pocket formed by the amino-terminal nine Gla residues. The binding results in the formation of a calcium-carboxylate network with an exposed amino-terminal hydrophobic loop that is the phospholipid-binding site. [86] Refinement of this structure and incorporation of calcium ions into the Gla-rich domain emphasize the importance of Gla to the formation of the calcium-carboxylate network and its role in structure.[105] The binding of calcium to the first EGF-like domain is mediated by a consensus sequence including Asp 47, Asp 49, Gln 50, Asp 64, and Tyr 69. Asp 47, Gln 50, and Asp 64 interact directly with calcium. [90] [106] [107] Astermark et al.[108] have demonstrated that whereas the Gla and EGF domains can bind calcium ions independently, the intact Gla-EGF domains bind calcium ions with higher affinity. A high-affinity calcium-binding site has also been described in the heavy chain of factor IX involving residues 235, 237, 240, and 245. [109]

Figure 108-6 Model of the interaction of factor IX and phospholipid membrane. The hydrophobic residues (black) that form the hydrophobic patch in the phospholipid-binding site of factor IX are buried in the phospholipid bilayer. The phosphatidylserine binds specifically through electrostatic interactions with amino acid side chains of the Gla domain.

MEMBRANE-BINDING PROPERTIES

The interaction of factor IX and factor IXa with phospholipid membranes has been studied using phospholipid vesicles. [97] Factor IX affinity for phosphatidylcholine-phosphatidylserine membranes is independent of the phosphatidylserine concentration at phosphatidylserine compositions of >2030% [110] a K_d of about 12 M has been measured. Factor IX binds to vesicles in the presence of Ca^{2+} but not in the presence of Mg^{2+} or EDTA. Furthermore, des--carboxy factor IX does not interact with phospholipid vesicles even in the presence of Ca^{2+} . These results emphasize the importance of the Gla-rich region in defining phospholipid-binding properties. Cross-linking studies using a photoactivatable amino acid at Leu 6 and Phe 9 suggest that these residues proximate or are buried in the lipid bilayer. [87]

Factors IX and IXa bind to bovine aortic endothelial cells and compete for the same site. [111] [112] Factor IX has been shown to bind to collagen IV with a K_d of 6.8 nM, which correlates with the K_d of 7.4 nM for the binding of factor IX to endothelial cells. [113] Factor IX binds to an endothelial cell extracellular matrix in the absence of intact cells. The interaction of factor IX with endothelial cells is inhibited by a Gla-containing peptide corresponding to residues 142 of factor IX; [114] the K_i for this interaction is about 0.05 M. A chimeric protein in which the Gla domain (147) of factor IX is substituted for the same domain in protein C is able to bind endothelial cells. This result suggests that the endothelial-binding site resides within this domain. [115] Cheung et al.[116] have utilized site-directed mutagenesis of the Gla domain of factor IX to show that residues 5 and 10 are required for the binding of factor IX to endothelial cells. The coagulant activity of the mutant proteins remained intact, suggesting distinct interactions between factor IX with endothelial cells and phospholipids. Although a specific receptor recognition element resides within residues 114, Gla-containing peptides of 114 and 124 do not compete with intact factor IX for binding to endothelial cells. [117] Furthermore, purified natural variants of factor IX with mutations with the hydrophobic stack domain or the first EGF-like domain did not compete effectively with wild-type factor IX for binding to endothelial cells. These results suggest that the functional integrity of the Gla domain in the interaction with endothelial cells depends on the hydrophobic stack and the first EGF-like domain.[118]

Activated platelets, but not resting platelets, bind factors IX and IXa. [119] [120] Factor IX and factor IXa share some common binding sites on activated platelets. There are 250300 sites per platelet for factor IX and 500600 sites per platelet for factor IXa. The interaction of factor IXa with platelets is at least in part mediated by the Gla domain.[121] Studies using a chimera in which the second EGF domain of factor X was substituted for that of factor IX exhibited decreased binding to platelets, suggesting that the second EGF domain may play a role in platelet binding. [122] In the presence of saturating concentrations of factors VIIIa and X, the K_d of factor IXa (K_d = 0.5 nM) binding is five times lower than that of factor IX. [123] [124]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

FORMATION OF THE TENASE COMPLEX

The assembly of factor IXa and factor VIIIa on phospholipid membranes constitutes the tenase complex (Fig. 108-7). Factor IXa and factor VIIIa interact on phospholipid membrane surfaces with a K_d of 2 nM with 1:1 molar stoichiometry.[125] The affinity of factor IXa for factor VIIIa is increased 10-fold in the presence of phospholipid. The rate of bond cleavage (k_{cat}) leading to the formation of factor Xa is increased 1,500-fold. [126] Activation of factor IX to factor IXa leads to the expression of a factor VIII-binding site and active enzyme site with full coagulant activity. [127] The factor IXa active site is distant from the membrane surface, but its structure is perturbed on interaction with factor VIIIa during the formation of the tenase complex. [128] Reciprocally, activation of factor VIII by thrombin yields factor VIIIa, which binds more tightly than factor VIII to factor IXa. [125]

The domains of factor IX involved in the tenase complex have been explored with a naturally occurring mutation and with chimeric proteins. The affinity of a naturally occurring mutation (Gly 12 Arg) for factor VIIIa is 172-fold less than that for factor IX, suggesting a role for the Gla domain in the formation of the tenase complex. [129] A chimera in which the first EGF domain of factor IX has been substituted by the first EGF domain of factor X has full or nearly full biologic activity, indicating that the first EGF domain is not involved in factor VIIIa binding. [100]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

ACTIVATION OF FACTOR IX BY THE INTRINSIC PATHWAY

Factor IX is a proenzyme with no catalytic activity. It is activated to factor IXa by factor XIa in the presence of calcium, or by factor VIIa and tissue factor in a reaction that occurs on a membrane surface and in the presence of calcium (Fig. 108-8). The kinetics of factor IX activation by factor VIIa and tissue factor or factor XIa are comparable. In contrast to the other vitamin K-dependent blood clotting proteins, membrane surfaces, including phospholipid vesicles or cell surfaces, do not enhance factor IX activation by factor XIa. The activation of factor IX New London (Pro 50 Glu) by factor XIa is abnormally slow. [130] This implicates the EGF domain in factor IX activation. When factor IX is activated by factor XIa, two peptide bonds are cleaved: one bond is located at Arg 145-Ala 146, and the other

Figure 108-7 A model of the structure of the tenase complex. The tenase complex (the enzyme complex capable of activating factor X to factor Xa) includes factor IXa as enzyme and factor VIIIa as cofactor bound to the membrane surface. The substrate factor X interacts with factor IXa, factor VIIIa, and the membrane.

bond is at Arg 180-Val 181 (Fig. 108-9).[131] With the release of the internal carbohydrate-rich activation fragment (M_r 11,000) from residues 146180, the factor IXa light chain (M_r 17,000) and heavy chain (M_r 28,000) remain bound by a single disulfide bond. The enzyme active site is located on the heavy chain. Cleavage of factor IX appears to occur via a processive mechanism in which both cleavages are made by factor XIa before factor IXa is released. [132]

Factor IX Chapel Hill (Arg 145 His), the first factor IX mutation to be defined at the molecular level, is the prototype of a genetic defect in which activation of a zymogen is impaired due to the mutation of an arginine preceding a sessile bond. [133] It has minimal coagulant activity.[97] Factors IX Chicago-2 (Arg 145 His)[134] and factor IX Albuquerque (Arg 145 Cys)[135] have mutations at the same site. In each of these mutations, the loss of the arginine at position 145 precludes the cleavage of the sessile bond separating the factor IX light chain from the activation peptide. Failure to cleave this bond results in a molecule that cleaves factor X very slowly. The active site of factor IXa is formed, however, as demonstrated by its ability to cleave synthetic substrates normally. [136] The function of the cleavage of the Arg 145-Ala 146 bond may serve to expose a binding site for factor VIIIa since factor IX binds factor VIII but is incapable

Figure 108-8 Pathways of factor IX activation. Factor IX is activated independently by either factor XIa or factor VIIa/tissue factor. Factor XIa can activate factor IX in the absence of membrane surfaces, but calcium ions are required. The complex of factor VIIa and tissue factor on membrane surfaces in the presence of calcium ions also converts factor IX to its active enzyme form.

of generating factor Xa.[137] Factor IX mutants at position 180 include factor IX Hilo (Arg 180 Gln), factor IX Milano (Arg 180 Gln), factor IX Deventer (Arg 180 Trp), and factor IX Nagoya (Arg 180 Trp), all resulting in hemophilia B_M , a type of hemophilia in which the patients mutant factor IX causes a marked prolongation of the ox brain thromboplastin time due to increased inhibition of the in vitro activation of factor VII. [138] [139] Factor IX Novara (Val 181 Phe)[139] and factor IX Tokyo (Val 182 Ala)[140] result in the hemophilia B_M phenotype, while factor IX Kashihara (Val 182 Phe) results in hemophilia B. [141] [142]

The activation of factor IX by factor XIa is highly metal selective, with optimal activation only in the presence of Ca^{2+} and suboptimal activation in the presence of Sr^{2+} .[94] [143] The K_m for the activation of factor IX by factor XIa without calcium is 18 M, and the k_{cat} is 2.4 min^{1} . In the presence of calcium, the K_m is decreased to 2 M, and the k_{cat} is increased to 10.4 min^{1} .[144] [145] Although the proteolytic activity of factor XIa is present on the light chain, the heavy chain of factor XIa may be necessary for the Ca^{2+} -dependent acceleration of factor IX activation. [145] [146] Experiments using anti-factor IX/Ca^{2+} -specific antibodies suggest that there may be a surface of factor XIa that interacts with factor IX in the presence of Ca^{2+} . An antibody directed against the heavy chain of factor XIa neutralized the enzyme competitively, but an antibody directed against the light chain neutralized the enzyme noncompetitively. [145] The region of the factor XIa heavy chain that interacts with factor IX has been localized to residues 134172 in the heavy chain of factor XI. [147] Furthermore, the presence or absence of calcium did not change the rate of activation of factor IX by factor XIa light chain.[145] On the basis of these studies and antibody inhibition studies using antibodies to factor IX, the heavy chain of factor XIa has been implicated as specifically interacting with the phospholipid-binding site of factor IX in the presence of Ca^{2+} .

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

ACTIVATION OF FACTOR IX BY THE EXTRINSIC PATHWAY

Factor IX is also activated by factor VIIa and tissue factor (Fig. 108-8). [126] [148] This reaction, dependent on calcium ions, is characterized by a K_m of 0.3 M.[149] [150] The k_{cat} for this reaction is between 13 and 68 min^{-1} . [149] [150] The activation of factor IX by factor VIIa and tissue factor is accelerated by the activation of factor IX to factor IXa by factor XIa.[151]

The relative importance of factor IX activation by factors XIa or VIIa and tissue factor has been evaluated by measuring the

Figure 108-9 Activation of factor IX by limited proteolysis. The zymogen factor IX has no enzymatic activity. On cleavage of the peptide bonds adjacent to Arg 145 and Arg 180, enzymatically active factor IXa is generated. Cleavage of these peptide bonds is associated with expression of enzyme activity and a factor VIIIa-binding site.

factor IX activation peptide in patients with factors VII and XI deficiency. [152] There was a significant reduction in the baseline levels of the factor IX activation peptide in patients with factor VII deficiency but not in patients with factor XI deficiency when compared with normal controls. Furthermore, the administration of recombinant factor VIIa to chimpanzees resulted in a significant increase in both the factor IX and factor X activation peptides at the same time point. [152] Infusion of recombinant factor VIIa into patients with factor VII deficiency causes an increase in the abnormally low levels of the factors IX and X activation peptides and prothrombin fragment F1.2.[153] These studies suggest that the activation of factor IX by factor VIIa and tissue factor is important in vivo.

Almus et al.[154] have evaluated the activation of factors IX and X by factor VIIa and tissue factor in an umbilical vein model. In this system the activation of factors IX and X occurs at the same rate. These results further substantiate the importance of both of these reactions in the initiation of the extrinsic pathway of blood coagulation.

ENZYMATIC ACTIVITY OF FACTOR IXa

Factor IXa is a serine protease that expresses its activity via the catalytic domain on the heavy chain. This activity is generated by the classic catalytic triad that in factor IXa is located at His 41, Asp 89, and Ser 185 in the heavy chain.

Once generated, factor IXa forms a complex with factor VIIIa on membrane surfaces in an interaction that is calcium dependent. In contrast to the solution-phase activation of factor IX by factor XIa, factor X is converted to its enzyme form, factor Xa, by factor IXa in complex with factor VIIIa on membrane surfaces: phospholipid vesicles, activated platelets, or endothelial cells. The activation of factor X by factor IXa has been evaluated under multiple experimental conditions. Calcium by itself accelerates factor IXa activation of factor X, but its more important role is to allow for the formation of the tenase complex on membrane surfaces. The presence of both factor VIIIa and membrane surfaces greatly accelerates the activation of factor X, while the presence of either of these cofactors alone has a minimal effect. [155] [156] The k_{cat} for factor X activation by factor IXa in the presence of factor VIIIa but without phospholipid vesicles is 0.058 min^{1} ; the same reaction without factor VIIIa but with phospholipid vesicles (25 M) has a k_{cat} of 0.095 min^{1} , whereas in the presence of factor VIIIa and phospholipid vesicles the reaction is greatly accelerated, with a k_{cat} of 1,740 min^{1} . [119] The activation of factor X by factor IXa is also supported by activated platelets. The k_{cat} for this reaction is 1,240 min^{1} , which is very close to the k_{cat} for factor X activation in the presence of phospholipid vesicles. These results suggest a physiologic role for platelets in this process. Stern et al. [157] [158] have demonstrated equal binding of factors IX and IXa to bovine aortic endothelial cells. There is an equivalent increase in binding of both factor IX and factor IXa in the presence of activated or unactivated factor VIII. [159] However, when factor X is added to the reaction mixture, a high-affinity binding site with relative specificity for factor IXa is expressed, and the interaction of factor IXa with endothelium is increased 10- to 40-fold. Factor X does not enhance factor IXa binding without the presence of factor VIII.

Physiologic inhibitors of factor IXa circulate in plasma. Factor IXa is inhibited by antithrombin III, which forms a 1:1 stoichiometric complex with factor IXa as well as other activated coagulation factors. This reaction is accelerated 1,000-fold by the addition of heparin. [160] [161] [162] [163] Protease nexin-2, an amyloid -protein precursor containing a Kunitz-type protease inhibitor domain, is an even more potent inhibitor of factor IXa than antithrombin III. [164] [165] However, it is present in plasma in only picomolar concentrations. Nonetheless, protease nexin-2 is an -granule component of platelets and may achieve physiologically significant concentrations in areas of platelet degranulation. [166]

Factor IX Eagle Rock and factor IX Bergamo are both characterized by the substitution of valine for Gly 363 and are functionally normal except for their inability to bind antithrombin III and their inability to activate factor X. [139] [167]

Defects Affecting Enzymatic Activity

Mutations within the catalytic domain of factor IX may decrease enzymatic activity. A mutation of IIe 397 Thr has been recognized in many hemophilia B families, including factor IX Vancouver, [168] factor IX Long Beach, [169] and factor IX Los Angeles. [167] This defect is near, but not within, the active site of factor IXa; it may alter the extended substrate-binding site for factor X. Factor IX Angers (Gly 396 Arg) has a mutation within the substrate-binding pocket of factor IXa that disrupts enzymatic activity. [170] Factor IX $B_{m\ Lake\ Elsinore}$ (Ala 390 Val) [171] also possesses a mutation within the substrate-binding pocket that interferes with enzymatic activity. Factor IX Eagle Rock (Gly 363 Val) [167] and factor IX Bergamo [122] both have mutations adjacent to Ser 365, the active site serine, that ablate enzymatic activity. A mutation of Arg 333 also leads to a defect in the ability to catalyze factor X cleavage.

MOLECULAR BASIS OF HEMOPHILIA B

Defects in Gene Structure That Cause Hemophilia B

More than 800 different patterns of molecular anomalies have been described in patients with hemophilia B. [64] One-third of these are caused by de novo mutations. Gross deletions, microdeletions, insertions, and missense and nonsense point mutations have all been described, making the factor IX molecule one of the best models for studying natural mutations in humans.

Gross deletions of the factor IX gene causes severe, antigen-negative hemophilia B (Fig. 108-10).[172] [173] They account for 6% of independent factor IX mutations. A subset of large deletions is thought to result from alternating purine and pyrimidine segments in which large hairpin structures form. [174] Gross deletions have been associated with anti-factor IX antibodies in response to replacement therapy with factor IX. [172] In a series of 62 families with hemophilia B, a family member developed an inhibitor in approximately one-third of families exhibiting deletions or nonsense mutations. [175] Family members carrying missense mutations did not develop inhibitors. Thus, while antibody production can be associated with gross gene deletions, not all such patients have demonstrated such a response. [176] [177] In addition, some patients with anti-factor IX antibodies do not possess gross gene deletions, [74] [178] and in at least one case antibodies developed in an antigen-positive patient.[178] Thus, the lack of circulating factor IX protein is not the sole factor controlling the

Figure 108-10 Factor IX gene deletions as a cause of hemophilia B. Deleted portions of factor IX gene are indicated by pink rectangles; an uncertain extent of deletion is indicated by red lines. The factor IX gene (exons 18) is shown in black.

development of an immunologic response to factor IX replacement therapy.

Smaller deletions of the factor IX gene also cause hemophilia B. Although most reported microdeletions are unique, at least two deletion hotspots have been found in areas where perfect hairpin loops are generated from imperfect loops.[179] Many other patterns of small deletions have been described. Factor IX Chicago-1 possesses a complex deletion of exons 5, 7, and 8, totaling approximately 25 kb.[180] Factor IX Seattle-1 contains an intragenic deletion of exons 5 and 6 of the factor IX gene, [181] resulting in the production of a truncated factor IX protein of 36,000 molecular weight that is excreted in the urine. [182] Factor IX Yemen[178] and factor IX Tubingen[178] each possess deletions of exons 13 of the factor IX gene, with variable amounts of the 5-flanking sequence also deleted. Factor IX Hanover has a deletion of exons 4 and 5, totaling 8 kb.[178] Factor IX Strasbourg contains a 2.8-kb intragenic deletion encompassing exon 4, the exon encoding the first EGF-like domain. [183] Despite possessing 30% of normal factor IX antigen levels, this family displays a severe hemophilic phenotype. Factor IX Ratingen shows a loss of exon 7, with a deletion of 1.5 kb.[178] Factor IX London-10 contains a deletion of the codon for Arg 37, [74] resulting in a severe hemophilic phenotype despite the presence of 12% of normal factor IX antigen levels. Factor IX Seattle-2 contains a deletion of a single adenine nucleotide at position 17,699 in exon 4 of the factor IX gene, corresponding to residue 85 of the factor IX molecule.[184] This results in a frameshift mutation, creating a stop codon at codon 86. Factor IX London-11 (deletion of bases 31,05931,060), factor IX London-12 (deletion of nucleotide 6,392), and factor IX Malmo-1 (deletion of nucleotides 30,95030,957) also result in frameshifts leading to premature stop codons. [74] It is unclear whether these mRNAs are processed normally, resulting in a truncated plasma protein secreted in the urine as above, or whether these frameshift mutations result in an unstable mRNA.

In other cases, point mutations can lead to the production of little to no factor IX antigen. Rees et al. [185] have described a point mutation within the obligatory donor splice junction of exon 6. This mutation results in the production of an improperly spliced mRNA, causing a defect in transcription that results in no factor IX antigen being produced by these patients. Factor IX Bordeaux (Lys 411 Stop), [170] factor IX Portland (Arg 252 Stop), [186] factor IX Malmo-3 (Arg 248 Stop),[74] Malmo-4 (Arg 29 Stop),[74] and Malmo-5 (Trp 194 Stop),[74] factor IX New York (Arg 338 Stop),[187] factor IX Bonn-1 (Arg 338 Stop),[178] an unnamed mutant (Arg 252 Stop),[188] and other mutations all possess nonsense mutations resulting in premature stop codons. In each case, the premature stop signal yields an antigen-negative phenotype.

Finally, several missense mutations, gene insertions, and combinations of gene insertion plus gene deletion have been described that result in markedly reduced levels of factor IX antigen (Fig. 108-11). Factor IX London-8 (Cys 336 Arg) results in the loss of a cysteine conserved in serine proteases. [74] This loss disrupts the tertiary structure of the catalytic domain. Factor IX London-9 (Asn 120 Tyr) also leads to a severe,

Figure 108-11 Missense and nonsense mutations in the factor IX amino acid DNA sequence as a cause of hemophilia B. Missense mutations are designated by red shading and nonsense mutations are designated by a red circle. Amino acids are designated by the one-letter code. , -carboxyglutamic acid; , -hydroxyaspartic acid.

antigen-negative phenotype.[74] Microinsertions appear to result from polymerase slippage events as evidenced by the presence of direct repeats in most cases. [174] Hemophilia B El Salvador contains a 6.1-kb insertion near exon 4 of the factor IX gene, [189] resulting in moderate hemophilia.

Antigen-Positive Hemophilia B

Approximately one-third of cases of hemophilia B fall within the group termed cross-reactive material positive (CRM+). Such patients have normal levels of factor IX antigen and variable levels of factor IX activity, owing to the presence of a dysfunctional factor IX molecule. Mutations have been described that affect post-translational protein processing, -carboxylation, lipid binding, EGF domain function, zymogen activation, and substrate recognition and/or enzymatic activity. In addition, a series of patients have been reported to display the hemophilia B $_{M}$ phenotype. This has proved to be a heterogeneous set of mutations, as noted in the following discussion.

A developing theme in understanding the molecular basis of hemophilia B is the discovery of duplicate mutations in apparently unrelated patients. To date, 597 unique point mutations (both missense and nonsense) have been reported. [64] Several groups have postulated that the CpG dinucleotide sequence is a mutational hotspot.[190] [191] [192] The CpG sequence is a component of four of the six arginine codons; as a mutational hotspot, it may represent an important cause for the development of spontaneous point mutations. Furthermore, using a mathematical model, the 20 CpG dinucleotides in the factor IX coding sequence showed an observed mutation rate 150 times the rate that would be expected for the predicted transition rate. [193] Of 51 single-base-pair substitutions found in one study, 27 were at CpG dinucleotides, which represents a 38-fold excess for mutations at these sites. [194] In another study, point mutations at CpG dinucleotides were estimated to be increased by 77-fold over the expected rate. [195]

In patients with mutant plasma proteins, the mutation of arginine to another amino acid also appears to be a developing theme. Insofar as internal point mutations are likely to destabilize protein structure and lead to markedly diminished circulating protein levels, patients preselected for circulating mutant protein antigen are likely to have amino acid substitutions on the protein surface. Arginines, located on the protein surface, are used by proteases of the trypsin family to hydrolyze adjacent bonds during protein processing and zymogen activation. It would thus appear, given the functional importance of arginines, that their mutation leads to phenotypically obvious defects in protein function.

Molecular Diagnosis

Hemophilia B is diagnosed by the finding of isolated, hereditary factor IX deficiency. Factor IX deficiency may be observed by prolongation of the activated partial thromboplastin time and by failure of plasma from these patients to correct the clotting time of known factor IX-deficient plasma. These findings, combined with a lifelong history of bleeding or a family history of bleeding disorders, secure the diagnosis. The level of factor IX antigen present in the plasma of each patient permits the hemophilia to be characterized as antigen negative or antigen positive. Within a particular cohort, the factor IX activity level is usually constant, reflecting that each family displays the same genetic defect and that each defect is associated with a particular phenotype.

The bleeding disorder associated with moderate or severe hemophilia B and the sex-linked nature of the disorder make genetic counseling for affected persons and potential carriers an important issue. Carrier analysis has been done by differentiating between factor IX activity and factor IX antigen levels. However, this method has been at best only 80% effective, partially because of the preponderance of mutations yielding markedly diminished factor IX antigen and partially because of lyonization, which causes differential levels of inactivation of the X chromosome carrying the mutant gene. [196]

With knowledge of the sequence of the factor IX gene, it is possible to probe for the precise genetic defect among potential carriers. If the genetic defect for a particular cohort is known, the DNA of potential carriers can be screened using stringent hybridization to oligonucleotide probes to detect whether they carry that genetic defect. This method is handicapped, because as many as one-third of hemophilia cases in any generation arise from new mutations. It would likely be difficult to detect these new mutations using probes for specific mutations.

Of greater value has been the detection of several restriction fragment length polymorphisms (RFLPs) within the factor IX gene that can be used for carrier detection (Fig. 108-10). A number of polymorphisms have been described within and adjacent to the factor IX gene. [197] These polymorphisms, when informative, give a >99% probability of a correct diagnosis. Using the ten polymorphisms available, assays of >90% of families are informative. In some studies, >80% are informative when the 5 MseI RFLP, the 3 HhaI RFLP, and the DdeI polymorphism are used.[198] It should be emphasized that these figures apply only to the white population, in whom the most extensive study of RFLPs has taken place. It is clear that the frequency of each polymorphism varies with the ethnic group being studied (Fig. 108-12), such that the polymorphisms currently employed for diagnosis within the white population are inadequate for determining carrier status in either the Japanese [199] or black population. [200]

To determine whether a person is a hemophilia B carrier, genomic DNA is isolated from the potential carrier, the patient with hemophilia B, and both parents of the potential carrier. That DNA is digested with the appropriate restriction enzymes, and the digested DNA is run on a gel matrix. The DNA is transferred to nitrocellulose, and a Southern blot is performed using labeled factor IX cDNA as the probe. The restriction maps are then compared with the goal of looking for any polymorphisms found in the patient with hemophilia but not in the normal parent. The same procedure can be used on DNA obtained by chorionic villous sampling to determine whether the fetus of a hemophilia B carrier will be a normal or an affected male, and whether a female fetus will be normal or will carry the hemophilia gene.

Even in the white population, some patients cannot be diagnosed with techniques that use polymorphisms. The application of polymerase chain reaction (PCR) technology to the detection of hemophilia carriers has changed the evaluation of patients

Figure 108-12 Restriction fragment length polymorphisms in the factor IX gene.

with hemophilia B. With PCR, specific exons are amplified and sequenced to determine the abnormality that led to hemophilia B. With this information, it is possible to determine whether that mutation is present in the genome of either potential carriers or the fetuses (or both) of those carriers and patients. This obviates the problem of genetic recombination that clouds the use of closely linked restriction polymorphisms to determine the presence or absence of a mutant gene. Moreover, with the use of PCR, it becomes possible to perform antenatal testing either on cells obtained by amniocentesis or on chorionic villous samples without having to wait the several weeks required to obtain enough fetal cells to do restriction digests.

Chapter 109 - Clinical Aspects and Therapy of Hemophilia

Jay Nelson Lozier
Craig M. Kessler

INTRODUCTION

. . . if the first son of a woman is circumcised and he dies and the second son is circumcised and he dies, you must not circumcise the third son. . . . Additionally, the sons of the womans sister should not be circumcised but the sons of her brother can be circumcised.

The Talmud (Yebamot 64b)

The existence of a sex-linked hereditary coagulopathy (probably hemophilia) was first recognized and described in the Talmud in the fifth century and eventually labeled as Haemorrhaphilia, or love of bleeding, in 1828 in the German medical literature. [1] With the development of a crude laboratory assay in 1893 to determine the condition of blood coagulability in clinical and experimental situations, the clotting times of plasma from individuals with hemophilia were noted to be greatly prolonged compared to nonbleeders;[2] however, mixing two sources of plasma corrected the abnormality in vitro.[3] By 1947, the defect in hemophilia had been attributed to a single deficient plasma protein, which was required for platelet utilization and thromboplastin generation. [4] [5] Shortly thereafter, the recognition by Pavlovsky[6] that the plasmas of some hemophiliacs did not always correct the in vitro or in vivo defects of other clinically identical hemophiliacs led to the appreciation that multiple types of hemophilia existed. The clinical entity related to the protein defect described by Brinkhous and Quick was termed hemophilia A and was shown to be related to deficiency of factor VIII (antihemophilic factor or antihemophilic globulin), whereas the other type was termed hemophilia B, and was due to factor IX deficiency (antihemophilic factor B, plasma thromboplastin component, or Christmas factor, named after an individual with the factor deficiency). [7] [8] These two types of hemophilia have an indistinguishable hereditary pattern (sex-linked recessive) and are similar clinically.

The pathophysiology of hemophilia A and B is based on the insufficient generation of thrombin by the factor IXa/factor VIIIa complex through the intrinsic pathway of the coagulation cascade. This is somewhat perplexing, however, because the factor VIIa/tissue factor complex produces enough factor Xa through the extrinsic pathway to prevent the bleeding manifestations of hemophilia despite the intrinsic pathway defect. Recent information indicates that formation of the tissue factor/factor VIIa complex is the initiating event in mammalian hemostasis and is triggered immediately following vascular injury when factor VII in plasma interacts with cellular membranes extrinsic to the vasculature, which express tissue factor on their surfaces. Furthermore, factor IX in the intrinsic pathway, not factor X, is the preferred substrate for the tissue factor/factor VIIa complex because the extrinsic pathway activation of factor X is inhibited by tissue factor pathway inhibitor after a small quantity of factor Xa has been formed[9] [10] [11] (Chap. 102). In this model, a trace amount of factor Xa generates the inactive intermediate product factor IX, which is converted to factor IXa by the tissue factor/factor VIIa complex. The factor IXa/VIIIa tenase complex subsequently accelerates factor Xa generation and thrombin production more than 50-fold through the

intrinsic pathway. A deficiency in either factor VIII or IX can thereby lead to ineffective hemostasis by inadequate thrombin generation.

EPIDEMIOLOGY

Accurate estimates of the incidence and prevalence of hemophilia depend on the reliable diagnosis and differentiation of hemophilia A and B from von Willebrand disease and other less common congenital bleeding disorders. Hemophilia A and B are clinically identical, [12] and therefore must be distinguished from von Willebrand disease, which is due to defective von Willebrand factor. [13] Hemophilia A is four to six times more common than hemophilia B, [14] [15] [16] [17] [18] [19] [20] [21] [22] [23] [24] [25] [26] [27] [28] and mutations that cause hemophilia occur throughout the genes for factor VIII [29] and factor IX. [30] Based on surveys of patients with hemophilia in North America and Europe, the annual incidence of hemophilia A has been estimated at approximately 1 in 5,000 male births (Table 109-1). The incidence of hemophilia B is estimated at about 1 in 30,000 male births. [28]

The prevalence of hemophilia indicates the number of patients alive with the disease at a given point in time. Hemophilia A and B are observed in all ethnic and racial groups. Some studies indicate a lower prevalence of hemophilia in the Chinese population, and others suggest that hemophilia occurs disproportionately in Caucasians, [31] [32] but the experience of most hemophilia clinicians in the United States is that the demographics of hemophilia mirror the general population (Table 109-2). [33]

The prevalence of hemophilia varies with age. The peak prevalence occurs in the second or third decade, [14] [15] [16] [17] [18] [19] [20] [21] [22] [23] [24] [25] [26] and it seems likely that the lower prevalence observed in younger men is due to underdiagnosis of mild hemophilia, whereas the lower prevalence in older men is likely due to excess mortality especially in those with severe disease. As the overall fitness of patients with hemophilia improves due to advances in therapy, and as the diagnosis of mild cases improves, there will probably be an overall increase in both the true and observed prevalence of hemophilia. [34] The epidemic of acquired immunodeficiency syndrome (AIDS), though devastating to infected individuals, has been predicted to have a transitory and relatively modest effect on the future prevalence of hemophilia. [32] Carrier testing and prenatal diagnosis (see box, Carrier Detection and Prenatal Diagnosis in Hemophilia) have not had a great impact on the incidence of hemophilia, because a substantial minority of cases are the result of unanticipated new mutations and not all known female carriers undergo prenatal diagnostic testing. Further,

TABLE 109-2 -- Prevalence of Hemophilia in Various Racial Groups in the United States

Combined Prevalence of Hemophilia A and B in Various Racial Groups	
Racial Group	**Prevalence (cases/100,000 males)**
Caucasian	13.4
African American	12.3
Hispanic American	11.4

Racial Distribution of Patients with Hemophilia A and B		
Group	**Hemophilia A**	**Hemophilia B**
Caucasian	71.7%	69.6%
African American	12.6%	17.2%
Hispanic American	7.8%	4.7%
Other/Unknown	7.9%	8.4%

Data from the Centers for Disease Control Hemophilia Surveillance System Project [33] show the prevalence and distribution of hemophilia A and B among different racial groups. The prevalence for each group is derived by dividing the number of cases of hemophilia A and B by the total number of males in a six-state region (Colorado, Georgia, Louisiana, Massachusetts, New York, and Oklahoma) in 1993-1994. The distribution of hemophilia A and B in various groups is derived from the number of cases of hemophilia A or B in each group divided by the total number of cases of hemophilia A and B.

pregnant carriers diagnosed with a hemophilic fetus do not always opt for pregnancy termination. [20] [21] [26] [35]

The hemophilias are more common than autosomal recessive bleeding disorders because disease is manifest in the first male to inherit a defective factor VIII or factor IX allele, unlike recessive diseases, which require inheritance of two defective alleles for disease to occur. Consanguinity is not a usual feature of families in which hemophilia occurs, in contrast to autosomal recessive bleeding disorders. Hemophilic females are exceedingly rare because the 50% factor levels typical of carriers protect against bleeding, and therefore most carriers are asymptomatic. Rarely, females may be affected due to unequal inactivation (lyonization) of factor VIII or factor IX alleles, hemizygosity for all or part of the X chromosome, or other mechanisms (see later discussion).

Three degrees of clinical severity correspond to the level of plasma coagulant factor activity. Those with factor VIII or factor IX levels <1% of normal have severe hemophilia characterized by frequent spontaneous bleeding into joints and soft tissues as

TABLE 109-1 -- Prevalence, Incidence, and Severity of Hemophilia in Various Countries

Population (year)	**Hemophilia A**			**Hemophilia B**

Italy[25]	8.2		65%[a]	1.5		70%[a]
Canada[26]	11.6		34%	2.7		24%

Studies are listed in chronological order based on date of publication.

[a]Severe disease is defined as coagulant factor activity levels of <1% of normal except in the United Kingdom and Italy where severe disease includes coagulant factor activity levels of <2% of normal.
[b]Percent severe disease reported for the Netherlands is the overall average for hemophilia A and B combined.

CARRIER DETECTION AND PRENATAL DIAGNOSIS IN HEMOPHILIA

Carrier testing and prenatal diagnosis can be offered to women who are interested in childbearing and have a family history of hemophilia. Carrier testing is particularly valuable to women who are related to obligate carrier females or males with hemophilia. It may also be important to other members of the family to ascertain the mechanism of mutation of the factor VIII or factor IX genes. For instance, germ line mutation in a maternal grandfather has different implications for maternal aunts of a patient with hemophilia than does germ line mutation in the mother of the patient. This analysis is especially pertinent in de novo cases of hemophilia. The generation in which the mutation has occurred may be ascertained through carrier testing of the patients mother.

Prenatal diagnosis may be useful even when pregnancy termination is not acceptable to the family on moral or ethical grounds. For instance, a prenatal diagnosis of hemophilia may be indication for cesarean section and perinatal factor replacement and may also allow more time for psychological preparation of the parents prior to delivery. Conversely, ruling out hemophilia as soon as possible is certainly advantageous to parents of a normal child.

For many years determination of the hemophilia phenotypic by factor VIII or factor IX activity assay was the only avenue for carrier testing and prenatal diagnosis. An accuracy of >90% for carrier detection and 95% for prenatal diagnosis has been achieved in laboratories with special expertise in blood coagulation testing using assays for factor VIII, factor IX, and von Willebrand factor. Certain limitations apply, however. Sampling of fetal blood for factor activity cannot be performed before about 16 weeks gestation, and procoagulant proteins in amniotic fluid can give spurious coagulant activity on coagulation factor assays. Furthermore, maternal factor IX (but not factor VIII) is found in amniotic fluid, which may contaminate fetal blood samples and make prenatal diagnosis of hemophilia B more difficult than hemophilia A. Also, a greater proportion of hemophilia B is associated with a CRM+ phenotype than is hemophilia A, which can limit prenatal diagnosis of hemophilia B by immunoassay. Phenotypic diagnosis of carriers can be misleading in females with extreme inactivation of the X chromosome with the abnormal factor VIII or factor IX allele. The analysis of factor VIII levels in potential carriers needs to take into account the age of the woman as well as ABO blood type, which affects the normal range of factor VIII and von Willebrand factor levels. Despite these limitations, phenotypic analysis still is useful as an adjunct to genotypic analysis, and may be the only option when key family members are not available for genetic analysis.

Genotypic analysis requires either that the specific gene defect is known or that the carrier be heterozygous for at least one DNA polymorphism within, or closely linked to, the gene in question. Factor VIII and factor IX polymorphisms are detected by observing different sizes of DNA fragments obtained after digestion with specific enzymes (restriction fragment length polymorphisms, or RFLPs). DNA from the affected male must be available for analysis if the genetic defect is not known in advance. Prenatal diagnosis by genotypic analysis has certain advantages over phenotypic analysis. Results are not affected by X inactivation, ABO blood type, or von Willebrand factor levels, as are factor activity assays used for phenotype analysis. Because less material is needed for genetic analysis, the test can be done during the first trimester (e.g., chorionic villus sampling at 12 weeks gestation).

When a carrier is heterozygous for an RFLP and the hemophilic males DNA is available for analysis, it is possible to determine which RFLP is associated with the gene defect. Fetal DNA can be characterized for the presence of the RFLP, and it can be determined whether an allele associated with the defective gene has been inherited or not. The analysis of fetal DNA for inheritance of the defective allele is a probabilistic venture by virtue of the fact that there is a (small) chance of recombination occurring between the marker site and the actual gene defect. Accordingly, the best markers for analysis are within the gene (less likely to be subject to recombination with the defect) or very close to the gene of interest. When the specific gene defect is known, the analysis becomes deterministic rather than probabilistic.

A number of intragenic polymorphisms for the factor VIII and factor IX genes have been characterized as have a number of extragenic polymorphisms closely linked to the factor VIII or IX genes. Intragenic sites are preferable because the frequency of recombination approaches zero as the distance between the polymorphism and the gene defect decreases. Where the specific gene defect is not known, RFLPs are sought for which the carrier female is heterozygous. The most useful of these are polymorphisms with two alleles with 50% frequency or better yet many different alleles with more or less equal distribution of frequency of alleles to maximize the likelihood that the female carrier is heterozygous for a polymorphic site. The latter is represented by the TaqI polymorphisms at St14, an extragenic site near the factor VIII gene. By analyzing multiple polymorphisms the likelihood of finding an informative site increases. Typically the ability to find an informative site increases to nearly 100% through the analysis of three or more different sites.

Polymerase chain reaction amplification of DNA and denaturing gradient gel electrophoresis analysis may facilitate rapid screening of mutations in the known coding sequence for factor VIII. However, this analysis does not account for intervening sequences, which comprise the vast majority of the gene. If the known male with hemophilia A is not available for analysis or if informative polymorphisms are not observed in the carrier female, it may be useful to analyze fetal DNA for the common intron 22 inversions responsible for almost half of all severe cases of hemophilia A.

well as prolonged bleeding with trauma or surgery. Those with 15% of normal levels have a moderate course characterized by occasional spontaneous bleeding and excessive bleeding with surgery or trauma, and levels >5% of normal seem to protect against spontaneous bleeding, although excessive bleeding with surgery or trauma still occurs.

Patients with severe or moderate disease are readily diagnosed due to spontaneous bleeding and joint disease, but mild hemophilia probably is substantially underdiagnosed. The proportion of hemophilia A patients with severe disease differs among series, ranging from as little as 30% to as much as 80% of cases (Table 109-1). The largest of these series seem to suggest a figure of 60%. Differing amounts of mild disease reported probably account for the discrepancy between reports. Furthermore,

in some reports severe disease is defined by factor VIII levels of <2%, whereas in other series it is diagnosed on the basis of levels <1% of normal (Table 109-1). The proportion of hemophilia A that is severe is greater than that for hemophilia B in which severe disease is found in 2045% of cases. [14] [15] [16] [17] [18] [19] [20] [21] [22] [23] [24] [25] [26]

GENETIC ASPECTS

Hemophilia A demonstrates sex-linked patterns of inheritance by virtue of the location of the factor VIII gene on the long arm of the X chromosome (Xq28). [36] The factor IX gene is also located on the long arm of the X chromosome about 1.5 megabases away, at Xq27. [37] Accordingly, males bearing either defective allele on their single X chromosome are affected with hemophilia, the severity of which is determined by the particular mutation. Hemophilic males do not transmit the gene to their sons except under extraordinary circumstances, [38] but all of their daughters are obligate carriers for hemophilia. Although female carriers are usually not affected there are a number of mechanisms by which they can be symptomatic with hemophilia, however. [39] Carriers with a defective allele on one X chromosome and a normal allele on the other X chromosome may undergo X chromosome inactivation (described by Mary Lyon), which results in unequal inactivation of alleles so that the defective (hemophilic) allele is expressed in preference to the normal allele. The lyonization process may be the result of random inactivation [40] [41] or may be nonrandom in some cases (i.e., a distinct tendency for inactivation of the normal X allele is seen in all females from the same kindred). [42] Females who have hemophilia by this process are said to be lyonized carriers. The phenotype in the lyonized carrier is no more severe than in the hemophilic male in such families because any expression from the normal allele in such carriers will ameliorate the hemophilia phenotype. Accordingly, symptomatic lyonized carriers are seen only in hemophilic kindred where the male phenotype is severe.

Other mechanisms for female hemophilia include homozygosity for the defective factor VIII allele or hemizygosity for the defective gene. Homozygosity may occur as the result of mating between a hemophilic male and a female carrier (related or not). This mechanism may be inferred if multiple hemophilic sons are born to a hemophilic woman, which has been confirmed in one case through detailed genetic analysis of the kindred. [43] Hemizygosity for the X chromosome can occur in females who have the 45, XO (Turner) karyotype limited to cells that synthesize factor VIII or IX (somatic mosaicism) [39] [44] or in all cells as a consequence of a germ line event (Turners syndrome). [45]

One report documents a female carrier who inherited an affected factor VIII allele from her mother (an unaffected carrier) and an X isochromosome from her nonhemophilic father; in this instance the expression of factor VIII from the isochromosome was defective and the daughter displayed severe hemophilia A. [46] In another case a structurally abnormal X chromosome deleted at the tip (Xq27) distal to a normal factor IX gene resulted in the inactivation of that chromosome, and expression from the other X chromosome revealed a defective factor IX gene for which she was a carrier. As a consequence she demonstrated severe hemophilia B. [47]

The evaluation of hemophilia in a female should begin with testing for von Willebrand disease as well as autosomal recessive coagulation factor deficiencies associated with a bleeding phenotype. In hemophilic females it is essential that a karyotype be done not only to rule out Turners syndrome but also to rule out a male (46, XY) karyotype associated with testicular feminization, which has been described in hemophilia A. [48] [49]

There is no single mutation responsible for hemophilia, in contrast to cystic fibrosis, sickle cell anemia, or Duchennes muscular dystrophy, which are caused by one or a limited number of mutations. Hundreds of point mutations, deletions, and inversions that cause hemophilia have been described throughout the factor VIII and factor IX genes (Chaps. 107 and 108). [28] [50]

ETIOLOGY AND PATHOGENESIS

The hallmark of hemophilia is bleeding into joints (hemarthrosis), which is quite painful and leads to chronic inflammation and deterioration not unlike that seen in rheumatoid arthritis. Abnormal bleeding originates from the subsynovial venous plexus underlying the joint capsule, where a lack of thromboplastic activity has been demonstrated.[51] The high degree of factor Xa inhibitory activity conveyed by the tissue factor pathway inhibitor synthesized by human synovial cells may also predispose hemophilic joints to bleeding [52] and may explain the impressive hemostatic response after intravenous administration of recombinant factor VIIa for acute hemarthroses in factor VIII inhibitor patients. [53] [54] Untreated, inadequately treated, or recurrent joint bleeds result in chronic synovial and intra-articular pathology produced by the toxic effects of hemosiderin and release of proteolytic enzymes (e.g., elastase, collagenase, etc.) from the cellular blood components. Synovial hypertrophy, hemosiderin deposition, fibrosis, and damage to cartilage progress until subchondral bone cyst formation becomes apparent on x-ray. Abnormal mechanical forces of weight bearing on these joints further exacerbate the damage and ultimately result in permanent deformities with subluxation, misalignment loss of mobility, occasional ankylosis, and unequal extremity lengths. Multiple joint involvement may be the result of quantitative loading through the joint [55] so that once hemophilic arthropathy compromises the function of one joint, destruction may be precipitated in another joint because of unusual and increased stresses placed on it to compensate for the dysfunction of the damaged joint. For example, an individual with a gross deformity of the knee from recurrent hemarthrosis may be unable to assume a standing position after sitting without shifting an inordinate amount of weight onto his elbows, wrists, and hands in an attempt to project his body forward and upward. Once standing, the flexion contracture of the knee will force the individual to assume a plantar flexion of the ipsilateral foot to minimize the length discrepancy between the two legs. This results in an unnatural weight-bearing position of the ankle, leading to increased bleeding, bone destruction, pain, and eventual valgus deformity.

Radiologically and clinically, hemophilic arthropathy evolves through five stages (Fig. 109-1). Stage 1 consists of intra- and periarticular swelling due to acute bleeding. The joint structure appears normal. Stage 2 is associated with loss of bone density around the joint and epiphyseal hypertrophy secondary to chronic synovial inflammation. Progression of the epiphyseal hypertrophy with widening of the intercondylar notch characterizes the changes in stage 3. The articular cartilage surfaces are not affected until stage 4, when secondary joint space narrowing also becomes apparent. Stage 5 is characterized by advanced erosion of the cartilage with loss of joint space, the presence of joint fusion, and development of fibrosis of the joint capsule.

Because x-ray and clinical examination frequently underestimate the extent of joint disease, new approaches of evaluation are being introduced. [56] Ultrasonography is particularly helpful in the evaluation of joints affected by acute or chronic effusions. The progression of synovial hypertrophy and the resolution of acute hemarthroses following treatment can be monitored by serial sonograms; however, the technique is insensitive to changes in bone and cartilage. Although computed tomography (CT) scanning has been disappointing for evaluating hemophilia joint disease, magnetic resonance imaging (MRI) permits improved discrimination of changes in the cartilage, synovium, and joint space; furthermore, signal characteristics vary with duration of disease. [57]

Figure 109-1 Radiographic changes associated with hemophilic arthropathy. **(A)** Multiple subchondral cysts in the head of the humerus are an early finding of hemophilic arthropathy in this radiograph of the shoulder. The glenohumeral joint space is still fairly well preserved and the range of motion is normal. **(B)** Widening of the intercon-dylar notch and near fusion of the femur and the medial tibial con-dyle are seen in this knee joint affected by hemophlic arthropathy. **(C)** Narrowing/fusion of the tibiotalar joint in the ankle.

CLINICAL PRESENTATION

The clinical presentations of patients with hemophilia A and B are indistinguishable. Hemophilia, especially severe disease with <1% of normal factor activity, is readily diagnosed, especially in patients with prior family history of hemophilia. The diagnosis of hemophilia is usually made on the basis of unusual bleeding symptoms early in life, and the age of first bleeding varies with the severity of the disease. Infants with severe disease typically present with their first bleeding between 12 and 18 months (despite undetectable factor VIII or factor IX activity); the first manifestations of disease in mild hemophilia are seen at 25 years of age. [12] [58] Severe hemophilia most often presents as easy bruising; mild to moderate disease is more often associated with bleeding after trauma or dental procedures. [12] Although all patients with severe disease have spontaneous hemarthroses, these are altogether rare before 9 months of age, presumably because there is little weight bearing until walking begins. [58]

It is remarkable that the trauma of childbirth does not cause intracranial hemorrhage any more often than it does, although some infants may be born with hemophilia A as a result of de novo mutation and die from intracranial hemorrhage at birth undiagnosed. A study of the modes of delivery and prenatal complications in 117 moderately or severely affected infants (hemophilia A and B) shows the risk of serious bleeding in conjunction with normal vaginal delivery to be small. [59] The use of vacuum extraction is a major risk factor and was associated with 10 cases of subgaleal/cephalic hematoma in this series. Cesarean section, even for those known to be affected in utero, does not eliminate the risk of intracranial hemorrhage. In addition, forceps deliveries and prolonged labor increase the risk of intracranial bleeds.[60] No bleeding complications have been reported with the use of fetal scalp electrodes and fetal blood sampling for intrapartum monitoring of affected neonates.[61]

It is often assumed that excessive bleeding with circumcision is usual for hemophilic infants. In fact, this occurs in less than half of severely affected infants after circumcision.[58] Notably, those who bleed are those circumcised several days later than those who do not. Thus, failure to bleed excessively with circumcision does not rule out hemophilia.

The individual with severe hemophilia can bleed from any anatomic site after negligible or unnoticed trauma. Although intra-articular and intramuscular bleeds are the most common and characteristic clinical symptoms of severe and moderate hemophilia, they are rare before the child enters his ambulatory years. In fact, the most common *presenting* manifestations of hemophilia A and B are soft tissue bleeds (41%), bleeding associated with intramuscular injections and surgery (16%), and oral bleeding from tongue or lip biting (11%). [62] Fourteen percent of the bleeding events were severe enough to require transfusion of packed red blood cells.

Soft tissue hemorrhage advances along tissue planes, and blood loss can be extensive because it is not confined to a closed space (e.g., the joint capsule) as in hemarthrosis. Because of this, soft tissue hemorrhage can be life-threatening. Intracranial hemorrhage was the leading cause of death prior to the AIDS epidemic and still remains the most common hemorrhagic cause of death. Hematuria and bleeding of the gastrointestinal tract are the most common problems, though less serious than intracranial hemorrhage. Retroperitoneal hematomas (Fig. 109-2) may occur spontaneously and extend downward along the psoas muscle through the inguinal canal into the thigh, or dissect upward along the vertebral muscles even as far as the neck.

Isolated hemorrhage into closed spaces such as the forearm can lead to a compartment syndrome characterized by compromise of nerve function and blood flow. If untreated by factor replacement and surgical decompression, hemorrhage may lead to permanent neuropathy or tissue necrosis. Untreated cases may result in loss of the limb. Compartment syndromes of the forearm can even be initiated by venipuncture at the antecubital fossa, and patients should be alert for its occurrence after phlebotomy.

The extreme examples of soft tissue hemorrhage, which are common in severe hemophilia A, are less common in moderate or mild disease. Moderate or mild disease may not be detected until adulthood (e.g., during dental extraction) when unexplained bleeding prompts evaluation. Routine preoperative laboratory tests may reveal a prolonged activated partial thromboplastin time (PTT) that triggers further testing and leads to a diagnosis of hemophilia. Some patients with mild disease serve

Figure 109-2 Retroperitoneal hemorrhage involving the iliopsoas muscle of the left iliac fossa in a patient with hemophilia A and a high-titer inhibitor.

in the military or engage in other hazardous pursuits, only to have hemophilia diagnosed later in life.

Intra-articular bleeding becomes problematic, usually between 2 and 3 years of age, and occurs most prominently in the knees, followed by the elbows and ankles. Bleeding into the shoulders, hips, and wrists is less common although trauma can precipitate bleeding in any joint. Bilateral involvement is not uncommon. [63]

In acute hemarthroses a tingling or burning sensation often precedes the onset of intense pain and swelling; joint mobility is compromised by pain and stiffness and the joint is maintained in a flexed position. Replacement of the deficient clotting factor reverses the pain in most cases and, once the bloody joint effusion resorbs, joint range of motion and function are regained.

Chronic hemophilic arthropathy is often painful with weight bearing and normal use, but frequently, the pain is related to the arthritic changes in the joint. Pain may disappear or subside once the joint becomes ankylosed. Muscle atrophy around the joints may lead to further instability, loss of use, valgus deformities, and increased bleeding due to loss of cushioning around the joint and uncoordinated function among muscle groups. Individuals with factor VIII and factor IX levels >20% of normal rarely develop hemophilic arthropathy even if they had experienced previous bleeds; however, one series describes an incidence of up to one-third in individuals with levels between 6% and 20% of normal.[64]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

LABORATORY EVALUATION

The hemophilias occur with various degrees of severity determined by the plasma concentration of factor VIII or factor IX. Typically, the same degree of severity exists within families, and there is little fluctuation of clotting factor levels within the individual over time. The exceptions to this include the so-called Heckathorns syndrome[65] in which factor VIII levels vary within affected family members; individuals with moderate or mild hemophilia A whose factor VIII levels vary as acute phase reactants with exercise, inflammation, and so forth; and the unusual variant of hemophilia B called factor IX Leyden [66] in which the reduced factor IX levels progressively rise after puberty, eventually approaching the normal range (34% increase per year through adolescence). This has been attributed to the effects of androgenic steroids on the mutated promoter region of the factor IX gene in these individuals. [67] [68]

Factor VIII and factor IX levels are assayed against a normal pooled plasma standard, which is designated as 100% activity or equivalent to 1.0 U/ml of factor VIII or factor IX. The normal range of factor VIII and factor IX levels varies between 50% and 150% although increases are associated in each with pregnancy and aging. The use of estrogen-containing contraceptives and replacement therapies produce substantially higher rises in factor VIII than factor IX. In the normal healthy premature and term neonate, factor IX (but not factor VIII) levels will typically be reduced to 2050% of normal and will rise to nearly normal adult levels within 6 months. This observation is attributed to hepatic immaturity at birth. In congenital factor VIII or factor IX deficiencies, individuals with undetectable activity (<0.01 U/ml) will experience the most severe and frequent spontaneous bleeding complications, whereas higher levels will manifest moderate (25% of normal activity) or mild (>5% of normal activity) symptomatology.

The whole blood clotting time, prothrombin consumption test, and the activated PTT are abnormal in hemophilia A and B because of intrinsic pathway coagulation protein deficiencies. Various other laboratory techniques are available for the specific determination of factor VIII and factor IX activities. The one-stage assay, based on the PTT, is most commonly used because of its reproducibility, simplicity, and cost. The two-stage

assay is more sensitive for the detection of low levels of factor VIII and factor IX. In Scandanavia, a chromogenic assay is used for the determination of factor VIII levels. There appear to be consistent differences in factor VIII assay results performed by chromogenic assay and by PTT in patients receiving recombinant factor VIII concentrates, with those determined by the chromogenic substrate method being approximately twice as high as those determined by the one-stage PTT method. [69]

Hemophilia A can usually be differentiated from von Willebrand disease in the laboratory by the presence of normal or increased von Willebrand factor antigen and ristocetin cofactor activity. [70] However, the rare von Willebrand 2N variant, in which the von Willebrand factor protein does not bind factor VIII, may be phenotypically identical to severe hemophilia A except for its autosomally transmitted inheritance pattern. [71] [72] Specialized assays to measure the factor VIII/von Willebrand factor protein-binding characteristics and genetic testing for the specific point mutations involved are necessary to diagnose this entity. Prolonged bleeding times, which are important for the diagnosis of von Willebrand disease, are normal in individuals with hemophilia. However, prolonged bleeding times have been documented in patients with hemophilia A and B in the absence of abnormal platelet aggregation assays or the surreptitious use of aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs) in several series of patients. [73] [74] Although there is no obvious explanation for this phenomenon, bleeding times tend to be more prolonged when the Simplate® device is used and correlate with severity of bleeding events, platelet IgG levels, circulating immune complexes, and vascular injury. The effects of concurrent hepatitis or human immunodeficiency virus (HIV) have not been evaluated.

Most individuals with severe deficiencies in factor VIII or factor IX (<1% activity) usually have undetectable levels of the corresponding factor antigen when assayed against a specific antibody and are designated cross-reactive material negative (CRM); moderately and mildly affected patients may have normal or slightly reduced levels of antigen (CRM+). [75] The clinical significance of CRM versus CRM+ status remains unclear; however, it has been conjectured that CRM individuals may be more predisposed than CRM+ individuals to the development of alloantibodies directed against their specific clotting factor protein defect. [76] A special subset of CRM+ hemophilia B, hemophilia B_M , is associated with an abnormal factor IX protein that prolongs the prothrombin time when an ox or bovine (rather than human) brain source of thromboplastin is used. This product of point mutations in the factor IX gene possesses decreased coagulation function and acts as a competitive inhibitor of factor VIIa. [77] [78]

Although an inhibitor to factor VIII or factor IX is clinically suspected when a bleeding episode fails to respond to an adequate dose of factor concentrate, laboratory confirmation is critical to the diagnosis and subsequent treatment strategy. For allo- (associated with a congenital defect) or auto- (associated with previously normal coagulation) antibody inhibitors, the patients prolonged PTT should be repeated after incubating patient plasma with normal plasma at 37°C for 12 hours. If the prolonged PTT does not correct, the presence of an inhibitor should be evaluated via specific clotting factor assays performed in multiple dilutions and subsequently quantitated according to the Bethesda method. The clotting factor against which the inhibitor is directed will remain persistently and equally deficient at all dilutions, whereas the apparent activity of other factors will increase as the inhibitor is diluted out. [79] [80] Dilutions of the patient plasma are incubated with an equal volume of normal plasma (standardized to contain 1.0 U/ml) for 2 hours at 37°C until a residual factor activity level falls within 2575% of the control mixture of normal plasma and buffer. A standard curve is established, which defines 1 Bethesda unit (BU, inhibitor potency that results in 50% neutralization of the factor VIII or factor IX activity in the pooled normal plasma). [81] Recently, the Nijmegen modification of the Bethesda method was described to increase the specificity of the assay in the very low range of factor VIII antibody inhibitor titers. This assay, which eliminates the pH-dependent variation of factor VIII activity in the incubation mixtures of the Bethesda assay and uses immunodepleted factor VIII-deficient plasma rather than a pooled normal plasma as the source of factor VIII, is usually reserved for research protocols because the clinically relevant inhibitors usually are >510 BU. [82] By convention, >0.6 BU is considered positive for the presence of an inhibitor; titers <5 BU are termed low-titer inhibitors and usually are not associated with anamnestic responses when sources of the specific clotting factor protein are administered. Inhibitors >10 BU are defined as high titer and are often associated with anamnestic responses. The most sensitive means of detecting an inhibitor antibody (which may be transitory or too low in concentration to measure in vitro), is to measure a decrease in the half-life of the factor VIII in vivo.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of hemophilia includes congenital bleeding disorders such as von Willebrand disease, platelet disorders (e.g., Glanzmanns thrombasthenia), and deficiency of various other coagulation factors such as factors V, VII, X, XI, or fibrinogen. In addition there are autoimmune syndromes in which antibodies to factor VIII may spontaneously develop, leading to acquired hemophilia. The diagnosis of hemophilia is made on the basis of family history, bleeding symptoms, physical examination, and laboratory evaluation. The hallmarks of severe hemophilia include prolonged bleeding with surgical procedures, trauma, or dental extraction, as well as hemarthroses and spontaneous bleeding into soft tissues. The last of these distinguishes severe hemophilia A from von Willebrand disease and platelet disorders, in which soft tissue hemorrhage and hemarthopathy are uncommon (except in severe, type 3 von Willebrand disease). In addition, a family history indicating autosomal dominant transmission is characteristic of von Willebrand disease rather than hemophilia, which is sex-linked recessive in its pattern of inheritance. Family history may be unrevealing in de novo presentations of hemophilia. Severe hemophilia A is not clinically distinguishable from severe hemophilia B either by historical features (family history, bleeding symptoms) or physical examination, and the two must be distinguished by specific factor assays for factor VIII and factor IX. The accurate diagnosis of hemophilia A and hemophilia B is critical for appropriate clinical management. Autosomally inherited disorders of coagulation factors V, VII, X, XI, and fibrinogen also must be diagnosed by specific coagulation factor assays.

Mild hemophilia A may be difficult to distinguish from von Willebrand disease because factor VIII levels tend to be depressed in the latter, and prolongation of the bleeding time (characteristic of von Willebrand disease but not hemophilia) may not be reliably present. Specific assays for von Willebrand factor and analysis of the von Willebrand factor multimeric pattern by gel electrophoresis may distinguish the two disorders. Repeat testing is sometimes required to make a definitive diagnosis in the case of von Willebrand disease, especially mild (type 1) forms of the disease.

TREATMENT

Factor Replacement Therapy

The key to treatment of bleeding in hemophilia is replacement of clotting factor to achieve hemostasis. The dose and choice of product are influenced by the severity of disease, the site and

TABLE 109-3 -- Guidelines for Replacement Dosing with Factor VIII and Factor IX

Type of Lesion	Desired Plasma Factor Level (% of normal)		Initial Dose (IU/kg body wt)		Duration of Therapy (days)
	VIII	IX	VIII	IX	
Mild (often spontaneous) hemarthrosis	30%	2030%	15	2030	q 812 h over 12 d for factor VIII; q 1224 h over 12 d for factor IX (Often only 1 dose required.)
Superficial hematoma					
Oropharyngeal or dental					
Severe epistaxis					
Persistent hematuria					
Major CNS trauma or hemorrhage; lumbar puncture or epidural anesthesia	80100%	80100%	>50	50	q 812 h over at least 1014 d for factor VIII; q 12 h over at least 1014 d for factor IX (High-purity products are recommended to avoid thrombotic complications.)
Surgery	(Levels should be maintained at least 72 h and then >50% for the duration of therapy.)				
Retroperitoneal hemorrhage					
Dental extraction with nerve block					
Severe GI bleeding					Continuous infusion with high purity products are recommended to avoid peak and trough level fluctuations and to save on overall factor concentrate utilization.

Abbreviations: CNS, central nervous system; GI, gastrointestinal.

severity of the bleeding, and the clinical scenario. The patients weight, inhibitor antibody status, and previous treatment history (especially with respect to exposure to blood-borne pathogens) also are important. The annual cost of factor replacement therapy for an adult treated weekly may range from $20,000 to $100,000, and the cost for inhibitor patients may be greater, particularly for those undergoing immune tolerance induction protocols. Therefore, patients are best managed in a comprehensive hemophilia center, where multispecialty expertise and ancillary support services exist for diagnosis, therapy, and management. The comprehensive hemophilia center also serves as a resource for patients with related bleeding disorders such as von Willebrand disease. Replacement therapy involves the education of the patient and his family in self-infusion techniques, the cornerstone of home-based treatment.

Guidelines for replacement therapy have been determined empirically over many years; however, the minimal doses of clotting factor replacement for adequate hemostasis have not been established (Tables 109-3 , 109-4 , and 109-5 and boxes, Choice of Concentrate and Treatment of Factor VIII Inhibitors). Typically, hemostasis for minor bleeding can be achieved at plasma factor levels of 2530% of normal (0.250.30 U/ml), whereas severe bleeding requires at least 50% of normal activity. Surgical procedures and life-threatening bleeding require

TABLE 109-4 -- Factor VIII Concentrates Available in the United States

Virucidal Method	Type/Name of Product	Manufacturer	Specific Activity (IU/mg nonalbumin protein)
Ultrapure Recombinant Factor VIII			
Immunoaffinity chromatography	Recombinate	Baxter	> 3,000
	Kogenate	Bayer	> 3,000
	Bioclate	Baxter[a]	>3,000
	Helixate	Bayer[a]	>3,000
Ultrapure Plasma-Derived Factor VIII			
Immunoaffinity chromatography and pasteurization (60°C, 10h)	Monoclate P	Centeon	> 3,000
Immunoaffinity chromatography, solvent detergent (TNBP/Triton X-100), heat treatment (25 ° C, >10 h)	Hemophil M	Baxter	> 3,000
	Monarc M	Baxter[b]	>3,000
Intermediate- and High-Purity Plasma-Derived Factor VIII			

Affinity chromatography, solvent detergent (TNBP and polysorbate 80), and terminal heating 80° C, 72h)	Alphanate SD	Alpha Therapeutics	830 (>400 when corrected for von Willebrand factor protein content)
Solvent detergent (TNBP/polysorbate 80)	Koate-HP	Bayer	9 22
Pasteurization (60° C, 10 h)	Humate-P	Centeon, Pharma	12
None	Hyate-C (porcine plasma-derived factor VIII concentrate used in treatment of inhibitor patients)	Speywood[a]	50

TABLE 109-5 -- Factor IX Concentrates Available in the United States

Virucidal Method	Type/Name of Product	Manufacturer	Specific Activity (IU/mg nonalbumin protein)
Ultrapure Recombinant Human Factor IX			
Affinity chromatography and ultrafiltration (Chinese hamster ovary cell lines maintained in serum-free medium)	BeneFIX	Genetics Institute	> 200 (albumin free) 20% lower recovery compared to plasma-derived factor IX; increase dose by 20%
Highly Purified Plasma-Derived Factor IX			
Dual affinity chromatography, solvent detergent (TNBP/Polysorbate 80), and nanofiltration	AlphaNine SD	Alpha Therapeutics	> 200
Immunoaffinity chromatography, solvent detergent (sodium thiocyanate), and ultrafiltration	Mononine	Centeon	> 190
Low-Purity, Plasma-Derived Factor IX			
Dry heat (80° C, 72 h)	Konyne 80	Bayer	1.25
Dry heat (68 °C, 144 h)	Proplex T	Baxter	1.25
Immunoaffinity chromatography, solvent detergent (sodium thiocyanate), and ultrafiltration	Mononine	Centeon	> 190

targets of 75100% of normal activity. For factor VIII replacement one may assume that each unit of factor VIII per kg body weight raises the plasma level by 2% (0.02 U/ml). Thus, injection of 1,750 U of factor VIII will provide for an incremental rise of 50% (0.5 U/ml) of normal (1,750 U/70 kg × 0.02 U/ml),

CHOICE OF CONCENTRATE: HIGH OR LOW PURITY; RECOMBINANT OR PLASMA DERIVED

In our hemophilia treatment center, the choice of product is approached as follows. Decisions are based on the fact that there is no difference in efficacy among the concentrates. Recombinant factor VIII or factor IX concentrates are recommended for all previously untreated patients, those who have been treated but remain HCV and HIV seronegative, and for mild and moderate severity disease when desmopressin is not sufficient (e.g., surgery or trauma). Plasma-derived products are recommended for HCV- and HIV-seropositive individuals. Because of the possibility that increased purity may preserve CD4 lymphocyte levels, a higher purity concentrate is preferred; however, if the CD4 count is significantly decreased to <200/mm^3 , then a lower purity concentrate may be prescribed. The use of anti-retroviral agents is more critical to the patients survival and overall quality of life than the choice of replacement product. For surgical procedures, high-purity products are preferred both to avoid the thrombogenic side effects of the less pure factor IX products in hemophilia B, but also to facilitate continuous infusion, which reduces the overall cost of replacement therapy. High-purity products, but not necessarily recombinant products, are preferred in immune tolerance induction and prophylaxis regimens. The use of plasma-derived products in these instances can reduce the expense dramatically.

All replacement therapy options should be discussed with the patient or his family. Patient preferences always should be considered seriously, particularly because extensive scientific data are not always available to determine the best treatment and because of the wide variation in cost among the clotting factor concentrates.

which then declines according to the pharmacokinetics associated with factor VIII. This calculation estimates the peak level, and it is common practice in critical bleeding situations to double the initial dose to ensure that the trough level after one half-life exceeds the desired value. Because factor VIII has a half-life of 812 hours, repeat dosing at least two or three times per day is required to maintain the desired factor VIII level. One-half of the initial dose is given every half-life (i.e., every 812 h) to maintain the desired factor VIII level.

Similar calculations can be made for dosing factor IX concentrates. Factor IX demonstrates a volume of distribution approximately twice that of factor VIII due to equilibration with the extravascular extracellular fluid compartment (in which factor VIII does not exchange), and a half-life of about 24 hours. One unit of factor IX administered per kg body weight results in a 1% (0.01 U/ml) increment in the circulating factor IX level in plasma. Thus 3,500 U of factor IX provides an incremental rise of 50% of normal (0.5 U/ml) (3,500 U/70 kg × 0.01 U/ml). For low-purity factor IX concentrates it is best to aim for a maximum level of 50% of normal to avoid thrombotic complications that have occurred with these preparations. This is not a problem with the highly purified factor IX concentrates now available. In fact, the lower recovery of recombinant factor IX that has been observed suggests increasing the dose of recombinant factor IX by 20% over the calculated dose. [76] Subsequent maintenance doses of factor IX are given every 1824 hours. For replacement therapy of hemophilia A or B, subsequent dosing is

TREATMENT OF FACTOR VIII INHIBITORS

For high-titer factor VIII inhibitor patients, standard factor IX complex concentrates are used as first-line therapies, particularly for episodic spontaneous bleeding at home. If the patient does not improve or experiences increased frequency or severity of bleeding, activated factor IX complex concentrates are prescribed. Porcine factor VIII concentrate is reserved for surgery if the Bethesda inhibitor titer is <50 BU. Elective major surgical procedures should be approached with much caution and should only be performed in a major hemophilia treatment center. Arrangements to obtain recombinant human factor VIIa should precede the surgery.

adjusted based on measured factor levels. The duration of treatment is determined by the rapidity of pain relief and recovery of range of motion of an affected joint, or resolution of a hematoma. For major surgery, replacement therapy is usually continued for at least 1014 days to allow for efficient wound healing and scar formation.

Intermittent bolus infusions of factor concentrates have been used successfully for many years. However, pharmacokinetics may vary between products and patients, and the wide fluctuations in factor levels during therapy can make management difficult at times. Continuous infusion protocols have been developed, which reduce factor utilization, facilitate laboratory monitoring of factor levels (since laboratory values reflect a steady state rather than a peak or a trough), and may decrease the overall cost of therapy. This approach has been associated with excellent hemostasis and safety and has been used with factor VIII, factor IX, porcine factor VIII, recombinant human factor VIIa, and activated prothombin complex concentrates for therapy of inhibitor patients. Some studies note a 3075% decrease in the use of concentrate with continuous infusions administered in the surgical setting, and also report a progressive decrease in the plasma clearance of coagulation factors. [83] [84] [85] Most high-purity concentrates maintain more than 80% of initial activity after 37 days without evidence of infectious complications. [86] A typical continuous infusion protocol begins with a bolus designed to achieve 100% of normal levels followed by an infusion of 2 U/kg/h. The results of factor VIII or factor IX levels obtained thereafter are used to guide changes in the infusion regimen. Typically, if the measured factor level is low, the infusion rate can be increased or a small bolus given to bring the levels up to the desired value. Addition of small amounts of heparin (15 U/ml of infusion) can reduce the incidence of local thrombophlebitis at the venous access site.

Clotting Factor Concentrates: Benefits and Risks

Blood-Borne Pathogens

Until the availability of recombinant factor VIII products in the late 1980s and recombinant factor IX in the late 1990s, patients with hemophilia were exposed to thousands of donors via plasma-derived concentrates. Patients treated before viral inactivation procedures were introduced in 1985 were therefore infected by various transfusion-transmitted infectious agents, including HIV, hepatitis A, B, C, and G, as well as parvovirus B19. Virtually all who were treated with plasma-derived concentrates before 1985 have been infected with hepatitis C virus (HCV). The HCV genotype in hemophiliacs reflects the origin of the donors from whom concentrates were derived so that recipients of concentrates derived from United States donors have predominantly the type 1 HCV genotype (>60%). The HCV genotype 1 has a poorer response to interferon- therapy and more frequently progresses to hepatic failure. [87] HCV infection usually produces asymptomatic hepatic transaminasemia, which can either be intermittent or persistent. Liver biopsy studies indicate that chronic active hepatitis or cirrhosis can occur with either presentation. Progression to liver failure occurs in approximately 1015% of seropositive patients within 20 years of exposure. [88] Coinfection with HIV accelerates the deteroration and increases the overall risk of developing liver failure over 20-fold. HCV RNA levels are significantly higher in HIV coinfected individuals, in contrast to the apparent inhibition of HCV replication observed in those coinfected with HCV and hepatitis B virus (HBV). Ethanol consumption, acetaminophen, and hepatotoxic drugs used in AIDS treatment can also exacerbate liver disease. Chronic HCV infection in hemophilia should be considered a significant problem in its own right because there is a 30-fold increase in the incidence of hepatocellular carcinoma compared to normal populations. Interferon- therapy may prevent or delay the onset of this complication. [89] [90]

Treatment of HCV with interferon- has produced mixed results. However, this is the only agent demonstrating consistent benefits in chronic HCV. Development of spontaneous, low-titer alloantibody inhibitors to factor VIII has been reported in hemophilia A patients undergoing long-term interferon- therapy. As for nonhemophiliacs, there is a 50% response rate with the initial course of interferon- defined by a normalization of serum transaminase levels and improvement of liver histology on biopsy after a 6-month course of therapy. HCV RNA typically disappears early in the course of treatment, only to return after termination of therapy. Only 1015% of patients experience a sustained remission. Patients coinfected with mixed HCV genotypes may demonstrate a change in predominant genotype during interferon therapy, which appears to predict a favorable clinical response. [91] Combining interferon with the purine nucleoside ribavirin has resulted in an increased proportion of initial responders and an increase in the number of long-term remissions.

Liver biopsy for hemophilia patients with liver enzyme abnormalities remains controversial, especially with the improvements in polymerase chain reaction assays for HCV RNA and genotyping. Liver biopsy may be useful to predict potential efficacy of interferon because liver enzymes and HCV RNA may not always correlate with histology in the HIV-infected patient. Percutaneous liver biopsies are associated with up to a 12.5% incidence of significant intraperitoneal hemorrhage, despite adequate clotting factor concentrate replacement. [92] The transjugular approach may circumvent the significant and frequently unacceptable risks associated with the percutaneous technique and also offers a noninvasive opportunity to relieve the symptoms of portal hypertension by establishing an intrahepatic portasystemic shunt. [93]

The risks of horizontal transmission of HCV from the infected hemophiliac to his sexual partner or subsequent vertical transmission of HCV to their unborn fetus appear to be minimal (<3%) unless the patient and the pregnant female are coinfected with HIV. Vertical HIV transmission (16% incidence) is more likely to occur in these situations. [94]

Hepatitis B should not be a major problem for patients with hemophilia due to the testing of plasma donors for hepatitis B surface antigen. Furthermore, the recombinant hepatitis B vaccine should be administered shortly after birth. HBV titers may disappear with the progression of AIDS, and in these patients vaccination should be repeated. Most HBV-seropositive patients were exposed to the virus in concentrates administered before 1985; approximately 5% are chronic carriers of hepatitis B surface antigen. These individuals are more likely to develop progressive hepatic failure or hepatocellular carcinoma and are susceptible to coinfection with the hepatitis D virus (or deltavirus), which accelerates liver failure.

Hepatitis A virus (HAV) transmission was not considered an important threat to the hemophilia community due to the fecal-oral route of transmission characteristic of the virus. However, HAV seroconversions were detected in several hemophiliacs treated with solvent-detergent extracted high-purity concentrates. [95] [96] Apparently, the virus entered the plasma pool from transiently viremic donors and escaped viral inactivation, because HAV is a nonenveloped virus. This example further demonstrates the vulnerability of the blood supply to nonenveloped viruses. To minimize the risk of HAV (as well as HIV-1 and HIV-2, HBV, and HCV) some manufacturers are subjecting their plasma-derived concentrates to polymerase chain reaction testing for viral nucleic acids in addition to the serologic screening of the donors for various viral pathogens. The HAV vaccine is recommended for all seronegative hemophilic individuals over the age of 2 years. The immune response to the vaccine in HIV-seropositive patients should be checked because additional booster doses may be needed.

The transmission of hepatitis E through factor concentrates

has not been recognized, and the incidence in hemophilia patients is no different from that in the nontransfused population. This is in contrast to hepatitis G virus (HGV), the newly discovered human flavivirus pathogen, which is distantly related to HCV. Approximately 1525% of hemophiliacs who have received nonviral attenuated concentrates are seropositive for HGV, compared to 3% of healthy blood donors. [97] HGV appears to be susceptible to the same viral inactivation

processes used for HCV and other lipid-enveloped viruses so that the risk of HGV transmission from currently available plasma-derived products should be minimal.

Human parvovirus B19, a single-stranded DNA virus, is associated with fifth disease (erythema infectiosum) in children, transient aplastic anemia in patients with chronic hemolytic diseases, and chronic bone marrow aplasia in patients with AIDS. Through transplacental transmission, B19 parvovirus can induce hydrops fetalis and fetal loss. Because infection is ubiquitous and frequently asymptomatic in healthy adults, viremia is often undetected. The prevalence of B19 viremia in normal blood donor populations ranges up to 1/1,000, [98] ensuring that most large plasma pools used to make factor concentrates are contaminated with virus. The seroprevalence of hemophiliacs treated repeatedly with plasma-derived concentrates approaches 80% even in those who have only received viral-attenuated products deemed safe from HCV and HIV.[99] [100] This is considerably higher than observed in age-matched control groups (approximately 40% seroprevalence). Previous exposure to B19 parvovirus was not affected by age, type or severity of hemophilia, HIV status, CD4 lymphocyte counts, or purity of the plasma-derived concentrate.[101] Only a few anecdotes describe acute hypoplastic anemia or pancytopenia in hemophiliacs. However, the long-term consequences of parvovirus infection in hemophiliacs has not been established. To date, parvovirus B19, a nonlipid-enveloped virus, has been resistant to inactivation by all available heating and solvent-detergent techniques, used alone or in combination, in the manufacture of concentrates. Adjunctive nanofiltration steps are currently being evaluated. Of concern to many physicians who care for patients with hemophilia is the fact that parvovirus B19 is representative of other nonlipid-enveloped viral pathogens (known or unknown) that might contaminate plasma-derived concentrates. These compelling considerations have served as the rationale for administering only recombinant factor VIII or factor IX concentrates to parvovirus B19-seronegative patients, previously untreated hemophiliacs, or pregnant carriers.

Porcine parvovirus has also inadvertently contaminated multiple lots of porcine factor VIII concentrate, used exclusively in patients with factor VIII inhibitors. Retrospective evaluations of recipients of this product have demonstrated no clinical infectious sequelae or immunologic evidence of seroconversions, suggesting a lack of cross-species infectivity.

The causative agent of the progressive dementia and spongiform encephalopathy characteristic of Creutzfeldt-Jakob disease (CJD) has been considered infectious since the mid 1960s; however, its transmissibility through the transfusion of blood or blood components remains controversial. This particle is devoid of nucleic acid and composed exclusively of a modified cellular prion protein with high -sheet content. Because it cannot be detected in the asymptomatic donor, is resistant to chemical or physical inactivation, and does not induce antibodies in the carrier, which could be used as a marker of exposure, it has become a theoretical threat to the hemophilia community. Epidemiologic studies have never determined that CJD can be transmitted to humans by blood components and have never identified any CJD-related deaths in the hemophilia or other heavily transfused populations. [102] The possibility of blood-borne transmission has not been completely excluded because of its decades-long incubation period prior to symptomatic disease. Animal data suggest that CJD can be transmitted experimentally by inoculating buffy coat cells from the peripheral blood of CJD patients or the Cohn fractions of pooled plasma from infected mice into the brains of other rodents. Furthermore, a variant form of CJD has been observed to occur in individuals <40 years old in the United Kingdom. Its neurologic presentation and its histopathologic similarity with bovine spongiform encephalopathy, a prion disease of cattle first recognized in 1996, have prompted speculation that it might represent the transmission of bovine spongiform encephalopathy to humans. These observations and concerns have led to the precautionary withdrawal of factor concentrates and albumin (used to stabilize the ultrahigh-purity monoclonal antibody purified factor VIII from plasma and the recombinant factor VIII products) derived from plasma pools containing material from suspected or confirmed donors with CJD. These uncertainties have spurred the development of recombinant clotting factor concentrates, which are synthesized in cell lines maintained without animal-derived nutrients and free of human albumin in their final formulations.

Noninfectious Complications of Replacement Therapy

Besides infectious complications, clotting factor concentrates produce remarkably few clinically significant adverse reactions. Transfusion-associated anaphylaxis is rarely observed although there are recent reports of anaphylaxis to factor IX concentrates in individuals with severe hemophilia B in close association with the development of a factor IX inhibitor.[103] Genetic analysis reveals complete deletion or rearrangements of the factor IX gene in most patients. Induction of immune tolerance to factor IX has not been generally successful, and these patients may be predisposed to developing nephrotic syndrome. [104] Any plasma-derived or recombinant factor IX concentrate is capable of producing such a complication; treatment of bleeding events with recombinant human factor VIIa is the only effective alternative. Urticarial reactions and low-grade fevers can be treated with antihistamines and acetaminophen. Older, intermediate- and low-purity concentrates were contaminated by measurable anti-A or anti-B isoaggulutinins that occasionally induced significant hemolysis in patients with blood types A or B. The low- and intermediate-purity products were also associated with the rare development of primary pulmonary hypertension.

Immune Effects of Replacement Therapy

Purity and enhanced specific activity are important advantages of the monoclonal antibody purified and recombinant clotting factor concentrates; however, their benefits to the immune system are less clear. Lymphocyte proliferation and cytokine production are significantly reduced by intermediate-purity factor VIII concentrates in in vitro lymphocyte culture systems compared to the ultrahigh-purity preparations, which are essentially inert. This has been correlated with the amount of transforming growth factor- contained in the various concentrates. [105] Prospective randomized controlled studies in patients with hemophilia A have demonstrated that immune suppression with chronic use of intermediate-purity products, as indicated by declines in the absolute CD4 lymphocyte counts, are significantly greater in HIV-seropositive individuals. CD4 lymphocyte counts are more stable in HIV-seropositive patients treated with ultrahigh-purity monoclonal antibody purified concentrate. Less skin test anergy was also appreciated with these products. [106] [107] Currently available intermediate-purity concentrates with higher specific activities (50200 IU/mg) also appear to be less effective in slowing the CD4 count decline than ultrahigh-purity products. The clinical significance of this observation is difficult to assess. Although the decreases in absolute CD4 counts associated with the less pure concentrates might be considered harbingers of hastened clinical deterioration

---

and progression to frank AIDS and death, no data currently support this possibility; neither does evidence suggest that the ultra-high-purity concentrates retard the development of AIDS.[108] These phenomena are attributed to the effects of contaminating plasma proteins in the intermediate-purity products, which may stun the immune system with repeated infusions. A direct correlation exists between cumulative use of these products and the decline of immune parameters.

Thrombotic Complications of Replacement Therapy

Thrombotic complications have not been commonly reported with the use of factor VIII concentrates. However, low-purity factor IX complex has been associated with occurrence of thrombotic complications when infused repeatedly in large amounts. Similar complications have been reported with administration of the activated factor IX complex concentrates used in inhibitor patients. Disseminated intravascular coagulation, deep venous thrombosis, pulmonary embolism, and fatal or life-threatening acute myocardial infarction in young men and boys have been described. The introduction of high-purity plasma-derived and recombinant factor IX preparations has virtually eliminated this thrombogenicity, and in vivo studies show little or no rise in the surrogate markers of coagulation activation (e.g., fibrinopeptide A, prothrombin fragment 1.2, etc.).

Adjunctive Therapeutic Measures

In most individuals with mild or moderate hemophilia A the expense of replacement therapy can be reduced and exposure to blood-borne pathogens can be eliminated through the administration of desmopressin (DDAVP: desamino-8-arginine vasopressin), a pharmacologic analog of the hormone 8-arginine vasopressin. DDAVP is usually administered intravenously or intranasally as a spray with subsequent rises of factor VIII coagulant activity adequate to achieve hemostasis for surgical procedures or symptomatic bleeding. Peak activity is observed within 30 minutes after intravenous infusion (DDAVP 0.3 g/kg body weight) and within 60 minutes after 300 g metered spray intranasally; peak factor VIII activity of two to five times baseline levels is typical. Because of the variability in individual response, potential candidates for this form of treatment should be tested in advance. Dosing can be repeated at 812-hour intervals; however, a progressive tachyphylaxis frequently occurs, making DDAVP less useful for long-term hemostatic support in the postoperative period. Furthermore, the antidiuretic effects of the drug may produce water intoxication and severe hyponatremia, particularly if free water intake is not restricted. Seizure activity, although uncommon, has been reported, predominantly in small children and the elderly, but may occur at any age. Monitoring of fluids and serum sodium levels should minimize these risks. Virtually all patients experience transient facial flushing; mild headaches and minimally decreased blood pressure are occasionally noted. DDAVP should be used cautiously in elderly men with risk factors for coronary or cerebral arterial thrombosis because there appears to be an increased risk of angina pectoris, myocardial infarction, or stroke following administration. This may be due to DDAVP-mediated release of supranormal von Willebrand factor protein multimers from endothelial cells, which can aggregate platelets in conditions of high shear stress. DDAVP also stimulates the release of tissue plasminogen activator from endothelial cells, producing potential fibrinolysis at the site of hemostasis. Therefore, for treatment or prevention of mucosal surface bleeding, such as dental, gastrointestinal, or vaginal (in carriers),

antifibrinolytic agents should be added immediately prior to DDAVP and continued for 57 days thereafter. Similarly, the adjunctive administration of antifibrinolytic agents such as epsilon-aminocaproic acid or tranexamic acid in combination with clotting factor concentrates enhances the control of bleeding during and after dental surgery in hemophilia A. Their use in hemophilia B should be reserved for patients receiving the high-purity factor IX concentrates because any hypercoagulable tendency induced by low-purity materials may be exacerbated by inhibiting the fibrinolytic system.

There is growing experience with the use of fibrin sealants in patients with hemophilia. Fibrin sealant can function both as a hemostatic agent and as a promoter of wound healing and has reduced blood loss and requirements for factor replacement therapy in major and minor surgical procedures, including circumcisions and dental procedures.[109] Fibrin sealants have also been used successfully to limit hemorrhage from the cavities remaining after the percutaneous evacuation of hemophilic pseudotumors (see box, Pseudotumors in Hemophilia).

Orthopedic and Musculoskeletal Bleeding

Occasionally, repetitive bleeding can occur in a single joint despite intensive prophylactic factor replacement therapy and physiotherapy. The synovitis and pain in this target joint warrant definitive treatment to prevent progressive degeneration. Open surgical or arthroscopic synovectomy can reduce the frequency and severity of hemarthoses and pain by removing inflamed tissue and most of the blood vessels in the joint. Synovectomy should not be performed with the sole intent of improving joint mobility because loss of motion in the affected joint often occurs after surgery. Synovectomy is not advisable for individuals in whom adequate hemostasis is precluded by high-titer inhibitors. Nonoperative synovectomy (synoviorthesis) using intra-articular injection of radioisotopes has been explored as a method to ablate inflamed synovial tissue. Synoviorthesis can be accomplished in an outpatient setting with only 1 or 2 days of replacement therapy and can be performed safely in inhibitor patients in whom control of bleeding is often problematic. Colloidal ^{32}P chromic phosphate has been the preferred agent for hemophilic arthropathy and results in better preservation of range of motion than operative synovectomy.[110] Synoviorthesis may not eliminate hemarthoses as effectively as operative synovectomy, however. Chromosomal breakages have been observed in 10% of a cohort of hemophiliacs (all but one seropositive for HIV) who underwent synoviorthesis since 1977,[111] and one individual has been reported to have developed acute leukemia after undergoing synoviorthesis (M. Manco-Johnson, personal communication). The risk of malignancy remains unclear because patients with rheumatoid arthritis who have received this treatment since the early 1970s have demonstrated no increase in cancer rates.

Orthotics may play an important role in management of joint disease and can serve as an interim measure before definitive reconstructive surgery. The goal of orthototic intervention is to transform a subluxed, flexed joint into a functional stiff limb rather than a functional articulation. Ankle guards and arch supports are useful in individuals with ankle arthropathy and can assist in maintaining and improving gait and weight bearing. Shoe lifts can equalize the length of the lower extremities. Otherwise, orthotics are applied most commonly to the knees and occasionally to the elbows. Dynamic braces equipped with adjustable hinges to correct extension deformities of joints with successive, painless manipulations have supplanted traditional plaster casting of the joint with serial extension wedging, which requires anesthesia, is painful, and does not permit active muscle contraction.[112] These methods do not address subluxation deformities; however, promising results have been reported with the Ilizarov apparatus, which applies significant skeletal-mediated forces simultaneously in both the subluxation and the extension planes.[112] [113]

Pain and deformity that limit mobility, quality of life, and performance status are indications for joint reconstruction. Arthroplasty with prosthetic joint replacement has been performed to regain functional knees, hips, elbows, and shoulders.

PSEUDOTUMORS IN HEMOPHILIA

Hemophilic pseudotumors are large encapsulated hematomata that represent progressive cystic swelling from persistent bleeding and incomplete resorption. This serious complication is evident in approximately 12% of severely affected patients, usually in adults, and is composed of clot and necrotic tissue. Three types of pseudotumors predominate in hemophilia. The most common type arises from repeated hemorrhage and inadequate clot resorption and is usually confined within fascial and muscle planes. Radiologically they appear as simple cysts and infrequently expand to involve adjacent structures or erode through the skin layers. The second type involves large muscle groups, such as the gluteus maximus and iliopsoas. These are especially problematic because they may gradually enlarge, develop a fibrous capsule, and eventually destroy adjacent underlying structures by pressure necrosis. Skeletal fractures and bony deformities produced by cortical erosion may result. The third and rarest type of pseudotumor arises from within bone itself, often secondary to subperiosteal bleeding. This lesion typically is observed in the long bones of the lower extremities and pelvis, but has been reported to occur within the calcaneus, cranium, and mandible (Fig. 109-3). As it expands, the periosteum is stripped and raised, leading to displacement and erosion of adjacent muscle and bone. Most pseudotumors arise in adults and occur in proximal skeletal structures; distal lesions occur more frequently in children before skeletal maturity and are associated with a better prognosis.

Pseudotumors are best diagnosed by CT scanning, magnetic resonance imaging, ultrasonography, and vascular injection studies. Although the presence of one or more progressively enlarging pelvic or skeletal masses in a hemophiliac is consistent with the diagnosis of a pseudotumor, the lesions may resemble osteomyelitis, metastatic neoplasms, Ewings sarcoma, primary osteosarcomas, tuberculosis abscesses, aneurysmal bone cysts, giant cell tumors, or plasmacytomas. Chondrosarcomas and liposarcomas have occurred in such patients. Preoperative biopsy is contraindicated because catastrophic complications including life-threatening bleeding infection are common. Distal pseudotumors respond well to conservative treatment consisting

Figure 109-3 Massive pseudotumor resulting from repeated intracranial hemorrhage in a patient with hemophilia.

of aggressive clotting factor replacement and cast immobilization. Because conservative treatment has not been nearly as successful for lesions of the proximal musculoskeleton, and complete regression is very rare,[187] this approach has been reserved primarily for individuals with high-titer inhibitors. High- and low-intensity radiotherapy regimens have been successful in eradicating pseudotumors in the long bones and may offer an alternative conservative approach.[188] Surgical extirpation is the most effective treatment for pseudotumors and is the treatment of choice when it can be carried out in major hemophilia centers. Nevertheless, operative mortality approaches 20%.[189] Depending on the size and location of the pseudotumor, the percutaneous evacuation of the cavity and subsequent introduction of fibrin sealant or cancellous bone can be considered.

[114] The improved durability and design of joint prostheses allows their use in younger patients in whom it is not unusual for knee prostheses to remain intact for over 15 years. Prosthetic loosening is observed in hip replacements within 610 years after surgery and is due to increased stresses on the joint probably due to weight bearing and abnormal torque produced by the ipsilateral or contralateral knee(s).[115] Staged surgical procedures or multiple joint procedures in a single operative session in individuals with hemophilia should be considered due to considerably lower costs of rehabilitation and clotting factor replacement using this approach.[116] An evaluation of orthopedic surgery in HIV-infected hemophiliacs with absolute CD4 lymphocyte counts of 200/mm ^{3} or less suggests that arthroplasty increases the risk of infection 10-fold, particularly *Staphylococcus* species prosthetic joint infection, chronic osteomyelitis, and sepsis.[117] This is not the universal experience,[118] but it indicates that surgical intervention should be based on the overall balance of risk and potential benefits.

Arthrodesis (surgical fixation) is reserved for painful joints with greatly compromised mobility. Fixation is most commonly performed on the ankle by interposition of autologous iliac crest bone, which fuses the juxtaposed bone surfaces. Fixation of bones into a single, well-aligned unit can be facilitated with intramedullary nails or external fixators; however, pin site infections may occur in up to 10% of patients. Recently, arthroscopic ankle arthrodesis has been developed using demineralized bone matrixbone marrow slurry as a graft substitute. Although this has not yet been widely applied for hemophilic arthropathy, it has the potential to obviate open surgery and reduce the need for factor replacement.[119] Ankle fusion allows patients good mobility in normal shoes because the joints of the feet and toes are less commonly affected by bleeds, and the pain and frequency of hemarthroses are markedly diminished. Supramalleolar varus osteotomy may be a useful alternative hemophilic arthropathy with secondary valgus deformity.[120]

Intramuscular Hematoma

Approximately 30% of bleeding episodes in individuals with hemophilia occur in muscles. Although most intramuscular hematomata are trivial and resolve spontaneously, many produce significant morbidity and, depending on their location and size, can result in mortality. Intramuscular bleeds occur less commonly than hemarthoses and usually are not life-threatening. The most serious hematomata occur in the iliopsoas muscle or retroperitoneal space, where they can bleed profusely and

mimic hip hemarthoses and appendicitis. Large hematomata can produce fever, neutrophilia, ecchymoses, hyperbilirubinemia, and elevations in lactic dehydrogenase levels. They may be painful and may impair the sensory and motor function of adjacent nerves, which they entrap and compress. Occasionally, flexion contractures involving muscles innervated by these nerves develop (i.e., the hip). Muscle bleeds can be precipitated by incidental trauma in severe hemophilia and by more significant degrees of trauma in moderate or mild disease (i.e., contact sport injuries). Iatrogenic hematomata may form in association with intramuscular injections of medications such as vaccines and can be prevented by administering replacement clotting factor beforehand. All significant muscle bleeds should be treated aggressively with clotting factor to raise the factor VIII or factor IX levels above 50% of normal.

Mucous Membrane Bleeding

Although fatal gastrointestinal tract bleeding was a greater problem prior to introduction of factor concentrates, significant hemorrhage has continued to occur in 13% of adult patients with hemophilia.[121] Gastric mucosal bleeding has become more common in recent years with the increased use of NSAIDs for treatment of the pain of chronic hemophilic hemarthropathy (see box, Pain Management in Patients with Hemophilia). NSAIDs have supplanted aspirin as the major cause of this complication. Aspirin in any form should be avoided altogether and NSAIDs prescribed judiciously for limited time periods under strict medical supervision in patients with hemophilia.

Hemorrhagic complications of portal hypertension in long-term survivors of viral hepatitis have appeared more commonly as hemophilia patients live longer. Massive, life-threatening melena and hematemesis can result from esophageal varices in patients with hemophilia complicated by portal hypertension. Sclerotherapy at the site of bleeding varices has been successful for therapy of gastrointestinal bleeding, as has the transjugular intravenous portal-systemic shunt procedure for decompression of varices, and is probably safer than aggressive open surgical procedures. In certain individuals orthotopic liver transplantation offers an additional option for the treatment of symptomatic portal hypertension complicating terminal liver failure. This approach has the additional advantage that it provides a cure of the underlying hemophilia by restoring normal coagulant factor synthesis. [122] [123] [124] Gastrointestinal blood loss in a patient with hemophilia demands an exhaustive evaluation for anatomic lesions, as in any other patient.

PAIN MANAGEMENT IN PATIENTS WITH HEMOPHILIA

Acute hemarthroses or soft tissue hemorrhages are associated with intense pain, which requires immediate analgesic relief. Chronic pain frequently accompanies hemophilic arthropathy, particularly while some joint mobility remains. Narcotic agents may be required; however, many individuals show addiction over time with frequent use. The reversible antiplatelet effects of the NSAIDs other than aspirin may be tolerated quite well in some patients for the acute and chronic pain of hemarthroses. However, aspirin is to be avoided because of its irreversible antiplatelet effects. [194] [195] Alternative agents for pain relief include a nonacetylated choline magnesium trisalicylate, paracetemol (not available in the United States), and acetaminophen combined with small amounts of codeine or synthetic codeine derivatives. These medications lack the anti-inflammatory effects of the NSAIDs.

Techniques of progressive muscle relaxation, guided imagery, and thermal biofeedback assessment of the arthritic joint may provide adjunctive means to reduce the need for narcotic analgesia,[196] but behavioral approaches to pain management in hemophilic arthropathy have had limited success when used alone. Acupuncture, transdermal nerve stimulation, and hypnosis may achieve similar results but may also mask pain such that the affected joint is not properly immobilized or attended to in a timely manner with clotting factor replacement.[197]

Bleeding from the mucous membranes of the nose and mouth is very common in hemophilia, and post-traumatic tongue bleeding must be treated aggressively to prevent progressive airway obstruction, which can develop rapidly. In infants the frenulum is a frequent site of bleeding, and as the hemophilic child grows older the loss of deciduous teeth and the eruption of secondary dentition can also be complicated by prolonged bleeding. Fortunately, these episodes usually respond well to antifibrinolytic agents (e.g., epsilon-aminocaproic acid, tranexamic acid) or fibrin sealants without factor replacement. For more difficult cases, factor replacement may be required. For major dental surgery, particularly those requiring nerve blocks, factor replacement to achieve 1525% of normal activity should be used to prevent bleeding into the tissue planes of the neck, which can lead to respiratory embarassment. In mild hemophilia, intranasal or subcutaneous/intravenous DDAVP is an excellent choice with or without antifibrinolytics or fibrin sealants. Spontaneous epistaxis is relatively uncommon without an anatomic lesion or trauma. Nevertheless, it may require factor replacement, packing, cauterization, and fibrinolytic therapy when it does occur. Urologic bleeding in hemophilia is discussed further in the box.

DEVELOPMENT OF ALLOANTIBODY INHIBITORS

One of the most problematic complications of hemophilia treatment is the development of alloantibody inhibitors, which neutralize the coagulant effects of replacement therapy. These are typically IgG antibodies, predominantly of the IgG4 subclass. Factor VIII inhibitors do not fix complement and thus do not produce end-organ damage seen with circulating immune complexes. In contrast, factor IX inhibitors can produce anaphylaxis and nephrotic syndrome in individuals with complete gene deletions.[76] [103] [104] So-called type I alloantibody inhibitors completely inactivate factor VII or IX activity with second-order kinetics. Autoantibody inhibitors in acquired hemophilia, on the other hand, function through type II kinetics and often do not completely inactivate factor VIII activity so that these patients appear always to have some residual measurable factor VIII activity. Finally, factor VIII alloantibody inhibitors manifest varying degrees of species specificity, typically cross-reacting with heterologous factor VIII protein (e.g., porcine plasma-derived factor VIII) with less avidity than with human factor VIII. Thus, porcine factor VIII concentrates can be used for therapy of high-titer inhibitors in which human factor VIII produces no discernable increment of activity.

Factor VIII and IX inhibitors, quantified in Bethesda units, are separated into high titer or high responder and low titer or low responder. The former is defined by levels of >10 BU or the development of an anamnestic response following any exposure to the clotting factor protein antigen while the latter usually has <5 BU and manifests no anamnestic response.

Studies of inhibitor epidemiology have been complicated by differing methods for ascertaining the rate of inhibitor formation and the retrospective nature of most previous studies. Formerly, inhibitors were only identified or sought when the patient became refractory to his usual clotting factor regimen. Retrospective surveys thus reported an inhibitor prevalence of 1520% in severe hemophilia A patients. Recent studies designed

UROLOGIC BLEEDING IN HEMOPHILIA

From 6690% of hemophiliacs will have experienced at least one episode of spontaneous hematuria during their lifetimes, typically first noted after the age of 12 years.[190] [191] The bleeding is usually episodic and painless unless intraureteral clots produce renal colic. It is unusual for bleeding to produce anemia.

The pathophysiology of hematuria in hemophilia is unclear. One study suggested that microscopic renal damage may result from the abnormal clearance of immune complexes in these individuals; however, impaired renal anatomy and function are not apparent in most cases unless there are repeated bouts of hematuria and obstruction.[192] Currently, the most frequent cause of hematuria in hemophiliacs on anti-HIV therapy is the nephrolithiasis associated with the HIV protease inhibitor indinavir (Crixavan), which forms characteristic crystals of the intact drug in the urine. [193] The crystalluria may produce intrarenal sludging, renal colic, and microscopic or gross hematuria. In addition, nephrotic syndrome has recently been recognized as a complication of immune tolerance in individuals with hemophilia B and alloantibodies to factor IX, which may also be immune complex mediated.[104]

Initial treatment of hematuria should consist of conservative measures such as increased fluid intake and administration of clotting factor concentrates (520 U/kg daily for 24 days if bleeding continues). Antifibrinolytic agents such as epsilon-aminocaproic acid or tranexamic acid can cause obstruction or anuria, particularly when the bleeding originates from the upper urinary tract, and they are not recommended unless bleeding is protracted and severe. Other etiologies of hematuria must be excluded, particularly nephrolithiasis, infection, and neoplasms. Extracorporeal shock wave lithotripsy of renal calculi can be performed uneventfully in hemophiliacs (even with inhibitors) under cover of adequate replacement therapy.

specifically to assess inhibitor development associated with newly introduced factor VIII concentrates have prospectively assessed inhibitor titers every 3 months, and in these studies 2452% of individuals with severe hemophilia A develop antibodies. Most occur early after a median of 912 days of exposure to factor VIII, and one-third will disappear despite continued administration of the same factor product. Half of these inhibitors are of persistently high titer unless immune tolerance induction is initiated. [125] Inhibitors may also arise in patients with mild or moderate hemophilia but are uncommon, with an estimated incidence of 313%. Little evidence exists to suggest that higher purity concentrates produce a higher incidence of alloantibody inhibitor formation. Rather, numerous host and genetic factors appear to be more relevant.

Because of the higher than expected incidence of alloantibody inhibitors that occur in hemophilic sibs, a number of studies have attempted to identify genetic markers for predisposition to inhibitor formation. The association of certain HLA haplotypes with inhibitor formation has never been firmly established despite much study. There is no specific molecular defect in the factor VIII gene, which is responsible for development of inhibitors in hemophilia A. However, individuals with large, multidomain gene defects (74%) and nonsense point mutations in the A3 coding domain (73%) are more prone to inhibitors. Fewer inhibitors occur with missense point mutations (3%), heavy chain mutations (8%), or the intron-22 inversions (20%). [126] [127] This would suggest that inhibitors develop primarily in patients who are lacking circulating factor VIII antigen and react to factor VIII concentrates as foreign protein. Recent data indicate a significantly higher incidence of inhibitors in African-Americans and Hispanic-Americans (50%), the genetic basis for which remains unknown. [128] Other risk factors must exist to explain why inhibitors develop in mild and moderate hemophilia or why many hemophilic relatives of inhibitor patients do not themselves form inhibitors.

The prevalence of factor IX alloantibody inhibitors in hemophilia B is very uncommon in comparison to hemophilia A, ranging from 1.53% in some series. These inhibitors seem to be correlated with the presence of large gene deletions and nonsense mutations. [76] [103] [129]

The majority (85%) of factor VIII alloantibody inhibitors are directed against the A2 or C2 domains of the factor VIII molecule, whereas a much smaller proportion are directed against the amino terminal region of the A3 domain. Anti-C2 and possible anti-A3 antibodies may interfere with binding of factor VIII to von Willebrand factor or to phospholipid. This results in rapid inactivation of factor VIII activity and prevents factor VIII from participating in its tenase complex functions. Antibodies in the A2 and A3 domains are adjacent to factor IXa-binding sites and may interfere with binding of factor VIII to factor IX. The bulk of anti-factor VIII antibodies in hemophilics are non-neutralizing and are directed against other parts of the factor VIII molecule. [130] Recently it has been suggested that these antibodies may accelerate factor VIII clearance from the circulation by the reticuloendothelial system. [131]

The treatment of alloantibody inhibitors is predicated first of all on their titer. The approach to low-responder inhibitors is straightforward with the administration of large enough doses of human factor VIII or IX concentrates to saturate the inhibitor and to provide adequate clotting factor activity levels. Generally this is readily

achieved, but a low responder may convert to a high responder without warning. Conversely, high-titer inhibitors may convert to low titers in the late stages of AIDS.

For the individual with high-titer factor VIII inhibitors, several treatment options are available, but none is universally applicable to all patients. Factor IX complex concentrates (formerly prothrombin complex concentrates) of the standard or activated varieties have become the first-line therapy for home self-administration regimens and for uncomplicated bleeding events. Dosing is empirical, usually 75 U/kg, repeated every 812 hours. These products are effective in 4864% of bleeding episodes, but their use is limited by their potential for inducing thrombotic complications and the inability to predict hemostatic response on the basis of laboratory testing.[132] The prothrombin time, activated PTT, and coagulation factor assays are not useful monitors because these products contain bypassing factors that artifactually shorten in vitro clotting assays in a manner that does not correlate to clinical hemostasis. Their repeated and prolonged use for surgical coverage is problematic due to the possibility of disseminated intravascular coagulation, especially in those with liver dysfunction.

An alternative agent for high-titer inhibitor therapy is porcine factor VIII. This treatment is efficacious in about 80% of patients. [133] Furthermore, this product permits measurement of factor VIII activity in vitro to predict the clinical response in vivo. Assays for cross-reactivity to human factor VIII should be performed prior to use to rule out a high anti-porcine factor VIII titer, which will negate the effect of the porcine factor VIII. Porcine factor VIII dosing is empirical, starting typically with a bolus of 100 U/kg followed by subsequent titration of dosing as guided by the factor VIII assays. Typically, factor VIII activity response to porcine factor VIII improves with repeated dosing, suggesting in vivo saturation of the circulating inhibitor by the porcine factor VIII. Unfortunately anamnestic responses to porcine factor VIII occur in 35% of patients, thus limiting the utility

of this product. Other side effects include fever, chills, and, rarely, thrombocytopenia, which may be due to activation of platelets by porcine von Willebrand factor. Porcine factor VIII has not been associated with the transmission of blood-borne viral pathogens. Its high price and limited availability have limited its popularity as a first-line therapy for inhibitor patients. For elective surgery, porcine factor VIII should be considered the first-line therapeutic agent unless contraindicated by inhibitor cross-reactivity against porcine factor VIII. During intensive therapy for surgery, 31% of patients will make high-titer antiporcine antibodies (>10 BU). [134]

An emerging therapeutic agent for high-titer inhibitor patients is recombinant human factor VIIa. Effective hemostasis with minimal adverse side effects has been achieved for therapy of hemarthrosis and soft tissue hemorrhage and for surgical coverage, administered at 90 g/kg as an intravenous bolus followed by repeat dosing every 23 hours as necessary.[135] Most importantly, this product has provided adequate hemostasis in very high-titer inhibitor patients who otherwise would not be candidates for surgical procedures due to previous failures with other bypassing agents. Recombinant human factor VIIa is also of considerable benefit to factor IX inhibitor patients.

For hemorrhagic emergencies that do not respond to the above approaches it may be necessary to reduce the circulating inhibitor titer with extracorporeal immunoabsoption using a *Staphylococcus* protein A column, which can adsorb the inhibitor antibody, thereby permitting replacement therapy with human factor VIII. This may also be performed to lower inhibitor titers at the start of immune tolerance induction protocols.

Immune tolerance induction is advantageous to inhibitor treatment because if the antibody can be permanently suppressed, future therapy is greatly simplified. Immune tolerance induction consists of prolonged desensitization during which factor concentrates are administered daily until the alloantibody inhibitor disappears. Results from an international registry indicate that immune tolerance induction is completely successful in up to 68% of patients and partially successful in another 8%.[136] The probability of success is greatest for those receiving high-dose protocols (>100 U/kg/d), those whose protocol was initiated early in the course of inhibitor development, and those with the lowest initial titers. Concomitant immunosuppression corticosteroids and cytotoxic agents are controversial and probably best avoided, especially in children. The best predictor of success is a 50% reduction in the titer within 6 months and total disappearance of the inhibitor within 1218 months. Complete elimination is defined as a final inhibitor titer of <0.6 BU, >60% of predicted recovery of infused factor within 30 minutes of administration, and a normal half-life of infused factor VIII or factor IX. Low-dose (<50 U/kg/d) protocols have been less successful.

Immune tolerance induction is an expensive option, and is often reserved for patients who require a major surgical procedure and are highly compliant. An indwelling intravenous device is often used.

PROGNOSIS

Before the widespread use of replacement therapy, the prognosis for patients with severe hemophilia was poor and the quality of life greatly diminished by hemophilic arthropathy. The outlook improved dramatically in the modern era of hemophilia treatment that began in the 1960s with the development of cryoprecipitate [139] and factor VIII concentrates[138] (for hemophilia A) and prothrombin complex concentrates[139] (for hemophilia B). It then became possible to achieve high levels of factor VIII or factor IX without volume overload, which limits plasma therapy. This permitted effective therapy of life-threatening soft tissue bleeding, which requires high doses of factor VIII or factor IX for prolonged periods. Furthermore, the convenience of factor concentrates made home therapy of hemarthroses practical. Use of lyophilized factor concentrates administered at home saved many patients from the delays, expense, and inconvenience of hospital- or clinic-based treatment with cryopreciptate or plasma. Factor concentrates facilitated prophylactic therapy, which has now been shown to virtually eliminate bleeding episodes and actually prevent joint deterioration, especially when started early in life (i.e., 12 years of age). [140] Many large studies of patients with hemophilia document the dramatic gains in life expectancy during the era of replacement therapy. The life expectancy of patients with severe hemophilia, which had remained more or less constant from the 19th century to the 1960s, rose from 11 years (or less) for severely affected patients to >50 or 60 years by the early 1980s in reported series. [14] [16] [20] [21] [22] [24] [141] [142] [143] Significant progress was evident even in patients with mild or moderate disease, whose life expectancies were closer to the normal population in the pretreatment era (Fig. 109-4).

Along with the benefits of replacement therapy came viral complications, the most devastating of which has been infection with HIV. HIV infection probably occurred in the late 1970s in heavily treated patients, and the first AIDS deaths in patients with hemophilia A were observed in the early 1980s. [144] Although the greatest rate of HIV seroconversion (>75%) occurred in severely affected hemophilia A patients who were heavily treated with factor VIII concentrates, 46% of patients with moderate disease and 25% with mild disease who were treated only once or infrequently also seroconverted for HIV. [145] The rate of HIV infection in severe hemophilia B (46%) was significantly lower than that of severe hemophilia A patients, as were the rates for those with moderate hemophilia B (27%) and mild hemophilia B (8%). This may reflect differences in concentrate preparation methods. [145] Overall, more than half of patients

INTRACRANIAL HEMORRHAGE

Intracranial hemorrhage is the second most frequent cause of death in individuals with hemophilia, behind AIDS. Ten percent of patients with severe hemophilia develop intracranial hemorrhage with a mortality rate of >30% and a significant incidence of psychoneurologic sequelae in the survivors. These include mental retardation, seizure disorders, and motor dysfunction. Because even minimal trauma to the head may precipitate severe hemorrhage and serious intracranial pathology, aggressive treatment with clotting factor concentrates should be initiated immediately to achieve 100% levels of factor VIII or IX, *even if there is only a clinical suspicion of bleeding*. Replacement therapy should precede any diagnostic procedures because <5% of acute head injuries in hemophiliacs are accompanied by early abnormalities on CT scan. [198] When intracranial injury is demonstrated on CT scans, neurologic deficits, vomiting, or altered mental status are apparent on physical examination. Neurosurgical intervention may be necessary but carries high risks despite maintaining adequate hemostasis with clotting factor concentrates.

Intracranial hemorrhage in the neonate is invariably preceded by mild to moderate head injury. The risk of serious bleeding associated with vaginal delivery is small, but vacuum extraction should be avoided when delivering offspring of known hemophilia carriers. In hemophilic adults, a recent increase in the incidence of intracranial bleeds has been noted and attributed to the compounded effects of end-stage hepatic failure (hepatitis C), the immune thrombocytopenia accompanying AIDS, or the bleeding complications associated with protease inhibitors for HIV treatment on the underlying congenital coagulopathy.

Figure 109-4 Effect of therapy with plasma and plasma-derived factor concentrates on the prognosis of hemophilia. Steady improvements in life expectancy are seen, particularly for patients with severe disease as factor concentrates have become widely available for treatment. Unfortunately, this trend has reversed in recent years as the viral complications of factor concentrate therapy have taken their toll. [14] [22] [141] [142] [143] [146]

with hemophilia were infected with HIV by 1983. Ironically, some patients who received certain heat-treated products early in the epidemic due to inhibitor antibodies were spared infection with HIV. The death rate for patients with hemophilia A more than tripled from a nadir of 0.4 deaths/1,000,000 population in 1979-1981 to 1.2 deaths/1,000,000 population in 1987-1989 in the United States, largely due to HIV, which caused 55% of all hemophilia deaths in the latter era. [146]

The natural history of hemophilia A depends largely on the severity of disease and the presence of concomitant viral illness. The leading cause of death has shifted in the era of replacement therapy from intracranial hemorrhage and other bleeding to viral complications of therapy, chiefly AIDS and cirrhosis from hepatitis. The overall mortality rate among all patients with hemophilia is approximately twice that of the normal male population [24] [32] [146] ; the mortality rate among severely affected patients is four to six times that of normal males. [142] [147] When viral complications of therapy are taken into account, the life expectancy of patients with no HIV or hepatitis is virtually the same as the male population for mild hemophilia A, and the life expectancy of patients with severe disease is only slightly less than the male population in general and the relative mortality is 1.2 times that of the normal male population. [147]

Bleeding events that threaten the life of patients with hemophilia A include intracranial hemorrhage (see box, Intracranial Hemorrhage) and soft tissue hemorrhage in

or around vital areas such as the airway or internal organs. The lifetime risk of intracranial hemorrhage has been estimated at 28% and accounts for one-third of all hemophilic deaths from hemorrhage despite advances in replacement therapy. [143] [148] [149] It is notable that there is only about 20% of the expected number of deaths from cardiovascular disease, suggesting a protective effect of hemophilia A. [34] [147]

Whether patients with inhibitor antibodies have a different life expectancy is not entirely clear. Although they do not bleed any more frequently than other patients with (severe) hemophilia, their bleeding episodes are more difficult to treat than those in severe hemophilia patients who can be treated with factor VIII. Where mortality and life expectancy have been compared in the two groups, the inhibitor patients life expectancy differs only slightly from that of the noninhibitor group. [147] Although inhibitor patients severe bleeding episodes are more likely to be fatal due to less than adequate therapy, fewer inhibitor patients have seroconverted for HIV. [142] [148]

Hemophilia as a chronic disease has been recognized to affect the physical and cognitive growth of individuals independent of HIV status. As primary prophylaxis emerges as a more acceptable approach to treatment, these problems may become less common; however, recent data from the United States indicate that a significant proportion (25%) of hemophilic children

---

ages 618 exhibit below-normal performance in motor skills, lower than expected academic performance (measured by IQ scores), and more behavioral and emotional problems than expected, as reported by parents. [150] The presence of HIV and the absolute CD4 counts were not related to neuropsychological performance at baseline. Causality has not been established, but the potential contributions of minimal head trauma with clinically inapparent bleeding and the effects of hemophilia on the emotional well-being of the family cannot be overlooked.

A significant impairment of physical stature and sexual maturation has been observed in HIV-infected boys with hemophilia as compared to uninfected boys or population norms. Differences were exaggerated in those with absolute CD4 lymphocyte counts <200/mm^3 . The discrepancy between total serum testosterone levels (compared to age-adjusted levels in HIV-uninfected boys) and observed physical changes is hypothesized to be related to decreased free testosterone resulting from increased levels of sex hormone-binding globulin. [151]

The combined morbidity and mortality associated with hemophilia and its treatment are a powerful argument for prophylactic treatment, safer concentrates, elimination of inhibitor antibodies where they occur, and gene therapy, which currently is the only prospect (short of liver transplantation) for the cure of hemophilia.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

GENE THERAPY

In recent years considerable effort has been devoted to gene therapy as a cure for hemophilia. Gene therapy may be defined as the attempt to express a missing or defective gene to replace its missing product or function. Presently only gene transfer into differentiated cells or tissues of patients (somatic cell gene therapy) is under investigation as a treatment for hemophilia. Somatic gene therapy could be performed by removing tissue from a patient, transducing cells in vitro, and returning modified cells to the individual (ex vivo gene therapy), or by gene transfer done in the patient (in vivo gene therapy). [152] The former requires substantial tissue culture of each individual patients cells and would amount to a custom application in each case, whereas in the latter approach a single vector preparation might be administered to a large number of patients, analogous to clotting factor concentrate therapy.

Hemophilia is well suited for gene therapy because relatively low levels of coagulant activity prevent severe disease. Clinical experience with factor replacement therapy indicates the benefit of therapy, which is prophylactic rather than reactive. Maintaining factor VIII or factor IX levels of >12% of normal starting early in life (from 12 years of age) prevents virtually all spontaneous bleeding and maintains normal joint structure and function. [140] [153] Furthermore, as the total dose of prophylactic factor replacement increases and the interval between doses decreases, the outcome improves, underscoring the benefits of continuous delivery of coagulant factor.[154] Continuous delivery of factor VIII or factor IX at a steady state of 1% of normal or more would provide clinically significant benefit and should be the initial therapeutic goal of gene therapy (see box, Prophylactic Factor Replacement Therapy).

The recent development of factor VIII and factor IX knockout mice[155] [156] [157] and the previously established hemophilia A and B canine colonies and cloning of the factor VIII and factor IX genes have facilitated research on hemophilia and gene therapy. Gene transfer has been attempted using vectors targeting liver, muscle, skin, bone marrow, and endothelial cells in normal and hemophilic animals (e.g., mice and canines). Factor VIII or factor IX gene transfer to liver, muscle, skin, vascular, or bone marrow cells in vivo with retroviral vectors has typically resulted in long-term gene expression at low levels. [158] [159] [160] [161] [162] [163] [164] [165] [166] [167] [168] [169]

Adenovirus-mediated gene transfer of genes for factor VIII or factor IX into liver has resulted in high levels of gene expression

PROPHYLACTIC FACTOR REPLACEMENT THERAPY

The Swedish experience demonstrates a decreasing need for orthopedic surgery in hemophiliacs who are treated from the age of 12 years (before arthopathy has begun) with a prophylactic regimen of clotting factor concentrate replacements.[140] [153] These series and others indicate that administering factor VIII or factor IX concentrates at 2540 U/kg three times weekly for hemophilia A and twice weekly for hemophilia B beginning in toddlers results in a significant reduction in spontaneous bleeds and arthropathy. The doses and frequency of replacement therapy are adjusted to prevent the factor VIII or factor IX levels from falling below 12% of normal, thereby converting severe hemophilia into mild or moderate disease. Primary prophylaxis results in short-term and sustained improvements in objective measures of the function and radiologic appearance of joints. Joint scores have remained at zero (i.e., no affected joints) over at least 5 years of observation in 79% of individuals whose regimens were initiated between the ages of 1 and 4.5 years. Outcome is directly related to the intensity of treatment and the level of compliance,[199] [200] and translates into decreased absence from school or work, fewer bleeds and days spent in the hospital, increased personal and professional productivity, improved overall performance status, and a healthier self-image.[199] Higher than usual doses of clotting factor concentrate in an attempt to minimize damage associated with episodes of joint bleeding (on demand regimen) do not produce as good orthopedic outcomes as primary prophylaxis.[199] Factor concentrate expense is substantially greater in primary prophylaxis, and the central access devices used to facilitate vascular access are associated with a significant incidence of sepsis and thrombosis. [201] [202] [203] Cost reductions can be realized if the factor is administered via continuous infusion and dosing based on measured pharmacokinetics. [202] [203] [204] There is no evidence that prophylaxis begun early in childhood increases the incidence of inhibitor antibody formation. Although primary prophylaxis may not be optimal for all individuals with severe hemophilia (or their families), the substantial benefits demonstrated in prospective studies cannot be overlooked but must be balanced against the costs, inconvenience, and acceptance by the patient and his family, as well as the viral safety of the concentrate chosen for the regimen.[205] The initiation of a prophylaxis regimen after years of on-demand replacement therapy for recurrent hemarthroses is designated secondary prophylaxis and has caused stabilization of articular function and joint scores over time; however, joint damage is not reversed and radiographic deterioration of previously damaged joints may continue to progress.[206] This alternate strategy may be useful for those in whom there is initial reluctance to begin primary prophylaxis.

of limited duration due to humoral and cell-mediated immunity. [170] [171] [172] [173] Investigators have removed more and more of the adenovirus genes from vectors, [174] [175] administered virus in the neonatal period to induce tolerance, [176] or administered immunosuppressives to circumvent the immune response.[177] [178] These methods may not be applicable to humans with hemophilia, however, especially those with acquired immunodeficiency states. More recently, adeno-associated virus (AAV) vectors have been tested for gene therapy of hemophilia. [179] [180] [181] [182] The most

promising results are now being obtained with recombinant AAV vectors expressing factor IX. Sustained, therapeutic levels of factor IX (20% of normal) have been observed in normal mice after AAV-factor IX vectors were delivered to the liver via portal vein injection, [181] and sustained levels of 47% of normal have been demonstrated in immunodeficient mice following intramuscular injection of AAV-factor IX vectors. [182]

Sustained expression of the factor VIII gene at therapeutic levels in vivo has proven to be problematic with retroviral and adenoviral vectors, [161] [162] [163] [164] [165] [166] [167] [168] [169] [170] [171] [172] [173] [183] and the large size of the factor VIII cDNA may rule out the use of AAV vectors, which cannot normally accomodate large transgenes. Furthermore, certain sequences within the factor VIII gene appear to interfere with efficient transcription and expression of factor VIII. [184] [185] [186]

It can be anticipated that gene therapy of hemophilia will be practical when the limitations of gene transfer vectors are eliminated. Vector safety, inhibitor antibody formation, and the optimal levels of factor VIII or factor IX transgene expression will emerge as issues for the hemophilia clinician to manage in the gene therapy era.

Chapter 110 - Inhibitors in Hemophilia

Donald I. Feinstein

INHIBITORS IN HEMOPHILIA A

Factor VIII inhibitors are antibodies that develop in patients with hemophilia A in response to factor VIII contained in various blood products. Most of these antibodies neutralize factor VIII coagulant activity. Although they do not increase the frequency of bleeding episodes, they make treatment of bleeding much more difficult. Some antibodies are directed toward nonfunctional determinants on the factor VIII molecule, but the clinical relevance of these antibodies is not clear. [1] They could result in increased clearance of transfused factor VIII and could explain why the half-life of factor VIII is reduced in some patients with undetectable levels of inhibitors affecting the function of factor VIII in vitro. The incidence of factor VIII inhibitors complicating hemophilia A is approximately 510% of all patients with hemophilia A and approximately 20% of those with severe hemophilia A.[2] [3] [4] In a meta-analysis of eight retrospective studies using crude or intermediate-purity products in high-responding, severe hemophiliac patients, the cumulative incidence of inhibitors in 451 patients was 20% after 16 years of treatment. [5]

Patients with low-titer inhibitors (35 Bethesda units) that do not rise after further exposure to factor VIII are known as low responders; this characterizes approximately 25% of hemophiliacs with inhibitors. Patients with inhibitors that rise markedly with further exposure to factor VIII (anamnestic response) are known as high responders; this characterizes approximately 75% of hemophiliacs with inhibitors. [6] Inhibitor titers usually begin to rise 23 days after exposure to factor VIII, reach a maximum within 721 days, and then decrease slowly (Fig. 110-1). Once formed, high-titer inhibitors tend to persist for long, although variable, periods, and detectable levels of inhibitor may be present 12 years later without re-exposure to factor VIII. By contrast, low-titer inhibitors in low responders occasionally disappear and may not reappear with exposure to factor VIII.

In studies of inhibitor formation in previously untreated patients receiving highly purified plasma-derived factor VIII, the incidence of inhibitors was 1835%, [7] [8] [9] and with intermediate-purity factor VIII concentrates, the incidence was 2552%. [10] [11] [12] [13] [14] In prospective studies using recombinant factor VIII in previously untreated patients, the incidence was 2429%.[11] [12] [15] In the latter studies, the inhibitors were detected early, with the median number of exposure days before inhibitor formation being 10 (range, 516 days). [11] [12] [15] Thus, most patients with severe hemophilia who are destined to develop an inhibitor do so early after exposure to factor VIII.[11] [12] [15] [16] However, the 2429% seen in the recombinant factor VIII trials may be an underestimate in that the duration of factor VIII treatment was limited in both reports. Using Kaplan-Meier analysis, the risk of inhibitor formation was 38% after 25 exposure days in the Recombinate trial and 36% after 18 exposure days in the Kogenate trial.[11] [15] [17] However,

Figure 110-1 Inducible and noninducible factor VIII inhibitors. Solid circles, high responder; open circles, low responder; arrows, factor VIII concentrate.

30% of the inhibitors were low titer and transient, and these patients were treated successfully with standard amounts of factor VIII for bleeding events. [11] [15] Low-titer, low-response inhibitors are also successfully continued on treatment. [11] [15] Thus, studies with highly purified and recombinant factor VIII have demonstrated no significant increase in the incidence of high-titer inhibitors. In addition, inhibitor development varies in the different studies because of the retrospective nature of many studies, the tendency to report mostly high-titer inhibitors, the use of more than one factor VIII product in individual patients, the variable time of patient follow-up, and the variable frequency of testing for inhibitors. The incidence of inhibitor development varies with the factor VIII product used. The most dramatic examples were the low incidence of inhibitor development reported from the Leuven Hemophilia Center when using lyophilized cryoprecipitate, [18] and the low incidence of inhibitors when using the Biotransfusion product from France, [19] contrasted to the high incidence associated with the use of a Dutch concentrate. [20] [21] [22] [23]

Although most inhibitors develop in severe or moderate forms of hemophilia A, well documented cases include patients with mild hemophilia A. [3] [24] [25] [26] [27] [28] [29] [30] In general, these patients develop only low-titer inhibitors after exposure to factor VIII. After abstinence from products containing factor VIII, the inhibitors disappear after 412 weeks, and the inhibitors do not necessarily reappear on re-exposure.

Pathophysiology

The reasons for the development of inhibitors in a minority of patients with hemophilia A is not understood. Brother pairs have a higher-than-expected incidence or absence of inhibitors. [16] [31] Another factor suggesting genetic susceptibility is the finding of a lesser incidence of human leukocyte antigen (HLA)-A1 and a higher incidence of certain complement components located close to HLA-DR in hemophiliacs with inhibitors. [32] However, recent studies correlating the molecular defect causing hemophilia A with the development of an inhibitor have shed some light on this subject. [4] [33] [34] [35] [36] The frequency of inhibitor development in patients with large multidomain deletions and in patients with nonsense mutations affecting the A3 domain of the molecule is approximately 7075%. [33] Nonsense mutations in the C1 or C2 domains, however, result in inhibitor formation in 27%, the intron 22 inversion (the most common genetic defect) in 20%, and a small deletion in 15%. [33] In contrast, factor VIII heavy chain nonsense mutations result in inhibitor formation in only 8% and a nonsense point mutation in 3%. [34] However, other factors must also be operative because hemophiliac relatives of inhibitor patients may not develop inhibitors. These other factors include immune responsiveness, product heterogeneity, and intensity of treatment. Shapiro and Hultin [24] suggested that immune tolerance might be involved to explain the development of inhibitors in patients with hemophilia A. Because factor VIII does not cross the placenta, tolerant hemophiliacs could be exposed to factor VIII in utero only as a result of maternofetal hemorrhage. Thus, according to this hypothesis, only nontolerant hemophiliacs would develop inhibitors after exposure to factor VIII. Induction of tolerance in hemophiliacs with inhibitors results in the disappearance of the inhibitor in a significant number of patients. [37] [38] [39] [40] [41] [42] [43] [44]

Characterization and Properties of Inhibitors

Factor VIII inhibitors in hemophilia A are IgG. Although light chain and heavy chain subtyping has usually demonstrated restricted heterogeneity, [45] [46] [47] [48] [49] [50] [51] [52] heavy chain subtyping of these antibodies has shown a significant predominance of the IgG_4 subtype.[47] [50] [53] IgG_4 does not fix complement, which might explain why immune complex disease does not develop in hemophiliacs. More recent studies have shown that hemophilia alloantibodies do not always have a predominance

of IgG_4 and may also contain IgG_1 and IgG_2 .[1] [54] Factor VIII inhibitors show species specificity, both in vitro and in vivo, in that human factor VIII is usually neutralized to a greater extent than is bovine or porcine factor VIII, and infusion of porcine factor VIII into a patient with an inhibitor often raises the factor VIII level.

The reaction between factor VIII and inhibitors is time- and temperature-dependent. Two different patterns of antigen antibody reaction have been described. In the type I pattern, characteristic of most alloantibodies, as seen in hemophiliacs, factor VIII is completely inactivated in the presence of excess inhibitor, [55] [56] [57] whereas in the type II pattern characteristic of most autoantibodies, the inhibitor frequently does not completely inactivate factor VIII in vitro in the presence of excess inhibitor.[45] [58] [59] [60] In the latter cases, despite the demonstration of a significant amount of residual factor VIII activity in vitro, the patient bleeds as if there were no coagulant function in vivo.[61] [62] The reason for the difference between type I and type II inhibitors is not understood. However, it has been found that most type II inhibitor plasmas have type I characteristics when tested with factor VIII that has been separated from von Willebrand factor.

The antigenic regions on the factor VIII molecule to which neutralizing factor VIII inhibitors bind have been identified. [4] [35] [54] [63] [64] [65] [66] [67] [68] [69] The epitopes to which alloantibodies or autoantibodies are directed are limited to certain areas of the factor VIII light or heavy chains [4] [35] [54] [63] [64] [65] [66] [67] [68] [69] (Fig. 110-2). The factor VIII molecule consists of two series of repeated homologous domains and a single B domain arranged in the following order: A1-A2-B-A3-C1-C2. Small regions rich in acidic amino acids are located between A1 and A2 (called AR1), A2 and B (AR2), and B and A3 (AR3).[35] The heavy chain consists of A1-AR1-A2-AR2-B, and the light chain consists of AR3-A3-C1-C2.[35] The A and C domains are required for functional activity, whereas the B domain is not. A variety of immunologic techniques have been used to characterize the parts of the factor VIII molecule to which antibodies bind. These include immunoblot analysis after sodium dodecyl sulfate-polyacrilamide gel electrophoresis of purified factor VIII, immunoprecipitation assays using recombinant polypeptide fragments of factor VIII, enzyme-linked immunosorbent assay techniques that measure antibody binding to intact recombinant or plasma-derived factor VIII, and the use of monoclonal anti-factor VIII antibodies derived from the plasma of inhibitor patients.[35] [66] [67] [68] [69] Anti-A2 and -C2 antibodies are present in approximately 68% of plasmas tested by immunoprecipitation assays using recombinant polypeptide fragments of factor VIII.[69] [70] [71] In addition, 46% of antibodies contain antibodies that bind to AR3.[69] [72] There are also less common AR1, A3, and C1 antibodies and antibodies to a light chain epitope outside of C2.[35] [54] [69] [73] [74] The antibody or combinations of antibodies that inhibit factor VIII activity usually consist of those with A2, C2, and AR3-A3-C1 epitopes because of the

Figure 110-2 Localization of factor VIII inhibitor antigens. **(A)** Thrombin cleavage fragments, **(B)** factor VIII domains, **(C)** inhibitor epitopes (hatched bars). Most antibodies are directed toward epitopes on the C2 domain, the A2 domain, or the amino terminal of the A3 domain.

ability of polypeptides containing those epitopes completely to neutralize inhibitor activity.[35] In addition to the C2 epitope, there probably exists one other distinct light chain epitope[35] and an epitope in AR1.[35]

Antibody patterns in hemophilic patients differ from those in autoantibody patients.[35] In a recent study, C2 antibodies were the only antibodies found in 48% of autoantibody patients, whereas this pattern occurred in only one of 34 hemophiliacs.[35] Moreover, 62% of autoantibody patterns were directed to a single epitope, in contrast to only 17% of hemophiliac patterns. Fewer autoantibody patients contained anti-A2 and anti-AR3-A3-C1 antibodies, and the occurrence of A2 plus C2 antibodies was also less common. Hemophiliacs treated with either plasma-derived factor VIII or recombinant factor VIII have equally complex patterns, but they differed in epitope specificity from one another.[35] The relative amounts of antibody to the A2 and C2 domains can vary over time, and neither level is always correlated with the inhibitor level.[35] [66]

Anti-C2 antibodies interfere with factor VIII function by blocking the binding of factor VIII to phospholipid, [35] [66] [75] whereas anti-A2 antibodies inhibit activated factor VIII function by blocking the conversion of factor X by the factor IXafactor VIII complex.[67] [69] Antibodies can interfere with von Willebrand factor binding, [18] [35] [69] [75] [76] and some antibodies reduce the rate at which thrombin-activated factor VIII is released from von Willebrand factor.[61] In addition, the characteristics of inhibitors produced by a given patient may change over the course of time.[1] [18] [35] [54] [63] [65] [77]

Laboratory Evaluation and Quantitation of Inhibitor Titer

The presence of an inhibitor to factor VIII should be suspected in a hemophiliac if transfused factor VIII appears either to have a short half-life or is not efficacious in achieving hemostasis, or both. This can be suspected in the laboratory whenever the partial thromboplastin time of a mixture of patient plasma and normal plasma, after incubation for 2 hours at 37°C, is longer than that of a mixture of patient plasma and hemophiliac plasma known not to contain an inhibitor. To confirm that an inhibitor is directed at factor VIII, a dilution of the patients plasma must be incubated with normal plasma, and factor VIII levels measured over 120 minutes. If the inhibitor is specific for factor VIII, factor VIII decreases over time. Although increased assay specificity can be obtained by performing parallel assays for factors XI, IX, and XII, a high-titer factor VIII inhibitor may inactivate factor VIII in the normal plasma substrate and result in a prolonged partial thromboplastin time while assaying other proteins in the intrinsic pathway. Whenever an inhibitor is suspected or when multiple factor assay results are abnormal, serial dilutions should be done. A true factor deficiency result is independent of the plasma dilution, whereas the effect of an inhibitor is dilution-dependent.

The Bethesda assay is used for quantitation of factor VIII inhibitors.[78] Factor VIII assays are done on 2-hr incubation mixtures of various dilutions of patient plasma with normal plasma. A test sample producing a residual factor VIII activity of 50% of the normal value is considered to contain 1 Bethesda unit of inhibitor per milliliter, and the inhibitor titer equals the reciprocal of the dilution of inhibitor plasma that neutralizes 50% of normal factor VIII. This assay can detect as little as 0.6 Bethesda unit. In the United Kingdom, the new Oxford method is used to quantitate factor VIII inhibitors, where factor VIII concentrate is used as the source of factor VIII along with a 4-hr incubation time.[79] One Bethesda unit equals 1.21 × 1 Oxford unit.[79] An inhibitor unit does not imply that any specific number of factor VIII units infused into the patient will neutralize any specific number of inhibitor units.

FACTORS TO BE CONSIDERED IN SELECTING A BLOOD PRODUCT FOR A BLEEDING EPISODE

1. If a hemorrhage is clinically significant, an attempt should be made to raise the plasma factor VIII level into the hemostatic range of 3050 U/ml.
2. Patients known to be high responders should not receive blood products containing factor VIII to treat minor hemorrhages, to avoid an anamnestic response (unless they are undergoing induction of immune tolerance). Conservative measures combined with the administration of factor IX complex concentrate are frequently adequate.
3. In those patients with a serious hemorrhage who are low responders with a low inhibitor level (<5 Bethesda units), high-purity human factor VIII can be given initially in an initial large bolus of 50150 U (or two to three times the patients usual dose), followed by a continuous infusion of 10 U/kg/hr. Alternatively, porcine factor VIII 50 U/kg can be used. Both low and high responders with low inhibitor levels of <5 Bethesda units with a minor hemorrhage can be most easily managed with factor IX complex concentrate in doses of 5075 U/kg repeated once or twice at 8- to 12-hour intervals as necessary.
4. If the level of inhibitor against human factor VIII is between 5 and 10 Bethesda units, larger doses of human factor VIII or porcine factor VIII, 75100 U/kg can be used.
5. If the level of inhibitor against human factor VIII is >10 Bethesda units but the level of inhibitor against porcine factor VIII is <10 Bethesda units, a larger dose of porcine factor VIII should be tried (100 U/kg).
6. If a patient has a moderately high inhibitor level of 1030 Bethesda units to both porcine and human factor VIII, the inhibitor level may be lowered by approximately 5066% by a 1.5-volume plasmapheresis or extracorporeal immunoadsorption, after which a large infusion of human or porcine factor VIII concentrate may achieve hemostatic levels. Alternatively, patients with moderately high inhibitor levels can be treated with factor IX complex or with the porcine factor VIII concentrate (particularly if the level of inhibitor against porcine factor VIII is <10 Bethesda units).
7. If a patient has a very high inhibitor level (>30 Bethesda units), the only alternatives are factor IX complex concentrates, the porcine concentrate (100150 U/kg), or recombinant factor VIIa.

Therapy

General Considerations

In hemophilia, the presence and titer of an inhibitor and whether the patient is a low or high responder are important determinants of immediate and future therapy. Minor hemorrhage may respond to conservative measures, such as immobilization and compression. For a hemorrhage requiring blood product therapy, two possible choices are available: (1) infusion of human or porcine factor VIII and, if the inhibitor titer is moderately high, preceding this therapy by maneuvers to lower the titer; or (2) infusion of an agent that bypasses the need for factor VIII, such as activated factor IX complex concentrates or factor VIIa.

High-Purity Human Factor VIII Concentrate

High-purity human factor VIII may be used successfully in the treatment of critical hemorrhages in either low or high responders with low inhibitor levels (<5 Bethesda units) and in patients with moderate inhibitor levels (1030 Bethesda units) after reduction of the inhibitor level by plasmapheresis or immunoadsorption. [80] [81] [82] [83] To neutralize the inhibitor and achieve a hemostatic level of 3050 U/ml, an adult patient is given an initial bolus of factor VIII of 50100 units/kg followed by a continuous infusion of 10 units/kg/hr. Alternatively, a large amount of factor VIII can be given every 14 hours (20 U of factor VIII for each Bethesda unit plus an additional 40 U/kg).[83] Because the dose of factor VIII concentrate needed to neutralize inhibitors and provide a hemostatic level of factor VIII cannot be predicted by the inhibitor level, factor VIII levels need to be assayed frequently to monitor the plasma factor VIII level achieved in vivo. However, although blood drawn for assay even a few minutes later may not have a measurable factor VIII level by the time the blood is processed and the assay completed, the infused factor VIII may achieve in vivo hemostasis before it is inactivated.

In patients who are high responders and who sustain a critical hemorrhage, hemostasis should be achieved early, before the anamnestic response occurs. As the factor VIII inhibitor level rises after several days of factor VIII therapy, factor VIII should be continued at a frequent interval or continuouslyhemostasis can be maintained because of the slow neutralization rate of factor VIII by the inhibitor. [55]

In a patient with low-level inhibitor (<5 Bethesda units), it may be possible to raise the level of factor VIII by infusing sufficient human factor VIII to neutralize the antibody and provide free factor VIII to achieve hemostasis. Patients with low inhibitor titers who are low responders can be treated effectively with two to three times the dose of factor VIII used in noninhibitor patients.

Porcine Factor VIII Concentrate

The suitability of a patient for porcine factor VIII depends partially on the degree of cross-reactivity of the patients inhibitor with porcine factor VIII. [84] [85] [86] [87] [88] [85] The level of inhibitor to porcine factor VIII can be determined in the Bethesda assay or the Oxford test by substituting porcine factor VIII for human factor VIII by diluting porcine factor VIII concentrate in human hemophilic plasma until the concentration of porcine factor VIII is 100 U/dl, as measured in a standard factor VIII assay. Although the degree of cross-reactivity can vary widely, according to an international survey of the use of porcine factor VIII in 154 inhibitor patients, it averaged 15%[88] (i.e., approximately 1 unit of antiporcine factor VIII equaled 6.5 units of antihuman factor VIII), with a range of 0200%. After treatment with porcine factor VIII, the degree of cross-reactivity increased. Thus, measurements of cross-reactivity are useful in predicting efficacy before the use of the porcine concentrate. In the international survey of 154 hemophilic inhibitor patients receiving porcine factor VIII, 80% of 2,472 bleeding episodes (mostly hemarthroses) had a good to excellent result, 13% had a fair result, and 7% had no response. [88] The median pretreatment cross-reactivity was 15%; 27% of patients had no cross-reactivity, and 2% of patients had 100% cross-reactivity. Most of the treatment failures were in patients with a high inhibitor titer, whereas inadequate porcine factor VIII dosage accounted for the failures in the remainder. The incidence of reactions after unselected inpatient infusions was 2.3% and usually included fever, chills, or rash. Most were dose-related and occurred only with larger doses. Only occasional patients had repeated allergic reactions unrelated to dose. A decrease in platelet count was seen in 60% of inpatient infusions but was usually insignificant, transient, and correlated

MANAGEMENT OF CRITICAL, LIFE-THREATENING HEMORRHAGES OR EMERGENCY SURGERY IN PATIENTS WITH INHIBITORS

In an emergent situation with a critical hemorrhage or with impending life-saving surgery, both a high responder and low responder should be initially treated with a bolus infusion of the porcine factor VIII concentrate 100 U/kg. Ten minutes after the infusion, blood should be drawn for factor VIII assay to determine the adequacy of the dose; if inadequate, the dose should be increased by 50 U/kg, until the patient has a postinfusion factor VIII level >3050%. Simultaneously, the preinfusion antibody titer to both porcine and human factor VIII can be determined. If the titer to porcine factor VIII is >10 Bethesda units and clinical efficacy has not been established, plasmapheresis can be performed, followed by a massive dose of porcine factor VIII. Once efficacy is established, the patient should be treated at frequent intervals or by continuous infusion at a dose of 1,000 U/hr or 10 U/kg/hr. Factor VIII levels should be monitored frequently. As long as hemostatic levels are achieved, the porcine concentrate should be continued for several days. If the inhibitor titer begins to rise and hemostatic levels can no longer be achieved, anti-inhibitor coagulant complex concentrate or factor IX complex concentrate should be used for several days.

If the patient does not respond initially to porcine factor VIII, anti-inhibitor complex concentrate may be administered, starting at a dose of 75 U/kg. Factor VIIa is currently available on a compassionate basis on research protocol by the manufacturer, but it clearly appears to be effective in these emergent situations.

with dose. In 65 evaluable patients, 31% of patients had a marked anamnestic response, 40% had an intermediate response, and 29% had no response. Some patients were continued on effective home therapy for long periods of time without developing antibodies to porcine factor VIII. However, approximately 30% of patients become resistant because of the development of high-titer porcine factor VIII antibodies. [90] Another retrospective survey of the use of porcine factor VIII in 45 patients with hemophilia A with inhibitors undergoing a variety of surgical procedures reported similar responses to those with acute bleeding episodes. [89]

Although dosage is relatively arbitrary, in patients with human inhibitor titers of <5 Bethesda units, 50 U of porcine factor VIII/kg should be given initially; in patients with 550 Bethesda units, 75100 U/kg is given initially. In patients with >50 Bethesda units, 100150 U/kg is administered. [89] The level of factor VIII achieved in vivo after the infusion is monitored to determine the adequacy of the dose administered. If the initial dose is inadequate, the dose is increased.

Factor IX Complex Concentrate

If human factor VIII cannot be used because the inhibitor level is too high, an attempt may be made to bypass the need for factor VIII by giving a factor IX complex concentrate.[91] [92] [93] [94] [95] [96] [97] [98] [99] These concentrates contain phospholipids, prothrombin, and factors VII, IX, and X, but the substance(s) responsible for factor VIII bypassing activity remain(s) unknown;[100] evidence suggests that it is activated factor IX.[101] [102] [103] These concentrates are of two types: regular unactivated intermediate-purity factor IX

complex concentrates (Konyne 80 [Miles-Cutter], profilnine HT, and Bebulin [Immuno]); and activated concentrates, so-called anti-inhibitor coagulant complex. Both types of concentrates contain various amounts of activated factors VII, IX, and X and phospholipids, and should be distinguished from the highly purified factor IX concentrates used in the treatment of hemophilia B. The activated concentrates (Autoplex [Baxter-Hyland]; FEIBA [Immuno]) contain a greater amount of the factor VIII bypassing material and are specifically designed for patients with factor VIII inhibitors. Both types of concentrates have proved efficacious in controlled clinical trials,[96] [97] and no significant differences between them have been demonstrated. However, some patients have successfully used anti-inhibitor coagulant complex in life-threatening situations in which the unactivated concentrates were ineffective. In a recent French multicenter retrospective survey of the use of FEIBA in 60 patients with factor VIII or IX inhibitors with 433 bleeding episodes or surgical procedures, efficacy was good to excellent in 81.3% of the episodes, whereas it was poor in the remainder.[104] Adverse effects were seen in only 5 of 433 episodes (12%), but an anamnestic response occurred in 17 of 54 evaluable patients (31.5%).

In addition to their unpredictable efficacy, these concentrates have other limitations. Dosage is arbitrary (5075 U/kg, three to four times per day at 8- to 12-hr intervals), and no reliable in vitro method is available that reflects in vivo efficacy. These concentrates also induce a hypercoagulable state and may be associated with thromboembolic complications when used in high dose. These concentrates contain a small amount of factor VIII antigen and can induce an anamnestic response after their use.[105] [106] If selected for use in critical situations, these concentrates should be used early in the course of the bleeding episode. [105] They are also the least expensive concentrate used in the treatment of inhibitor patients.

Human Factor VIIa Concentrate

Purified components of the prothrombin complex have been used to treat hemorrhages in patients with inhibitors. A highly purified concentrate containing factor VIIa achieved good hemostasis[107] and, subsequently, a recombinant preparation of human factor VIIa has shown significant efficacy in patients with inhibitors. [108] [109] In a survey of more than 240 patients, many of whom consisted of hemophilia A or B patients with inhibitors, the recombinant factor VIIa concentrate was used successfully for critical bleeds or for surgery. [110] Dosage and interval of dosing is still being evaluated, but usually it is initiated with doses of 90 g/kg and the same dose is repeated every 23 hours (half-life is 2.9 hours) for one to two times for spontaneous bleeds and every 23 hours for 48 hours for surgical procedures followed by tapering doses over several days. Efficacy has been reported in approximately 90% of patients with spontaneous bleeds and in approximately 80% of patients undergoing surgical procedures.[110] Treatment is not influenced by the inhibitor titer and is equally effective in hemophilia A or hemophilia B. Antibodies to factor VII do not occur except in factor VII-deficient patients.[111] No specific assay has been established that reflects clinical efficacy. The safety profile has been excellent and thrombotic events are rare.

Suppression of Inhibitors

Long-term goals in the management of these patients should be aimed at the prevention of anamnesis and suppression of further antibody production. Immunosuppressive therapy has been attempted in many patients, with variable and unpredictable results. [24] [112] [113] [114] [115] [116] [117] In general, with few exceptions, corticosteroid therapy alone is not efficacious in patients with hemophilia A and inhibitors. [117] By contrast, Dormandy and Sultan[118] collected the experience of many investigators using cyclophosphamide and factor VIII. Some degree of success was achieved on 40 occasions in 18 of 45 patients. The data reported by Hultin et al[117] are in agreement with these observations. Although total elimination of antibody occurs very rarely, immunosuppressive therapy may be helpful in patients requiring factor VIII infusion, particularly low responders with low inhibitor titers. [117] Rarely, treatment of inhibitors soon after their appearance and before reexposure to factor VIII may be an important determinant of successful outcome.[117] The use of immunosuppressive drugs has not gained wide acceptance.

The induction of immune tolerance by the frequent regular infusions of factor VIII can be effective, but the financial implications of this therapy are great. [37] [40] [41] [42] [43] [44] [85] A patient who is a high responder with a high-titer inhibitor is given daily or alternate-day infusions of human factor VIII. [37] [40] [41] [42] [44] [85] After chronic administration of factor VIII, the inhibitor titer first increases and then progressively decreases, with most patients achieving either a low or undetectable titer. Moreover, the patient no longer has anamnesis with continued exposure to factor VIII. Similar results have been achieved at some centers, either with less amounts of factor VIII[38] [43] [85] [119] [120] [121] or by giving factor VIII repeatedly but at irregular intervals. [122] Immune tolerance usually must be maintained by giving low doses of factor VIII every few days.

Recently published data from an international registry of patients treated with an immune tolerance protocol provide a concise summary of the effectiveness of these

regimens.[40] The report includes the data from 158 patients from 40 centers who were on therapy long enough to evaluate efficacy. Tolerance was attained in 107 patients (68%), 12 (8%) had a partial response (high responders converted to low responders), and 39 patients were unresponsive. Multivariate regression analysis revealed that the highest probability of success was independently associated with the dosage used (>100 IU/kg/day) and with the level of inhibitor at enrollment (<10 Bethesda units). Thus, the best results were obtained using high doses of factor VIII and starting with a low inhibitor titer (even though 82% of these patients were high responders). Therefore, it is probably important to initiate immune tolerance therapy long after the anamnestic response has dissipated. Although the best results were obtained with high doses of factor VIII, low-dose protocols can also be effective, but predominantly in those with low or intermediate inhibitor titers or in those started soon after discovery of the inhibitor. [40] [43] Mean time to the development of tolerance was 37 months, and once tolerance was achieved, only 1 of 107 patients relapsed after an average follow-up period of 5 years. Younger patients have a better chance of success in a shorter time than adults. A recent report of treatment in 21 children described elimination of the inhibitor in 19 in a median time of 4 months. [41] A successful outcome and the length of time needed to induce immune tolerance were indirectly related to the number of factor VIII exposure days or when the tolerance regimen was interrupted. There was no correlation with the length of the interval between the initial inhibitor detection and the onset of immune tolerance therapy. Thus, immune tolerance regimens should be initiated as soon as possible, after detection, preferably when the inhibitor titer is <10 Bethesda units.

The mechanism by which frequent infusions of factor VIII reduce levels of anti-factor VIII antibodies is not understood. However, patients treated successfully produce anti-idiotypic antibodies. [4] [123]

Successful regimens using factor VIII infusions combined with immunosuppressive drugs appear to shorten the induction of immune tolerance significantly, attaining remission at a much lower cost.[42] [124] High-dose intravenous immunoglobulin given together with high-dose factor VIII and cyclophosphamide sometimes preceded by extracorporeal immunoadsorption appears to have a synergistic effect in achieving a state of immune tolerance. [42] [125] [126] Intravenous IgG may have both a short- and long-term immunosuppressive effect.[127] [128] [129] [130] Anti-idiotypic

antibodies are present in the IgG preparations; [130] [131] [132] [133] the emergence of anti-idiotypic antibodies may be the explanation for the occurrence of spontaneous remission and some instances of remission induced by immunosuppressive agents. [131] [134] [135]

INHIBITORS IN HEMOPHILIA B

Inhibitors to factor IX occur in hemophilia B secondary to alloimmunization after transfusion, similar to hemophilia A. Although the overall incidence of inhibitors complicating hemophilia B is only approximately 3%, [24] [136] the incidence in patients with severe hemophilia B is approximately 12%. [24] Patients with major gene deletions or nonsense mutations who do not have demonstrable factor IX protein antigen in their plasma may be especially susceptible to the development of factor IX antibodies.[137] [138] In contrast, in patients with missense mutations, the incidence of inhibitors is very low. [138] Approximately 80% of patients have a significant anamnestic response after transfusion with plasma products containing factor IX.

Like factor VIII inhibitors, factor IX inhibitors are IgG and some are predominantly IgG_4.[24] [139] [140] [141] Some have restricted light chain and heavy chain heterogeneity,[140] [142] whereas others are polyclonal.[141] [143] The kinetic behavior of factor IX inhibitors differs from that of factor VIII inhibitors in that factor IX inhibitors produce an immediate loss of factor IX activity, with no progressive loss on further incubation. [11] [92]

Laboratory Evaluation and Quantitation

Factor IX inhibitors should be suspected in a hemophiliac if transfused factor IX either appears to have a short half-life or is not efficacious in achieving hemostasis, or both. This can be suspected in the laboratory whenever a partial thromboplastin time of a mixture of the patients plasma and normal plasma is longer than that of a mixture of the patients plasma and factor IX-deficient plasma known not to contain an inhibitor. Specificity can be determined by doing factor IX assays of an incubation mixture of the patients plasma and normal plasma over time. A modification of the Bethesda assay is used to quantitate the inhibitor level. [78]

Therapy

In patients with hemophilia B who have inhibitors, the clinical course is not different from that seen in those with hemophilia A with inhibitors. Many of these cases can be managed with factor IX complex concentrates or the anti-inhibitor/coagulant complex. Whether the efficacy of these concentrates is due to neutralization of the inhibitor or to bypassing activity similar to that observed in hemophilia A, or both, is unknown.

Alternatively, these patients can be treated with two to three times the usual dose of highly purified factor IX concentrate in an attempt to neutralize the inhibitor and achieve a hemostatic level of factor IX. Patients who are high responders with low inhibitor titers can be treated similarly, with the caveat that anamnesis will occur within a few days. In low or high responders with moderate inhibitor titers, plasmapheresis can be used adjunctively before infusion of any of the aforementioned concentrates. In patients with high-titer inhibitors, the only alternatives are prothrombin complex concentrates, anti-inhibitor/coagulant complex concentrates, or the recombinant factor VIIa concentrate.[108] [144] The latter has been used effectively in patients with factor IX inhibitors, using dosage regimens similar to the ones discussed previously for the treatment of factor VIII inhibitors. [108]

In addition, regimens for induction of immunotolerance have been achieved in hemophilia B patients with and without the use of high doses of intravenous IgG and cyclophosphamide, sometimes preceded by extracorporeal immunoadsorption. [42] [145]

There have been several reports of life-threatening anaphylactic or anaphylactoid reactions in young children with hemophilia and inhibitors on exposure to factor IX concentrates.[146] [147] The factor IX inhibitors are detected in most simultaneously with the occurrence of the allergic reaction. Most of the patients have factor IX gene deletions or major derangements.[147] Immune tolerance regimens have resulted in very poor response in these patients, but bleeding episodes have been managed successfully with recombinant factor VIIa concentrate.

Chapter 111 - Other Clotting Factor Deficiencies

Harold R. Roberts
Maureane Hoffman

INTRODUCTION

This chapter describes the biology and clinical manifestations of deficiencies of prothrombin, factor V, factor VII, factors XXIII, and familial multiple clotting factor deficiencies. Table 1111 lists these clotting factor deficiencies and some of their characteristics.

PROTHROMBIN DEFICIENCY (HYPOPROTHROMBINEMIA AND DYSPROTHROMBINEMIA)

History and Epidemiology

At the turn of the century, Morawitz (1905) formulated a basic theory of coagulation in which fibrinogen was converted to fibrin by a substance he called *fibrin ferment*, or thrombin.[1] In his theory, a precursor molecule, prothrombin, was activated by a hypothetical enzyme (thrombokinase) to yield thrombin. Morawitzs cascade was much more simple than that which is known to exist today, but it was essentially correct. True congenital hypoprothrombinemia or dysprothrombinemia is exceedingly rare; fewer than 30 kindred have been well-studied. [2] Hypoprothrombinemia or dysprothrombinemia has no known predilection for any racial or ethnic group.

Genetics and Molecular Biology

The prothrombin gene consists of 14 exons and occupies approximately 24 kilobases of DNA near the centromere of chromosome 11. [3] The gene codes for a signal peptide; a propeptide region; a gamma-carboxy glutamic acid domain, which is dependent on vitamin K for post-translational modification of ten glutamic acid residues; two kringle regions; and a catalytic domain. [4] Prothrombin is a single-chain glycoprotein with a molecular weight of 72,000. It is synthesized in the liver and is normally present in the plasma at a concentration of 100 g/ml, making it the second most abundant coagulation protein after fibrinogen. Prothrombin undergoes cleavage at several sites to

TABLE 111-1 -- Clotting Factor Deficiencies: General Information

Factor Human Deficiency	Gene Location	Normal Circulating Half-life	Estimated Incidence	Bleeding Severity
II	11p11q12	3 days	Very rare	Mildmoderate
V	1q21q25	36 hours	1:1 million	Moderate
VII	13q34	36 hours	1:500,000	Mildsevere
VIII	Xq28	12 hours	1:10,000	Mildsevere
IX	Xq27	24 hours	1:30,000	Mildsevere
X	13q34	40 hours	1:500,000	Mildsevere
XI	4q32q35	80 hours	Rare[a]	Mildmoderate
XII	5q33qter	5070 hours	?	No bleeding
XIII	*A* subunit: 6p24p25	9 days	<1:1 million	Moderatesevere
	B subunit: 1q31q32			

[a] *Rare except in those of Ashkenazi Jewish descent.*

yield the active serine protease thrombin, which consists of an A chain linked to a B chain by a disulfide bridge. The proteolytic conversion of prothrombin to thrombin requires factor Xa, calcium, and phospholipids and is accelerated 300-fold by the presence of activated factor V. [5] Thrombin performs a multitude of functions. Its procoagulant actions include: proteolysis of fibrinopeptides A and B from fibrinogen; activation of factors V, VIII, and XIII, and induction of platelet aggregation. These functions are balanced by thrombin-mediated activation of protein C. Thrombin functions as an anticoagulant when complexed with thrombomodulin, a component of the endothelial cell surface. The complex activates protein C, which in turn inhibits coagulation by degrading factors Va and VIIIa. Thrombin also has cytokine and growth factor-like activities.[6] For example, it is chemotactic and mitogenic for mononuclear phagocytes, fibroblasts, smooth muscle cells, and endothelial cells.

Pathogenesis

A variety of mutations in the prothrombin gene have been discovered. These mutations cause either decreased production of prothrombin or production of a dysfunctional molecule with reduced activity. The subsequent decrease in thrombin activity results in absent or defective clot formation, defective platelet aggregation, and defects in other pathways normally activated by thrombin. The clinical severity of bleeding depends on the particular defect. Table 1112 depicts some of the known variants of prothrombin, which are inherited in an autosomal fashion. [7] [8] [9] [10] [11] [12] [13] [14] [15] [16] [17] [18] [19] [20] [21] [22] [23] [24] [25] [26] [27] [28] [29] [30] [31] [32]

Clinical Manifestations

Bleeding associated with prothrombin deficiency typically consists of easy bruising, epistaxis, soft tissue hemorrhage, postoperative bleeding, and, in females, menorrhagia and/or metrorrhagia. Hemarthroses have also been described, but are not common. [33] The correlation between prothrombin levels and severity of bleeding is poor. For example, there are asymptomatic patients with prothrombin activities of 15% of normal (e.g., prothrombin Salatka), whereas patients with prothrombin San Juan are symptomatic with prothrombin activities in the 25% range. [34] Because all known cases of congenital hypo- or dysprothrombinemia have detectable prothrombin levels, it is possible that complete absence of prothrombin activity is incompatible with life.

Recently, a mutation in the 3 untranslated region of the prothrombin gene has been described that is associated with increased levels of circulating prothrombin. [35] It is not clear how this mutation leads to higher prothrombin levels. However, the increased level of prothrombin in these individuals is associated with an increased risk of thrombosis.

Laboratory Evaluation

Congenital prothrombin deficiency is marked by prolongation of the prothrombin time and the partial thromboplastin time (PTT). The bleeding time is normal. The prolonged prothrombin

In this and subsequent tables, amino acids are designated by a three-letter code. Patients exhibited a bleeding tendency unless otherwise noted.

time and PTT are corrected if the patients plasma is mixed with equal amounts of normal plasma. In true hypoprothrombinemia, both the functional and antigenic assays for prothrombin reveal decreased levels. Dysprothrombinemia results in decreased prothrombin activity, but the prothrombin antigen level may be normal or only slightly decreased. Specific diagnosis of prothrombin defects rests upon functional and antigenic assays.

Differential Diagnosis

Patients with a bleeding tendency and prolongation of the prothrombin time and PTT may be suspected of having a deficiency of prothrombin, but deficiencies of factor V, factor X, and multiple factor deficiencies should also be considered. A definitive diagnosis of hereditary prothrombin deficiency requires a specific assay for prothrombin and demonstration that levels of other clotting factors are normal.

Acquired prothrombin deficiency due to liver disease, vitamin K deficiency, or warfarin can be distinguished by demonstrating low levels of all of the vitamin K-dependent factors.

The term lupus anticoagulant is commonly used to describe an autoantibody that results in a prolonged PTT in vitro. These antibodies were once thought to be directed against phospholipids. However, the majority are directed against phospholipid-binding proteins, especially $_2$ -glycoprotein I.[36] Such antibodies are generally associated with an increased risk of thrombosis, and are rarely associated with a bleeding tendency. However, a small subset of these antibodies are directed against prothrombin. These antibodies may inhibit prothrombin activity directly,[37] or they may accelerate clearance of prothrombin, resulting in a true prothrombin deficiency.[38] The acquired hypoprothrombinemia may be associated with bleeding, particularly soft tissue hemorrhage, which may be so severe as to be life-threatening.[39] [40] In these cases, the PT is prolonged.

Therapy

Because prothrombin has a long half-life (about 3 days), most patients can be treated with plasma in doses of 1520 ml/kg body weight as a loading dose, followed by 3 ml/kg body weight every 1224 hours. Plasma levels 30% of normal are usually sufficient to treat bleeding episodes. Plasma exchange may be employed to achieve higher levels before surgery. Prothrombin complex concentrates, generally used to treat hemophilia B, also contain significant levels of prothrombin. These can be used to treat prothrombin deficiency, but care should be excercised, since their use has been associated with thromboembolic complications. Highly purified factor IX concentrates do not contain significant amounts of prothrombin and should not be used to treat prothrombin deficiency. Table 1113 lists some of the prothrombin complex concentrates and the amount of prothrombin contained in each. Highly purified prothrombin concentrates are not presently available for clinical use.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

FACTOR V DEFICIENCY

History and Epidemiology

As early as 1939, it was known that clotting factors other than prothrombin influenced the prothrombin time. In 1943, Quick found that the prothrombin time of aged plasma was prolonged. He postulated that there was a labile factor present in plasma that was different from prothrombin but was required for a normal prothrombin time.[41] At about the same time

TABLE 111-3 -- Composition of Selected Factor IX Concentrates

Product (manufacturer)	Relative Amount of Factor[a]			
	Prothrombin	VII	IX	X
Prothrombin complex concentrates

	Thrombin	VIIa	IXa	Xa	XIa
Activated prothrombin complex concentrates					
Autoplex T (Baxter/Hyland)	5	69	178	47	6
FEIBA (Immuno)	?				

[a] Data expressed in units of activity normalized to the amount of factor IX present.

Owren studied a woman with a lifelong history of bleeding. He concluded that she was deficient in a factor present in plasma which, in contrast to prothrombin, was not adsorbed to aluminum hydroxide. Owrens studies were carried out during the Nazi occupation of Norway, and he was unable to report his studies until 1947. [42] Eventually it was found that Owrens patient was deficient in labile factor, which we now know as factor V.

Deficiency of factor V is a rare condition with an incidence of approximately one per million. [43] About 150 cases have been reported. The deficiency shows no known predilection for members of any racial or ethnic group. Consanguinity has frequently been observed in the families of affected patients.

Genetics and Molecular Biology

Factor V deficiency is inherited as an autosomal recessive trait, with a gene frequency of $5^{10} \times 10^{4}$.[44] The factor V gene is located at 1q2125, near genes coding for the selectin leukocyte adhesion molecules.[45] Factor V is composed of several domains or modules, and is closely related to factor VIII. The two proteins are about 40% homologous in primary structure and their genes are arranged in a nearly identical fashion. [46] Both proteins have three A domains, one B domain, and two C domains.[45] The A domains of factor V bear 30% homology with the copper-binding protein, ceruloplasmin. Copper has been detected in human factor V, but its function is unclear. The tandem C domains are homologous to duplicated domains in human and murine milk fat globule proteins. The B domain of factor V is not required for procoagulant activity. It is removed from the factor V molecule during its activation by thrombin. Unlike the A and C domains, the B domain is not homologous to factor VIII. Neither is the B domain well conserved between different mammalian species.

The factor V glycoprotein (330,000 molecular weight, 13% carbohydrate) is synthesized in the liver (plasma factor V) and in the megakaryocytes (platelet factor V), although other tissues may synthesize small amounts (e.g., vascular endothelium, monocytes). Plasma factor V circulates at a concentration of about 7 g/ml. [47] Platelet factor V is found within the -granules and is released upon platelet activation and degranulation. [48] It is identical to plasma factor V and accounts for 20% of the total factor V in blood. For full activity, the factor V must be activated by thrombin or factor Xa. Thrombin cleaves arginyl residues in human factor V at positions 709, 1,018, and 1,545. The active molecule, containing a light and heavy chain linked by calcium ions, serves as an essential cofactor for factor Xa conversion of prothrombin to thrombin. The phospholipid and cell-surface binding sites of factor Va are located on the light chain, whereas the heavy chain is thought to bind prothrombin.[46]

Factor Va is inactivated when it is cleaved at two additional sites by activated protein C (APC), a reaction that requires protein S as a cofactor. This inactivation process is clearly of physiological significance, since a mutation in factor V (Arg ^{506} Gln) that abolishes one of the APC cleavage sites (factor V Leiden) is associated with an increased risk of thrombosis.[49]

Pathogenesis

The hemorrhagic tendency in factor V deficiency is a direct consequence of the lack of its activity both in plasma and platelets. Some deficient patients have normal levels of factor V antigen but low levels of functional activity. [43] [50] [51] [52] Patients severely deficient in plasma factor V are generally deficient in platelet factor V as

well. One variant, factor V Quebec, exists in which a brother and sister with abnormal bleeding had moderately reduced plasma levels (40% of normal), but severely reduced platelet factor V (24% of normal).[51] The bleeding defect in this family suggests that platelet factor V is important for hemostasis. However, it appears that the factor V Quebec disorder is associated with a defect that leads to degradation of most proteins of the -granules. [53] Thus, other abnormalities may contribute to the bleeding tendency in these patients.

Clinical Manifestations

Factor V deficiency has a wide range of clinical manifestations. Even though severe hemorrhage may occur in patients with <1% factor V, bleeding is not as frequent as that seen in severe hemophilia A patients. Mild and moderate forms of factor V deficiency most likely reflect genetic heterogeneity of the disorder. Severe factor V deficiency commonly presents with abnormal bruising, epistaxis, soft tissue hemorrhages, and occasional hemarthroses. Crippling hemophilic arthropathy is not common, but hemorrhage involving the central nervous system has been observed. Bleeding from the umbilical stump is frequent. Women commonly experience abnormal menstrual bleeding and postpartum hemorrhage. About one-half of patients are diagnosed in adulthood. One family has also been reported with congenital factor V deficiency and recurrent thromboembolic events. [54]

Laboratory Evaluation

Laboratory features of severe deficiency are shown in Table 1114 . Both the prothrombin time and PTT are prolonged, whereas the thrombin time is normal. The bleeding time may be prolonged in severe factor V deficiency since platelet factor

TABLE 111-4 -- Typical Laboratory Values for Factor V-Deficient Patients

Assay	Moderate	Severe	Normal
PT (sec)	15	55	12
aPTT (sec)	40	60	26
Thrombin time (sec)	11	11	11
Bleeding time (min)	7	7>15	39
Factor V (% normal)	27	<1	100

V is virtually undetectable in these patients. Conclusive diagnosis of the deficiency requires a specific factor V assay.

Differential Diagnosis

Hereditary factor V deficiency must be distinguished from a combined deficiency of factors V and VIII, which is also inherited. In the latter condition, both factor V and factor VIII levels are about 1520% of normal. Acquired factor V deficiency occurs in patients with liver disease. It is also reduced in patients with disseminated intravascular coagulation. Inhibitors to factor V occur in some patients with congenital factor V deficiency and rarely in otherwise normal patients who develop these inhibitors spontaneously. Factor V inhibitors have been documented in association with the use of topical bovine thrombin preparations (which contain bovine factor V) in cardiac surgery,[55] and in patients treated with antibiotics such as streptomycin. Inhibitors to factor V can be detected by showing that the patients plasma inhibits factor V activity in normal plasma.

Therapy

Fresh-frozen plasma is the mainstay of treatment for bleeding episodes in deficient patients. No commercial factor V concentrates are available, and cryoprecipitate is not rich in this protein. Although platelets contain factor V and can correct the bleeding defect in deficient patients, platelet transfusions are not the treatment of choice because of the possible induction of antiplatelet alloantibodies. However, transfusions of normal platelets may be useful in patients with circulating inhibitors to factor V, since platelet factor V may be available in a milieu protected from inhibitors. [56]

Levels of 25% of normal are usually sufficient for many mild or moderate bleeding episodes. [57] This level can be achieved by the use of plasma at an initial dose of 1520 ml/kg of body weight, followed by 36 ml/kg of body weight daily for 7 days post-surgery. Care must be taken to monitor for evidence of volume overload when large amounts of plasma are infused. Daily plasma infusions for surgery seem reasonable, since the half-life of factor V is about 36 hours. [57] In the case of severe bleeding, or in preparation for surgery, higher levels may be obtained by plasma exchange. [58]

FACTOR VII DEFICIENCY

History and Epidemiology

The first reported case of factor VII deficiency was described by Alexander in 1951. [59] In the index case, plasma from a child with congenital bleeding displayed a prolonged prothrombin time that could be corrected by aged serum, but not by barium sulfate-adsorbed plasma. Factor VII deficiency is inherited as an autosomal recessive trait and affects males and females equally, with an incidence estimated to be about one in 500,000.

Genetics and Molecular Biology

The gene for factor VII is found on chromosome 13, adjacent to the gene for factor X. [60] Evidence exists for a regulatory element on chromosome 8 that controls factor VII expression, which occurs in the liver. [61] As a vitamin K-dependent factor, factor VII contains -carboxyglutamyl (Gla) residues that are necessary for calcium-dependent lipid binding, as well as two epidermal growth factor-like regions (EGF domains) and a catalytic domain with typical serine protease features. [62] [63]

Factor VII circulates in the plasma at a concentration of 0.5 g/ml. Factor VII is rapidly activated upon binding to its cofactor, tissue factor. Activated factor VII (factor VIIa) bound to tissue factor can catalyze activation of additional factor VII. However, it is not clear what protease is responsible for activation of the first factor VII molecules during hemostasis. Tissue factor is a membrane-associated glycoprotein that is not normally expressed by cells in contact with blood. When blood escapes from the vasculature at a site of injury, the binding of factor VII to extravascular tissue factor is the primary physiologic trigger of the coagulation cascade. [64] [65] [66] The factor VIIa/tissue factor complex then activates both factor X and factor IX. [67] Factor VIIa/tissue factor has been thought of as the first component of the extrinsic pathway, in which it activates factor X, which combines with factor Va to activate prothrombin to thrombin. However, it is now clear that discrete "instrinsic" and "extrinsic" pathways do not exist in vivo. Activation of factor X by factor VIIa/tissue factor is insufficient to support hemostasis. Factor IX activated by factor VIIa/tissue factor combines with its cofactor factor VIIIa to produce additional factor Xa on the platelet surface, [68] [69] which then activates enough prothrombin for successful clot formation.

Increased levels of plasma factor VII are a risk factor for cardiovascular disease, whereas decreased levels of factor VII may be associated with a decreased risk.

Pathogenesis

Because the factor VIIa/tissue factor complex is the key initiator of coagulation in vivo, a deficiency of factor VII can result in significant clinical manifestations. Individuals with severe deficiency (<1% activity) can have clinical bleeding as serious as those with severe classical hemophilia. However, about half of the factor VII deficient patients are asymptomatic, including at least three who apparently have <1% factor VII activity. [70] Generally, individuals who are homozygous or doubly heterozygous for a factor VII mutation are more likely than heterozygotes to express a clinical bleeding tendency. There is not, however, a very good correlation between factor VII coagulant activities measured in the laboratory and bleeding manifestations. This is partly due to the fact that different factor VII mutants express different levels of coagulant activity when assayed in the presence of tissue factor from different species. The genetic defects responsible for many of the dysfunctional factor VII molecules have been determined and catalogued. [71] A detailed database of the mutations is maintained on the World Wide Web at: http://europium.mrc.rpms.ac.uk/usr/WWW/WebPages/FVII/database.dir/titlepage.htm. Selected variants are listed in Table 1115 . In addition, three polymorphisms in the factor VII gene have been found, which affect the plasma level of the factor VII protein. An Arg Gln substitution at residue 353 is associated with a 2025% reduction in plasma factor VII activity. [72] A decanucleotide insertion at nucleotide 323 and a polymorphism in intron 7 are associated with reduced factor VII antigen and activity. [73] [74]

Diminished availability or defective function of tissue factor has never been documented as a cause of decreased factor VII activity. The phenotype of homozygous tissue factor knockout mice is that of embryonic death at about 8.5 days of gestation. [75]

Clinical Manifestations

Factor VII deficiency commonly presents as easy bruising, soft tissue hemorrhage, epistaxis, and, in women, menorrhagia and metrorrhagia. Hemarthroses and crippling hemophilic arthropathy occur in severely affected patients (<1% activity) and may be as severe as that seen in hemophilia A and B. [76] Bleeding in factor VII deficiency is usually easier to control than that seen in hemophilia A and B. Intracranial hemorrhage has been reported, especially in neonates after vaginal delivery. One series cites a 16% incidence of intracranial bleeding in 75 patients with factor VII deficiency, a complication frequently associated with a fatal outcome. [77] Postpartum hemorrhage is seen in patients

with factor VII levels below 1020% of normal. Postoperative bleeding is more likely in severely affected patients, although exceptions have been reported.

Laboratory Evaluation

Factor VII deficiency is the only hereditary clotting factor deficiency that causes an isolated prolongation of the prothrombin time in the presence of a normal PTT. Occasionally patients with certain mutations in factor VII have a prolonged PTT, but this is very rare. Bleeding time is usually normal. A specific factor VII assay is required to confirm the diagnosis. Typical laboratory features of factor VII deficiency are presented in Table 111-6 . The activity can vary dramatically, depending on the source of tissue factor used in the in vitro assay. Variants of factor VII deficiency can be distinguished on the basis of their reactivity toward tissue factors of different animal species.[78] [79] [80] [81] [82] [83] [84]

Differential Diagnosis

Hereditary factor VII deficiency may be suspected in any male or female patient with a lifelong history of excessive bleeding, whether spontaneous or traumatic, especially in those with isolated prolongation of the prothrombin time. Factor X deficiency and some variants of factor IX deficiency (hemophilia B_M), may also exhibit prolonged prothrombin times. In contrast to factor VII deficiency, the PTT is also prolonged in the latter two conditions.

Liver disease, warfarin ingestion, or vitamin K deficiency may mimic factor VII deficiency. These disorders may be distinguished from hereditary deficiency by measuring other vitamin K-dependent factors. There is an inherited combined deficiency

TABLE 111-6 -- Typical Laboratory Values for Severe Factor VII Deficiency

Assay	Severe	Normal

aPTT (sec)	28	26
Thrombin time (sec)	11	11
Factor VII (%)	<1	100

of prothrombin, factors VII, IX, and X (familial multiple factor deficiency, type III). In some reported cases of this syndrome, factor VII levels are lower than those of the other vitamin K-dependent factors. In addition, combined deficiency of factors VII and X has been reported (see Table 11111).

Inhibitors to factor VII have been reported to develop in some patients with hereditary factor VII deficiency following replacement therapy. [85]

Therapy

In the United States, factor VII deficiency is treated with fresh-frozen plasma or prothrombin complex concentrates that contain factor VII (Table 1113). Purified factor VII concentrates from both plasma and recombinant sources are available in Europe, but are not yet approved in the United States. Because the half-life of factor VII is about 3.5 hours, it is difficult to maintain normal levels with plasma replacement alone. Fortunately, it is not usually necessary to raise factor VII levels to 100% to achieve adequate hemostasis. Although the minimum hemostatic level is not known, an increase to 1525% of normal generally results in normal hemostasis, even as prophylaxis for surgery. Replacement therapy given every 612 hours is satisfactory for most hemorrhagic episodes despite the short in vivo half life of factor VII.

For spontaneous hemorrhage or mild trauma, therapeutic factor VII levels of 510% are sufficient to stop bleeding. This can be achieved by administering plasma at a dose of 510 ml/kg body weight and repeating the dose every 812 hours for 12 days. For major hemorrhage or surgery, plasma may be given as a loading dose of 1520 ml/kg body weight and followed by 36 ml/kg body weight every 812 hours until healing of surgical wounds occurs. This may require 57 days of treatment.

The use of plasma carries with it the risk of transmission of viral diseases, particularly hepatitis C. Other disadvantages of plasma are the potential for volume overload and the inability to achieve high levels of factor VII. For these reasons, prothrombin complex concentrates containing factor VII may be useful. Their successful use at a dose of 50 U/kg body weight every 8 hours for 24 hours, followed by plasma infusions thereafter, has been reported for major orthopaedic surgery.[86]

Highly purified factor VII concentrates are useful in treating

patients with severe bleeding or as prophylaxis for surgery or childbirth. [87] [88] Recombinant factor VIIa has proven effective in clinical trials as a treatment for bleeding in hemophilia A and B patients with inhibitors, and in limited numbers of factor VII-deficient patients. The amount of factor VII replacement required for surgery is unclear.

FACTOR X DEFICIENCY

History and Epidemiology

During the 1950s, two groups of researchers independently discovered factor X. The index patient, named Stuart, was originally thought to have factor VII deficiency, but his plasma was later shown to correct the defect in the plasma from the original factor VII deficient patient. [89] A British group simultaneously studied a subject named Prower, leading to the original designation of factor X as Stuart-Prower factor. Factor X deficiency has no predilection for any particular racial or ethnic group and is found worldwide. The incidence is estimated at one per 500,000. Consanguinity has been shown in a number of families with factor X deficiency, including that of the index patient, whose mother and father were aunt and nephew.

Genetics and Molecular Biology

Factor X deficiency is transmitted as an autosomal recessive trait. [90] The gene encoding factor X has been localized to chromosome 13 at postition 13q34, less than three kilobases from the factor VII gene. It consists of eight exons arranged in a fashion similar to the genes of factor IX and factor VII. [91] [92] Factor X mRNA is expressed primarily, but not exclusively, in liver. [93] Mature factor X circulates as a two-chain molecule. The light chain has a molecular weight of 17,000 and the heavy chain has a weight of 40,000. Like the other vitamin K-dependent factors, the protein contains a Gla domain, two EGF-like domains, an activation peptide region, and a catalytic domain typical of serine proteases. In addition to its 11 -carboxyglutamic acid residues, factor X also has a -hydroxy-aspartic acid residue at position 63. Cleavage between Arg^{194} and Ile^{195} releases the 52 amino acid activation peptide and converts factor X to its active form. Activation is carried out physiologically by the factor VIIa/TF complex (as reflected in the prothrombin time test) or the factor IXa/VIIIa complex (as reflected in the PTT). Russell viper venom (RVV) will cleave factor X at the same site, and has been used in laboratory tests of factor X activity. Factor Xa, in the presence of its cofactors (factor Va, calcium, and phospholipids), rapidly converts prothrombin to thrombin.

Pathogenesis

The molecular defect has been identified in a number of patients with factor X deficiency. The defect in the original patient is the substitution of Val^{298} to Met. Other factor X variants have been described in varying depth (Table 1117). [94] [95] [96] [97] [98] [99] The known factor X mutations have been detailed by Cooper et al. [97]

The various missense mutations that have been described have provided information about structure-function relationships in factor X. For example, mutations in glutamic acids that are post-translationally modified by -carboxylation have shown that these residues are important in calcium-mediated binding to lipid membranes. In addition, they are critical in maintaining the protein in the correct calcium-dependent conformation for activation, cofactor binding and proteolytic activity. Roma is a variant in which a Thr^{318} Met mutation on the surface of the molecule affects activation by the factor IXa/factor VIIIa complex to a greater degree than activation by the factor VIIa/TF complex. In contrast, the Vorarlberg variant resulting from a Gla [14] Lys mutation is very poorly activated by factor VIIa/TF, but normally by factor IXa/VIIIa.

Clinical Manifestations

Hemarthroses, retroperitoneal hematomas and other soft tissue hemorrhages, hematuria, pseudotumors, and menorrhagia are observed in patients with severe factor X deficiency. Severe bleeding episodes comparable to those seen in classic hemophilia may occur, including crippling hemophilic arthropathy. Excessive bleeding is uncommon in mild disease. Patients with 15% or greater levels of factor X usually have very few hemorrhagic episodes, although bleeding may occur with major surgery or trauma.

Laboratory Evaluation

Typical laboratory findings in factor X deficiency are depicted in Table 1118 . In screening tests of coagulation, the prothrombin

time and the PTT are prolonged, whereas the thrombin time is normal. The Russells viper venom time, which measures the direct activation of factor X, is also prolonged. Specific factor X assays are required for the diagnosis. The bleeding time is normal even in severely affected patients.

Differential Diagnosis

Acquired factor X deficiency occurs in liver disease and as a result of warfarin ingestion or vitamin K deficiency. In these instances other vitamin K-dependent factors are also reduced. Acquired factor X deficiency may accompany amyloidosis, [100] and rarely as a consequence of an acquired inhibitor. [101] [102] In the setting of amyloidosis, there is essentially no recovery of transfused factor X, as if a circulating inhibitor to factor X were present. However, in vitro mixing assays show no inhibitor in the plasma. Factor X deficiency in amyloidosis is a consequence of adsorption of factor X by extracellular amyloid. Replacement therapy is futile and improvement is most often seen during therapy for the underlying cause of amyloidosis. [103] Splenectomy may be of value in correcting the factor X deficiency of amyloidosis, presumably via the resultant debulking of splenic amyloid. [104] Hereditary factor X deficiency must be distinguished from various hereditary combined deficiencies of clotting factors.

Therapy

Transfusion with fresh-frozen plasma may be used to treat patients with congenital factor X deficiency. Plasma is given as an initial dose of 1520 ml/kg of body weight, followed by 36 ml/kg body weight every 24 hours. The biologic half-life of factor X is about 40 hours. Thus, administration of plasma every 12 hours results in a progressive increase in factor X concentration. About 80% of administered factor X remains intravascularly shortly after infusion. Prothrombin complex concentrates, rich in factor X, have been used to prepare patients for surgery or to treat serious bleeding from trauma or surgery. Table 1113 displays the proportion of factor X present in selected concentrates.

Factor X levels of about 1015% provide adequate hemostasis for hemarthroses and uncomplicated soft tissue hemorrhage. Because of the risk of thromboembolism and DIC with high doses or prolonged administration of prothrombin complex concentrates containing factor X, it is not recommended that factor X levels of >50% of normal be exceeded unless absolutely necessary. Pure factor X concentrates have been prepared by affinity chromatographic procedures using monoclonal antibodies, but these concentrates are not yet available commercially.

FACTOR XI DEFICIENCY

History and Epidemiology

Factor XI deficiency was first recognized as an inherited blood-clotting factor defect by Rosenthal and colleagues in 1953. [105] These workers described three related patients, one male and two females, who had a history of bleeding after dental extraction. The observation that plasma from the affected patients corrected the clotting defects of plasma from patients known to be deficient in other clotting factors implied the absence of a previously undescribed protein, later designated factor XI.

Factor XI deficiency occurs most often in Ashkenazi Jews, but also occurs in non-Jewish populations. [106] The calculated gene frequency for factor XI deficiency among Ashkenazi Jews is 4.3%, so appreciable numbers of homozygous patients may be expected. [107]

Genetics and Molecular Biology

Factor XI deficiency is inherited as an autosomal recessive trait. The gene contains fifteen exons and is located on chromosome 4q32q35. [108] After secretion as a homodimer from the liver, factor XI circulates in plasma at a concentration of approximately five g/ml. It is composed of two identical disulfide-linked monomers of 80,000 molecular weight which exhibit significant homology with prekallikrein. [109] Factor XI is activated by cleavage at the Arg^{369} -Ile^{370} bond in each monomer. This cleavage yields two amino-terminal heavy chains with a molecular weight of 50,000, and two carboxy-terminal light chains with a molecular weight of 30,000. Each heavy chain is composed of four tandem repeats called apple domains. Apple domain-1 binds high-molecular-weight kininogen; apple domain-2 binds factor IX, and apple domain-4 has sites that bind factor XIIa. [110] [111] [112] The light chains are homologous with other serine proteases, and each contains a catalytic site for activation of factor IX.

Factor XI is readily activated by factor XIIa. However, factor XII deficiency is not associated with a bleeding tendency, suggesting that another means of activating factor XI operates in vivo. Thrombin can activate factor XI in the presence of nonphysiologic cofactors, such as sulfatides. [113] [114] Platelets can support activation of sufficient factor XI by thrombin to accelerate coagulation in an in vitro model system. [115] Thus, it is likely that thrombin may serve as a physiological feedback activator of factor XI during normal coagulation.

Pathogenesis

Presently, three different point mutations account for most analyzed cases of factor XI deficiency. [116] [117] Type I mutations occur at the splice junction boundary of the last intron, resulting in either disruption of mRNA splicing or premature translation termination. A mutation in exon 5 resulting in a premature stop codon (nonsense mutation) has been designated as a type II mutation. The type III mutation in the ninth exon causes substitution of leucine for phenylalanine at postion 238 (mis-sense mutation). In small population studies, the type II and type III mutations are the most common, and compound heterozygosity (type II/III) is found frequently in affected patients. Although genotype appears to correlate with the factor XI levels observed (see Table 1119), a clear correlation of genotype with bleeding tendency has not been established.

Very low factor XI levels are not always associated with a bleeding tendency, an observation that has not been adequately explained. Evidence indicates that factor XI-like activity exists on platelet membranes and it has been suggested that such activity may compensate for deficiency of plasma factor XI in some cases. [118] Platelet factor XI has a lower molecular weight and a different electrophoretic migration than that of plasma factor XI, although the two activities cannot be distinguished immunologically.

Clinical Manifestations

Affected patients can be divided into those with major deficiency (20% of normal), and those with minor deficiency. [119]

TABLE 111-9 -- Factor XI Levels in Homozygous or Compound Heterozygous Factor XI Deficiency[a]

Mutation Type		Factor XI Level (%)	aPTT (sec)
Allele 1	**Allele 2**		
II	II	1.2	108
III	III	9.7	85
II	III	3.3	67
II		52	39
III		67	36
Normal	Normal	>100	32

[a] Adapted from Seligsohn,[107] with permission.

Patients with major deficiency may experience excessive bleeding and are usually homozygotes or compound heterozygoyes. Patients with minor deficiencies have little or no bleeding and are usually heterozygous for the disorder. Although hemorrhagic symptoms do not always strictly correlate with the factor XI level, [120] patients with a family history of bleeding in affected relatives likely will have similar bleeding tendencies. Similarly, patients without a history of bleeding usually do not experience hemorrhage even after trauma.

Those patients who do bleed usually do so only after trauma or surgery. Even patients with very low factor XI levels do not have hemorrhagic episodes as frequently or prominently as those seen in hemophilia A and B. Epistaxis, soft tissue hemorrhage, and bleeding after dental extractions may occur. Hemarthroses are very

uncommon and chronic disabling joint disease is not observed. Affected women may experience menorrhagia. Postoperative bleeding may be seen in severely affected patients. The risk of bleeding may be significantly enhanced in patients taking aspirin. [121]

Laboratory Evaluation

The PTT is prolonged in factor XI deficiency, whereas the prothrombin time and thrombin time are normal. A specific assay of factor XI activity is necessary to confirm the diagnosis. Assays of other clotting factors may be necessary to exclude a combined hereditary deficiency of factor XI and other factors. Plasma for factor XI assays should be drawn into nonwettable tubes and rapidly assayed. The clotting defect in factor XI deficiency cannot always be detected when plasma is exposed to glass or if it is assayed after the plasma is frozen and thawed.

Differential Diagnosis

Factor XI deficiency should be suspected in any patient with a prolonged PTT, especially if the family history suggests a mild to moderate life-long bleeding disorder that affects both males and females. Factor XI deficiency has been described in a familial multiple factor deficiency syndrome (FMFD type V) in which factors VIII, IX, and XI are decreased. This syndrome has been described for five patients, more than predicted on the basis of coincidence alone. A combined factor XI-factor IX deficiency has also been described as part of type VI familial multiple factor deficiency. [122]

Acquired factor XI deficiency occurs in patients who develop inhibitors to this protein. Anti-factor XI antibodies occur in patients with systemic lupus erythematosus and other immunologic diseases. Acquired deficiency can be distinguished from the hereditary form on the basis of a history of recent onset and by showing inhibiting activity in the patients plasma. Factor XI deficiency has been described as a common finding in patients with Noonans syndrome, which is characterized by congenital cardiac abnormalities, short stature, and mental retardation. [123] [124]

Therapy

Soft tissue bleeding may not require treatment. When therapy is required, fresh-frozen plasma or the supernatant from cryoprecipitate-poor plasma is used. Commercial factor XI concentrates are of limited availability. [125] Plasma exchange may be required if the hemorrhage cannot be controlled with plasma alone. The plasma half-life of factor XI is approximately 80 hours. Plasma can be administered as a loading dose of 1520 ml/kg body weight, followed by 36 ml/kg body weight every 12 hours until hemostasis is achieved. Factor XI levels of 3040% have been reported with plasma replacement therapy. The risk of hepatitis is proportional to the number of units of plasma infused.

Surgical procedures performed on factor XI deficient patients vary from cataract surgery to open heart surgery. [126] [127] These have been safely carried out with plasma replacement therapy. Antifibrinolytics, such as epsilon-aminocaproic acid or tranexamic acid, may be useful adjuncts in controlling bleeding. However, such agents should not be used in patients with hematuria, since clots refractory to lysis may be difficult to evacuate from the genitourinary tract. Bleeding following prostatectomy can be difficult to control even with aggressive therapy. Such patients may require plasma exchange to achieve higher levels of factor XI. The administration of antifibrinolytic agents alone is often sufficient to prevent hemorrhage after dental extractions.

Despite reports that some factor XI deficient patients may not bleed during surgery, the physician may have no way to ascertain which patients will not bleed. A history of past significant surgery without therapy and uncomplicated by bleeding strongly suggests but does not guarantee satisfactory hemostasis with subsequent surgery. When in doubt, factor XI deficient patients should be treated with plasma prior to surgery.

Alloantibodies to factor XI have been described and are most likely to occur in severely affected patients. These antibodies inhibit factor XI activity and represent a major complication of therapy. One patient with a factor XI inhibitor and severe bleeding failed to respond to maximal plasma therapy but responded dramatically to infusions of an activated prothrombin complex concentrate. [128]

A commercial factor XI concentrate is available in Europe, but is not licensed in the United States.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

DEFICIENCY OF THE CONTACT FACTORS

Factor XII, prekallikrein (PK), and high-molecular-weight kininogen (HK), in addition to factor XI, are the major factors involved in the so-called contact phase of coagulation. Subjects with a deficiency of factor XII, PK, or HK have no bleeding tendency, but do exhibit a prolonged PTT. These factors are thought to be important as mediators of various host-defense mechanisms including inflammation, fibrinolysis, and control of blood pressure. [129] The role of the contact factors in coagulation is not clear. They may not play a significant role in normal hemostasis, since their deficiencies are not associated with clinical bleeding, even in patients undergoing major surgery. Although deficiencies of factor XII, PK, and HK are not associated with bleeding, it is important to distinguish them from deficiencies of factors VIII, IX, and XI, which are accompanied by defective hemostasis.

Factor XII Deficiency

Factor XII (Hageman factor) deficiency was first described by Ratnoff and Colopy in 1955. [130] The original patient, Mr. John Hageman, had no history of excessive bleeding; his in vitro clotting abnormality was discovered during a preoperative evaluation. Several hundred cases of factor XII deficiency have since been described. Factor XII levels are lower in patients of Asian descent than in other ethnic groups.

TABLE 111-10 -- Selected Dysfunctional Factor XII Variants

Valencia	4170	<1	ND	ND

ND, not determined.

The factor XII protein is synthesized in the liver and is present in normal plasma at about 30 g/ml. [131] The mature factor XII protein has a molecular weight of about 80,000, and consists of a single polypeptide chain. The protein is activated when cleaved at a single site (Arg^{353}-Val^{354}) by plasma kallikrein. The domain organization of the heavy chain of factor XII is homologous to tissue plasminogen activator and urokinase. The gene for factor XII has been mapped to 5q33qter. Several dysfunctional factor XII molecules have been described (see Table 11110). There have been no convincing reports of excessive bleeding associated with factor XII deficiency, even with major surgical procedures. Decreased plasminogen activator activity described in factor XII-deficient patients may be associated with defective fibrinolysis and an increased risk of thromboembolism. [132] In a group of patients with recurrent venous thrombosis, about 10% were found to be heterozygous for factor XII deficiency. [133] Activated factor XII is inhibited by antithrombin III, -2 antiplasmin, and C1-esterase inhibitor.

The hallmark of severe factor XII deficiency is a markedly prolonged PTT, often to greater than 100 seconds, in a patient with no history of bleeding. The prothrombin time and thrombin times are normal. In most patients the bleeding time is normal although exceptions have been noted. A specific factor XII assay is required to confirm the diagnosis.

Prekallikrein Deficiency

Prekallikrein (Fletcher factor) deficiency was first described in 1965 by Hathaway, who observed patients with a markedly prolonged PTT who had no history of abnormal bleeding. [134] The disorder is inherited in an autosomal recessive pattern. Plasma from affected patients corrected the clotting defect of plasma deficient in all other known clotting factors including factors XI and XII. In addition, the prolonged PTT of prekallikrein-deficient plasma was corrected by exposure to glass. The hallmark of prekallikrein deficiency is a markedly prolonged PTT, corrected by exposure to glass, in patients with no bleeding tendencies. [134] A specific assay is required for diagnosis.

High-Molecular-Weight Kininogen Deficiency

Patients with high-molecular-weight kininogen (also referred to as Williams, Fleaujeac, or Fitzgerald factor) deficiency also exhibit a prolonged PTT, but have no bleeding abnormality. The disorder is inherited as an autosomal recessive characteristic. Some patients are also deficient in low-molecular-weight kininogen. Both factor XI and prekallekrein circulate in a complex with high molecular weight kininogen, a necessary cofactor for activation of factor XII as well as PK and factor XI.

FACTOR XIII DEFICIENCY

History and Epidemiology

The existence of factor XIII (fibrin-stabilizing factor) was first postulated by Robbins in 1944 when he showed that fibrin formed from purified components was soluble in weak acids, whereas fibrin formed in the presence of serum or plasma resulted in formation of an insoluble clot. [135] In 1960 Duckert described the first recognized case of a clinical bleeding diathesis due to congenital deficiency of this protein. [136] Fibrin stabilizing factor was given the designation factor XIII in 1963. Since its first description, more than 100 cases of factor XIII deficiency have been reported. No racial or ethnic group is disproportionately affected, and the incidence is estimated at one in several million.

Genetics and Molecular Biology

Factor XIII deficiency is inherited as an autosomal recessive trait. Heterozygotes are not affected with bleeding, although heterozygous females may have a higher than normal incidence of spontaneous abortions than do normal women. The gene for the *A* subunit is at 6p2425, near the HLA locus; the gene for the *B* subunit is located at 1q3132.1. [137] [138] [139] [140]

Factor XIII circulates in the plasma at a concentration of 1020 g/ml. [141] Factor XIII is not homologous to any of the other coagulation factors, but is one of a family of transglutaminases. The protein exists in plasma as a tetramer consisting of two *A* subunits and two *B* subunits. Each subunit has a molecular weight of about 85,000, and the complete protein has a molecular weight of approximately 330,000. Factor XIII catalyzes cross-linking between -glutamyl and epsilon-lysyl groups of different fibrin strands. This cross-linking renders the fibrin meshwork rigid and insoluble, even in mild organic acids. The catalytic activity of factor XIII resides in the *A* subunits. Although plasma factor XIII is synthesized in the liver, a dimer of the two *A* subunits (lacking the *B* unit but retaining activity) is produced in megakaryocytes and placental tissue. The amino acid sequence of the *A* subunit and the nucleotide sequence of its cDNA have been determined. [137] [142] A reactive thiol group is unmasked by thrombin cleavage at the amino terminus of the *A* subunit. Further thrombin cleavage at the carboxy terminus inactivates the enzyme by disrupting a calmodulin-like calcium binding site. The protein sequence and cDNA sequence of the *B* subunit, which has no enzymatic activity, reveals ten repeating homologous domains that resemble those of $_2$ -glycoprotein I. [143] The *B* subunits act primarily as carriers for the *A* subunits.

Pathogenesis

Three forms of factor XIII deficiency have been described. In type I deficiency, both subunits *A* and *B* are lacking; in type II deficiency the *A* subunit is lacking but subunit *B* is present; in type III the *B* subunit is lacking. [144] [145] Specific mutations have been reported in the A chain, including a dinucleotide deletion leading to premature termination, and a point mutation at the exon/intron junction after exon 14. A mutation in the B chain has been described at the acceptor splice junction of intron A. The majority of patients with factor XIII deficiency have an absent or defective *A* subunit. Factor XIII deficiency has been reported as the result of acquired inhibitory antibodies; these have been associated with isoniazid use. [146]

Clinical Manifestations

The hallmarks of severe factor XIII deficiency are umbilical stump bleeding in the neonatal period; intracranial hemorrhage with little or no trauma; recurrent soft tissue hemorrhage with tendency to form hemorrhagic cysts (pseudotumors); and, in females, recurrent spontaneous abortion. Males may also show oligospermia and infertility. The bleeding associated with factor XIII deficiency is usually associated with trauma, except in the case of intracranial hemorrhage which may occur in the absence of known trauma. Intracranial hemorrhage is reported in up to 25% of patients in some series. [147] Surprisingly, bleeding at the

time of surgery is not excessive, although delayed bleeding can occur. Poor wound healing and abnormal scar formation are characteristic of this disease. Unlike hemophilia A or B, hemarthroses are not usually observed.

Laboratory Evaluation

Factor XIII deficiency is marked by normal coagulation screening tests (prothrombin time, PTT, thrombin time, and bleeding time) despite a convincing history of bleeding. The most useful assays for factor XIII activity exploit the solubility of non-cross-linked fibrin clots in 5 M urea or weak organic acids. Clots formed in factor XIII-deficient plasma are soluble within minutes in such solutions, whereas normal clots remain insoluble for at least 24 hours. The test of solubility in 1% monochloroacetic acid is said to be more sensitive than solubility in 5 M urea, although the latter is more specific for factor XIII deficiency. Other tests for factor XIII activity use measurements of incorporation of fluorescent amino acids into casein, or ammonia production by the amidase activity of factor XIII. [148]

Differential Diagnosis

The clinical presentation of factor XIII deficiency may be confused with abnormalities of fibrinogen that may also present with umbilical stump bleeding, soft tissue hemorrhage, and recurrent abortions. These two conditions may be readily distinguished on the basis of screening tests of coagulation, which are all abnormal with fibrinogen defects but normal with factor XIII deficiency. Specific factor XIII assays confirm the diagnosis.

Acquired factor XIII deficiency has been reported in association with exacerbations of Henoch-Schonlein purpura. The deficiency of factor XIII seems to correlate with abdominal pain and bloody diarrhea. Infusions of factor XIII not only restore normal factor XIII levels, but also decrease the severity and duration of these symptoms during exacerbations. [149]

Therapy

Treatment of factor XIII deficiency is simplified by the fact that factor XIII has a half-life of 9 days. Minimal factor XIII activity, perhaps as little as 5%, may be sufficient to prevent bleeding complications. [150] Prophylactic therapy is practical for these reasons and is advisable due to the significant risk of intracranial hemorrhage. Prophylaxis can be accomplished by the use of fresh-frozen plasma, given as 1 or 2 units every 46 weeks. [125] Cryoprecipitate also contains factor XIII, and can be given in doses of 1 bag per 1020 kg body weight every 34 weeks. Factor XIII concentrates (Fibrogammin, Hoechst) are available in Europe, and have been used successfully in the prevention of hemorrhagic complications. [125] In one report, soft tissue hemorrhage occurred when the interval between prophylactic transfusions

exceeded 6 weeks.[150] A factor XIII-deficient patient suffered repeated spontaneous abortions until started on prophylactic plasma transfusions every 14 days or infusions of a commercial factor XIII concentrate every 21 days. The two pregnancies that followed were uncomplicated. [151]

FAMILIAL MULTIPLE FACTOR DEFICIENCIES

A number of familial multiple factor deficiencies have been described as shown in Table 11111 . Two of these syndromes, combined factor V-factor VIII deficiency, and combined deficiency of factors II, VII, IX, and X, have been well characterized. [122] [152]

Combined Factor VFactor VIII Deficiency (Type I FMFD)

In this syndrome factor V and VIII levels range between 515% of normal. Analysis of affected members of a number of different

TABLE 111-11 -- Familial Multiple Coagulation Factor Deficiencies

Type	Deficient Factors
I	V, VIII
II	VIII, IX
III	II, VII, IX, X
IV	VII, VIII
V	VIII, IX, XI
VI	IX, XI
VII	VII, X

kindred suggested that the combined defect is due to a single genetic defect in a small region of chromosome 18. [153] The defect is due to a mutation of a protein of the endoplasmic reticulum-intermediate golgi compartment, previously named ERGIC-53. [154] The function of this protein is not known. This protein might serve as a molecular chaparone for factors V and VIII during their post-translational modification and transit through the Golgi apparatus.

Bleeding in patients with FMFD type I usually occurs only after trauma, and may be severe during and after surgery unless replacement therapy is given. Plasma is the only source of factor V, although safe and effective factor VIII concentrates are available. In preparation for surgery, plasma exchange should be performed to raise the factor V levels to near normal. After plasma exchange, factor levels can be maintained with fresh frozen plasma and factor VIII concentrates.

Deficiency of Factors II, VII, IX, and X (Type III FMFD)

A number of reports describe patients with a combined congenital deficiency of factors II, VII, IX, and X, as well as protein C and protein S. One of the first patients reported had a severe bleeding tendency requiring treatment with high doses of vitamin K. [155] Malabsorption and other causes of vitamin K deficiency or surreptitious warfarin ingestion were excluded. Parents of affected children have not been clinically affected but, interestingly, parents of one affected child had markedly decreased urinary excretion of -carboxyglutamic acid, suggesting a defect in vitamin K-dependent carboxylation of glutamic acid residues in the vitamin K-dependent factors. The clotting defect in some patients has been partially corrected by vitamin K administration; in other patients vitamin K has had no effect. The vitamin K carboxylase gene has been studied in five patients with the disorder, but only one exhibited a mutation. [156] Two of the patients appeared to have a defect in the vitamin K reductase gene. A defect in either the carboxylase or reductase could lead to impaired carboxylation of glutamic acid residues in the vitamin K-dependent clotting factors.

Bleeding in these patients may be severe. In some patients, high doses of oral vitamin K may be of benefit. When excessive bleeding occurs, patients can be treated with plasma or, if necessary, with prothrombin complex concentrates that contain all of the vitamin K-dependent factors. Care must be taken when using such concentrates to avoid thrombotic complications by using the lowest effective doses.

Other Combined Deficiencies

The other combined factor deficiencies listed in Table 11111 are very rare. Recently, a combined deficiency of factors VII and X has been reported. [157] Abnormal bleeding in these patients does occur, and requires replacement therapy with plasma or, where possible, specific clotting factor concentrates.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

PREFERRED APPROACH

The preferred treatment for any clotting factor deficiency or defect is specific replacement therapy using a purified concentrate. Purified preparations of factors VII, XI, and X are available in certain countries but these products are not yet available in the United States. However, for prothrombin, factor VII, or factor X deficiency prothrombin complex concentrates (PCCs) are widely available and represent more purified clotting factor concentrates than plasma. Several different PCC preparations are shown in Table 1113 , which lists the relative concentrations of each factor compared to 100 units of factor IX. Initially the greatest use of PCCs was for the treatment of hemophilia B. However, more highly purified preparations of factor IX are now available both from plasma and recombinant sources and these are products of choice for treatment of hemophilia B. At present, the greatest use of PCCs is for the treatment of patients with inhibitors to factor VIII or IX, since PCCs contain varying amounts of activated forms of factors VII, IX, and X and possess so-called inhibitor bypassing activity. Although PCCs are used mainly to treat patients with inhibitors, they are also quite useful for the treatment of deficiencies of the vitamin K-dependent factors. PCCs should be used with care and for the shortest time possible, however, since they have been associated with thromboembolic events including myocardial infarction, deep venous thrombosis, and pulmonary embolism.

In many instances, plasma infusions can be given to treat individual clotting factor deficiencies. For example, plasma is the main source for replacement of factor V and XI deficiency. The main drawback in the use of plasma is the danger of volume overload. Elderly patients or patients with significant cardiovascular disease may experience congestive heart failure when using large doses of plasma. In these instances, PCCs should be used if the patient is deficient in prothrombin or factors VII or X. In the case of factor XI or factor V deficiency, plasma exchange transfusion should be considered. The other danger of plasma, in addition to volume overload, is the risk of transmissible disease which although rare, still remains a possibility that is compounded when large amounts of plasma are administered. The relative risks of transmissing viral diseases following plasma transfusion are: HIV, 1 in 493,000; HCV, 1 in 103,000; HBV, 1 in 63,000; and HTLV, 1 in 641,000.

Chapter 112 - Quantitative and Qualitative Disorders of Fibrinogen

José Martinez

INTRODUCTION

Human fibrinogen is a 340-kDa glycoprotein that circulates in plasma at a concentration of approximately 300 mg/dl. The fibrinogen molecule is a dimer consisting of two identical halves, each of which is composed of three nonidentical polypeptides termed the A-, B-, and -chains (Fig. 112-1). The halves of the molecule are connected at the amino-terminal central domain (N-terminal) by hydrophobic interactions and by interchain disulfide bonds, one linking the A-chains, two linking the -chains, and one the A-chain to the B-chain.[1] [2] [3] [4] The two -chains are linked in an antiparallel manner and the three polypeptides of each half of the fibrinogen molecule are also

Figure 112-1 Model of human fibrinogen and fibrin. Each half of the molecule is composed of three chains, A, B, and . The amino-terminal regions of the six chains are linked in the central domain (E domain) by disulfide bonds that form the dimer. In this region, fibrinopeptides A and B are cleaved from the A- and B-chains, respectively, by thrombin, which converts fibrinogen into fibrin monomer. The two nodular regions at the C-terminal (D domain) contain the complementary binding sites for the central determinants exposed on release of the fibrinopeptides. Depicted in the figure are also segments of the fibrinogen molecule that bind tissue plasminogen activator (tPA), $_2$ -antiplasmin, factor XIII, and of thrombin (IIa) to fibrin. The C-terminal -peptide or the RGD peptide of the C-terminal of the A-chain intervene in the binding of fibrinogen with platelets and other cells. *(Adapted from Mosseson,[5] with permission.)*

connected by a series of disulfide bridges.[1] [2] Elucidation of the amino acid sequence of each chain has revealed the A-chain to consist of 610, the B-chain of 461, and the -chain of 411 amino acids.[1] [2] Attached to the B- and -chains are four carbohydrate side chains, linked through *N*-acetylglucosamine to asparagine 52 of each -chain and asparagine 364 of each B-chain; the A-chain does not contain carbohydrates.[5] The molecular masses of the A-, B-, and -chains (including amino acid and carbohydrate components) are 66.5, 54.3, and 48.5 kDa, respectively.[2] Electron microscopy has revealed a trinodular structure with a central nodule linked through two thin rods to two peripheral nodules (Fig. 112-1).[6] This structure is consistent with results obtained by proteolytic cleavage of fibrinogen with cyanogen bromide or plasmin,[7] [8] a process that yields a central dimeric fragment (fragment E) corresponding to the central nodule and two peripheral monomeric fragments (fragments D) corresponding to the peripheral nodules visualized by electron microscopy (Fig. 112-1).

Plasma fibrinogen is synthesized exclusively by the hepatocyte,[9] [10] and the synthesis of the three chains is under the coordinated control of three separate genes localized on chromosome 4.[11] [12] [13] Subsequent to assembly of the constituent polypeptide chains and the addition of carbohydrate side chains, the mature molecule is secreted into the circulation where it manifests a half-life of 4 days and a fractional catabolic rate of 25%/day.[14] [15]

Fibrinogen plays a central role in three major functional processes: (1) The soluble fibrinogen molecule is converted into soluble fibrin during the process of blood coagulation. (2) The polymerized fibrin serves as a template for the localized assembly and activation of the fibrinolytic system, which modulates fibrin deposition and clot dissolution.[3] Fibrinogen binds to vascular cells such as platelets, where it supports platelet aggregation, and to endothelial cells, where it participates in tissue repair. The conversion of fibrinogen into insoluble fibrin can be divided into three distinct phases: (1) enzymatic cleavage of fibrinopeptides by thrombin, (2) fibrin polymerization, and (3) fibrin stabilization via covalent cross-linking by factor XIIIa. In the first phase, thrombin cleaves the Arg16-Gly17 bond of the A-chain and the Arg14-Gly15 bond of the B-chain, resulting in the release of two molecules of fibrinopeptide A (FPA) and two of fibrinopeptide B (FPB) per molecule of fibrinogen.[3] [16] [17] Fibrinopeptide release from the constituent A- and B-chains of fibrinogen results in the formation of fibrin monomer, the constituent chains of which are now referred to as the -, -, and -chains. Although the proteolytic cleavage of FPA and FPB by thrombin appears to be simultaneous, the cleavage of FPA actually occurs prior to and more rapidly than that of FPB.[16] [17] Moreover, the cleavage of FPA is sufficient to induce clot formation, whereas the exclusive cleavage of FPB does not lead to fibrin formation under physiologic conditions.[18] The association of thrombin with fibrinogen is, in part, mediated through its catalytic site as shown by nuclear magnetic resonance and x-ray crystallographic studies of thrombin bound to a discrete segment of the N-terminal of the A-chain. However, thrombin also binds to fibrin(ogen) through a noncatalytic site called the fibrinogen recognition site, which binds to a locus formed by the N-terminus of the -chain (2750) and the N-terminus of the -chain (1542 and Ala 68).[3] [19] Recent studies also identified a high-affinity binding site of thrombin on fibrin(ogen) on the C-terminal region of the chain variant.[20]

In intact fibrinogen, the negatively charged fibrinopeptides play a role in maintaining the dispersion of individual fibrinogen molecules, as evidenced by the fact that subsequent to their cleavage by thrombin the resulting fibrin monomers spontaneously polymerize. The polymerization process involves the reciprocal non-covalent interaction of molecular determinants in

the fragment-E region of the molecule that are exposed by the removal of FPA with complementary binding sites located in the fragment-D region of an adjacent fibrin monomer. The resulting dimer, which is arranged in a half-staggered overlap (Fig. 112-2), continues to grow in length by the staggered addition of fibrin monomers, resulting in the formation of a two-stranded, half-staggered polymer referred to as a protofibril, the basic structural unit of the fibrin clot.[3] [21] [22] The half-staggered polymerization process brings two D domains of longitudinally aligned fibrin molecules of each row of the protofibril into close contact with one another, forming DD contacts as shown by recent x-ray crystallographic analysis of fibrin fragment D.[23] These interactions further stabilize the non-covalently associated fibrin protofibril (Fig. 112-2). Polymerization continues with the formation of long, double-stranded protofibrils that ultimately associate laterally to form thick fibrin bundles.[3] [21] [22] The cleavage of FPB occurs mainly during the initial phase of fibrin polymerization and exposes determinants that are complementary with binding sites located in the C-terminal region of the molecule.[3] [16] This interaction seems to increase the rate of formation of thin fibrils as well as the lateral aggregation to form thick fibrin fibers.[3] The three-dimensional fibrin matrix is completed by branching of the fibers at specific contact points located in the fiber bundles.[3] Several of the polymerization sites within fibrin have been identified. The N-terminus of the fibrin -chain (1720; GPRV) participates in the interaction of the A determinant with the complementary binding site located in fragment D.[1] [3] [24] Crystal structural studies of the C-terminal region of the -chain showed that amino acids Gln329, Asp330, His340, and Asp364 and Arg375 form a pocket for the complementary binding of A GPRP,[24] and mutations of these amino acids cause polymerization defects as seen in several dysfibrinogenemias. In addition, the N-terminus of the fibrin -chain also participates in the assembly of fibrin by binding to a complementary site

located in the C-terminus, but the localization of this binding site remains controversial.

The final stage of fibrin formation is characterized by the factor XIIIa-mediated formation of covalent amide bonds between the epsilon-amino groups of specific lysine residues and -$CONH_2$ groups of certain glutamine residues.[25] These covalent bonds are first formed between opposing -chains of end-to-end aligned D domains (DD contact sites) of two fibrin molecules. The dimerization of the -chain formed by bridges between lysine 406 of one -chain and glutamine 398 of the opposing -chain is then followed by progressive covalent cross-linking of multiple -chains. [3] [26] As a result of this extensive covalent stabilization, the fibrin clot is rendered more compact and resistant to both mechanical disruption and dissolution by plasmin. [27]

In addition to plasma fibrinogen, the circulating blood contains a very small pool of fibrinogen, which is present within the platelet -granules. Although some studies have shown that fibrinogen is synthesized by the megakaryocyte,[28] more recent

Figure 112-2 Model of fibrin assembly showing two sets of complementary binding sites. The A fibrinopeptides are represented by semicircles and the B fibrinopeptides by triangles. After cleavage of the fibrinopeptides, the binding sites are exposed, the A site is represented by a circular hole and the B by a triangular. Complementary to these sites in the E domain are those located in the D domain, which are represented by knobs; -sites are circular knobs, and -sites are triangular. After cleavage of FPA, the A site of the E domain of one molecule interacts with the a site of the D domain of another molecule forming a half-staggered overlap dimer. Additional fibrin monomer units associate through the DD contacts. The protofibril is formed by two rows linked by DD contacts, where the monomers of one row are arranged in a half-staggered overlap with respect to the monomers of the other row. Removal of FPB exposes the B-sites, and this interaction promotes the lateral association of protofibrils into fibrin fibers. *(Adapted from Weisel,[22] with permission.)*

investigations have demonstrated that both megakaryocytes and platelets are capable of internalizing fibrinogen from plasma via a process mediated by GPIIb/IIIa. [29] Plasma fibrinogen exhibits -chain heterogeneity due to differential splicing of the hepatic mRNA. [3] This heterogeneity is manifested by the presence of a minor component, termed , in which the last four amino acids of the -chain are replaced by an extended carboxyl-terminal sequence. [3] The -chain is not present in platelet fibrinogen[3] and does not support platelet aggregation, probably due to the lack of interaction of with GPIIb/IIIa of the platelet. [3] [30] [31] Platelet fibrinogen is secreted after stimulation and plays a role in supporting hemostasis. [3]

CLASSIFICATION OF FIBRINOGEN ABNORMALITIES

Fibrinogen abnormalities can be classified as being either congenital or acquired, with both groups manifesting quantitative defects (i.e., afibrinogenemia, hypofibrinogenemia, or hyperfibrinogenemia) or qualitative alterations of the fibrinogen molecule (dysfibrinogenemia). In a few instances, both quantitative and qualitative abnormalities can be present in the same patient (e.g., hypodysfibrinogenemia). The congenital disorders of fibrinogen are reviewed first, after which, the acquired disorders will be considered.

CONGENITAL DISORDERS OF FIBRINOGEN

Afibrinogenemia and Hypofibrinogenemia

Congenital afibrinogenemia has been described in approximately 150 families, [32] but low levels of fibrinogen may have been undetected owing to the insensitivity of the methods used to quantitate the fibrinogen concentration. Less frequently, families with subnormal amounts of fibrinogen have been reported, and it is possible that in some of these cases the low fibrinogen concentration may have been associated with the presence of an abnormal molecule (i.e., hypodysfibrinogenemia).

Clinical manifestations in patients with fibrinogen disorders are related to the plasma fibrinogen concentration. Patients with afibrinogenemia may exhibit bleeding symptoms of variable severity. Umbilical cord bleeding can be the first hemorrhagic manifestation of this disorder and can be the cause of death in the newborn. [32] [33] [34] Later in life, gum bleeding, epistaxis, menorrhagia, [35] gastrointestinal hemorrhage, and hemarthrosis can present with varying intensity; but intracranial bleeding is the leading cause of death in this group of patients. [33] [34] [35] [36] Spontaneous abortions and abruptio placentae have also been described, even in cases with only moderate hypofibrinogenemia. [37] [38] [39] [40] Bleeding in hypofibrinogenemia usually occurs in patients with fibrinogen concentrations below 50 mg/dl, [32] and the hemorrhagic manifestations are usually associated with trauma or surgical procedures. Oddly, some patients with hypofibrinogenemia die as a result of thrombotic episodes and pulmonary embolization, although some of these episodes may have been precipitated by fibrinogen infusions. [41] [42] [43] Occasionally, the newly synthesized fibrinogen is not secreted and accumulates in the cisternae of the rough endoplasmic reticulum of the hepatocyte, resulting in a storage disease with mild elevations of serum liver enzymes. [44] [45]

Pathogenesis and Inheritance

Congenital afibrinogenemia appears to be caused by a biosynthetic defect because autologous fibrinogen injected into afibrinogenemic patients shows a normal plasma survival. [46] [47] However, it is also possible that the low plasma fibrinogen level is caused by the biosynthesis of a defective molecule that is not secreted into the circulation. [44] [45] In most cases, the fibrinolytic system is normal as are the levels of the other coagulation factors, which supports the concept of decreased biosynthesis as opposed to increased utilization as the cause of the hypofibrinogenemia.

Afibrinogenemia is inherited as an autosomal recessive disorder, and consanguinity is common in these families. [32] [33] [34] The inheritance pattern of hypofibrinogenemia is more complicated. In some families, the abnormality is only present in one parent and inheritance seems to be dominant. In other families, low levels of fibrinogen in both parents suggest a recessive mode of transmission. [32] [33] Analysis of the A-, B-, and -chain genes in two families with afibrinogenemia failed to reveal any gross abnormalities such as deletions or gross rearrangements of these genes. [48]

Laboratory Findings

All tests based on the appearance of a fibrin clot are abnormal in patients with afibrinogenemia and severe hypofibrinogenemia. These include the whole blood clotting time, the plasma recalcification time, the partial thromboplastin time (PTT), the prothrombin time (PT), and especially the thrombin and reptilase times. These abnormalities can be corrected by addition of either normal plasma or purified normal fibrinogen. Definitive diagnosis is made by immunologic measurements of the fibrinogen concentration, which are sufficiently sensitive to detect nanogram quantities of fibrinogen per milliliter of plasma. [49] [50] Measurements of fibrinogen as clottable protein are unreliable because some abnormal fibrinogens do not convert into fibrin. Other coagulation abnormalities in these patients include a prolonged bleeding time and abnormal platelet aggregation, especially with epinephrine and suboptimal concentrations of adenosine diphosphate. [50] [51] [52] The prolongation of the bleeding time and the defect in platelet aggregation can be corrected by the infusion of plasma or fibrinogen. [50] [51] [52]

Prognosis

Patients with afibrinogenemia and severe hypofibrinogenemia have a high incidence of hemorrhagic manifestations, especially in the neonatal period; and bleeding is the cause of death in approximately one-third of such patients. [33] The availability of plasma and fibrinogen concentrates in the form of cryoprecipitate and the prompt treatment of bleeding complications should improve the survival of these patients; however, some of these patients unfortunately can develop antibodies to fibrinogen, which render the treatment ineffective.

Treatment

Patients with congenital afibrinogenemia or severe hypofibrinogenemia may require replacement therapy to control episodes of active bleeding or as preparation for surgical procedures. Most patients receive fibrinogen replacement in the form of cryoprecipitate, a plasma-derived concentrate that contains approximately 300 mg fibrinogen per unit (i.e., a 3050 ml bag). An adult with afibrinogenemia and a plasma volume of 3 L will require approximately 12 U cryoprecipitate to increase the plasma fibrinogen level to about 100 mg/dl, a concentration that provides normal hemostasis for surgical procedures. [53] [54] This calculation takes into consideration an extravascular distribution of fibrinogen of 30%. Because fibrinogen is catabolized at a rate of 25%/day, the patient should subsequently receive one-third of the starting dose daily for as long as treatment is necessary. Cryoprecipitate is also used during pregnancy to prevent spontaneous abortion and to assist these patients in carrying their pregnancies to term. [55] Major complications of therapy include hepatitis and allergic reactions. Rarely, treatment with cryoprecipitate is followed by allergic reaction and

development of antifibrinogen antibodies. [33] [56] Some patients undergoing therapy have experienced thrombosis. [41] [42] [43] In cases of mild bleeding or bleeding during minor surgical procedures, treatment can be instituted by replacing one-third of the patient's estimated plasma volume with normal plasma.

Congenital Dysfibrinogenemia

Congenital dysfibrinogenemia is characterized by the biosynthesis of a structurally abnormal fibrinogen molecule that exhibits altered functional properties and commonly exhibits an abnormal thrombin-mediated conversion to fibrin. The various mutants described carry the name of the city of origin of the patient initially affected with a particular dysfibrinogenemia. [57] Since the description of the first family with dysfibrinogenemia, fibrinogen Paris, [58] in 1964, more than 250 families with abnormal fibrinogens have been reported. [59] [60] Roughly 60% of all cases exhibit no clinical manifestations, whereas hemorrhage occurs in 28%, thrombosis in 20%, and hemorrhage and thrombosis in 2% of the cases. The abnormal fibrinogen has been rarely associated with impaired wound healing or spontaneous abortion. [59]

In more than 83 of these fibrinogen mutants, the molecular structural defect has been identified. [59] [60] Approximately 55 mutations involve FPA and FPB and areas surrounding their cleavage sites, and approximately 20 variants involve the polymerization region of the -chain. In another 5 mutations, other regions of the fibrinogen molecule are involved.[59] [60] One of the aims of the study of dysfibrinogenemias is to correlate structural abnormalities of the fibrinogen molecule with functional alterations that may or may not exhibit clinical symptoms. However, this type of correlation is often hampered by inadequate knowledge concerning the molecular aberration of fibrinogen. Furthermore, clinical manifestations such as mild post-traumatic bleeding or single episodes of thrombosis may be unrelated to the presence of the abnormal fibrinogen.

Functional defects are usually reflected as abnormalities in one or more phases of the fibrinogen-to-fibrin conversion. These include: (1) impaired release of fibrinopeptides, (2) defects in fibrin polymerization, or (3) failure of the polymerized fibrin to undergo normal covalent stabilization by factor XIIIa. In addition, abnormal fibrinogens that do not support proper assembly of the fibrinolytic system or that interact abnormally with platelets, endothelial cells, or calcium have also been described (see later discussion).

In the following discussion, congenital fibrinogen disorders are classified on the basis of the most prominent functional abnormalities of the mutant molecules. Only those abnormal fibrinogens with known structural defects and very distinct functional or clinical properties are discussed. For a more complete listing of the many dysfibrinogenemias described, the reader is referred to recent reviews. [59]

Biochemical Abnormalities and Clinical Manifestations

Congenital Dysfibrinogenemia with Abnormal Fibrinopeptide Release

The proteolytic phase of fibrinogen conversion to fibrin can be studied by a detailed analysis of the rate of release of FPA and FPB by thrombin or by snake venom enzymes that specifically cleave either A or B fibrinopeptides. The rates of cleavage can be followed by radioimmunoassays specific for each fibrinopeptide or by high-performance liquid chromatography. In some of the abnormal fibrinogens, the fibrinopeptides are not released by thrombin or are released at a slow rate; in others the cleaved fibrinopeptide is structurally abnormal. [60] DNA sequencing also plays an important role in the identification of mutations of the three genes of fibrinogen. In addition to abnormal fibrinopeptide release, some congenital dysfibrinogenemias exhibit secondary delays in fibrin polymerization.

Fibrinogen Bethesda was the first mutant fibrinogen described as showing impaired release of fibrinopeptides, which was associated with a mild bleeding disorder. [61] Fibrinogen Detroit was the first abnormal fibrinogen in which a specific amino acid substitution was identified. [62] The most common mutation site in the fibrinogen molecule is Arg16 of the A-chain (Table 112-1). Because thrombin cleaves the Arg16-Gly17 bond, the release of FPA from these mutant molecules is impaired. Two different substitutions have thus far been reported to occur at this position. Most commonly, Arg16 is replaced by His, forming a bond that is not cleaved by reptilase. Almost as frequent, Arg16 is substituted by Cys, and this bond is resistant to thrombin cleavage (Table 112-1). The replacement of Arg by Cys changes the structure of the N-terminus of the mutant by forming an additional intramolecular A Cys16-A Cys16 disulfide bond. [63]

Most patients with Arg16 substitutions are heterozygous. However, homozygous cases involving the two different substitutions at the Arg thrombin cleavage site manifest hemorrhagic disorders,[64] as exemplified by fibrinogens Metz, [75] [76] Giessen I,[69] [70] and Bicêtre.[68] Some heterozygous individuals also have had bleeding symptoms due, for example, to fibrinogens Birmingham I, but this mutant was associated with abnormal von Willebrand factor. [72] Heterozygous individuals with approximately 50% normal fibrinogen should not have bleeding manifestations, but most of these mutants inhibit the conversion of the normal fibrinogen to fibrin, and this inhibition may play a role in the bleeding tendency.

Fibrinogens Detroit [16] [62] and Munich[59] [79] involve substitutions at A Arg19 by Ser and Asn, respectively; in another mutantfibrinogen Mannheim [80] A Arg19 is substituted by Gly. Substitutions at A Arg19 are usually associated with hemorrhagic tendency. Because this area of the -chain is involved in fibrin polymerization subsequent to FPA release, these mutants show a marked delay in the rate of fibrin polymerization. The delayed release of FPB reported for fibrinogen Detroit probably occurs secondary to defective polymerization related to the Arg19 substitution. [16] Three mutants with substitutions within fibrinopeptide A (Table 112-1)fibrinogens Lille, Rouen, and Mitaka IImanifest defective cleavage of FPA, [65] [66] [67] which is probably due to impaired binding of thrombin to this region of the A-chain.[81]

Abnormal cleavage of fibrinopeptides has also been observed in fibrinogen mutations involving the N-terminal region of the B-chain. A unique abnormality is present in fibrinogen New York, characterized by the slow release of FPA and a 50% decrease in total release of FPB, associated with delayed polymerization. The biochemical defect is a deletion of amino acids 9 through 72 of the B-chain, a segment that includes part of FPB (amino acids 114) and of a plasmin-derived peptide (amino acids 142). Transcriptionally, the deleted segment of the polypeptide corresponds to exon 2 of the B-chain gene. [83] The clinical expression of this abnormal fibrinogen is a tendency to thrombosis [82] (see following). Fibrinogen Ijmuiden[59] [84] has a substitution at the thrombin cleavage site Arg14-Gly15 and is replaced by Cys of the B-chain, resulting in a 50% decrease in total FPB release, thereby indicating a heterozygous condition. The additional cysteines present in the mutant either form disulfide bridges between fibrinogen and albumin or remain as free sulfhydryl groups. [84] These mutants show delayed fibrin polymerization, which confirms a role for the exposure of a polymerization site in the B-chain subsequent to the cleavage of FPB. [17] The examples described above illustrate the relationship between cleavage of fibrinopeptides and fibrin polymerization. Several members of fibrinogen Naples (same family as Milano II) were affected by venous and arterial thromboses. Characterization of the abnormal fibrinogen by DNA analysis shows a mutation GCT to ACT, which results in the substitution of B Ala68 by Thr. [86] [87] [88] The possible correlation between defective

thrombin binding and thrombosis is discussed in the following sections.

Congenital Dysfibrinogenemias with Polymerization Defects

In this group, the abnormal fibrinogens exhibit a primary delay in fibrin polymerization without an obvious abnormality in fibrinopeptide release. Although the patients show an increased tendency to hemorrhage, some present with thrombosis, spontaneous abortion, or rarely, wound dehiscence. The structural aberrations usually occur in the N- or C-terminal regions of the A- and B-chains or toward the C-terminal regions of the -chains (Table 112-2). The first group is exemplified by fibrinogen Kyoto II, in which the A Pro18 is replaced by Leu.[89] Mutations toward the C-terminus affect fibrin polymerization as shown in fibrinogen Lima, a homozygous A Arg141-Ser mutant associated with a mild bleeding disorder.[90] Fibrinogen Lima and Caracas II[91] represent two of several dysfibrinogenemias where an amino acid substitution results in the formation of a new consensus sequence for the attachment of an additional N-linked oligosaccharide (Table 112-2). In the case of fibrinogen Lima, the polymerization defect appears to be due to an increased content of sialic acid because the removal of this monosaccharide markedly improved the rate of fibrin polymerization. Increased content of sialic acid, although without additional N-linked oligosaccharides, has been previously demonstrated to be responsible for the functional abnormality of the dysfibrinogenemia of liver disease (see Acquired Abnormalities of Dysfibrinogenemias). In fibrinogen Dusart (Paris V) and Chapel Hill III, the A Arg 554 is replaced by Cys, resulting in the formation of disulfide bonds that link fibrinogen to albumin. [92] [93] [94] [95] [96] [97] The linkage of albumin to fibrinogen is possibly responsible for inhibition of fibrin polymerization, decrease in plasminogen binding, and results in defective t-PA-induced activation of bound plasminogen. It is likely that the defect in the assembly and activation of the fibrinolytic system on the mutant fibrinogen is responsible for the severe thrombotic tendency of the affected individuals.[92] [93] [94] [95] [96] [97] Fibrinogen Milano III is characterized by a mutation after A 451 resulting in a frame shift that codes for insertion of two new residues, Trp452 and Ser453, which terminates the chain.[98] The propositus is a homozygous for this mutation and presented with venous thrombosis.

Fibrinogens Nijmegen and Pontoise involve mutations of the B-chain. In fibrinogen Nijmegen, B Arg64 is replaced by Cys, resulting in complexation with albumin and other proteins. A portion of mutant molecules contain free sulfhydryl groups.[84] [99] The formation of fibrinogen-protein complexes along with the free sulfhydryl groups could account for the observed alterations in fibrin polymerization and t-PA-induced activation of plasminogen bound to the mutant. [99] In fibrinogen Pontoise, B Ala335 is replaced by Thr,[100] resulting in the expression of a new N-linked glycosylation site because Asn is present at position 333.

Mutations in the -chain are more common than mutations of the B-chain. These include an Arg275 substitution for His, or by Cys, which occurs in several abnormal fibrinogens, and these substitutions at Arg275 may interfere with the longitudinal DD contacts formed during fibrin polymerization [23] (Table 112-2). Substitution of Arg275 for His is associated with bleeding or thrombosis or is clinically silent. Substitution of Arg for Cys does not lead to clinical manifestations. Several substitutions of the -chain involve the polymerization pocket,[24] as seen in fibrinogen Nagoya, Milano I, Kyoto III, Matsumoto I, and Osaka V (Table 112-2). Mutation at Met310 with Thr in fibrinogen Asahi I introduces a new consensus for an additional N-linked glycosylation site at Asn308. [111] [112] The bleeding disorder may be due to the additional oligosaccharide that could be responsible for inhibiting fibrin polymerization and cross-linking. Certain dysfibrinogenemias are structurally characterized by deletions or elongation of the -chain. The prototype of this group is fibrinogen Paris I, a mutant in which the elongated -chain is responsible both for delayed polymerization and for abnormal factor XIIIa-mediated cross-linking. [117] [118] Fibrinogen Vlissingen is structurally characterized by a six-base deletion encoding amino acids Asn319 and Asp320.[113] This mutant exhibits defects in fibrin polymerization and calcium binding. Clinically, it appears to be associated with thrombotic tendency.[113]

Congenital Dysfibrinogenemia with Alterations of Cross-linking

Although there are no abnormal fibrinogens characterized exclusively by defective factor XIIIa-mediated cross-linking,

[b] Homozygous.

several mutants exhibit defective cross-linking in addition to abnormalities of fibrinopeptide release or fibrin polymerization. A noted example is fibrinogen Paris I, which exhibits defective -chain cross-linking along with delayed polymerization. Both of these functional abnormalities are the result of the extended -chain. [117] [118] Fibrinogen Asahi I contains additional N-linked carbohydrate in the C-terminus of the -chain and also shows a delay in the formation of cross-linking. [111] [112] Fibrinogen Marburg also exhibits defective cross-linking of the -chains due to truncation of the C-terminal region of the A-chain (see following discussion). In contrast,

fibrinogen Dusart shows an increase rate of -chain cross-linking, an abnormality that may contribute to the thrombotic tendency. [119]

Congenital Hypodysfibrinogenemias

Congenital hypodysfibrinogenemia includes those cases in which structurally abnormal fibrinogens with altered functional activity are present with total plasma fibrinogen concentrations arbitrarily defined as below 150 mg/dl as measured immunologically or by other physicochemical methods. Measurements of clottable protein are not reliable because the abnormal molecules do not always incorporate into the clot. About 15 hypodysfibrinogenemias have been fairly well characterized, and the functional properties and clinical expression of some of these mutants are presented in Table 112-3 . In the first clear case of hypodysfibrinogenemia, involving fibrinogen Parma, [120] the patient had a severe bleeding disorder that was corrected by the infusion of normal fibrinogen, which seemed to exhibit a normal plasma survival. On the other hand, fibrinogens Philadelphia [15] and Bethesda III[121] have almost identical properties including normal fibrinopeptide release, defective fibrin polymerization, and increased catabolic rate of the autologous protein but normal survival of the homologous protein. These findings indicate that an intrinsic molecular defect of the mutant fibrinogen is responsible for the observed hypercatabolism leading to the hypofibrinogenemia.

In contrast, patients with fibrinogen Giessen II show decreased survival of the homologous (normal) protein, indicating an extrinsic (plasmin-like) factor is responsible for mediating

the hypercatabolism of fibrinogen.[122] Fibrinogens Chapel Hill I [123] and Baltimore II[124] also show normal survival of both the homologous and autologous proteins, indicating that a low biosynthetic rate or impaired secretion is responsible for the hypofibrinogenemia. Fibrinogen Marburg is structurally characterized by deletion after amino acid 461-Lys of the A-chain as the result of a single base substitution A to T, forming TAA stop codon. [125] The mutant fibrinogen exhibits delayed fibrin polymerization and appears to be disulfide linked to albumin. The abnormal protein did not support the attachment of endothelial cells, suggesting that the RGD peptide of the C-terminus of the normal A-chain is important in this process. [125] Fibrinogen Otago exhibits a truncated A-chain at residue 271, caused by a cytosine insertion at A 268 producing a frame shift that translates into three new amino acids 268270 and stop codon at 271. Functionally, this mutant is characterized by severe hypofibrinogenemia and abnormal fibrin polymerization. Clinically, the major manifestations were abortions and impaired wound healing, [126] abnormalities that are also expressed by patients with severe hypofibrinogenemia.

The functional defect in hypodysfibrinogenemias is heterogenous; delayed fibrin polymerization is the predominant defect, but abnormal release of fibrinopeptides is also seen (Table 112-3). The major clinical expression in hypodysfibrinogenemia is bleeding, but repeated spontaneous abortions and thrombosis have also been reported (Table 112-3).

Pathogenesis of Thrombosis and Delayed Wound Healing in Dysfibrinogenemias

Approximately 45 dysfibrinogenemias that predispose to arterial or venous thrombosis have been described. Although some of the affected individuals experienced isolated thrombotic episodes, these may have been unrelated to the abnormal fibrinogen. [59] [64] In other cases, frequent episodes of arterial or venous thrombosis in a particular patient or in several of the affected family members suggest a causal relationship. Although the mechanisms by which the abnormal fibrinogens promote thrombus formation are largely unknown, analysis of the biochemical properties of the mutant molecules may offer some clues. Several mutant fibrinogens have an impaired ability to bind thrombin, and the excess free thrombin is available to interact with normal fibrinogen molecules or to induce platelet activation, leading to the formation of platelet aggregates. Fibrinogens New York, [82] [83] Naples,[86] [87] [88] and Pamplona II,[127] which also exhibits impaired release of FPB, belong to this group. In other cases, increased thrombosis may be the result of defective fibrinolysis as a result of impaired plasminogen activation or increased resistance of the mutant molecule to cleavage by plasmin. Indeed, fibrinogens Dusart and Chapel Hill III, [92] [93] [94] [95] [96] [97] Nijmegen,[84] [99] Ijmuiden,[84] and Pamplona II[127] exhibit decrease plasminogen binding and defective t-PA activation of the bound plasminogen. Although these mutants also show abnormal conversion of fibrinogen to fibrin, their thrombotic tendency may be related to the defective assembly or activation of the fibrinolytic system.

Other clinical manifestations of dysfibrinogenemias include delayed wound healing and wound dehiscence, as reported for fibrinogens Paris I, [117] [118] Cleveland I,[128] Caracas I,[129] and Otago.[126] The abnormal factor XIIIa-mediated cross-linking of these mutants and the resulting decreased strength of the clots may be responsible for the healing abnormalities. Patients with factor XIII deficiency also manifest defects of the healing process. Recurrent spontaneous abortions (mainly in the first trimester) associated with bleeding or thrombosis have also been reported in several dysfibrinogenemias (Tables 112-1 , 112-2 , and 112-3).

Laboratory Tests

Abnormalities in routine coagulation assays, particularly the PT or PTT, usually provide the first evidence for the presence of an abnormal fibrinogen. The PT is more sensitive than the PTT, but an even more sensitive and specific test is the thrombin time, which in some patients is so prolonged that a visible clot never forms. The reptilase and ancrod times are also useful diagnostic tests when dysfibrinogenemia is suspected. [59] [64] Measurement of the plasma fibrinogen concentration in patients with dysfibrinogenemia can give variable results depending on the type of analytic method used. Frequently, the fibrinogen concentration appears low when measured as clottable protein, especially when methods based on the rate of fibrin formation are utilized. [59] [64] This may be due to the fact that several of the abnormal fibrinogens have an inhibitory effect on the clotting of normal plasma. Furthermore, because the abnormal fibrinogen may not be incorporated into the clot, the soluble molecules that remain in serum can be mistaken for fibrin degradation

products, which thereby leads to the misdiagnosis of an active fibrinolytic system, as in disseminated intravascular coagulation (DIC). In most cases of dysfibrinogenemia, the plasma fibrinogen concentration is actually normal when measured immunologically, and the discrepancy between clottable protein and

immunologically measured fibrinogen is a characteristic feature of dysfibrinogenemia. In some instances, however, the abnormal fibrinogen is in fact present in low amounts, as in the hypodysfibrinogenemias.

Inheritance

Although the vast majority of dysfibrinogenemias are heterozygous, the homozygous condition with no normal fibrinogen has been documented in 11 families. In the case of fibrinogen Metz, the parents were consanguineous and the condition in the propositus was homozygous. [75] [76] Similar findings have been reported for fibrinogen Detroit[16] [62] among others. Some mutants release only 50% of either FPA or FPB.[59] [60] In other instances, the amino acid substitution is also present in half of the molecules.[59] [60] Using immunologic, electrophoretic, and chromatographic methods, two distinct populations of fibrinogen have been identified in several mutants.[60]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

ACQUIRED ABNORMALITIES OF FIBRINOGEN

Acquired abnormalities of fibrinogen may be classified into three groups: (1) hyperfibrinogenemia, (2) hypofibrinogenemia, and (3) dysfibrinogenemia.

Hyperfibrinogenemia

Plasma fibrinogen levels increase significantly with age, with lifestyle habits such as cigarette smoking, and in certain pathologic conditions such as hypertension, obesity, and diabetes mellitus.[130] [131] [132] [133] However, even among normal individuals, the plasma fibrinogen concentration varies, and although the exact regulatory mechanisms are not elucidated, recent studies indicate that in part fibrinogen levels may be genetically controlled. For example, high plasma fibrinogen concentrations have been observed in normal individuals exhibiting a specific nucleotide sequence polymorphism at the 5 untranslated region of the B gene. [134] [135] However, this polymorphic site is only present in a minority of the population. [134] [135] In contrast, fibrinogen behaves as an acute-phase reactant protein; therefore, its concentration is sensitive to inflammatory responses.[136] In this process, the release of interleukin-6 by macrophages leads to an increase in transcription of the B-gene, resulting in elevated levels of fibrinogen. [137] [138]

The concentration of plasma fibrinogen has important clinical implications, as indicated by several studies demonstrating that hyperfibrinogenemia is an independent risk factor in stroke and in ischemic heart disease. [139] [140] [141] [142] For example, plasma fibrinogen concentration in the upper third of the population increased the risk of ischemic heart disease threefold when compared with those in the lower third of the population. [139] Even small increments in the level of fibrinogen such as one standard deviation (0.6 mg/ml) above the mean markedly increase the risk of ischemic heart disease. [139] When other risk factors for ischemic heart disease and stroke such as hypertension, serum cholesterol, age, diabetes, and smoking were considered, high levels of fibrinogen were still evident as an important risk factor. [139] [140] [141] [142] The pathophysiologic mechanisms by which elevated fibrinogen causes vascular damage is unknown, [143] [144] and it is possible that the high concentration of plasma fibrinogen may be due to cytokines released from areas of vascular damage. In this case, hyperfibrinogenemia can be considered to be a marker of the disease and may not play a role as a causative agent in the development of vascular damage. [143] [144] The high levels of plasma fibrinogen can be part of the inflammatory response, and an increase in fibrinogen levels may be similar to the observed increase in C-reactive protein, as recently reported to occur in patients with coronary vascular disease.[145] Other studies also showed that individuals with the genetic polymorphism of the B-chain, which may be associated with high levels of plasma fibrinogen, do not show an increased incidence of coronary artery disease, [146] [147] suggesting that hyperfibrinogenemia is not the primary cause of cardiovascular diseases.

Hypofibrinogenemia

Low levels of plasma fibrinogen can be caused by a relative decrease in biosynthesis of this protein by the hepatocyte or by an increased rate of its catabolism. In some clinical disorders, both mechanisms may be involved in the development of hypofibrinogenemia. Normal or increased levels of plasma fibrinogen are common in liver disease, but moderate hypofibrinogenemia (i.e., a fibrinogen level <100 mg/dl) may be present in fulminant hepatic failure or in decompensated liver cirrhosis. [148] The low levels of fibrinogen correlate with mucosal hemorrhage that is unrelated to esophageal varices, which may be present in these patients. [149] In addition, severe hypofibrinogenemia usually carries a poor prognosis.[148] The origin of hypofibrinogenemia in this group of patients is multifactorial. In addition to impaired hepatic fibrinogen synthesis,[150] increased catabolism has been observed.[151] An active fibrinolytic system does not seem to play a crucial role in the development of hypofibrinogenemia because the treatment of these patients with fibrinolytic inhibitors does not significantly change the rate of fibrinogen catabolism. [151] These findings, along with an increase of FPA level and fibrinogen-fibrin degradation products [152] indicate that DIC is a contributing factor in the hypofibrinogenemia of some patients with liver disease. Hypofibrinogenemia is also present in patients with acute or chronic DIC of different etiologies, and a low fibrinogen level should alert the physician about this possibility (Chap. 117).

Other causes of low plasma fibrinogen concentration include the administration of certain drugs; for example, L-asparaginase can induce a severe hypofibrinogenemia, which infrequently can cause bleeding manifestations. [153] [154] [155] [156] Although the treatment with L-asparaginase leads to a decrease in the concentration of several plasma proteins, such as plasminogen and antithrombin III, [157] the levels of fibrinogen are markedly decreased, frequently below 20 mg/dl. [156] In contrast, the concentration of other coagulation factors is normal or slightly decreased. [155] [156] Some clinical studies and experimental work in rabbits indicate that impaired synthesis rather than increased catabolism is the cause of the hypofibrinogenemia in this group of patients. [158] [159] Mild decrease of plasma fibrinogen concentration has also been reported in patients treated with valproic acid. [160]

Dysfibrinogenemias

Diverse diseases affecting the liver parenchyma not only produce quantitative alterations of plasma fibrinogen but may also induce dysfibrinogenemia (Chap. 147). The alteration of functional properties of fibrinogen is the most common cause of dysfibrinogenemia. In severe liver diseases of varied etiology, including liver cirrhosis, viral and toxic hepatitis, approximately 50% of the patients exhibit the characteristic dysfibrinogenemia of liver disease. [161] [162] [163] [164] Patients with hepatoma exhibit the same abnormality.[165] [166] The abnormal fibrinogen is characterized functionally by impaired polymerization of fibrin, which explains the prolongation of the thrombin time. Both the cleavage of fibrinopeptides and the cross-linking of fibrin are normal. [161] [162] [163] [164] [165] [166] The structural defect of this abnormal fibrinogen is an increased

content of carbohydrate and in particular of sialic acid. [167] An increase in galactose and *N*-acetylglucosamine with normal mannose is consistent with increased branching of the oligosaccharides rather than the presence of new carbohydrate linkages. [168] Normalization of the thrombin time and of fibrin monomer polymerization is observed after enzymatic removal of the sialic acid from the abnormal fibrinogen. [167]

It is interesting that normal fetal fibrinogen exhibits biochemical and functional properties similar to those described in the abnormal fibrinogen of liver disease, [169] which suggests the possibility that activation of dormant carbohydrate enzymes in the diseased liver is a factor involved in the increase in carbohydrate content. [170] An abnormal fibrinogen with biochemical and functional properties similar to those found in patients with liver disease has been described in hypernephroma as part of the paraneoplastic syndrome; this abnormality abated after removal of the tumor but appeared again with the presence of metastasis. [171]

Functional abnormalities of fibrinogen can be secondary to fibrinogen autoantibodies. An inhibition of the release of fibrinopeptides by thrombin was described in a young female with a mild bleeding disorder. The isolated inhibitor was identified as an antibody of the IgG class that specifically interfered with the interaction of thrombin with fibrinogen but did not interfere with other functional activities of this enzyme. [172] Antibodies of the IgG class able to impair the polymerization of fibrin monomers have been described in association with systemic lupus erythematosus and also in a patient with ulcerative colitis and postnecrotic liver cirrhosis or without underlying disorder. [173] [174] Although some of these patients exhibit bleeding manifestations, [172] [174] in others the presence of the antibody was associated with

thrombosis,[173] but the thrombosis could be related to some other coagulation abnormality, such as lupus anticoagulant, rather than to the fibrinogen antibody. [173] Similarly, thrombotic episodes have been observed in several patients with systemic lupus erythematosus and prolonged thrombin time. [64] A third type of an IgG antibody with specificity against the cross-linking sites of fibrinogen and normal factor XIII activity was described in a patient with sarcoidosis treated with isoniazid. This antibody seemed to be responsible for the patient's mild bleeding disorder. [175]

The monoclonal immunoglobulin of multiple myeloma can prolong the thrombin time by inhibiting fibrin monomer polymerization (Chap. 118).[64] [176] [177] Although this effect is mediated by the $F(ab)_2$ fragment of the monoclonal protein, a specific antibody-antigen reaction between the monoclonal and fibrinogen has not been demonstrated. Thus, in addition to acting as specific antibodies to fibrinogen, as discussed above, [175] immunoglobulins may also act by some other as yet undefined mechanism.[64] [176] [177] [178] Some of these interactions may lead to clinical manifestations, but most frequently they are clinically silent.

In patients with active bleeding due to paraproteinemias, extensive plasma exchange seems to improve the hemorrhagic tendency. [178] Abnormal thrombin- or reptilase-induced ability of fibrinogen to clot has been noted in about 40% of patients with systemic light chain amyloidosis. [179] The isolated fibrinogen molecule demonstrated normal ability to clot, and an unidentified factor unrelated to the paraproteinemia was responsible for inhibiting the conversion of fibrinogen to fibrin. [179] Defective formation of fibrin by thrombin is also present in patients who have circulating heparin or heparin-like substance. However, in these cases, the addition of protamine to the patient's plasma shortens the thrombin time; in addition, reptilase-induced clotting ability is close to normal. [180] [181] [182] The identification of plasma factors that interfere with thrombin clotting ability of fibrinogen leading to dysfibrinogenemia can be clearly made by examining the functional properties of purified patient fibrinogen.

Cryofibrinogenemia

Cryofibrinogenemia refers to the presence of plasma, of fibrinogen that precipitates at low temperatures, usually at 4°C. The amount of cryofibrinogen present in the precipitate can be variable from traces to 100 mg percent. [184] The cold temperature-induced precipitation of proteins from plasma but not from the serum distinguishes cryofibrinogenemia from cryoglobulinemia, a condition in which proteins, mainly immunoglobulins, precipitate from serum. Cryofibrinogenemia is frequently associated with autoimmune diseases, neoplasms, thrombotic disorders, and infectious processes.[184] [185] This condition can also be present as a primary disorder [186] and can be detected in about 3% of hospitalized patients. [184] [185] Although cryofibrinogenemia is clinically silent in the majority of cases, in some patients it can cause cold hypersensitivity, cutaneous ulcerations, peripheral gangrene, and arterial or venous thrombosis. [184] [185] The cause of ulcerations and peripheral gangrene seems to be secondary to intravascular deposition of fibrin(ogen) in small arteries and arterioles, without evidence of vasculitis. [187] Several studies have demonstrated that the plasma cryoprecipitate is composed of fibrinogen-fibrin and fibronectin, and it appears that all three components are necessary for in vitro cryoprecipitation. [188] Although the natural history of this disorder is not known, it seems that some patients have spontaneous remission, whereas in others the disease progresses, requiring therapeutic intervention. Anticoagulation with heparin or coumadin appears to be effective in some cases. [186] Steroids and immunosuppressive drugs have also been used in patients who do not respond to other forms of therapy. [187] In patients with severe manifestations, such as peripheral gangrene, plasmapheresis induced a temporary improvement.[189] A marked resolution of the cutaneous manifestations of cryofibrinogenemia was observed in seven patients after treatment with stanozolol,[190] an agent that increases fibrinolytic activity. Cryofibrinogenemia should be suspected in patients with cold sensitivity and peripheral ischemia, especially with skin ulcerations, and in patients who do not have other causes for vascular occlusion.

PROGNOSIS AND TREATMENT

The majority of patients with congenital dysfibrinogenemia are asymptomatic and do not require treatment. Active bleeding can be corrected with replacement therapy; and in those patients with a history of bleeding, replacement therapy can be instituted before surgery or procedures that involve a high risk of hemorrhage. Replacement therapy using plasma or cryoprecipitate can be prescribed according to the guidelines outlined in the afibrinogenemia section. It appears that thrombotic complications have led to the death of several patients. In patients who present with thrombosis, anticoagulant therapy should be recommended on the basis of criteria similar to those of other hypercoagulable states. Recurrent spontaneous abortions have been reported in several families, but continuous replacement of fibrinogen in the form of cryoprecipitate may permit full-term pregnancy. [126]

Chapter 113 - Structure, Biology, and Genetics of von Willebrand Factor

David Ginsburg
Denisa D. Wagner

INTRODUCTION

The adhesive glycoprotein von Willebrand factor (vWF) was named after Dr. Erich von Willebrand, who described in 1926 a new bleeding disorder [1] distinct from hemophilia. von Willebrand disease (vWD) was later recognized to be caused by qualitative or quantitative defects in vWF. [2] vWF circulates in plasma at concentrations of 510 g/ml. Some of the molecules are complexed with factor VIII, apparently protecting factor VIII against degradation. [3] vWF is synthesized by only two cell types: endothelial cells and megakaryocytes. [4] [5] [6] Besides plasma, vWF is found in platelets, endothelial cells, and the basement membrane of blood vessels. [7] All these pools of vWF contribute to the proteins main function: to promote attachment of platelets to areas of vessel injury. To optimize the availability of vWF at the site of injury, a highly active form of the protein is stored in secretory granules of platelets and endothelial cells. [8] When these cells sense tissue injury (e.g., by contact with thrombin), they instantly mobilize the stored protein. The released vWF binds to glycoprotein Ib (GPIb) on the platelet surface [9] [10] [11] [12] and to components of the basement membrane, [13] forming a bridge that can withstand the high sheer stress of blood flow. vWF is necessary for this initial attachment step of platelets to the injured area. [14] Together with other adhesive proteins, such as fibrinogen, fibronectin, and thrombospondin, vWF interacts with the GPIIb/IIIa on activated platelets and contributes to platelet spreading and aggregation. [15] [16] vWF is a large protein composed of many subunits held together covalently by disulfide bonds. [17] In this way, the protein acquires multiple binding sites for platelets and the basement membrane, which may strengthen its interactions during hemostasis.

The vWF Gene

von Willebrand factor cDNA was cloned in 1985. [18] [19] [20] [21] The full-length cDNA sequence predicts a protein of 309,000 molecular weight (2,813 amino acids). In addition, the location of N- and O-linked glycosylation sites within the mature vWF subunit have been determined by direct protein analysis. [22] Comparison of the cDNA and primary amino acid sequences identified a large propeptide (741 amino acids) preceding the mature vWF subunit sequence. This propeptide is identical to a previously observed immunologic activity in plasma termed vW antigen II. This propeptide plays an important role in vWF multimer assembly and processing, but has no known function after secretion. The vWF gene is located on the short arm of human chromosome 12 [18] [20] and a partial, nonfunctional duplication (pseudogene) is on human chromosome 22. [23] The structures of the unusually large vWF gene and pseudogene are shown schematically in Figure 1131 . [24] [25] The gene is composed of 52 exons spanning a total of approximately 180 kb of the human genome. It is similar in size to the factor VIII gene (Chap. 107) and >100 times larger than the gene for -globin (Chap. 29). The vWF gene accounts for approximately 0.1% of human chromosome 12. The vWF pseudogene duplicates the middle portion of the gene from exon 23 to 34 including the intervening sequences. The pseudogene is approximately 97% homologous to the authentic gene, indicating that it has arisen fairly recently in evolution. [25]

Analysis of the vWF amino acid sequence identifies a pattern of homologous repeated segments, designated by the letters AD in Figure 1131 . This pattern suggests that the vWF gene arose by a complex series of partial gene duplications. The expression of the vWF gene is tightly regulated and restricted exclusively to endothelial cells and megakaryocytes. For this reason, vWF is frequently used as a primary histochemical marker to identify cells of endothelial cell origin. A 734-base pair DNA fragment extending from approximately 500 base pairs upstream of the transcription start site into the first intron confers endothelial cell-specific vWF gene expression in vitro, [26] and directs gene expression to a subpopulation of endothelial cells in transgenic mice. [27] However, as in the case of -globin, another highly tissue-specific regulated gene (Chap. 29), critical transcription regulatory sequences located a great distance from the 5 end of the vWF gene may be required for the high-level expression observed in a wide range of endothelial cells in vivo.

Comparison of the vWF DNA sequence to that of other known genes identifies potential relationship to a number of other adhesive proteins. A superfamily of proteins sharing sequence similarity with vWF A domains contains a number of proteins associated with the extracellular matrix, hemostasis or cell adhesion. [28] The crystal structure of the vWF A3 domain has recently been solved [29] [30] and is remarkably similar to the structure for the homologous I domain of the integrin 2/1, [31] although the metal ion-dependent structure common to at least several I domains is not required for the collagen binding function of the vWF A3 domain. [29] A possible relationship between the C repeats of vWF and segments of thrombospondin and procollagen has also been noted, [32] as well as homology of the D domains to a sperm membrane protein that binds to the extracellular matrix of the egg. [33] [34] [35]

Exons of vWF range in size from 40 base pairs to 1.4 kb for exon 28, one of the larger known single exons. This latter exon encompasses most of the A1 and A2 homologous repeats, a region containing several important vWF functional domains, as well as a large number of human mutations associated with type 2A and 2B vWD.

DOMAIN STRUCTURE

von Willebrand factor exists as a series of multimers varying in molecular weight between 0.5 (dimer) and 20 million (multimer). Electron microscopic observations of the vWF molecules revealed that they are filamentous and contain subunits arranged in a head-to-head and tail-to-tail configuration. [36] [37] The building block of multimers is a dimer, held together by disulfide bond(s) located near the C-terminal end of each subunit. The dimers are joined to each other by disulfide bonds located near the N-terminal end of the mature subunit. [38] [39] The mature subunit has a mass of about 270 kd and contains 18.7% carbohydrate. [22] N- and O-linked carbohydrates are found clustered at both ends of the subunit. All 169 cysteine residues (8.2% of the amino acid content) are involved in interchain or intrachain

Figure 113-1 The structure of the vWF gene and protein. The structures of the vWF gene and pseudogene are indicated schematically at the top of the figure. The corresponding protein is also depicted, including the homologous repeat domain structure. The localization within vWF of point mutations associated with vWD variants are also indicated. *(Adapted from Ginsburg and Bowie, [126] with permission.)*

disulfide bonds. [40] [41] Two Arg-Gly-Asp (RGD) sequences are found in pro-vWF (Fig. 1131). The one on vWF is a part of the binding site for the platelet integrin receptor, GPIIb/IIIa. [16] The significance of the other RGD sequence located on the propeptide is not known (Fig. 1131).

Several functional domains in vWF have been identified on the vWF subunit [42] (Fig. 1131). Two collagen-binding sites have been mapped to the mature vWF subunit [43] [44] and potentially a third to the propeptide. [45] However, studies of recombinant vWF suggest that the major physiologically active binding site for fibrillar collagen lies within the A3 domain. [46] [47] vWF also has at least two binding sites for heparin [48] [49] and may interact with heparin-like molecules in the basement membrane. The factor VIII-binding domain is located in the N-terminal portion of the vWF subunit [50] and interacts with the N-terminal portion of the factor VIII light chain. [51] [52] vWF also has affinity for two platelet receptors. Its binding to GPIb plays a pivotal role in the early events of hemostasis, leading to the attachment of platelets to the area of injury. [10] [14] Several potential, short binding sequences for GPIb on vWF have been identified, all localized to a large disulfide loop contained within the vWF A1 repeat [53] [54] (Fig. 1131). This site appears to interact with the N-terminal portion of the -chain of GPIb. [55] The binding region of vWF to GPIIb/IIIa on activated platelets is located in the C-terminal portion of the mature subunit. This recognition site can be specifically inhibited by the Arg-Gly-Asp sequence contained within peptides [56] and is therefore likely to include the Arg-Gly-Asp-Ser sequence. [16] [57] vWF (with other adhesive proteins such as fibrinogen and fibronectin) may compete for binding to this glycoprotein.

BIOSYNTHESIS

The processing steps leading to the formation of mature vWF multimers have been studied chiefly in endothelial cells, [58] but evaluation of megakaryocyte biosynthesis indicates an identical pattern of synthesis [6] (Fig. 1132). vWF is first synthesized as a pro-vWF monomer. [59] [60] [61] Co-translationally, high-mannose carbohydrate is added to the polypeptide chain. There are 13 potential N-linked glycosylation sites on mature vWF and 4 on

Figure 113-2 Map of processing steps in the biosynthesis of vWF. Interchain disulfide bonds are formed in two steps (dimerization and multimerization, pink). The propeptide is cleaved late in vWF processing (prosequence cleavage, red). *(Adapted from Handin and Wagner,[7] with permission.)*

the propeptide. While residing within the endoplasmic reticulum, the C-termini of the pro-vWF subunits are linked together by an unknown number of disulfide bonds.[62] If initial glycosylation is inhibited by the drug tunicamycin, the protein remains monomeric. The monomeric protein synthesized in the presence of tunicamycin is internally degraded and is not secreted from the cells. [63] Only dimeric molecules are transported to the Golgi apparatus, where their processing continues.

In the Golgi apparatus, common modifications, including the addition of O-linked carbohydrate, high-mannose carbohydrate processing, and sulfation, take place (Fig. 1132). In addition, a unique processing event includes the multimerization of dimers by disulfide bond formation. [7] vWF is the only protein known that has disulfide bonds formed late in protein synthesis, as disulfide bonds are usually formed in the endoplasmic reticulum. The latter process is catalyzed by the enzyme disulfide isomerase.[64] The contents of the last compartment of the Golgi apparatus (trans-Golgi) and the post-Golgi secretory vesicles are slightly acidic. [65] It is likely that multimerization occurs in these acidic compartments because this process can be completely inhibited by culturing cells in the presence of a weak base [63] that increases the pH of acidic cellular compartments. The vWF propeptide plays an active role in the interdimer disulfide bond formation. When prepro-vWF cDNA is expressed in COS (a monkey kidney cell line) or other cells that normally do not synthesize vWF, these cells are capable of supporting vWF multimerization. By contrast, if pre-vWF cDNA (with the cDNA coding for the propeptide deleted) is expressed in these cells, only dimeric molecules are synthesized and secreted. [66] [67] In in vitro multimerization experiments, pro-vWF dimers spontaneously form larger multimers, whereas vWF mature dimers remain dimeric. The in vitro multimerization is promoted by a slightly acidic environment (optimal pH is 5.8) and will not occur at a neutral or basic pH. [68] Under these acidic pH conditions the propeptide may catalyze disulfide bond formation among the mature vWF subunits. The propeptide contains sequences similar to those found at the active site of protein disulfide isomerase. These are cysteines separated by two amino acids that readily interchange with disulfide bonds in the substrate. When an additional amino acid was inserted between the cysteines of the propeptide by site specific mutagenesis, the vWF expressed did not form multimers. [69] During the biosynthesis of vWF multimers, the propeptide does self-associate, but it is not known whether this association is linked to noncovalent multimer assembly that likely precedes the interchain disulfide bond formation. [70]

The propeptide cleavage is one of the final processing steps in the biosynthesis of vWF. Similar to other prosequences, the vWF propeptide is cleaved adjacent to two basic amino acids, Lys-Arg at residues 2 and 1. An Arg at 4 position from the cleavage site is also part of the cleavage recognition sequence, providing evidence that an enzyme with furin/PACE-like specificity is responsible for the intracellular prosequence cleavage. [71] Multimerization and propeptide cleavage are separate events. Multimers secreted by endothelial cells in culture contain both pro-vWF and mature vWF subunits. [61] [72] Also, the culturing of endothelial cells in the presence of weak bases inhibits multimerization completely, whereas propeptide cleavage is only slightly affected. [63] Finally, site-specific mutagenesis of the cleavage site inhibits propeptide cleavage, but the expressed protein has a normal multimeric composition. [73] Propeptide cleavage and multimerization occur after sulfation in the trans-Golgi network, but prior to formation of the Weibel-Palade body. [74]

Although vWF processing is chiefly intracellular, some modifications to the protein likely occur after secretion. Cleavage of the propeptide, which begins in the trans-Golgi compartment, may continue extracellularly. This hypothesis is based on the observation that vWF in normal plasma is composed of only mature subunits, whereas vWF secreted constitutively from endothelial cells in culture contains both pro-vWF and mature subunits. [61] [72] The largest vWF multimers found in plasma are smaller than those found in endothelial cells. [75] A plasma protease has recently been defined that appears to specifically cleave vWF in the circulation, resulting in reduction of unusually large multimers to smaller species. [76] [77] The major proteolytic cleavage site for vWF in plasma maps to the peptide bond between Tyr 842 and Met 843 in the vWF A2 domain,[78] and recombinant vWF deleted in the A2 domain is resistant to proteolysis. [79] Mutant vWF in group II type 2A vWD exhibits increased susceptibility to cleavage by this protease, [80] the proposed mechanism for loss of large vWF multimers in this disorder. In addition, a deficiency of this protease activity has been proposed to play a role in the pathogenesis of chronic relapsing thrombotic thrombocytopenic purpura. [81]

VON WILLEBRAND FACTOR STORAGE AND SECRETION

von Willebrand factor is the only known adhesive protein that is stored and undergoes regulated secretion from cells other than platelets. [58] Both the platelet pool and the endothelial pool of vWF are important physiologically, as demonstrated by crossed bone marrow transplantation experiments between normal and vWD pigs. [82] [83] In platelets, vWF is present in the -granules with many other stored proteins. In the Weibel-Palade bodies of endothelial cells, only vWF and its propeptide are found. [84] [85] [86] In both organelles, the stored vWF molecules appear to form tubular structures, 150 A in diameter. [87] [88] These tubules are absent in the -granules of pigs with vWD. [89] A transmembrane glycoprotein of the -granule, P-selectin, [90] [91] is a component of the Weibel-Palade body membrane. [92] Like vWF, the biosynthesis of this protein is restricted to endothelial cells and to megakaryocytes. When expressed on the plasma membrane, P-selectin promotes the adhesion of monocytes, neutrophils, and some other subsets of leukocytes. [93] [94] The only other recognized component of Weibel-Palade bodies is CD63, a highly glycosylated protein found in lysosomes, which is also expressed on activated platelets. [95] [96] Weibel-Palade bodies originate from the Golgi apparatus. They are up to 4 m long and 0.1 m thick (Fig. 1133) and are found in endothelial cells of virtually all blood vessels types. There is, however, variation in the number of Weibel-Palade bodies per cell in endothelium of different origin. [8]

Fully processed vWF is secreted from cultured endothelial cells by one of two pathways. [97] The constitutive pathway is directly coupled to vWF synthesis and occurs without stimulation. The regulated pathway, involving vWF stored in Weibel-Palade bodies, is initiated by the action of secretagogues. The two pathways differ in that the regulated pathway depends on the microtubular cytoskeleton, while constitutive secretion continues even from cells with depolymerized microtubules. [98] Constitutive secretion occurs evenly in an apical and basolateral direction. By contrast, release from Weibel-Palade bodies is highly polarized in the basolateral direction. Formation of thrombin and fibrin during vascular injury disrupts the endothelial monolayer, which may lead to the release of stored vWF into the lumen. [99] Another important difference between the two pathways is the biologic activity of the vWF secreted. Although mostly small multimers are secreted constitutively, only the largest, biologically most potent multimers are stored in Weibel-Palade bodies [86] [100] (Fig. 1134). It is not known whether the large multimers are selected for storage or whether the conditions found in the Weibel-Palade body promote multimer assembly. The vWF stored in platelet -granules is also enriched in large multimers. [101] All the N-terminal D domains (D1D3) appear to be necessary for vWF storage. Deletions of these individual domains lead to constitutive secretion of the expressed protein. [102] [103] Although the propolypeptide remains in the

Weibel-Palade bodies noncovalently associated with the mature subunit, [74] cleavage of the prosequence has to occur for efficient formation of the storage granules. [104] The biologic function of the two secretory pathways may be different. The small multimers secreted constitutively may be used as carrier proteins for factor VIII; the largest multimers released from Weibel-Palade bodies at the time of vascular injury may act to attach platelets and the injured endothelium to the vessel wall. Some of the released large vWF molecules remain associated with the endothelial membrane, [100] likely interacting with integrin-type receptors. [105] The functional significance of this transient membrane pool of vWF is unknown.

Several secretagogues for vWF that may be of physiologic importance include thrombin, [106] fibrin, [107] histamine, [108] and the terminal complement proteins C5b-9. [109] The release of Weibel-Palade bodies appears to be coupled to Ca^{2} + influx. Thrombin activity as a secretagogue is related to its proteolytic activity and the cleavage of a specific receptor. [97] [106] [110] Interaction with a cellular receptor is a likely mechanism for fibrin release of vWF. A specific N-terminal fragment of the fibrin -chain appears

Figure 113-3 Weibel-Palade bodies of endothelial cells. **(A)** Immunofluorescence staining of a human umbilical vein endothelial cell with anti-vWF antiserum. vWF is present in the perinuclear region, where it is synthesized and in the Weibel-Palade bodies (arrowhead) throughout the cytoplasm. Bar = 10 m. **(B)** Electron micrograph of Weibel-Palade bodies of the same origin. Bar = 0.5 m.

Figure 113-4 Multimeric composition of vWF secreted by endothelial cells in culture. Human umbilical vein endothelial cells were metabolically labeled with ^{35}S-methionine and the constitutively secreted protein () and that released during a 10-minute treatment with the secretagogue A23187(+) were purified and analyzed nonreduced on an agarose gel. The autoradiograph of the gel is shown. The protein secreted constitutively is composed predominantly of small multimers, while the vWF secreted from Weibel-Palade bodies is only of high molecular weight (HMW multimers). *(Adapted from Sporn et al., [100] with permission.)*

to interact with the endothelium. [111] Histamine-induced release can be blocked by histamine H_1 -receptor antagonists. [108] None of the vasoactive agents that cause the rapid rise in levels of vWF in plasma, including 1-deamino-8- D-arginine, vasopressin (DDAVP), causes vWF release from endothelial cells in vitro. [112] It is likely that these agents act through an as yet unknown intermediate. This hypothesis is supported by the observation that plasma from DDAVP-treated normal subjects stimulates release of vWF from cultured endothelial cells. [113] vWF is an unusual molecule in that it interacts specifically with two types of transmembrane receptors: the GPIb receptor of platelets and the integrin-type receptors, such as the GPIIb/IIIa complex on platelets and the vitronectin receptor on endothelial cells. Binding to these receptors is enhanced by the presence of large numbers of binding sites on the vWF multimers. The adhesive activity of the very large multimers is so great that they are kept sequestered in storage organelles and are rapidly released locally at the site of vascular injury.

VON WILLEBRAND DISEASE

Molecular Genetics

With the availability of vWF cDNA and genomic sequences, a molecular genetic approach to the characterization of vWD became possible. Southern blot analysis identified large gene deletions as the molecular basis for vWD in a small subset of patients with severe, or type 3, disease. [23] [114] [115] [116] With the advent of the polymerase chain reaction, extensive direct DNA sequence analysis has been conducted on material from patients with a variety of vWD variants, using platelets as a source for vWF mRNA, or by direct analysis of genomic DNA. Rapid progress has been made over the past few years, and a large number of human mutations have been cataloged.[2] [117] A database of known vWF mutations and polymorphisms is maintained by a consortium of workers in the field and can be accessed through the Internet at http://mmg2.im.med.umich.edu/VWF (Fig. 1135 (Figure Not Available)). Molecular genetic analysis has shed important light on the molecular pathogenesis of vWD and promises to improve diagnosis. For some vWD variants, mutations have been identified in the majority of patients studied, and precise diagnosis and classification by DNA screening may soon become practical.

von Willebrand disease can be divided into two general categories: those variants due to a pure quantitative deficiency and

---

Figure 113-5 (Figure Not Available) von Willebrand disease mutations. The location of all point mutations and small, in frame insertions/deletions reported to the vWD database (http://mmg2.im.med.umich.edu/vwf) as of 1997 are shown schematically here within the vWF domain structure. The relative positions of each of the 52 vWF exons are shown below. *(From Nichols and Ginsburg,[2] with permission.)*

those due to a qualitative structural or functional abnormality within the vWF protein. This is similar to the distinction in the hemoglobinopathies between quantitative abnormalities of globin synthesis (thalassemia) and qualitative structural or functional abnormalities within the protein subunit, such as in the other hemoglobinopathies. Total disruption of gene function by deletion of a segment of the gene or a nonsense mutation (abrupt termination of the protein by insertion of a stop codon into the coding sequence) results in quantitative vWF abnormalities. Conversely, the vast majority of qualitative variants are due to mutations resulting in single amino acid substitutions that interfere with protein structure or function. Based on this improved understanding of molecular pathogenesis, a revised classification scheme for vWD has been developed. [118]

Types 1 and 3

Quantitative vWF abnormalities can be either mild or pronounced. Patients with type 3 (severe vWD) suffer from a profound bleeding disorder (Chap. 114) with very little or no detectable plasma or platelet vWF. Type 3 vWD is a relatively rare disease, with an incidence of approximately 1/1 million. [119] By contrast, type 1 is the most common form of vWD, accounting for 7080% of cases; it is associated with a mild to moderate quantitative decrease in vWF (levels in the range of 2050% of normal). Type 3 vWD appears to result from the inheritance of a dysfunctional vWF gene from both parents. Gene deletions varying from 2.3 kb to >180 kb have been identified in several patients and may be associated with an increased risk of developing vWF inhibitor antibodies. [23] [114] [115] [116] Several other defects resulting in complete loss of vWF function have been identified in patients with type 3 vWD, including nondeletion defects resulting in loss of mRNA expression, [120] as well as specific nonsense mutations or frameshift mutations resulting in disruption of the vWF protein coding sequence [2] [121] (Fig. 1135 (Figure Not Available)).

Only a limited number of point mutations responsible for type 1 and 3 vWD have been identified, compared to the large number of mutations reported for the less common qualitative vWD variants described in the following section (Fig. 1135 (Figure Not Available)). This is due, at least in part, to the necessary complexity of screening all 52 exons of the vWF gene in a patient with type 1 or 3 vWD. In contrast, for many of the qualitative variants, the observed clustering of mutations focuses the search to a limited region of vWF. Several mutations resulting in truncation or disruption of the vWF protein coding sequence have been identified in patients with type 3 vWD. A particularly common frameshift mutation in exon 18, due to deletion of a single cytosine in sequence CCCCCC, accounts for approximately 50% of type 3 vWD alleles in Sweden and has also been shown to be the molecular defect in the original patient reported by von Willebrand. [122] The resulting frameshift produces a stable mRNA encoding a truncated protein that is rapidly degraded in the cell. [123]

This mutation is also common in the German population,[124] but not in the United States.[123]

In the most straightforward model, type 1 vWD would simply represent the heterozygous form of type 3 vWD. However, there is some controversy on this point. [121] Type 3 vWD has classically been defined as recessive in inheritance and parents, who are obligate carriers for the defect, are often completely asymptomatic, with normal laboratory numbers.[23] [114] [115] However, in other cases, parents are affected with classic type 1 vWD. Few mutations have been identified in pure type 1 families because most analyses have concentrated on type 3 vWD. It has been suggested that type 1 vWD mutations may more often produce a mutant vWF subunit that interferes in a dominant negative way with the normal allele, accounting for the autosomal dominant inheritance and resulting in particularly reduced vWF levels in these patients.[121] Mutations at cysteine residues in the D3 domain of vWF were recently identified in several patients with moderately severe vWD. Expression of recombinant vWF carrying one of these mutations (Cys 386 Arg) resulted in a mutant protein that was retained within the endoplasmic reticulum, potentially acted in a dominant negative manner when co-transfected with wild-type vWF. [125]

The reported prevalence of type 1 vWD (1% of the population [126] [127]) would predict a much higher frequency of type 3 vWD (1/40,000) than is observed (1/1 million). Thus, the possibility of locus heterogeneity (i.e., defects in other genes giving rise to a disorder clinically indistinguishable from vWD) has been proposed. [128] Consistent with this idea, studies of an animal model of type 1 vWD in the mouse have identified a single gene on mouse chromosome 11 distinct from the murine vWF gene that results in reductions of plasma vWF levels of up to 20-fold. [129] Although comparable effects for non-vWF genes in human vWD have not yet been demonstrated, other genetic factors are known to significantly modify human vWF levels, including ABO blood group (Chap. 114). The effects of such modifying genes are likely to determine the penetrance of symptomatic type 1 vWD in type 3 heterozygotes. Although the combined effects of several modifier genes could conceivably account for type 1 vWD in a subset of patients with two normal vWF gene alleles, all genetic analysis of human vWD to date has been consistent with linkage to the vWF gene.[2] [121]

Type 2A vWD

Type 2A vWD is the most common qualitative abnormality of vWF and is associated with selective loss of large and intermediate-sized vWF multimers (Chap. 114). Direct sequence analysis from platelet mRNA and genomic DNA has identified a panel of mutations within vWF exon 28 accounting for a majority of patients with type 2A vWD.[2] [117] Nearly all of these mutations are clustered within the vWF A2 repeat (Figs. 1131 and 1135 (Figure Not Available)). One particular mutation (Arg 834 Trp) accounts for approximately one-third of type 2A vWD cases around the world. In vitro analysis of recombinant vWF containing type 2A vWD mutations suggests that two distinct mechanisms contribute to the pathogenesis of this disorder [130] (Fig. 1136). In the first group, the single amino acid substitution results in a defect in vWF intracellular processing, with retention of the abnormal vWF in the endoplasmic reticulum. In the second group, vWF synthesis and processing in vitro is normal and the loss of multimers appears to occur via increased sensitivity to proteolysis in plasma [131] at a site within the type 2A vWD mutation cluster in the vWF A2 domain.[78] The protease most likely responsible for this cleavage has recently been characterized. [76] [77] Recombinant vWF carrying type 2A mutations shows increased sensitivity [80] and recombinant vWF deleted for the A2 domain is resistant to cleavage by this protease. [79] Infusion of recombinant

Figure 113-6 Two mechanisms for the molecular pathogenesis of type 2A vWD. Each vWF monomer is indicated as a gray arrow with the normal sequence indicated by white boxes and mutant sequence by black boxes. Within the cell, mixed dimers are formed, as well as homodimers of mutant and wild-type monomers. In group II, full-size multimers are assembled and proteolyzed after secretion. In group I, mutant subunits are held up in the endoplasmic reticulum; only homomultimers of normal subunits are secreted, predominantly of small size.

vWF carrying a type 2A mutation into mice suggests that cleavage also occurs in vivo. [132]

Type 2B vWD

Type 2B vWD is also characterized by the loss of large vWF multimers but through a unique mechanism, distinct from those described above for type 2A vWD. A panel of mutations has been identified in type 2B vWD patients, all located within a short stretch of the vWF A1 domain [117] [133] [134] (Fig. 1135 (Figure Not Available)). Four of these mutations, clustered within a 35 amino acid segment of the 2,813 amino acid vWF coding sequence, account for >90% of type 2B vWD patients studied.[117] Thus, screening for this panel of mutations could provide precise and rapid DNA diagnosis for this disorder.

These observations also identify a critical region of vWF involved in binding to the platelet GpIb receptor. Each of these single amino acid substitutions is thought to result in a unique gain of function, leading to spontaneous binding of vWF to platelets. [135] [136] Under normal conditions, plasma vWF is inert in its interaction toward platelets until it encounters an exposed subendothelial surface. Binding of vWF to collagen or other ligands within the vessel wall at sites of vascular injury presumably results in a secondary conformational change, which then facilitates binding to the GpIb platelet receptor. In type 2B vWD, the mutant vWF is capable of spontaneously binding to GpIb in the absence of subendothelial contact. Analysis of recombinant vWF demonstrates very similar increases in vWF binding to platelets for each of six distinct type 2B vWD mutations, supporting the hypothesis that the vWF GpIb binding domain can adopt either a discrete on or off conformation.[137] The large multimers appear to have the highest affinity for GpIb (presumably because of multivalency) and are rapidly cleared from plasma, along with the bound platelets, resulting in the characteristic loss of large multimers as well as thrombocytopenia. Recent studies also suggest that binding of type 2B vWF to circulating platelets may block platelet adhesion to collagen, contributing to the bleeding diathesis. [138]

Type 2N vWD

Type 2N is a unique variant of vWD that has important implications for the differential diagnosis of hemophilia and provides an instructive example of genetic locus heterogeneity. Rare cases of autosomal hemophilia have been reported in the past, in which deficiencies in factor VIII activity were inherited in an apparently autosomal manner.[139] [140] Biochemical analysis in several families identified a defect residing within the patients plasma vWF, interfering with its ability to bind and stabilize factor VIII.[141] [142] This variant is termed type 2N under the revised classification of vWD, [118] although sometimes referred to as vWD Normandy after the province of origin of one of the first patients. [143]

The DNA sequence analysis in type 2N vWD has identified several mutations, all clustered in a region at the N-terminus of vWF previously shown to be important for factor VIII binding[117] (Figs. 1131 and 1135 (Figure Not Available)). One of these mutations, Arg 91 Gln, appears to be particularly common. [144] Although usually silent in the heterozygote, homozygosity or compound heterozygosity for a type 2N vWF allele can result in clinically significant factor VIII deficiency. Thus, type 2N vWD should be considered in the differential diagnosis of hemophilia A, particularly in a female patient or in the context of other features suggesting an autosomal pattern of inheritance.[143] Most type 2N vWD mutations result in only mild to moderate reductions in plasma factor VIII. However, at least one mutation (Gln 24 Lys) is associated with factor VIII levels as low as 1%, when coinherited with a type 3 vWD allele. [145] This latter observation suggests that a diagnosis of type 2N vWD should also be considered in patients with more profound reductions in factor VIII level.

Prenatal Diagnosis

With the advent of molecular tools for the analysis of vWD, prenatal diagnosis has become possible and has been applied in a select number of cases. [146] [147] [148] Given the generally mild clinical manifestations of most vWD variants, prenatal diagnosis is generally not indicated. However, in the case of type 3 or severe vWD, the indications for prenatal diagnosis are similar to those of severe hemophilia. For those vWD variants for which the mutation is known, direct analysis of chorionic villus samples or amniotic fluid can be performed rapidly by polymerase chain reaction and can be expected to provide a highly accurate, specific and rapid diagnosis. For vWD families in which the specific mutation is unknown, genetic linkage analysis can be performed using a large panel of highly informative restriction fragment length polymorphisms.[149] One particularly useful polymorphism is a highly variable TCTA repeat in intron 40, which has been reported to have over 100 distinct alleles.[149] Although all cases of vWD analyzed to date appear to be linked to defects within the vWF gene, the possibility of locus heterogeneity (i.e., involvement of other genes outside of vWF) should be considered when performing this kind of analysis.

Chapter 114 - Clinical Aspects of and Therapy for von Willebrand Disease

Gilbert C. White II
Robert R. Montgomery

von Willebrand disease (vWD) is a genetically and clinically heterogeneous inherited hemorrhagic disorder caused by a deficiency or dysfunction of von Willebrand factor (vWF), a large adhesive glycoprotein in plasma, platelets, and endothelial cells. As a result, the interaction of blood platelets with the vessel wall is defective and primary hemostasis is impaired. vWD is perhaps the most common hereditary bleeding disorder, and is more common than either hemophilia A or hemophilia B.

von Willebrand disease was first reported in 1926 by Erik von Willebrand, [1] who described a 5-year-old Finnish girl from the Aoland Islands with a bleeding disorder that could be distinguished from classic hemophilia by an autosomal pattern of inheritance, mucocutaneous hemorrhage rather than joint and soft tissue hemorrhage, a prolonged bleeding time, and normal clot retraction. Of 66 family members, 23 had a similar hemorrhagic diathesis. Two years later, George Minot [2] reported a similar bleeding disorder in five patients and described the intermittent nature of the bleeding disorder. von Willebrand originally attributed the bleeding defect in his patients to either a platelet defect or abnormal capillaries. [3] [4] [5] In 1953, three independent groups reported deficiency of factor VIII in vWD, [6] [7] [8] and in 1957, Nilsson and co-workers[9] showed that the infusion of fraction I-0 from normal human plasma led to a greater-than-expected increase in factor VIII levels in patients with vWD, suggesting that the defect might be found in the plasma. More important, the infusion of fraction I-0 from hemophilic plasma also led to a greater-than-expected rise in factor VIII, indicating that the plasma component was something other than factor VIII. [10]

The abnormal interaction between platelets and the vessel wall in vWD was first demonstrated in 1960 by Borchgrevink [11] and was confirmed by numerous workers.[12] [13] [14] [15] The next major discovery was the observation by Zimmerman et al[16] that an antigen associated with factor VIII was decreased in patients with vWD. This antigen is now known as vWF and is a protein distinct from factor VIII. The in vitro measurement of vWF activity was further facilitated by the observation by Howard and Firkin[17] that ristocetin, an antibiotic isolated from the actinomycete species *Nocardia lurida*, induced agglutination of platelets in the presence of vWF. The primary structure of vWF was determined in 1985 when the gene for vWF was independently cloned and sequenced by four groups. [18] [19] [20] [21]

PREVALENCE

Population studies indicate that the prevalence of vWD in the general population is 0.821.6%. [22] However, this is probably an underestimate of the true prevalence because of difficulties in the laboratory diagnosis of the disease. Severe, type 3 vWD is much rarer, with a prevalence of approximately 1 in 1 million.

GENETICS

von Willebrand disease is inherited in an autosomal manner. Males and females are affected approximately equally, and each child of an individual heterozygous for a vWF abnormality has a 50% chance of inheriting the abnormal gene (Fig. 1141). In classic autosomal recessive disorders, heterozygous offspring are phenotypically normal, whereas in dominant disorders, heterozygous offspring are phenotypically affected. Most patients with vWD show an autosomal dominant pattern of inheritance, although the variability of the laboratory findings and the variability of the clinical expression of the disease implies that penetrance is often incomplete. Although most cases of vWD occur as autosomal dominants, including most type 1 and 2 cases, recent studies suggest that autosomal recessive vWD may be more common than previously recognized. The two reported families with type 2C vWD appear to fit this pattern, [23] [24] and reports of recessive inheritance in type 2A[25] and type 1[26] disease have appeared. This recessive inheritance may account for some of the laboratory variability in vWD described previously. Some patients with severe type 3 disease also show recessive genetics, as evidenced by asymptomatic consanguineous parents. However,

Figure 114-1 Autosomal pattern of inheritance typical of von Willebrand disease (vWD). In this hypothetical pedigree, two families with different defects in the von Willebrand factor gene are illustrated. The pattern of inheritance is a typical autosomal dominant pattern in which people inheriting an abnormal gene from either parent express the defect. A double heterozygote, who would have severe, type 3 vWD is illustrated. White symbols indicate normal people; pink symbols indicate a heterozygote for defect I; red symbols indicate a heterozygote for defect II; and black symbols indicate a double heterozygote.

other patients with type 3 disease appear to be homozygotes or compound heterozygotes for type 1 genetic defects, inheriting a different abnormal symptomatic gene from each parent. The severity of the disease in the latter is related to the inheritance of a double gene defect and not to a recessive defect.

LABORATORY DIAGNOSIS

The standard laboratory work-up for vWD consists of five tests: vWF activity, vWF antigen, factor VIII activity, vWF multimeric analysis, and bleeding time (Table 1141). Analysis of the multimeric composition of vWF is required for accurate classification of vWD subtypes (see Chap. 106).

vWF Activity

Ristocetin co-factor activity (vWF:RCoF) is a functional assay for vWF that measures the vWF-supported agglutination of human platelets by ristocetin. Several methods of quantifying vWF activity have been described. [27] [28] [29] In most, ristocetin is added to a suspension of washed formalin- or paraformaldehyde-fixed platelets in the presence of patient plasma as a source of vWF, and agglutination is assessed macroscopically or in an aggregometer. The initial rate of agglutination is proportional to the concentration of plasma vWF. The vWF activity is compared with the activity of normal plasma (assigned an arbitrary activity of 1 U/ml) and expressed in units per deciliter or as a percentage of the activity in normal plasma. Normal plasma levels of vWF are 50200 U/dl. The vWF activity may be decreased artifactually in people with ristocetin-binding proteins in plasma (e.g., vancomycin). [30]

In some laboratories, vWF activity is measured by using platelet-rich plasma from the patient and performing ristocetin-induced platelet aggregation. Because this assay uses the patients own platelets, it gives abnormal results in conditions in which interaction of vWF with platelet membrane glycoprotein (GP) Ib (its receptor on the platelet surface) is impaired. Thus, in patients with Bernard-Soulier syndrome, a disorder in which there is a congenital absence of GP Ib, ristocetin-induced platelet aggregation is absent. [31] Ristocetin co-factor assay with fixed normal platelets is normal in the plasma of patients with Bernard-Soulier syndrome.

Another method for measuring vWF activity is by collagen binding assay. Patient plasma is added to pepsin-digested type III collagen immobilized on microtiter wells. Bound and therefore active vWF is detected using a polyclonal rabbit anti-human vWFhorseradish peroxidase conjugate. The vWF bound is compared with the binding from normal plasma (assigned an arbitrary activity of 1 U/ml) and expressed in units per deciliter or as a percentage of the activity in normal plasma.

TABLE 114-1 -- Laboratory Tests in von Willebrand Disease

Function	Test[a]
vWF activity	Ristocetin-induced platelet agglutination (vWF:RCoF) Ristocetin-induced platelet aggregation Botrocetin-induced platelet agglutination Glass bead retention
vWF antigen	Laurell immunoassay Enzyme-linked immunosorbent assay
Factor VIII	Coagulation assay
Plateletvessel wall	Bleeding time

RCoF, ristocetin co-factor; vWF, von Willebrand factor.

[a] Ristocetin is a glycopeptide derived from the actinomycete *Nocardia lurida.* Botrocetin is derived from the venom of *Bothrops jararaca* and other *Bothrops* spp.

vWF Antigen

The assay for vWF antigen (vWF:Ag) is usually performed with use of a rabbit antibody to vWF by either quantitative immunoassay (Laurell technique) or enzyme-linked immunosorbent assay.[32] [33] Because vWF is a very large glycoprotein, Laurell quantitative immunoelectrophoresis must be performed slowly (1218 hours) or the assay will be too sensitive to the smallest multimers of vWF, which migrate faster. The Laurell technique may overestimate the smallermolecular-weight multimers, resulting in a false elevation of vWF:Ag in type 2A vWD. The levels of vWF:Ag are compared with a normal human plasma pool and expressed as units per deciliter. Normal values are 50200 U/dl. Blood type significantly affects the normal level of vWF protein, type AB plasma having up to twice the vWF:Ag level as type O plasma. Some laboratories have developed different normal ranges for each blood type. [34] Because vWF is an acute-phase reactant, levels are increased during stress, pregnancy, and in the newborn after vaginal delivery. Reduced plasma vWF may be found in patients who are hypothyroid, but their levels return to normal when they become euthyroid.[35]

Factor VIII Activity

Factor VIII coagulant activity is usually measured by a one-stage assay using human factor VIII-deficient plasma as substrate. [36] Substrate plasmas that have been immunodepleted of factor VIII have also been used, but may give abnormal results because vWF is also removed during the immunodepletion. Normal factor VIII levels are 60150%. Factor VIII levels may also be reduced in patients with hemophilia A, factor VIII inhibitors, and diffuse intravascular coagulation.

Bleeding Time

The bleeding time is a general test of plateletvessel wall interactions [37] (see Chap. 131). In most places, the bleeding time is performed using a modification of the technique described by Ivy et al.[38] [39] [40] Standardized incisions are made on the volar aspect of the forearm, keeping venous pressure at 40 mm Hg with a blood pressure cuff. Blood is blotted to filter paper every 30 seconds and the bleeding time is taken as the time to cessation of bleeding. Although the bleeding time provides an indication of primary hemostatic function, it is difficult to standardize and dependent on the experience of the person performing the test.

Quick[41] observed that the bleeding time in vWD was sensitive to aspirin and that 650 mg of aspirin would prolong the bleeding more in a patient with vWD than in normal people. He proposed the aspirin tolerance test as a diagnostic test for vWD, although it is also prolonged in a variety of platelet function defects.

vWF Multimers

In normal human plasma, vWF is present as a series of repeating subunits, which represent multimers of the approximately 300-kd vWF protein. These multimers

range in size from a dimer of 600 kd to over 20,000 kd in increments of 600 kd (Fig. 1142). The highestmolecular-weight multimers mediate platelet adhesion. [42] Separation of vWF into its multimeric components is accomplished using sodium dodecyl sulfate (SDS)-agarose electrophoresis. [43] On SDS-agarose gels with higher amounts of agarose, fewer multimers are visible, but the resolution is enhanced so satellite bands are visualized, whereas on gels of lower agarose content, all the multimers may be visualized but the resolution is reduced. Thus, the highmolecular-weight multimers that mediate platelet adhesion are best characterized using 0.65% agarose.[44] On gels containing 23% agarose, satellite banding is enhanced such that the multimeric subunits appear in three or more discrete bands. [45]

Figure 114-2 von Willebrand factor (vWF) multimers. vWF multimers can be studied in low (0.65%) and high (23%) concentrations of agarose. The lower concentration is preferable to evaluate highmolecular-weight multimers, whereas the separation of complex multimers requires the high concentrations of agarose. **(A)** Illustration of 0.65% agarose separation of vWF multimers. Samples include plasma from patients with thrombotic thrombocytopenic purpura (lane A), diffuse intravascular coagulation (lane B), ventricular septal defects (lane C), normal plasma (lane D), severe, type 3 vWD (lane E), type 1 vWD (lane F), type 2A vWD (lane G), and type 2B vWD (lane H). **(B)** Complex multimer separation. Each multimer seen in 0.65% agarose can be resolved into three to five bands using the higher concentrations of agarose. Plasma from patients with types 2A and 2B vWD has an increase in the more rapidly moving satellite band (satellite band 5). *(Courtesy of R. R. Montgomery.)*

Other Tests

Platelet aggregation or agglutination with ristocetin or with botrocetin, a protein isolated from the venom of *Bothrops jararaca*, [46] is also useful for classification. Both compounds aggregate platelets in a vWF-dependent manner, although they interact with different sequences of the vWF molecule. [47] At 0.30.5 mg/ml, ristocetin causes aggregation of platelet-rich plasma from patients with type 2B and platelet-type, pseudo-vWD, but does not cause aggregation of platelet-rich plasma from normal patients or from patients with type 1 vWD.

Platelet adherence to columns containing glass beads is reduced in vWD, [48] but is not specific and is rarely used today. Another useful diagnostic test is the response to plasma infusion of normal or hemophilic plasma. In a patient with vWD, this results in a sustained rise in factor VIII activity, which contrasts with the shorter biologic half-life that is observed when normal plasma is transfused in patients with hemophilia. [10] This phenomenon, called de novo synthesis, may also have therapeutic benefits but is no longer used as a diagnostic test because of concerns about the viral safety of blood products.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

DIAGNOSIS

The diagnosis of vWD is established by finding reduced plasma levels of vWF activity, vWF:Ag, or factor VIII, or a prolonged bleeding time. In the classic case, all four laboratory tests are abnormal and the diagnosis is not difficult. However, on some occasions all four tests are normal, whereas on others, only one of the four is abnormal. When only the factor VIII is abnormal, vWD can be confused with hemophilia A, and when only the bleeding time is abnormal, it can be confused with a primary platelet disorder.

Repeated testing may be necessary to establish the diagnosis of vWD. The difficulty in diagnosing vWD has been emphasized by Goldin et al, [49] Miller et al,[50] and Abildgaard et al.[51] In the studies by Goldin et al, and Miller et al of two large kindreds with vWD, vWF activity, vWF:Ag, factor VIII, and bleeding time were determined and correlated with bleeding symptoms. The results indicated two important facts. First, within each kindred whose affected members all possessed the same genetic defect, there was remarkable diversity in the phenotype, with 8 different combinations of abnormal test results out of a possible 16 in one family and 10 in the other. Second, of 26 people who were genetically affected as determined by pedigree analysis, 11 had a normal panel of tests. Thus, normal values do not exclude a diagnosis of vWD. This conclusion is supported by the studies of Abildgaard et al, who found a normal panel of tests in 29 of 202 tests performed on 50 patients with confirmed vWD. In addition, they confirmed the phenotypic diversity observed by Goldin et al and Miller et al, with all 16 possible combinations of abnormal findings in their population of patients. Finally, they showed that when patients with vWD were followed with serial tests, the pattern of abnormality could change, sometimes within a matter of weeks, and that a person with vWD may demonstrate five or six different patterns [51] (Fig. 1143).

A recent study by Eikenboom and co-workers[26] may provide an explanation for some of the variability in vWD. They found that within a given kindred, the variability in laboratory findings could be roughly correlated with the gene defect, and that differences between people with the same gene defect within the kindred roughly correlated with blood group type. In addition, allelic interplay may account for some of the variability in vWD phenotype. For example, in one of Eikenbooms kindred, the phenotypic expression of the Normandy defect was affected by a second abnormal vWF allele. This suggests

Figure 114-3 Pattern of abnormalities in von Willebrand disease (vWD). From 25 families with vWD, 50 affected people were tested on a total of 202 occasions. The pattern of results in each person is shown by the dots in the column below that person. For example, in family 7, individual 1 was studied twice and showed an abnormal bleeding time and normal VIII, vWF, and vWF:Ag on both occasions. In family 5, individual 1 was studied on seven occasions and showed six different patterns of results, including all normal, isolated vWF abnormality, isolated bleeding time abnormality, bleeding time and vWF abnormality, bleeding time and vWF:Ag abnormality, and bleeding time, vWF, and vWF:Ag abnormality. BT, bleeding time; VIII, factor VIII activity; vWF, von Willebrand factor activity. *(From Abildgaard CF et al,[51] with permission.)*

that the underlying gene defect in vWD, along with other factors such as allelic interplay, blood type, pregnancy, and stress, play an important role in the phenotypic expression in the disease.

Because the factor VIII level is variably reduced in vWD, the activated partial thromboplastin time, which is typically prolonged only when the factor VIII level is <30%, is often normal in vWD. The prothrombin time and thrombin clotting time are normal, and the platelet count is normal in most patients but may be reduced in patients with type 2B or platelet-type vWD.

von Willebrand disease can usually be distinguished from classic hemophilia (Table 1142). The vWF activity, vWF:Ag, and bleeding time are normal in hemophilia. However, because some patients with vWD may present with an isolated factor VIII deficiency, it is important to take a careful family history to exclude an X-linked pattern of inheritance. Repeated testing may also be required to distinguish vWD from hemophilia. Qualitative platelet defects (i.e., defects due to aspirin ingestion) should also be considered in the differential diagnosis of vWD. A careful drug history may help to distinguish patients with drug-related platelet defects.

CLASSIFICATION

Historical studies using crossed immunoelectrophoresis showed that some patients had an electrophoretically abnormal protein, so it became possible to classify patients based on the presence or absence of such an abnormal molecule.[52] [53] [54] [55] By this technique, approximately 1015% of patients were shown to have an electrophoretically abnormal vWF protein. A subsequent classification of vWD was based on the findings of vWF multimer analysis.[56] The current classification of vWD is based more on molecular mechanisms. Three general types of vWD are

DIAGNOSTIC DIFFICULTIES IN VON WILLEBRAND DISEASE

Test	1	2	3	4	5	6
Factor VIII	89%	94%	67%	71%	35%	81%
vWF	101%	88%	81%	62%	55%	78%
vWF:Ag	95%	92%	75%	65%	52%	75%
Bleeding time	6.5	8	8	9	11.5	8

This case illustrates the difficulties that may be encountered in the diagnosis of vWD. The patient, a 34-year-old woman with a mild bleeding disorder characterized by excessive bleeding after wisdom tooth extraction, but no bleeding after an automobile accident complicated by a fractured femur, was tested on six occasions over a 2-year period. Her blood type was A, and she was not on oral contraceptives at any time during the testing period. The initial testing was negative, and multimeric analysis showed a normal pattern. Subsequent testing 6 months later was again within normal limits. Testing on a third occasion 3 months later showed a borderline factor VIII level and bleeding time, but was otherwise negative. Repeat tests 1 month later were negative, although the vWF and vWF:Ag were borderline. Testing performed 8 months later before dental work was positive and consistent with a diagnosis of vWD. Her last tests, 1 year after dental work, were again negative.

recognized: type 1 vWD, which is a partial quantitative deficiency of vWF; type 2 vWD, which is a qualitative deficiency of vWF; and type 3 vWD, which is severe vWD (Table 1143).[57]

Type 1

In type 1 vWD, there is a partial quantitative deficiency of vWF. This is the most commonly diagnosed type of vWD, accounting for approximately 7080% of cases. The characteristic finding in type 1 vWD is the demonstration on multimer analysis that all multimers in plasma are present and in the same relative proportion as in normal plasma, but are reduced. The reduction in multimers is variable among patients and may be variable on different occasions in any given patient. Plasma levels of factor VIII, vWF, and vWF:Ag may be reduced, usually concordantly, but also may be normal, and the bleeding time may be either prolonged or normal.

Patients previously reported as IA, [58] I-1, I-2, and I-3,[59] and I-platelet normal and I-platelet low[60] are included in this category (Table 1144).

Several forms of type 1 vWD have been reported based on platelet vWF content. Most patients with type 1 vWD have a parallel reduction in plasma and platelet vWF. Patients with decreased plasma vWF multimers but normal platelet vWF multimers have been termed type I-2 [59] or type I-platelet normal[60] to distinguish them from the more common type 1 vWD, termed type I-1 or type I-platelet low. It has been suggested that platelet-low vWD is caused by defective production of

vWF, whereas platelet-normal vWD results from impaired release of vWF from cellular stores. An additional variant in which plasma vWF multimers were normal and platelet vWF multimers were reduced has been termed type I-3. [59] Interestingly, the bleeding time in patients with type I-platelet normal is normal or nearly normal, suggesting that platelet vWF may correlate more strongly with bleeding tendency. [60] [61] Furthermore, patients with normal platelet vWF may have a better response to 1-desamino-8-D-arginine vasopressin (DDAVP).

TABLE 114-3 -- Classification of von Willebrand Disease

Type	vWF	vWF:Ag	Factor VIII	Multimers	RIPA[a]	Cryo[b]

2N (qualitative variants with markedly decreased affinity for factor VIII)	nl	nl		Normal multimers		
3 (nearly complete deficiency of vWF)				All multimers absent		
Platelet-type (qualitative defect in platelet glycoprotein Ib with increased affinity for vWF)				Large multimers decreased	+	+

Ag, antigen; nl, normal; RIPA, ristocetin-induced platelet aggregation; vWF, von Willebrand factor.

[a] Ristocetin-induced aggregation of the patients platelets in patient plasma with low concentrations (0.5 mg/ml) of ristocetin.

[b] *Cryo* refers to platelet aggregation in patient platelet-rich plasma after addition of normal human cryoprecipitate.

It is generally assumed that promoter mutations, nonsense mutations, frameshift mutations, and large deletions account for most type 1 defects. In some patients with type 1 disease, silent alleles that produce undetectable or greatly reduced amounts of mRNA for vWF have been demonstrated. [62] [63] [64] [65] Point mutations producing premature truncation of the vWF protein and missense mutations within functional domains of vWF have also been demonstrated. [26] [65]

Type 2

In type 2 vWD, there is a qualitative abnormality of vWF. Patients may have normal levels of vWF protein, but the protein is dysfunctional. These variants account for 1530% of cases.

Type 2A vWD refers to a qualitative variant of vWD in which there is defective plateletvWF interactions associated with the absence of the high and middlemolecular-weight vWF multimers in plasma. Satellite multimer bands may or may not be normal. The hemostatic abnormality in type 2A vWD is due to the absence of the hemostatically effective large vWF multimers. Platelet aggregation in response to ristocetin is reduced in proportion to the deficiency of highmolecular-weight vWF multimers. At least two distinct mechanisms account for the usual type 2A phenotype: (1) abnormal cellular assembly of vWF multimers, and (2) increased susceptibility of vWF to proteolysis in vivo. [66] [67] [68] Platelet vWF in patients with abnormal cellular assembly of vWF is similar to that in plasma and is normal in patients with increased susceptibility to proteolysis.

Patients previously classified as II-1, II-2, and II-3, [59] I-platelet discordant, [60] IIA, IB, [69] IIC, [70] IID, [71] IIE, [72] IIF, [73] IIG, [74] IIH, [75] and II-I [76] are included in this category (see Table 1144).

Evaluation of platelet mRNA from patients with type 2A vWD [67] [77] [78] [79] [80] has demonstrated missense mutations in the A2 domain (Fig. 1144). Expression of the cDNA for these defects in COS cells resulted in the suspected abnormal vWF multimers in some patients but normal multimers in others. [67]

Type 2B vWD is caused by a qualitative abnormality of vWF in which there is increased plateletvWF interaction due to an increased affinity of vWF for its platelet receptor, GP Ib. Patients previously classified as IIB, I-New York, [81] and Malmö [82] are included in this category (see Table 1144). In the usual form of type 2B vWD, there is an absence from plasma of only the

Figure 114-4 Molecular defects in types 2A and 2B von Willebrand disease. Schematic drawing of the A1 and A2 domains of von Willebrand factor (vWF) that lie within exon 28 and form the GP Ib-binding domain of vWF. Type 2A mutations are indicated by open circles. Type 2B mutations are indicated by closed circles. The mutations shown are those that have been established by in vitro expression.

highestmolecular-weight multimers. The middle and lowmolecular-weight multimers are present in normal amounts and in the same relative proportions as in normal plasma. The hallmark of type 2B vWD is an enhanced aggregation of the patients platelets in the presence of reduced concentrations of ristocetin. At a concentration of 0.30.5 mg/ml, ristocetin does not usually induce aggregation of normal platelets, but in type 2B disease, 0.30.5 mg/ml of ristocetin stimulates a full aggregation response. The highmolecular-weight multimers missing in plasma are present in platelets, suggesting that all of the vWF multimers are synthesized and that the absence of the highmolecular-weight forms is due to increased turnover of the highmolecular-weight multimers [83] because of the increased affinity of vWF for GP Ib. [84] Patients with type 2B vWD often have mild thrombocytopenia.

Most of the known mutations reported in type 2B vWD are within or very near a disulfide loop (C509C695) of vWF [85] [86] [87] [88] [89] that has been shown to interact with GP Ib (see Fig. 1144).

Type 2M vWD refers to qualitative variants in which there is decreased plateletvWF interaction that is not caused by the absence of highmolecular-weight multimers. Previous vWD types B,[90] Vicenza, [91] IC,[92] and ID[93] are grouped in this category (see Table 1144). The vWF multimer distribution is typically normal, and there may even be larger-than-normal multimers. The satellite bands may be abnormal. In vWD type B and type 2M $^{\text{Milwaukee-1}}$, the defect was shown to cause decreased binding of vWF to platelet GP Ib. [90] [94]

Type 2N vWD, also termed Normandy type vWD, is a qualitative abnormality of vWF in which there is defective interaction with factor VIII. This form of vWD masquerades as an autosomal form of hemophilia A.[95] [96] Patients with this variant have reduced levels of factor VIII, typically 515%, with normal levels of vWF and vWF:Ag. The bleeding time is normal. The molecular defect in vWD Normandy is in the region of vWF involved in binding factor VIII and results in impaired formation of the vWFfactor VIII complex. [97] [98] [99] [100] As a result, the half-life of factor VIII in the circulation is markedly shortened and factor VIII levels are reduced. The phenotypic expression of the Normandy variant occurs only if the person is homozygous for the defect or if the other allele is a second vWD allele with reduced or absent levels of normal vWF, such that only the abnormal factor VIII binding allele is predominantly expressed.

Type 3 (Severe Type)

Type 3 is a severe form of vWD, with nearly complete deficiency of vWF. Usually, vWF activity and vWF:Ag are undetectable, and factor VIII levels are typically markedly reduced (to <10%). The bleeding time is prolonged, usually to >20 minutes. Multimeric analysis of plasma from patients with type 3 disease shows essentially no multimers because of the marked reduction in vWF. This severe form of vWD may be the result of a homozygous defect or of compound heterozygosity.[101]

Four families with severe type 3 vWD have been found to have deletions of the vWF gene. [102] [103] Three families in Italy, one the product of a consanguineous marriage, were shown to have a homozygous deletion of the entire vWF gene, whereas a family in Wales was found to be homozygous for a 2.3-kb frameshift deletion that includes exon 42. In all four families, severe vWD was associated with the development of alloantibody inhibitors to vWF. Another family was identified in whom there was a complete heterozygous deletion of the vWF gene in the proband and one asymptomatic parent, suggesting that a different genetic abnormality was inherited from the second parent and that the proband was a compound heterozygote for vWF defects. An additional 20 patients with severe type 3 vWD were studied and had no evidence of a deletion.

Platelet-Type, Pseudo-vWD

Platelet-type, pseudo-vWD, first described by Miller and Castella [104] and by Weiss and co-workers,[105] is a primary platelet disorder involving the platelet receptor for vWF. Phenotypically, patients with platelet-type, pseudo-vWD are similar to patients with type 2B disease: multimeric analysis reveals absence of the highestmolecular-weight multimers; factor VIII, vWF activity, and vWF:Ag are variably reduced; and the bleeding time is prolonged. Aggregation is enhanced in response to low concentrations of ristocetin (0.30.5 mg/ml), and mild thrombocytopenia is commonly present. However, in contrast to type 2B vWD, in which the abnormality is in the vWF itself, the defect in platelet-type, pseudo-vWD is in the platelet receptor for vWF, which has an increased affinity for normal vWF. The deficiency of the highmolecular-weight multimers is thought to occur as a result of increased utilization secondary to the increased affinity of platelets for vWF. Platelet-type, pseudo-vWD can be distinguished from type 2B disease by addition of normal human cryoprecipitate to the patients platelet-rich plasma. [106] In platelet-type disease, the cryoprecipitate induces platelet aggregation, whereas in type 2B disease it does not. Platelet-type, pseudo-vWD can also be distinguished from type 2B disease by the differential binding of the patients plasma vWF to formalin-fixed platelets. Unlike the response to cryoprecipitate, this method can be performed with previously frozen plasma.[107]

The molecular causes of this disorder have yet to be clearly defined. A putative mutation at position 233 of the GP Ib -chain, resulting in a substitution of a valine for a glycine, has been reported.[108]

Acquired vWD

von Willebrand disease may be acquired in people who were previously normal. In most cases, this is caused by antibodies to vWF that neutralize vWF activity. Patients present with new-onset bruising and bleeding. vWF activity, vWF:Ag, and factor VIII are markedly reduced, and the bleeding time is prolonged. Inhibitors may occur in otherwise healthy people, but often are associated with an underlying disorder such as lymphoproliferative disorders, benign monoclonal gammopathies, and other diseases characterized by immunologic abnormalities. [109] [110] [111] [112] [113] [114] [115] [116] [117] [118]

Acquired vWD may also occur in the absence of antibodies when there is increased utilization of vWF. For example, people with cardiac disease, particularly ventricular septal defect or valvular heart disease, may acquire a deficiency of the highmolecular-weight vWF multimers and present with a pattern consistent with type 2B vWD, with decreased factor VIII, decreased vWF, decreased vWF:Ag, and an absence of high molecular-weight multimers. Repair of the cardiac defect may result in normalization of vWF.

CLINICAL MANIFESTATIONS

The hemorrhagic tendency in vWD is highly variable and depends on the type and severity of disease. Patients with types 1 and 2 disease may have mild bleeding symptoms characterized by hemorrhage from delicate mucocutaneous tissues. Epistaxis, easy bruising, and gastrointestinal bleeding are common. Delayed hematoma formation and hemarthroses, characteristic of hemophilia A, are not a prominent feature in these patients. In women, the most frequent symptom is menorrhagia, which may be severe and out of proportion to other hemorrhagic symptoms. vWD should be prominently considered in the differential diagnosis of menorrhagia. Untreated, menorrhagia may lead to iron deficiency and anemia. Menorrhagia probably accounts for the disproportionate number of women who are

referred for evaluation of vWD. Post-traumatic, postsurgical, and dental bleeding may be severe and can be the presenting manifestation. Interestingly, pregnancy in women with vWD is usually tolerated well because plasma vWF and factor VIII levels increase during pregnancy, reaching a peak in the third trimester and falling rapidly postpartum. In patients with type 1 vWD, this rise is associated with a reduction in hemorrhagic symptoms. However, in patients with variants such as type 2B or platelet-type, pseudo-vWD, the elevated levels of abnormal vWF may increase the spontaneous binding to platelets and result in more marked thrombocytopenia. Similarly, levels of vWF and factor VIII are elevated in the newborn infant, particularly with vaginal delivery. This increase probably reduces the likelihood of bleeding but makes the diagnosis of vWD difficult in the newborn.

Although characteristic bleeding symptoms occur in patients with vWD, the absence of bleeding symptoms does not rule out this diagnosis. In the studies of Goldin et al,[49] Miller et al,[50] and Abildgaard et al,[51] approximately one half of patients with documented type 1 or 2 vWD had no history of bleeding despite reduced factor VIII or vWF levels on at least some occasions.

Patients with severe, or type 3, vWD have a severe hemorrhagic tendency. Spontaneous hemorrhage from mucous membranes and the gastrointestinal tract can be frequent and may be life threatening. Usually, hemorrhage after dental and other surgical procedures can be controlled only by replacement therapy. Perhaps because of the low factor VIII levels, deep hematoma and joint hemorrhages similar to those in hemophilia may occur. In women, menorrhagia is severe and, before hormonal therapy was available, often required extreme treatment such as ovarian ablation by radiation, a practice not currently recommended.

Angiodysplasia refers to small telangiectases in the wall of the small intestine and colon that occur in some patients with vWD, [119] [120] [121] more commonly in those >50 years of age and typically in those with type 3 disease. Although it is not clear that these are linked disorders, the presence of angiodysplasia in vWD can be a serious and disabling complication. Bleeding from angiodysplasia may present as melena or occult gastrointestinal bleeding, but typically presents with recurrent episodes of acute blood loss. Cycles of hematochezia resulting in hypotension and cessation of bleeding, followed days to weeks later by hematochezia, hypotension, and cessation of bleeding, may occur. Colonoscopy may reveal a bleeding site, but more often shows multiple telangiectases without a defined source of bleeding. Rarely, bleeding can be brisk enough to be visible by angiography. Operative intervention is not recommended unless a source of recurrent bleeding has been definitively identified. Estrogen therapy may be effective. [122]

Mitral valve prolapse has been reported to occur with increased frequency in vWD, perhaps as a linked mesenchymal disorder. [123] [124] However, a subsequent report describes a normal frequency of mitral valve prolapse in patients with vWD. [125]

Inhibitors to vWF in patients with vWD are alloantibodies, usually IgG, which inhibit the hemostatic function of vWF. They are uncommon and occur only in patients with severe type 3 disease,[126] among whom the prevalence of inhibitors has been estimated to be 78%. There is almost always a prior history of exposure to exogenous vWF, as either plasma, cryoprecipitate, or factor VIII concentrates. Patients with deletion of the vWF gene as the cause of their disease may be at higher risk for the development of inhibitors. [102] [103] A familial tendency to inhibitor formation has also been noted. [127] The presence of an inhibitor to vWF in a patient with vWD is suggested by the failure to respond clinically to replacement therapy, by decreased recovery of infused vWF, and by lack of correction of the bleeding time. Confirmation of the presence of an antibody requires the demonstration of an inhibitor of ristocetin-induced platelet aggregation

SURGERY IN VON WILLEBRAND DISEASE

Surgical and dental procedures, including major surgical procedures, may be safely undertaken in patients with most types of vWD. In patients with type 1 disease, treatment with DDAVP starting 1 hour before surgery and once a day thereafter for 23 days usually suffices for minor procedures such as dental extraction. For more extensive surgery, DDAVP may also be used, but Humate-P or Alphanate should be available should DDAVP fail to control hemostasis. Baseline factor VIII and bleeding time should be determined within 1 week of surgery. Approximately 12 hours before surgery, DDAVP is given at a dose of 0.3 g/kg body weight. If the baseline factor VIII or bleeding time is abnormal, these should be repeated 3060 minutes after DDAVP and shown to be normal before proceeding with surgery. After surgery, DDAVP may be given once a day until wound healing is complete. Factor VIII and vWF activity should be determined 3060 minutes after each dose of DDAVP.

In patients with type 2 vWD, the approach to surgery is similar to that in type 1 disease, except that replacement therapy with blood products usually is required. Because it is subjected to virucidal treatment, Humate-P or Alphanate is preferred by most physicians. Baseline factor VIII and bleeding time are determined within 1 week of surgery. Replacement therapy is started 12 hours before surgery at a dose calculated to correct the factor VIII level, and the factor VIII and bleeding time determinations are repeated to ensure correction before surgery. After surgery, treatment is given every 12 hours until wound healing is complete. Factor VIII and vWF activity are determined daily.

In patients with type 3 (severe) vWD, replacement therapy with Humate-P or Alphanate with or without DDAVP aimed at correction of the bleeding time and the factor VIII level is required for minor and major procedures. For minor procedures, treatment should be continued for 23 days; for major surgery, it should be continued for 510 days.

in the patients plasma. In most cases, antibodies to vWF also appear to inhibit factor VIII activity. [109] However, some antibodies do not inhibit function but promote accelerated clearance of transfused vWF. Those antibodies must be demonstrated by mixing the patients antibody with normal vWF and demonstrating antigenantibody binding. [126]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

THERAPY

The aim of therapy in vWD is correction of both the bleeding time and coagulation abnormalities. This is generally accomplished by raising plasma levels of vWF and factor VIII to normal. Because the bleeding time is sensitive only to the highestmolecular-weight multimeric forms, the source of the vWF and its multimeric composition are important. For example, intermediate-purity factor VIII concentrates contain large amounts of vWF, but most of this consists of low and middlemolecular-weight multimers.[128] As a result, vWF levels increase after administration of these concentrates, but the bleeding time is not corrected. [129] Several agents have been shown to provide effective therapy for patients with vWD; the choice of agent depends on the type of disease and the severity of bleeding.

DDAVP

After observations that epinephrine and stress increase levels of factor VIII and vWF in normal individuals, Ruggeri et al [127] and Mannucci et al[130] began studies to evaluate the effect of vasopressin and the synthetic vasopressin analog, DDAVP, on factor VIII levels in patients with factor VIII deficiency, including vWD. They showed that DDAVP had the same effect on factor VIII and vWF activity as vasopressin, but had <1% the pressor effect of the parent compound. Because of the rapid rise in factor VIII and vWF after administration of DDAVP, it has been suggested that the drug has a post-translational effect, perhaps through the release of vWF from intracellular storage sites in endothelial cells. One study has demonstrated the loss of vWF staining of capillary endothelial cells after DDAVP administration. [131]

DDAVP (desmopressin acetate; Rorer) is available in intranasal or intravenous forms. The intravenous preparation (4 mg/ml) can be administered intravenously or subcutaneously with essentially equivalent results. [132] [133] [134] In patients with type 1 vWD, a reproducible two- or threefold increase in vWF activity (and factor VIII) and shortening of the bleeding time occur within 1530 minutes of DDAVP administration. The dose of DDAVP is 0.20.3 g/kg body weight intravenously in a volume of 50100 ml over 30 minutes. For subcutaneous administration, the intravenous DDAVP preparation is used at the same dose with injection of <1.5 ml/site (a single treatment may require three or four subcutaneous injections). Two intranasal preparations are available, one of which, a dilute solution (100 g/ml) used for patients with diabetes insipidus, does not consistently raise plasma levels of vWF or factor VIII and should not be used in vWD. A more concentrated (1.5 mg/ml) intranasal preparation of DDAVP is effective, and at a dose of 150 mg (75 g/nostril) produces results equivalent to 0.2 g/kg of intravenous DDAVP. [135] [136] Because of the risk of hyponatremia, DDAVP should be administered no more than once a day and a serum sodium should be measured daily if DDAVP is administered on consecutive days. DDAVP should be used with extreme caution in infants because of the risk of seizures from fluid retention.

Because it stimulates a reproducible increase in vWF activity and is a synthetic product with none of the viral risks of plasma-derived products, DDAVP has become the treatment of choice in most patients with vWD. It is effective for most patients with type 1 disease, who have reduced amounts of a functionally normal vWF molecule. The effective response to DDAVP should preferably be demonstrated by carrying out a therapeutic trial infusion before the time when emergency or surgical use is required. Because it increases plasma levels of vWF by releasing endogenous stores, it usually is not effective in patients with types 2 or 3 disease, who either synthesize an abnormal protein or who do not produce functional vWF. However, reports of response to DDAVP in some patients with type 2A vWD suggest that these patients should have a trial of DDAVP to determine if it is effective. Treatment with DDAVP is ineffective in the treatment of type 3 vWD. However, DDAVP may enhance the response to cryoprecipitate in type 3 vWD, and may be useful when full correction of the bleeding time is required. [137] In type 2B and platelet-type, pseudo-vWD, the administration of DDAVP may result in increased thrombocytopenia. [138]

Plasma Products

Humate-P, a pasteurized, intermediate-purity factor VIII concentrate, and Alphanate, a solventdetergent-extracted, intermediate-purity factor VIII concentrate, have been reported to contain some of the highmolecular-weight vWF multimers and have been used to treat patients with vWD successfully, with correction of factor VIII, vWF, and bleeding time.[139] Other intermediate-purity factor VIII concentrates contain appreciable amounts of vWF, but only the middle and lowmolecular-weight multimers are present (Fig. 1145). Treatment with these concentrates can raise factor VIII and vWF:Ag levels, but the bleeding time may remain uncorrected. High-purity plasma factor VIII concentrates and recombinant factor VIII concentrates contain little or no vWF.

Cryoprecipitate is a plasma fraction that contains factor VIII, vWF, fibrinogen, and fibronectin, which is obtained by harvesting the precipitate that forms when frozen plasma is warmed to 4°C. The yield of factor VIII and vWF in cryoprecipitate can be increased two- to fivefold by administration of DDAVP to the blood donor before plasmapheresis. The full range of plasma vWF multimers is present in cryoprecipitate. Cryoprecipitate is now prepared from donors screened for antibody to human immunodeficiency virus type I (HIV-1), so that the risk of HIV transmission with cryoprecipitate is low. Nevertheless, cryoprecipitate has been reported to transmit both hepatitis B and hepatitis C, and because there is no virus inactivation step, there is a small but finite risk of HIV-1 transmission. The risk of viral transmission can be further reduced by using cryoprecipitate

Figure 114-5 von Willebrand factor multimers in commercial factor VIII concentrates. Multimer gel is run with 0.65% agarose. The lanes contain normal plasma (NP) and various commercial factor VIII concentrates: Koate-HP, Koate-HS, Humate-P, Kryobulin, Profilate-SD, and AHF-SD. The highmolecular-weight multimers are variably deficient in all of the concentrates. *(Courtesy of R. R. Montgomery.)*

from parents or family members. [140] Each bag of cryoprecipitate contains approximately 100 U of factor VIII and 100 U of vWF activity. Because vWF levels are reduced in people with type O blood, plasma from donors with type A, B, and AB blood is preferred as the source of vWF. [141] Like DDAVP, cryoprecipitate may induce thrombocytopenia in patients with platelet-type, pseudo-vWD.

Although some patients with type 2A vWD have been reported to respond to DDAVP, the response is often transient. For this reason, plasma products are the treatment of choice in most patients with types 2 and 3 vWD (Table 1145).

Recombinant vWF

A recombinant vWF has been synthesized in Chinese hamster ovary cells, co-expressed with furin. [142] Compared with plasma vWF, the recombinant protein is fully glycosylated and undergoes proper protein processing, with dimer formation in the endoplasmic reticulum and N-terminal disulfide bonding to form multimers. Nevertheless, although recombinant vWF is highly multimered, the satellite multimer bands characteristic of plasma vWF, which result from cleavage of the Tyr842-Met843 bond by depolymerase, [143] are not present in the recombinant vWF. Thus, recombinant vWF is more like platelet vWF. Functionally, the recombinant protein binds to collagen like plasma vWF and has the same ristocetin co-factor activity as plasma vWF. The specific activity of the recombinant protein is 60 U/mg, and is comparable to plasma vWF. In preliminary studies in pigs with vWD, recombinant vWF corrects the hemostatic defect. [144]

Hormonal Therapy

Oral progestational agents increase factor VIII and vWF by unclear mechanisms. They may be useful in women, especially when menstrual bleeding constitutes the major clinical symptoms.

Other Treatments

Local hemostatic agents such as fibrinolytic inhibitors (Amicar, tranexamic acid), fibrillar collagen preparations (Avitene), and fibrin glue may be useful in external bleeding such as that due to dental procedures.

Complications

DDAVP may cause thrombocytopenia in patients with type 2B and platelet-type, pseudo-vWD. [138] [145] Reports of thrombosis associated with administration of DDAVP are rare. [146] [147] Water intoxication with extreme hyponatremia may also occur with DDAVP, and intravenous fluids must be administered with caution in patients receiving this drug. [148] Because of these effects on water balance, DDAVP is not recommended for children <1 year of age. Cryoprecipitate may transmit hepatitis viruses and, rarely, HIV-1. The risk of hepatitis must always be considered, and patients should be appropriately immunized when indicated. Humate-P and Alphanate appear to be safe from viral transmission. Inhibitors to vWF develop only in the most severely affected patients undergoing replacement therapy.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

PROGNOSIS

The prognosis in mild forms of vWD is excellent. Bleeding is typically mild, and life-threatening episodes of bleeding are rare. The risk of severe hemorrhage is greatly decreased by accurate diagnosis of the disease and education of both the patient and physician with respect to treatment. Patients with mild forms of vWD can expect a normal life span, but the prognosis in severe, type 3 vWD is more guarded; in the latter situation, life-threatening hemorrhage may occur despite the safe and effective forms of treatment available. The appearance of inhibitors in patients with severe vWD causes additional complications, often preventing adequate treatment.

Chapter 115 - Vitamin K: Metabolism and Disorders

Barbara C. Furie
Bruce Furie

INTRODUCTION

Vitamin K plays a critical role in the post-translational modification of the blood coagulation proteins, factors VII, IX, and X, and prothrombin, and of the plasma regulatory proteins, proteins C and S. Vitamin K serves as a cofactor for an enzymatic reaction that converts glutamic acid residues in the NH_2 -termini of these proteins into -carboxyglutamic acid residues (Fig. 115-1).[1] [2] There are three well-defined classes of -carboxyglutamic acid-containing proteins, although more are likely to be discovered: (1) the mammalian vitamin K-dependent blood clotting and regulatory proteins, (2) -carboxyglutamic acid-containing proteins of vertebrate mineralized tissue, and (3) conotoxins of the marine snail, *Conus*. The -carboxyglutamic acid residues confer essential metal-binding properties on the vitamin K-dependent proteins.[3] If -carboxylation is impaired either as a result of vitamin K deficiency or through pharmacologic intervention, the newly synthesized vitamin K-dependent proteins are secreted into the blood in their des--carboxy or "abnormal" forms. The des--carboxylated proteins cannot bind Ca^{2+}, and the physiologically important metal ion-mediated binding to phospholipid vesicles or cell membranes does not occur. [4] Since many critical enzymatic reactions of blood coagulation proceed on membrane surfaces, coagulation and its regulation are impaired. Therefore, vitamin K metabolism is essential to normal hemostatic and antithrombotic mechanisms. Indeed, inhibition of vitamin K action is the primary mechanism of oral anticoagulant therapy.

MECHANISM OF ACTION OF VITAMIN K

In its role as a cofactor for the vitamin K-dependent carboxylase, vitamin K participates in a series of linked enzyme reactions that result in the generation of -carboxyglutamic acid and the regeneration of active cofactor. This series of reactions is known as the vitamin K cycle (Fig. 115-2). In addition to the enzyme, the reduced form of vitamin K and a glutamic acid-containing polypeptide substrate, the reactions require carbon dioxide and molecular oxygen. In the first reaction in the cycle (Fig. 115-2), an H^+ is abstracted from the -carbon of the glutamyl residue and a carboxyl group is added. [5] Concomitantly, the cofactor, vitamin K, is converted from the reduced to the epoxide form.[6] The enzyme that catalyzes these reactions is the vitamin K-dependent carboxylase, which catalyzes both carboxylation and epoxide formation. These two activities are associated with a

Figure 115-1 Reactants in the vitamin K-dependent carboxylation pathway.

Figure 115-2 The vitamin K cycle. Reduced vitamin K, the hydroquinone form, is a cofactor for the conversion of glutamate to -carboxyglutamate by the vitamin K-dependent carboxylase, also known as the vitamin K epoxidase. Concomitant with conversion of glutamate to -carboxyglutamate, the hydroquinone is converted to 2,3-vitamin K epoxide. The epoxide can be converted to vitamin K quinone by the vitamin K epoxide reductase. Vitamin K quinone can be reduced by two pathways to the vitamin K hydroquinone, completing the cycle.

single enzyme.[7] The vitamin K-dependent carboxylase is a single-chain protein with a molecular weight of 94,000 composed of a single polypeptide chain of 758 amino acids.[8] [9] [10] This enzyme is an integral membrane protein that binds directly to the -carboxylation recognition site on the precursor forms of the vitamin K-dependent proteins.[11] The vitamin K-dependent carboxylase is located in both the endoplasmic reticulum and the Golgi apparatus. [12] [13] However, carboxylation is an efficient process such that carboxylation of protein substrates is completed in the endoplasmic reticulum. [14] The presence of carboxylase in the Golgi apparatus is likely due to the recycling of the membrane-bound enzyme between the endoplasmic reticulum and the Golgi apparatus.

The active site responsible for glutamate binding, identified using the affinity label bromo-acetyl-FLEELY, is located in the N-terminal one-third of the protein. [15] The complementary site on the carboxylase that binds the propeptide carboxylation recognition site also resides in part in the N-terminal one-third of the protein. [16] Regions around residues 234, 406, and 513 define in part the propeptide-binding site while regions around residue 359 are involved in catalysis. [17] The vitamin K epoxidase activity of the protein requires a C-terminal region of this enzyme for this activity. [18] In the absence of propeptide and glutamate-containing substrate, the carboxylase lacks vitamin K epoxidase activity. When these substrates are added to the enzyme, vitamin K epoxidase activity is up-regulated. [19]

As epoxidation occurs concomitant with carboxylation and because vitamin K either from dietary sources or gut flora is in the quinone form, tissues in which -carboxylation takes place must have a mechanism for generating the reduced form of vitamin K. Several enzymes have been identified that perform this function. [20] Vitamin K epoxide reductase, a dithiol requiring enzyme, reduces vitamin K epoxide to vitamin K quinone (Fig. 115-2). Two enzymatic activities, including the epoxide reductase, have been identified that convert vitamin K quinone to the biologically active hydroquinone (Fig. 115-2). The epoxide reductase activity results from an enzyme complex that resides in the endoplasmic reticulum membrane and includes an epoxide hydrolase and a member(s) of the glutathione S-transferase super gene family.[21]

The mechanism by which vitamin K functions as a cofactor with the -carboxylase remains uncertain. The most attractive hypothesis is that an active oxygenated species of vitamin K abstracts a hydrogen from the -carbon of glutamic acid, with subsequent collapse of the activated vitamin K species to vitamin K epoxide and the addition of carbon dioxide to the -carbon of glutamic acid. [22] Oxygen and vitamin KH_2 -dependent exchange of tritium from tritiated water to the -carbon of a glutamic acid in a carboxylase substrate at low carbon dioxide concentrations have been taken as evidence of a carbanion mechanism. [23] Based on a nonenzymatic model, a "base strength amplification mechanism" has been proposed to explain the conversion of vitamin KH_2 into an oxygenated intermediate of sufficient basicity to abstract a hydrogen from the -carbon of a glutamyl residue in a carboxylase substrate. [24] [25] [26] This reaction scheme suggests that epoxidation of vitamin KH_2 by the vitamin K-dependent carboxylase can occur in the absence of formation of -carboxyglutamic acid but that carboxylation cannot occur in the absence of epoxidation.

NATURE OF THE SUBSTRATE

Although many tissues contain the enzymes to carry out -carboxylation and the reactions of the vitamin K cycle, the primary site of synthesis of the vitamin K-dependent proteins of the blood is the liver. These proteins are synthesized with both a signal sequence and a propeptide. The canonical leader sequences provide the signal that indicates that the protein is to be secreted and thus allows the growing polypeptide chain to be translocated to the rough endoplasmic reticulum. All sequences of the propeptides of the vitamin K-dependent proteins are highly homologous and unique to this class of proteins. [27] These propeptides serve as recognition signals that designate these proteins as substrates for the vitamin K-dependent

carboxylase.[28] The -carboxylation recognition site resides on the N-terminus of the propeptide. It is extended by a 10-residue amphipathic -helix. [29] The propeptide of the precursor forms of the vitamin K-dependent proteins serves three functions: (1) to direct -carboxylation by the -carboxylase, [28] (2) to inhibit binding of the carboxylated precursor proteins to membranes,[30] and (3) to up-regulate vitamin K epoxidase activity of the carboxylase. [19]

VITAMIN K

Forms and Distribution

The vitamin K family of chemical compounds has many members. Vitamin K_1 (2-methyl-3-phytyl-1,4-naphthoquinone) is the major form of the vitamin found in plants. Animal tissue and bacteria produce menaquinones, a series of vitamin K forms similar in structure to vitamin K_1 but with varying lengths of unsaturated polyprenyl groups at the 3 position.

Nutritional Sources

Vitamin K is an essential fat-soluble vitamin. The diet is the primary source of vitamin K in humans. Leafy green vegetables, in particular, are a good source of vitamin K_1 ,[31] although vitamin K_1 is widely distributed in the normal human diet. A contribution to adequate vitamin K intake in humans may be provided by the vitamin K_2 synthesized by intestinal bacteria.[32] The daily dietary requirement for the vitamin has been estimated to be 100200 g/day. [33]

Physiology

Vitamin K is absorbed in the ileum. The presence of bile salts and normal fat absorption are required for effective uptake. The storage pool of vitamin K is modest. In the absence of a dietary source of the vitamin, this storage pool can be exhausted within 1 week in an otherwise normal person. Such a deficiency does not generally lead to clinical manifestations, as the vitamin K synthesized by gut flora is available to provide suboptimal but adequate synthesis of vitamin K-dependent proteins.

VITAMIN K DISORDERS

Hemorrhagic Disease of the Newborn

Hemorrhagic disease of the newborn, due to vitamin K deficiency, develops during the first week of life, usually between days 2 and 7 (see Chap. 102).[31] [32] [33] [34] [35] [36] Clinical manifestations include bleeding in the skin or from mucosal surfaces, circumcision, or venopuncture sites. [37] Rarely, internal bleeding, including retroperitoneal or intracranial hemorrhage, is the primary manifestation of hemorrhagic disease of the newborn. These ominous complications are the rationale for the use of vitamin K prophylaxis in neonates.

Almost all neonates are vitamin K deficient, presumably as a result of deficient vitamin K nutriture in the pregnant mother during the third trimester and because of the lack of colonization of the colon by bacteria that produce vitamin K in the neonate. [38] However, this deficiency is further aggravated in some patients by inadequate dietary intake of vitamin K. This disorder is more prevalent in breast-fed babies, since human milk, in contrast to cow's milk, contains only 15 g/L of vitamin K. [37] [39]

Neonates with hemorrhagic disease of the newborn have a prolonged prothrombin time (PT) and partial thromboplastin time (PTT). However, it is critical to distinguish whether the prolongation of these times is a manifestation of the deficiency of the vitamin K-dependent proteins due to vitamin K deficiency or to decreased synthetic capacity of the liver in newborns. Elevation of the abnormal (des--carboxy) prothrombin (PIVKA-II) antigen level is indicative of vitamin K deficiency, since this form of prothrombin appears only when post-translational -carboxylation is impaired, but not when protein synthesis is impaired. [38] Administration of vitamin K (100 g) corrects the deficiency state and usually does not need to be repeated in the otherwise healthy infant.

Prophylactic vitamin K has been in use for in-hospital births for the past 30 years. Vitamin K (100 g to 1 mg) is administered intramuscularly to the newborn immediately after birth. At these doses, vitamin K administration carries little morbidity and can prevent hemorrhagic disease of the newborn. Some of these vitamin K protocols are under revision. [40]

Acquired Vitamin K Deficiency

Dietary Deficiency States and Antibiotics

The requirement for vitamin K is sufficiently low relative to the vitamin K content of a normal diet that clinically significant vitamin K deficiency does not occur as a result of inadequate dietary intake. Although sensitive markers of vitamin K deficiency, such as abnormal (des--carboxy) prothrombin antigen, [41] indicate that diet truly depleted of vitamin K can lead to mild vitamin K deficiency, no evidence shows that an inadequate diet alone can have clinical manifestations. Bacteria in the large intestine produce functional forms of vitamin K. In the absence of dietary vitamin K, small amounts of vitamin K in the large intestine are absorbed passively and prevent severe vitamin K deficiency. In patients medicated with antibiotics that destroy the intestinal flora, this vitamin K source is eliminated. Thus, a common setting of vitamin K deficiency is the case of inadequate or minimal dietary intake treated simultaneously with antibiotics (Fig. 115-3). This form of vitamin K deficiency occurs within 13 weeks, after depletion of body stores of vitamin K. [42]

Malabsorption syndromes are commonly associated with vitamin K deficiency. Defects in the enterohepatic circulation due to biliary disease interfere with absorption of fat-soluble vitamins in the ileum. Primary biliary cirrhosis, [43] cholestatic hepatitis, and other causes of cholestasis may lead to impaired absorption of vitamin K. Furthermore, intestinal malabsorption, as in sprue or regional enteritis, impairs vitamin K utilization. Older

REVERSAL OF LONG-ACTING VITAMIN K ANTAGONISTS ("SUPERWARFARINS")

The long-acting vitamin K antagonists employed as rodenticides lead to pronounced bleeding syndromes following factitious or accidental ingestion of these compounds. After diagnosis and confirmation of the diagnosis, treatment can remain challenging because the inhibition of the complete synthesis of the vitamin K-dependent proteins may continue for months after initial exposure, even in the absence of re-exposure. Fresh frozen plasma is used routinely to treat major bleeding complications, but this therapy is associated with a risk of blood-borne infection. Although it is desirable to correct or paritally correct the PT, the use of prophylactic fresh frozen plasma chronically carries significant risks and expense. Because of the potency of the second-generation rodenticides and their fat solubility, vitamin K_1 at normal doses of administration is ineffective. However, daily doses of 100150 mg of vitamin K_1 administered orally have been effective in normalizing the PT. Over time, the dose of vitamin K_1 needed to correct the PT can be adjusted downward, so that only the required amounts of vitamin K are employed.

Figure 115-3 Abnormal (des-carboxy) prothrombin antigen as a marker for vitamin K deficiency. Normal subjects have no detectable abnormal prothrombin. Vitamin K deficiency arises as a result of disorders of absorption, including mild abnormalities in otherwise normal elderly subjects, or because of impaired intake.

adults also have evidence of mild vitamin K deficiency, presumably because of intestinal malabsorption. [44]

Vitamin K Antagonists

Drugs that inhibit the reutilization of vitamin K lead to a buildup of vitamin K epoxide at the expense of vitamin K hydroquinone. Warfarin and related vitamin K antagonists, whether ingested accidentally, factitiously, or as an overdose of oral anticoagulant therapy, lead to a deficiency of the vitamin K-dependent proteins, prolongation of the PT and PTT, and clinical bleeding manifestations. [45] [46] [47] Although such patients are not vitamin K deficient, the clinical and laboratory manifestations due to vitamin K antagonists are identical to those of vitamin K deficiency. Factitious warfarin ingestion may be seen as a component of a major psychiatric disturbance. Despite repeated denials of use of such medications by suspect patients, this diagnosis must be considered in all patients with *acquired* deficiency of all the vitamin K-dependent proteins. Measurement of serum warfarin level can confirm such suspicions. With the introduction of second-generation rodenticides that inhibit vitamin K action, including brodifacoum, cases of factitious ingestion and accidental poisonings have been increasingly reported. [48] [49] [50] [51] [52]

[53] [54] [55] These long-acting poisons, now widely available (e.g., D-Con), can lead to prolongation of the PT for over 1 year after a single dose; fatalities have been reported.[56] Chemically distinct from warfarin, these compounds are not detected in serum warfarin assays. Specific serum assays have been developed. [57] [58] [59]

Other drugs cause a vitamin K deficiency-like state as well and respond to vitamin K therapy. Excessive doses of aspirin cause hypoprothrombinemia, [60] presumably due to oxidation of vitamin K. Although the mechanism is not completely understood, certain antibiotics, such as moxalactam and cefamandole, cause hypoprothrombinemia.[61] [62] [63] [64] Malnourished patients, even those with an initially normal PT, often develop vitamin K deficiency after intravenous antibiotic therapy.[65]

Hereditary Defects of Vitamin K Utilization

Hereditary combined deficiencies of the vitamin K-dependent proteins, including prothrombin, factor IX, factor X, and factor VII, have been documented in six pedigrees.[66] [67] [68] [69] [70] Although the molecular bases for this phenotype are mostly unknown, defects in the absorption and transport of vitamin K might be anticipated to manifest with this clinical presentation. In addition, abnormalities of the vitamin K-dependent carboxylase or other enzymes within the vitamin K cycle would lead to a deficiency of these proteins. In one case, a point mutation at residue 394 of the carboxylase appears to be the cause of combined deficiency of the vitamin K-dependent proteins in one family.[71] Some cases have been responsive to high daily doses of vitamin K.[66] Other cases have been resistant to vitamin K therapy, which emphasizes the heterogeneity of this disorder.

Therapy for Vitamin K Deficiency

Vitamin K deficiency is treated by the administration of vitamin K_1. The preferred route of administration depends on the urgency for correcting the bleeding tendency and on the risk of inducing local hematoma formation. If the bleeding is severe or life-threatening, fresh frozen plasma should be administered. Because of the risk of transmission of viral infection, the use of

THERAPY FOR VITAMIN K DEFICIENCY

The approach to the treatment of vitamin K deficiency depends on the clinical setting and the severity of bleeding. Except in the face of serious internal bleeding, reversal of the vitamin K deficiency by the administration of vitamin K is generally adequate. If the PT is significantly prolonged to indicate that a bleeding complication may be induced by intramuscular injection, that route of administration of vitamin K_1 (Aquamephyton) should be avoided. Since the delivery of vitamin K by the subcutaneous route is variable, intravenous vitamin K_1 (Aquamephyton, 1015 mg) is the recommended approach, as it ensures rapid delivery. However, intravenous vitamin K_1 does require monitoring, because of early reports of severe allergic reactions with the intravenous route of administration; care must be given to initiate rapid reversal of an untoward reaction. With vitamin K, the PT should return toward the normal range within 12 hours and should have corrected within 2448 hours. Serious bleeding complications attributed to vitamin K deficiency, such as intracranial bleeding, must be reversed immediately. Despite the rapid action of vitamin K, administration of vitamin K should be preceded by the infusion of fresh frozen plasma. This blood component contains all the vitamin K-dependent blood-clotting proteins. In sufficient quantities, fresh frozen plasma can correct, or nearly correct, the PT, as well as the bleeding tendency.

Patients with vitamin K deficiency without bleeding manifestations can be treated with oral vitamin K or, as in patients with chronic vitamin K deficiency secondary to malabsorption syndromes, with subcutaneous vitamin K.

blood products must be weighed carefully. There is no role for currently available concentrates of the vitamin K-dependent proteins because of the risk of transmission of viral disease.

Chapter 116 - Inhibitors of Blood Coagulation

Donald I. Feinstein

Acquired inhibitors of blood coagulation, also known as circulating anticoagulants, are pathologic macromolecules in blood that directly inhibit blood clotting proteins or reactions involving blood clotting. Most have been characterized as antibodies. These inhibitors arise secondary to transfusion of plasma proteins in patients with hereditary bleeding disorders, or may arise de novo in patients with previously normal hemostatic mechanisms.

ACQUIRED INHIBITORS OF FACTOR VIII

Clinical Setting

Virtually all inhibitors of factor VIII are recognized because of their interference with or neutralization of factor VIII activity. Most occur in four clinical situations: alloantibody inhibitors in hemophilia A, postpartum, in association with various immunologic disorders, and in older patients without any associated disorder. The last three occur with an estimated incidence of 0.21.0/1 × 10 persons/year. [1]

In 1981, Green and Lechner[2] surveyed 215 patients with factor VIII inhibitors in an effort to gather demographic information regarding spontaneously arising inhibitors to factor VIII. The gender incidence was approximately equal, and almost 60% of the patients were >60 years of age. No associated disease was found in 50% of patients, but rheumatoid arthritis, systemic lupus erythematosus (SLE), drug reactions, dermatologic disorders, and different types of malignancies (solid tumors and lymphoproliferative) were each seen in 815% of the total group. In 13.5% of cases, the disorder occurred during the postpartum period. These associations have been corroborated by other reports. [3] Overall mortality was 22%. Approximately 38% showed eventual spontaneous disappearance of the inhibitor. The spontaneous remission rate was confirmed by Lottenberg et al, [1] who reported that among 16 patients receiving no immunosuppressive therapy, 5 had spontaneous remissions.

Factor VIII Inhibitors Occurring in Patients with Immunologic Disorders and in Patients Without Underlying Disease

Immune disorders associated with factor VIII inhibitors include rheumatoid arthritis, [4] [5] SLE and other systemic autoimmune diseases,[4] [5] [6] penicillin or other drug reactions,[7] bronchial asthma, [4] [5] inflammatory bowel disease,[5] erythema multiforme,[5] dermatitis herpetiformis,[5] graft-versus-host disease,[8] and interferon-therapy.[9] [10] Occasionally, factor VIII inhibitors are associated with monoclonal gammopathies. Most patients have no underlying disease.

Factor VIII Inhibitors Occurring Postpartum

Factor VIII inhibitors can occur during the postpartum period, [4] [5] [6] [11] [12] [13] and rarely during pregnancy.[14] Most often, the inhibitor occurs after the birth of the first or second child. Although a bleeding tendency may become evident immediately or after a prolonged interval, there is usually a 2- to 5-month delay before the diagnosis is made. The course in these patients is variable, but the inhibitor disappears spontaneously in most patients after 1218 months. [11] In 51 patients with postpartum inhibitors, the survival rate was 97% at 2 years, and Kaplan-Meier analysis revealed a probability of complete remission of almost 100%. [13] The median time to complete remission was 11 months, an interval shortened with immunosuppressive drugs but not with steroids alone.

In patients who became pregnant again after the occurrence of a postpartum factor VIII inhibitor, [12] none of those in remission have had a recurrence. The cause of these postpartum inhibitors is unknown.

Properties of Spontaneously Acquired Factor VIII Inhibitors

With rare exceptions, factor VIII inhibitors are IgG antibodies. These inhibitors have restricted heterogeneity because many possess either or light chains. [5] [7] [15] [16] [17] [18] [19] [20] [21] These inhibitors frequently contain mixtures of heavy chain subclasses. Hultin et al [19] found that both hemophilic and nonhemophilic inhibitors contain mixtures of IgG_1 and IgG_4 subclasses. The high incidence of factor VIII inhibitors containing a subpopulation of IgG_4 is significant because this subclass constitutes <5% of plasma IgG. The inhibitors are specific for factor VIII activity, and most do not interfere with the activities of von Willebrand factor (vWF) within the factor VIIIvWF complex. vWF antigen and function are normal in patients with such inhibitors. Factor VIII inhibitors do not participate in complement fixation; [5] [6] they show species specificity both in vitro and in vivo in that human factor VIII is generally neutralized to a greater extent than bovine or porcine factor VIII. Infusion of bovine or porcine factor VIII into a patient with an inhibitor often raises the factor VIII level. [22]

The kinetics of the reaction between factor VIII and most hemophilic inhibitors is first order with respect to both factor VIII

and to inhibitor (type I).[23] [24] The inhibitor can be completely neutralized by excess factor VIII.[23] [25] A time dependence of the neutralization of factor VIII sometimes requires 12 hours to reach equilibrium at low inhibitor concentrations. [23] [24] Neutralization occasionally takes place in an initial rapid phase, followed by a very slow second phase.[26] [27] [28] [29] By contrast, inhibitors arising in most nonhemophiliac patients frequently differ in their reaction kinetics from inhibitors arising in hemophiliac patients.[27] [30] [31] A linear relationship between the inhibitor concentration and the amount of factor VIII inactivated is observed with hemophilia inhibitors (type I), but not with most spontaneous inhibitors (type II). Thus, most spontaneous inhibitors do not totally inactivate factor VIII in vitro. Although most factor VIII inhibitor patients have no factor VIII in the plasma, the occasional patient exhibits some plasma factor VIII activity. [6] [28] [31] [32]

Epitope Specificity of Factor VIII Antibodies

The antigenic regions on the factor VIII molecule to which neutralizing factor VIII inhibitors bind have been identified. [33] [34] [35] [36] [37] [38] [39] [40] [41] [42] [43] The epitopes to which alloantibodies or autoantibodies are directed are limited to certain areas of the factor VIII light or heavy chains. [33] [34] [35] [36] [37] [38] [39] [40] [41] [42] [43] The factor VIII molecule consists of two series of repeated homologous domains and a single B domain arranged in the following order: A1-A2-B-A3-C1-C2 (see Chap. 107). Small regions rich in acidic amino acids are located between A1 and A2 (called AR1), A2 and B (AR2), and B and A3 (AR3). [39] The heavy chain consists of A1-AR1-A2-AR2-B and the light chain consists of AR3-A3-C1-C2. [39] The A and C domains are required for functional activity, whereas the B domain is not. Anti-A2 and -C2 antibodies are present in approximately 68% of plasmas tested by immunoprecipitation assays using recombinant polypeptide fragments of factor VIII. [43] [44] [45] In addition, 46% of antibodies contain antibodies that bind to AR3. [43] [46] There are also less common AR1, A3, and C1 antibodies and antibodies to a light chain epitope outside of C2.[43] [47] [48] The antibody or combinations of antibodies that inhibit factor VIII activity usually consist of those with A2, C2, and AR3-A3-C1 epitopes because of the ability of polypeptides containing those epitopes completely to neutralize inhibitor activity. [39] In addition to the C2 epitope, there probably exists one other distinct light chain epitope and an epitope in AR1. [39]

Antibody patterns in hemophiliac patients differ from those in autoantibody patients. [39] Forty-eight percent of autoantibody patients have C2 as their sole antibody, whereas this pattern occurred in only 1 of 34 hemophiliacs. [39] Moreover, 62% of autoantibody patterns are directed to a single epitope, in contrast to only 17% of hemophilic patterns. Fewer autoantibody patients contain anti-A2 and anti-AR3-A3-C1 antibodies, and the occurrence of A2 plus C2 antibodies is also less common. Hemophiliacs treated with either plasma-derived factor VIII or recombinant factor VIII have equally complex patterns, but differ in epitope specificity from one

another.[39] The relative amounts of antibody to the A2 and C2 domains can vary, and neither level is always correlated with the inhibitor level. [39] [42]

Anti-C2 antibodies interfere with factor VIII function by blocking the binding of factor VIII to phospholipid, [39] [40] whereas anti-A2 antibodies inhibit activated factor VIII function by blocking the formation of the complex of factor IXa, factor VIII, and factor X. [41] [43] Some antibodies can interfere with vWF binding, [39] [43] [49] [50] [51] and some antibodies reduce the rate at which thrombin-activated factor VIII is released from vWF. [52] The inhibitor produced by a given patient may change over the course of time and a few non-neutralizing antibodies may occur. [1] [33] [34] [35] [36] [37]

Recognition, Identification, and Quantitation of Factor VIII Inhibitors

The presence of a factor VIII inhibitor should be suspected whenever a patient with no prior bleeding history presents with spontaneous massive bruising or with large, unexplained hematomas. The partial thromboplastin time (PTT) is prolonged, whereas the prothrombin time (PT) and thrombin time are normal. The PTT of a mixture of the patients plasma and normal plasma is also prolonged, although inactivation of factor VIII may require preincubation for 12 hours. [26] [27] [53] [54] Confirmation that an inhibitor acts specifically with factor VIII requires incubating the patients plasma diluted with an equal volume of normal plasma and performing assays of factors VIII, IX, XI, and XII at 0, 60, and 120 minutes. If the inhibitor is specific for factor VIII, only factor VIII decreases over time. A technique that uses the PTT rather than a factor VIII assay detects weak inhibitors of <0.4 Bethesda units. [53] [54]

Quantitative inhibitor measurements are important in the emergency management of hemorrhage and for evaluation of long-term therapy. A standard unit of measurement, termed the Bethesda unit,[55] is best suited for the measurement of inhibitors arising in hemophiliacs, but the complexity of reaction kinetics and variations in antibody affinities for factor VIII, particularly in nonhemophilic inhibitors with high residual factor VIII, limit standardization. Because of the latter, it may be difficult accurately to determine the inhibitor titer in nonhemophiliac patients with spontaneously acquired inhibitors. The results of the Bethesda assay underestimate the actual in vivo level of human factor VIII autoantibodies. Thus, assay results are less valuable in guiding therapy than they are in hemophiliac patients with inhibitors. Moreover, there is little correlation between the factor VIII level, titer of inhibitor, and degree of prolongation of the partial thromboplastin time with bleeding complications. In England, the New Oxford method is used to quantitate factor VIII inhibitors, [56] with 1 Bethesda unit equaling approximately 1.21 times 1 New Oxford unit. The Bethesda assay does not ensure pH control during the incubation period and this may result in nonantibody-mediated inactivation of factor VIII. A modified assay has been proposed that replaces the imidazole buffer with immunodepleted factor VIII-deficient plasma. [57]

Therapy of Patients with Factor VIII Inhibitors

The major objectives in the treatment of these patients are twofold: (1) the treatment of acute bleeding episodes, and (2) the elimination of the autoantibody to factor VIII. When a patient with an inhibitor hemorrhages, conservative measures, including immobilization, compression, and possibly epsilon-aminocaproic acid, should be considered. The use of intramuscular injections or aspirin-containing compounds is contraindicated.

The indication for the use of factor VIII concentrates or factor IX complex concentrate is serious active bleeding. If the patient is not actively bleeding, transfusion is not indicated. Unlike inhibitors associated with hemophilia A, most spontaneously acquired inhibitors are not inducible when the patient is exposed to factor VIII. When the patient is bleeding, porcine factor VIII, [3] highly purified human factor VIII, or recombinant factor VIII is indicated. Human autoantibodies usually have less affinity for porcine factor VIII than for human factor VIII and cross-reactivity with autoantibodies is <5%, compared with 2025% with alloantibodies. [3] Consequently, less concentrate is necessary to achieve effective hemostasis. [3] [22] [58] A report from the International Acquired Hemophilia Study Group provided data on 65 patients with factor VIII autoantibodies treated with porcine factor VIII. [59] The treatment schedule varied from a simple infusion to three to four infusions/day for several days. The average number of infusions per patient was 11, with the average length of treatment being 8.5 days. A wide range of doses was used, but the mean initial dose was 85 IU/kg. An excellent or good response was reported in 78% of the patients, a fair response in 12%, and poor response in 10%. The pretreatment median level of the anti-human factor VIII inhibitor was 38 Bethesda units, with a range of 1.21,024, whereas the average

MANAGEMENT OF SPONTANEOUSLY ACQUIRED FACTOR VIII INHIBITORS

CONSERVATIVE MEASURES

When a patient with an inhibitor has a hemorrhage, conservative hemostatic measures should be used to complement whatever other therapy is used. These measures include immobilization, compression, local application of hemostatic agents, and, on occasion, administration of epsilon-aminocaproic acid. The patient should not receive intramuscular injections, unnecessary venipunctures, aspirincontaining compounds, or nonsteroidal anti-inflammatory drugs. If the patient has a low inhibitor level (<3 Bethesda units) then desmopressin (DDAVP) 0.3 g/kg can be given immediately.

SELECTION OF A BLOOD PRODUCT

For patients who are actively bleeding, therapeutic options include treatment with porcine factor VIII concentrate (Hyate:C), human plasma-derived or recombinant factor VIII concentrates, factor IX complex concentrates, and recombinant factor VIIa. If the patient is not actively bleeding, transfusion is unnecessary. Unlike inhibitors associated with hemophilia A, most spontaneously acquired inhibitors do not increase in titer after exposure to factor VIII. Thus, this consideration should not impede transfusion therapy. Because human autoantibodies usually have less affinity for porcine factor VIII than for human factor VIII, porcine factor VIII concentrate is preferable to achieve effective hemostasis.

The titer of the inhibitor and its reactivity to porcine factor VIII determines the amount of factor VIII to be used. If the titer is low (<5 Bethesda units), a large dose of factor VIII sufficient to neutralize all of the circulating inhibitor and provide enough excess factor VIII to achieve a plasma factor VIII of 0.3 U/ml (30%) can be given. This can be usually achieved by giving a rapid infusion of porcine factor VIII of approximately 75 U/kg, or alternatively by giving 150 U/kg of human factor VIII concentrate followed by a continuous infusion of 10 U/kg/hr. Alternatively, a large amount of either porcine or human factor VIII can be given every 14 hours, giving 20 units of factor VIII/kg for each Bethesda unit plus an additional 40 U/kg. If a patient has a moderately high inhibitor level of 530 Bethesda units, the inhibitor level may be lowered by approximately 5065% by a 1.5-volume plasmapheresis, or alternatively by using one of several methods of extracorporeal immunoadsorption. After apheresis or immunoadsorption, the patient is initially given either porcine factor VIII (75100 U/kg) or human factor VIII (150 U/kg), followed by a continuous infusion in the same dose noted previously. If plasmapheresis cannot be done promptly or if the patient has a very high titer inhibitor (>30 Bethesda units), it is impossible to achieve hemostatic levels of factor VIII except by using porcine factor VIII (100150 U/kg) or by bypassing the site of inhibitor action with factor IX complex concentrate with a dose of 75 U/kg or recombinant factor VIIa at a dose of 90 g/kg. The inhibitor plasma should be tested against porcine factor VIII in vitro before its use but, if it is not immediately available, then assume that it is approximately <5 Bethesda units and infuse porcine factor VIII as noted previously. If neither human nor porcine factor VIII inhibitor titers are readily available, then freeze plasma to be subsequently sent to a reference laboratory and infuse porcine factor VIII. Continuous use of repeated infusions over an extended period may result in the development of antibodies to the porcine factor VIII, resulting in a lack of efficacy. In a rare patient, anaphylaxis complicates therapy with the porcine concentrate.

IMMUNOSUPPRESSION OF THE INHIBITOR

The long-term goal in the management of these patients should be aimed at immunosuppression of the autoantibody production. Although many immunosuppressive regimens have proved efficacious, we initiate therapy with intravenous IgG (1 g/kg) for 2 days. Immunosuppressive therapy with prednisone 80 mg/day PO and cyclophosphamide (2 mg/kg/day PO) is initiated concurrently with IVIG. Inhibitor titers are determined every 12 weeks. This regimen is continued for 4 weeks. If a significant decrease in titer occurs (>50% reduction), the regimen is continued until there is no further decrease in titer. If there is no significant decrease in titer, then the regimen is discontinued. Alternatively, a similar immunosuppressive regimen can be used, preceded by an infusion of factor VIII. Human factor VIII (50100 U/kg) is followed by prednisone (100 mg/day for 5 days), cyclophosphamide (500 mg/m^2 IV on day 1), and vincristine (2 mg IV on day 1). This regimen is repeated at 34 weeks. If the neutrophil nadir is >2,500/l, then the cyclophosphamide dose is increased to 750 mg/m^2. If the inhibitor titer is not decreased after three cycles, the regimen is discontinued.

If the preceding regimen is unsuccessful, the patient is placed on azathioprine (2 mg/kg) and inhibitor titers are performed. If no significant response occurs in 8 weeks, the regimen is discontinued and cyclosporine or interferon- therapy is tried.

level of antiporcine factor VIII was 2 Bethesda units, with a range of 015. The clinical response was not related to the titer of antibody to either human or porcine factor VIII, the dose of porcine factor VIII infused, or the factor VIII level after the initial infusion. The concentrate was well tolerated by 90% of patients, with only one anaphylactic reaction. No episodes of significant thrombocytopenia occurred. Ten patients (15%) had an increase in antiporcine factor VIII inhibitor titers. An important parameter in determining the type and amount of factor VIII to be infused is the titer of the inhibitor and its reactivity to porcine factor VIII. If the titer is low (<5 Bethesda units), a large dose of factor VIII sufficient to neutralize all the circulating inhibitor and provide enough excess factor VIII to achieve a plasma factor VIII of 0.3 U/ml can be given. This can usually be achieved with the rapid infusion of porcine factor VIII (5075 U/kg) or human factor VIII (150 U/kg), followed by a continuous infusion at 10 units kg/hr. Alternatively, a large amount of either porcine or human factor VIII can be given every 14 hours, giving 20 units of factor VIII/kg for each Bethesda unit plus an additional 40 units/kg. [60] If a patient has a moderately high inhibitor level of 530 Bethesda units, the inhibitor level may be lowered by approximately 5090% by plasmapheresis or, alternatively, by one of several methods of extracorporeal immunoadsorption. [61] [62] After apheresis or immunoadsorption, the patient is given a bolus of either porcine factor VIII (75100 U/kg) or human factor VIII (150 U/kg), followed by a continuous infusion of factor VIII. If the patient has a high-titer inhibitor of >30 Bethesda units, it is impossible to achieve hemostasis, except with porcine factor VIII (100150 U/kg), factor IX complex concentrate (5075 U/kg), or recombinant factor VIIa (90 g/kg). Inhibitor plasma should be tested against porcine factor VIII in vitro before its use; continuous use or repeated

infusions over an extended time may result in the development of antibodies to the porcine or human factor VIII. [3] [59] In an occasional patient, allergic reactions or thrombocytopenia complicates therapy with porcine factor VIII. [3] [59] [63]

Factor VIII levels must be assayed frequently to monitor the plasma factor VIII level achieved in vivo, particularly after the infusion of a factor VIII concentrate. The infused factor VIII may be efficacious in vivo before it is inactivated.

Factor IX complex concentrates can also be used to control bleeding in patients with factor VIII inhibitors, particularly when the inhibitor titer is high. [64] [65] [66] [67] [68] These concentrates exhibit a procoagulant activity that bypasses the factor VIII-dependent clotting reactions. Two types of factor IX complex concentrate have been used in the treatment of patients with factor VIII inhibitors: regular unactivated intermediate-purity factor IX complex concentrates (Konyne 80, profilnine HT, and Bebulin); and activated concentrates, so-called anti-inhibitor coagulant complex. Both types of concentrates contain various amounts of activated factors VII, IX, and X and phospholipids, and should be distinguished from the highly purified factor IX concentrates used in the treatment of hemophilia B. The activated concentrates (Autoplex; FEIBA) contain a greater amount of the factor VIII bypassing material and are specifically designed for patients with factor VIII inhibitors. Both types of concentrates have proved efficacious in hemophiliacs with inhibitors in controlled clinical trials. [67] [69] However, some investigators have used anti-inhibitor coagulant complex in life-threatening situations in which the unactivated concentrates were ineffective. Factor IX complex concentrates are also effective in achieving hemostasis in patients with high-titer spontaneously acquired inhibitors. In a recent French multicenter retrospective survey of the use of FEIBA in 60 patients with factor VIII or IX inhibitors (6 of whom had spontaneously acquired inhibitors) with 433 bleeding episodes or surgical procedures, efficacy was good to excellent in 81.3% of the episodes, whereas it was poor in the remainder. [70] Adverse effects were seen in only 5 of 433 episodes (12%), but an anamnestic response occurred in 17 of 54 evaluable patients (31.5%).

Purified components of the prothrombin complex have been used to treat hemorrhages in patients with inhibitors. A highly purified concentrate containing factor VIIa achieved good hemostasis[71] and, subsequently, a recombinant preparation of human factor VIIa has shown significant efficacy in patients with inhibitors. [72] [73] In a survey of more than 240 patients, many of whom consisted of patients with spontaneously acquired factor VIII inhibitors, the recombinant factor VIIa concentrate was used successfully for critical bleeds or for surgery. [74] Dosage and interval of dosing is still being evaluated, but factor VIIa therapy is initiated with doses of 90 g/kg, and this dose is repeated every 23 hours (half-life is 2.9 hours) for one to two times for spontaneous bleeds and every 23 hours for 48 hours for surgical procedures, followed by tapering doses over several days. Efficacy has been reported in approximately 90% of patients with spontaneous bleeds and in approximately 80% of patients undergoing surgical procedures. [74] Treatment is not influenced by the inhibitor titer, and no specific assay reflects clinical efficacy. Antibodies to factor VII do not occur except in factor VII deficient patients. [75] The safety profile has been excellent and thrombotic events are rare.

Long-term goals in the management of these patients should be aimed at immunosuppression of the autoantibody production. Assessment of immunosuppressive therapy is difficult because inhibitors occasionally disappear spontaneously, particularly in patients with postpartum inhibitors and patients with drug-induced inhibitors.[2] Many patients respond to corticosteroids alone; in one report of 16 patients receiving only steroids, [76] 7 were complete responders, 4 partial responders, and 5 nonresponders. The time to response averaged approximately 16 days. In their 1981 survey, Green and Lechner [2] found that inhibitors disappeared in 22 of 41 steroid-treated patients. In a prospective, multicenter, controlled clinical trial, antibody disappeared in 10 of 30 patients treated with prednisone alone (1 mg/kg) in the first three weeks, and in 3 of 4 other patients randomized to continue prednisone after the first 3 weeks of prednisone therapy. [77] In patients resistant to steroids, the use of cytotoxic agents, particularly cyclophosphamide either alone or in combination with corticosteroids, can be efficacious. In the controlled trial noted previously, antibody disappeared in three of six patients randomized to oral cyclophosphamide and prednisone after the patients were resistant to prednisone alone in the first 3 weeks. Eight patients did not respond. In this trial, the titer of antibody was significantly lower in responders than in nonresponders, and most responses occurred within 6 weeks of starting therapy.

The use of factor VIII concentrate infusion before immunosuppressive therapy was first proposed by Green. [78] The hypothesis proposed that the factor VIII concentrate infusion stimulates the abnormal clone of immune cells responsible for autoantibody synthesis and results in a greater cytotoxic effect by the immunosuppressive therapy. A combination of cyclophosphamide, vincristine, and prednisone every 3 weeks, preceded by an infusion of factor VIII concentrate (50100 U/kg) resulted in complete disappearance of the inhibitor in 11 of 12 patients. [79] The responses occurred rapidly, usually within only two or three courses, and remissions in all patients were durable over 25 years.

The initial inhibitor titer may be an important prognostic factor in the treatment of these patients. [80] Patients with inhibitor titers of <510 Bethesda units respond rapidly, whereas those with higher titers respond more slowly or fail to respond.

In a recent report, nine consecutive patients with a spontaneously acquired factor VIII autoantibody were treated with oral cyclophosphamide (100200 mg/day) and prednisone (5080 mg/day) until the inhibitor titer reached zero, followed by slowly decreasing doses. [81] All patients achieved a complete remission, with a median time of 3 weeks to resolution of all bleeding symptoms and a median time to undetectable factor VIII inhibitor of 12 weeks (range, 337 weeks). Two patients had a relapse as the immunosuppressive drugs were tapered, but the patients reattained a complete response with reinstitution of therapy. Initial titers of factor VIII inhibitor levels ranged from 2.5 to 1,040 units (mean, 174), and the patients with higher inhibitor titers required a longer duration of therapy. The results of this study, along with the results of the prospective clinical trial reported by Green et al, [77] strongly suggest that the initial immunosuppressive treatment of choice is oral prednisone and cyclophosphamide; a preliminary dose of human factor VIII is unnecessary. Immunosuppressive therapy should be continued as long as the inhibitor titer is decreasing because patients with high inhibitor titers respond more slowly than patients with low inhibitor titers. Patients with inhibitors who have high residual factor VIII levels in vitro (0.040.34 U/ml) respond well. [32]

Azathioprine in doses of 100200 mg/day (or 2 mg/kg/day) has also proved effective; Green and Lechner [2] found 19 of 28 patients to respond completely. In addition, Söhngen et al[82] reported five patients who responded to a combination of corticosteroids and azathioprine within 6 weeks of initiating therapy. There have also been cases reported in which cyclosporine [83] or interferon- [84] resulted in a complete response.

Any response to immunosuppressive therapy generally occurs within 612 weeks. If the titer has not decreased significantly in that period, therapy should be discontinued. Although most patients who obtain a complete response do not recur, an occasional patient relapses early at the time of tapering or withdrawal of immunosuppressive therapy, and an occasional patient relapses several months later.

Spontaneously acquired factor VIII inhibitors respond to

high-dose intravenous IgG (IVIG). [85] In a prospective, multicenter study of high-dose IVIG, 19 patients received either 1 g/kg × 2 days or 400 mg/kg × 5 days, followed by periodic maintenance doses. [86] A rapid decline in inhibitor titer occurred in 34 days in two patients and a gradual decline occurred in four other patients, with nadirs occurring several weeks to many months after starting therapy. Concurrent therapy with prednisone could have contributed to the response in two patients. Thus, the response rate was estimated to be between 25% and 37.5%. The mechanism by which patients with inhibitors respond to intravenous IgG is unknown. However, IgG may have both a short- and long-term immunosuppressive effect. [87] [88] [89] Anti-idiotypic antibodies are present in the IgG preparations; [90] [91] [92] [93] the emergence of anti-idiotypic antibodies may be the explanation for the occasional spontaneous remission and some instances of remission induced by immunosuppressive agents. [91] [94] [95]

The administration of 1-deamino-8-*D*-arginine vasopressin (DDAVP) can briefly raise the factor VIII level in patients who have very low inhibitor titers (<3 Bethesda units) and whose antibodies have type II reaction kinetics. [96]

ACQUIRED INHIBITORS OF VON WILLEBRAND FACTOR

Patients with von Willebrand disease may acquire inhibitors after plasma transfusion. Moreover, an acquired syndrome similar to hereditary von Willebrand disease with onset later in life has been described. [97] [98] [99] [100] [101] [102] [103] [104] [105] [106] [107] [108] This acquired syndrome may occur in previously healthy people, or it may be associated with SLE, lymphoproliferative disorders, myeloproliferative disorders, hypothyroidism, and Wilms tumor. The presence of an inhibitor is frequently associated with a monoclonal immunoglobulin, but whether the serum M component has inhibitory activity has not been determined unequivocally. [103] [104] [106] [107] The clinical course in these patients has been variable, from mild bruising and mucous membrane bleeding to severe and life-threatening bleeding.

Laboratory studies usually show a reduction of ristocetin co-factor activity, vWF antigen, and factor VIII activity, and a prolonged bleeding time. In some cases, the patients plasma impairs ristocetin co-factor activity of normal plasma [99] [104] [105] [106] or results in a decreased level of vWF in normal plasma. Recently, in two cases of acquired von Willebrand disease, IgG antibodies could be demonstrated by a competitive enzyme-linked immunosorbent assay (ELISA) procedure. [109] In contrast, inhibitory activity cannot usually be demonstrated in the patients plasma when incubating the patients plasma and normal plasma, and measuring vWF activity, vWF antigen, or factor VIII. [104] [105] [106] [107] In one patient,[101] correction of the abnormality followed radiation therapy for lymphoma; in another patient, who had Waldenström macroglobulinemia,[103] vWF was detected on the monoclonal lymphocyte surface. These findings would suggest that in some patients with this syndrome, vWF can bind to cellular surfaces. With few exceptions, [100] none of the inhibitors had inhibitory activity in vitro against factor VIII clotting activity.

Multimer analysis of plasma from patients with acquired von Willebrand disease has yielded variable results. In 7 patients, [104] multimer analysis showed no alteration of multimeric structure (similar to type I von Willebrand disease), whereas 10 other patients [104] [105] [106] lacked highmolecular-weight multimers (similar to type II von Willebrand disease). These findings would suggest that these antibodies are heterogeneous and are directed against different epitopes of the vWF molecule.

Thus, acquired von Willebrand disease may result from several different pathophysiologic mechanisms. In one type, the inhibitor inactivates the biologic activity of vWF. In a second type, the inhibitor binds to a site on the vWF molecule lacking biologic activity, thus causing rapid clearance of vWF from the circulation because of the formation of immune complexes. In a third type, vWF binds to cellular surfaces. In the second and third types, no inhibitor activity against vWF can be demonstrated in vitro.

Infusion of plasma or cryoprecipitate in patients with acquired von Willebrand disease does not result in the expected increase in vWF activity. The secondary rise in factor VIII activity, characteristically seen in transfused patients with hereditary von Willebrand disease, does not occur. Despite these findings, transfusion of cryoprecipitate or factor VIII concentrate containing vWF activity (Humate-P, alphanate, or koate HP) or administration of DDAVP in a bleeding patient may result in a transient and blunted rise in vWF activity, vWF antigen, and factor VIII, such that effective hemostasis may be achieved. Several cases of acquired von Willebrand disease have been reported that responded rapidly to high-dose intravenous IgG (400 mg/kg/day × 5 or 1 g/kg × 2 days). [110] [111] [112] [113] Although the responses may be transient, in a few patients the response may last for 23 weeks. Moreover, after recurrence repeat administration of IVIG may result in repeated responses.

ACQUIRED INHIBITORS OF FACTOR V

Rarely, factor V inhibitors occur in patients with hereditary factor V deficiency after transfusion. [114] However, most factor V inhibitors occur spontaneously in older, previously healthy patients in the absence of a common underlying disease. [114] [115] [116] [117] [118] [119] [120] [121] [122] [123] [124] [125] The most common association seen in approximately two-thirds of the cases is a surgical procedure preceding the development of the inhibitor. [126] Other significant associations include blood transfusion, -lactam antibiotics, and malignant diseases. [126] Many of the cases that followed surgery were associated with the use of topical bovine or fibrin glue. Both of these substances contain bovine thrombin and small amounts of bovine factor V that can result in the production of anti-bovine thrombin antibodies or anti-bovine factor V antibodies that cross-react with human thrombin and factor V. [127] Despite the various associations with factor V antibodies, in approximately 20% of cases no associations can be identified, [126] and in these patients, true autoantibodies to factor V presumably are present.

The degree of clinical bleeding in these patients varies, in contrast to the uniformly severe bleeding in patients with factor VIII inhibitors. This extreme variabilityfrom no clinical sequelae to fatal hemorrhagecan possibly be explained by the accessibility of platelet factor V to the antibody. [124] [125] Studies by Nesheim et al [124] on a patient with a factor V inhibitor suggest that platelet factor V is relatively protected from an anti-factor V antibody in whole blood, even though plasma factor V is completely neutralized. Thus, platelet factor V may play a key role in maintaining hemostatic competency in the presence of a factor V inhibitor. This hypothesis is supported by the efficacy of platelet concentrates in a factor V inhibitor patient. [119] Fresh frozen plasma failed to effect hemostasis, but on four separate occasions, effective hemostasis was achieved with platelet transfusions. Two other patients responded to platelet transfusions, but others were not responsive. The course of the factor V inhibitor is short lived in most patients, disappearing within 10 weeks. Removal of the antibody by plasmapheresis or immunoadsorption resulted in decreased bleeding in some patients. [126] Whether steroids or other immunosuppressive agents influence the natural history of the inhibitors is unclear. The inhibitor may disappear with immunosuppressive therapy, [119] [122] [123] or it may disappear spontaneously without specific therapy. [114] [118]

The laboratory identification of a factor V inhibitor is based on coagulation assays. Both the PTT and PT are prolonged, and normal plasma fails to correct these assays. These findings in the presence of a normal thrombin time should strongly suggest the presence of a factor V inhibitor. [114] The demonstration that a mixture of the patients plasma and normal plasma specifically

lacks factor V clotting activity is required for a definitive diagnosis. Most of the factor V inhibitors are polyclonal IgG, but one was identified as both IgM and IgG, and another as IgA and IgG. [118]

ACQUIRED INHIBITORS OF FACTORS VII, IX, AND X AND PROTHROMBIN

Except for the prothrombin antibody associated with the lupus anticoagulant, spontaneously acquired inhibitors to factors VII, IX, and X or prothrombin are rare. Bajaj et al[128] described a patient in whom hypoprothrombinemia developed because of an antibody that bound to a prothrombin epitope without inhibition of coagulant activity. Unlike the hypoprothrombinemia associated with the lupus anticoagulant, this patients plasma did not contain antibody activity against anionic phospholipids, and the antibody bound to the NH_2 -terminal end of the prothrombin molecule.

Hawiger et al[129] described a patient with SLE and severe thrombocytopenia, in whom spontaneous bleeding from multiple sites developed, whose plasma contained an antibody that reacted with bovine thrombin. Scully et al [130] reported a patient who bled excessively after dental extraction and from the gastrointestinal tract. This patient had a prolonged PTT, PT, and thrombin time and a normal Reptilase time, and the immunoglobulin fraction of her plasma bound to both thrombin and prothrombin. Barthels and Heimburger[131] described a patient with cirrhosis and bleeding who had a prolonged PTT, PT, and thrombin time. The patients IgG prolonged the thrombin time but did not affect fibrin polymerization. In addition, in three other patients with an autoimmune disorder, thrombin inhibitors associated with bleeding developed,[132] [133] [134] and an occasional patient has been described with a thrombin inhibitor without any underlying disease. [135] In contrast, a rare patient may acquire a thrombin inhibitor affecting the anticoagulant function of thrombin causing thrombosis rather than bleeding. [136] [137] Stricker et al[138] described three postsurgical patients with prosthetic cardiac valves, in whom antibodies to human and bovine thrombin developed. All three patients had prolonged PTT and thrombin time. The thrombin time did not correct on mixing with normal plasma or protamine, but the Reptilase time was normal. Further studies of these patients have shown that these antibodies develop in patients exposed to topical thrombin or fibrin glue preparations during surgical procedures. [139] [140] [141] [142] In fact, in 3350% of patients exposed to such preparations, antibodies to bovine thrombin or bovine factor Va [127] [139] [140] [141] [142] develop that can cross-react with their human counterparts, resulting in prolonged clotting tests, particularly the thrombin time. [141] [142] Fortunately, most of these patients do not bleed, but some have excessive bleeding that can be fatal.

Two patients in whom IgG autoantibodies to factor VII developed had a prolonged PT but a normal PTT. [143] [144] In addition, Weisdorf et al[145] described a patient with severe aplastic anemia who had acquired factor VII deficiency. A factor VII-binding immunoglobulin in the patients plasma bound to factor VII, resulting in rapid clearance of the immune complex. There also have been several patients with hereditary factor VII deficiency who have become alloimmunized after being treated with recombinant factor VIIa concentrate.[75]

Spontaneously acquired factor IX inhibitors are extremely rare. [146] [147] [148] [149] [150] The clinical setting in which these inhibitors occur is similar to that associated with the development of factor VIII inhibitors. Three were associated with SLE and two with the postpartum state. Most seem to disappear within 17 months of onset, but whether immunosuppressive therapy alters the natural history is unknown.

Three documented cases of a factor X inhibitor have been reported. [151] [152] These patients were elderly without underlying disease who had the sudden onset of a bleeding diathesis. In two of three cases, the inhibitor was characterized as IgG antibodies and disappeared spontaneously without specific therapy.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

ACQUIRED INHIBITORS OF FACTORS XI AND XII

Inhibitors directed against factors XI or XII have been reported. [153] [154] [155] [156] [157] [158] [159] Some were detected in patients with hereditary factor XI deficiency after transfusions, whereas most occurred spontaneously in patients with SLE. Many of these patients also had low factor XII levels. Zucker et al [156] studied several patients on long-term chlorpromazine therapy in whom asymptomatic IgM inhibitors of the intrinsic phase of blood coagulation developed. The inhibitor resulted in decreased measurements of all the plasma clotting factors in the intrinsic pathway and was shown to interfere with the coagulant activity of contact product. These inhibitors may be similar to those described by Canoso et al [160] in patients on long-term, high-dose phenothiazine therapy. Except for those with hereditary factor XI deficiency, none of the patients in whom inhibitors to the contact system developed has had excessive bleeding.

ACQUIRED INHIBITORS THAT AFFECT FIBRIN STABILIZATION, FIBRINOGEN, OR FIBRIN POLYMERIZATION

The terminal phase of blood coagulation is characterized by the cleavage of fibrinopeptides A and B from fibrinogen, polymerization of fibrin monomers, and the covalent cross-linking of the - and -chains of fibrin by factor XIIIa. Spontaneously acquired inhibitors of each of these reactions have been described.

Inhibitors of fibrinogen have been reported in patients with hereditary afibrinogenemia after transfusion. [161] In addition, Marciniak and Greenwood [162] reported a patient in whom a polyclonal IgG antibody developed that caused a delay in the release of fibrinopeptide A from normal fibrinogen reacting with thrombin, which retarded the onset of clot formation. This patient had a prolonged PTT, PT, thrombin time, and Reptilase time. The isolated inhibitor prolonged the thrombin time of normal plasma.

A high incidence of prolonged plasma thrombin time has been observed in patients with SLE. Galanakis et al [163] found that two such patients had monoclonal antibodies that reacted with different parts of fibrin and fibrinogen, delaying fibrin polymerization. In addition, autoantibodies that inhibit fibrin monomer polymerization have developed in some patients. [164] [165]

Although a variety of abnormalities of hemostasis are associated with monoclonal gammopathies, [166] isolated M proteins can interfere with the conversion of fibrinogen to fibrin monomer or with the aggregation of fibrin monomers into polymers. [166] [167] [168] Coleman et al[168] provided indirect evidence that at least some M proteins act as antibodies because Fab fragments of IgG monoclonal proteins were more inhibiting than intact protein, the isolated chains, or the Fc fragments.

Spontaneous inhibitors of fibrin stabilization can lead to severe hemorrhagic complications, some fatal. [5] [7] [169] [170] [171] [172] [173] [174] [175] [176] [177] [178] Of the 14 reported patients, 6 showed the development of an inhibitor while taking isoniazid.

Because noncross-linked fibrin clots could result from neutralization of factor XIII by (1) inhibition of activation to XIIIa, (2) inhibition of factor XIIIa, or (3) interference with the cross-linking sites on fibrinogen, the inhibitors may have more than one site of action. A patient who had been taking isoniazid for 8 years, described by Rosenberg et al,[176] was shown to have an antibody directed against the cross-linking sites on fibrinogen, but factor XIII levels were normal. By contrast, an inhibitor prevented the activation of factor XIII by thrombin but did not bind factor XIIIa. [172] [175] In other cases, the inhibitor interfered directly with factor XIIIa activity.

A classification scheme for the three types of factor XIII inhibitors is based on the step of the reaction sequence that is inhibited. Type I inhibitors are directed against the activation of the factor XIII zymogen but do not interfere with transamidase activity. Type II inhibitors impair the transamidase activity of factor XIIIa. Type III inhibitors complex with the fibrin substrate and prevent its binding by factor XIIIa. A fourth type of inhibitor was recently reported [179] where the antibody inhibited factor XIII activity by binding to the fibrin binding site on factor XIII. This inhibitor was characterized as an IgG antibody, and disappeared with immunosuppressive therapy.

HEPARIN-LIKE ANTICOAGULANTS

The development of spontaneously acquired heparin-like anticoagulants has been reported in patients with neoplasms or those undergoing suramin therapy for the treatment of adrenocortical carcinoma.[180] [181] [182] [183] [184] [185] [186] [187] Reports of heparin-like anticoagulants associated with neoplastic disorders [180] [181] [182] [184] [185] [186] include cases of plasma cell malignancies and a severe hemorrhagic disorder.[179] [180] [183] Coagulation studies are characterized by a prolonged thrombin time that can be corrected by the addition of protamine sulfate, toluidine blue, or heparinase to the patients plasma. All these inhibitors possess biochemical and physicochemical properties of glycosaminoglycans. One patient treated intravenously with protamine sulfate showed an improvement in his laboratory study results, as well as decreased bleeding.[184]

A complex coagulopathy was reported in three women receiving suramin for adrenocortical carcinoma.[183] The severe hepatocellular dysfunction that developed accounted for some of the coagulopathy. In addition, each patient acquired a potent inhibitor to the thrombin time, which increased markedly during exacerbations of hepatic injury. Anticoagulant activity was eliminated in vitro by a combination of heparitinase and chondroitinase ABC, suggesting that the activity was mediated by heparan sulfate and dermatan sulfate. Because suramin inhibits enzymes that normally degrade glycosaminoglycans, hepatic injury was hypothesized to cause the release of glycosaminoglycans, which then accumulate because of failure of degradation.

LUPUS ANTICOAGULANT

General Considerations

The lupus anticoagulant is an antibody that prolongs phospholipid-dependent coagulation tests in vitro. It was given this name in 1972 because clear proof of its site of action was lacking and because the anticoagulant had been recognized in patients with SLE. [7] It is a misnomer because the lupus anticoagulant is more frequently encountered in patients without lupus, [7] [188] and is associated with thrombosis rather than with bleeding. [7] [188] Immunoglobulins reacting with other hemostatic factors, such as vWF, [189] factors VIII, [190] IX, and XI, and inhibitors of thrombin and fibrin polymerization, have also been described in patients with SLE, but they are rare compared with the lupus anticoagulant.

Patients with the lupus anticoagulant who do not have established SLE fall into several different categories: (1) patients with lupus-like chronic autoimmune disorders but without findings that fit the criteria for the diagnosis of SLE; [191] [192] [193] (2) patients with other chronic systemic autoimmune disorders; (3) patients presenting with a venous or arterial thrombotic event for which no underlying cause may be apparent; [194] [195] [196] [197] [198] [199] (4) patients receiving certain drugs, including procainamide [200] and phenothiazines [16] [201] (a high prevalence of the lupus anticoagulant and a positive antinuclear antibody test are observed in psychotic patients receiving long-term chlorpromazine therapy [201]); other drugs or biologics that may induce the lupus anticoagulant include hydralazine, quinidine, and possibly -interferon; (5) patients with a recent acute viral infection, [202] [203] in whom the antibody is usually transient; (6) patients with human immunodeficiency virus infection; [204] [205] [206] [207] (7) women with recurrent fetal wastage; [192] [208] [209] [210] [211] [212] [213] [214] [215] and (8) patients seeking medical attention for a variety of disorders in whom the lupus anticoagulant is discovered as an incidental finding (frequently, such cases are discovered because of a prolonged PTT performed as a routine preoperative evaluation).

The antiphospholipid antibody syndrome can be defined by the presence of the lupus anticoagulant, the presence of elevated levels of anti-cardiolipin antibody plus one or more of the following: (1) venous thromboembolism, (2) arterial thromboembolism, (3) increased fetal loss, or (4) thrombocytopenia. The syndrome may be primary when not associated with SLE and secondary when it occurs in association with SLE. [216] [217]

The prevalence of lupus anticoagulant in patients with SLE in which the PTT test was used for its detection is approximately 10%. [7] [218] However, a higher prevalence of approximately 50% is found when a modified PTT with a reduced concentration of phospholipid is used to detect the anticoagulant. [192] Moreover, using the kaolin clotting timea test with increased sensitivity for detecting low-titer lupus anticoagulants because it contains no added exogenous phospholipidevidence of inhibitor activity can be demonstrated in the plasma of 3050% of randomly selected patients with SLE. [219] The percentage approximates the 4244% incidence of the frequency of anti-cardiolipin antibodies in patients with SLE. [220]

The prevalence of positive tests for lupus anticoagulant and anti-cardiolipin antibody in a normal population has been reported in several studies. [221] [222] [223] Because of the non-Gaussian distribution of anti-cardiolipin antibody levels in normal subjects, the cut-off points between normal and abnormal results is difficult to determine. [216] [223] The prevalences of elevated levels of IgG and IgM anti-cardiolipin antibody in a nonpregnant population were 57% and 59%, respectively, whereas the prevalence of lupus anticoagulant was 4%. The prevalences of elevated levels of IgG and IgM anti-cardiolipin antibody in healthy pregnant women were 23% and 4%, respectively. [224] [225] [226] Most of these were low titer; only 0.2% were high titer.

Properties, Epitope Specificity, Mechanism of Action, and Relationship to Anti-cardiolipin Antibodies

Both lupus anticoagulants and anti-cardiolipin antibodies are immunoglobulins that were originally thought to react only with phospholipid. Further studies of antibody specificity revealed that anti-cardiolipin antibodies were directed against epitopes on $_2$ -GPI [227] [228] and lupus anticoagulants were directed against epitopes on prothrombin. [229] [230] These studies initially postulated that these proteins, when bound to phospholipid, formed neoepitopes to which antibody developed. However, recent studies now suggest that these antibodies react directly with epitopes on $_2$ -GPI and prothrombin, and then the antigenantibody complex subsequently binds to anionic phospholipid. [229] Anti-cardiolipin antibodies are low-affinity monovalent antibodies to $_2$ -GPI when in solution, and the monovalent complexes bind weakly to anionic phospholipids. However, when the antigen density is high, bivalent complexes are formed that have a high affinity for phospholipid surfaces. [231] [232]

The lupus anticoagulant is either an IgG or IgM immunoglobulin. In some patientsfor example, those in whom it arises secondary to long-term chlorpromazine therapyit is IgM; [201] in other patients, it is IgG, [188] and in still others, it may be both IgG and IgM. [188] Transplacental transfer of the inhibitor has been reported, [233] which would be compatible with an IgG inhibitor.

The immunoglobulins responsible for the lupus anticoagulant effect react to in vitro assay systems with anionic phospholipids. Reducing the phospholipid component of clotting

DIAGNOSTIC APPROACH TO INHIBITORS

The approach to patients with abnormal coagulation tests should initially include a complete history regarding excessive bleeding, particularly as it relates to hemostatic challenges and thrombotic problems, either venous or arterial. Initial laboratory studies should include a repeat of the abnormal coagulation test on a mixture of the patients plasma and normal plasma. Correction of the abnormal test indicates a deficiency state, whereas poor correction indicates the presence of an inhibitor.

APPROACH TO INHIBITORS ASSOCIATED WITH BLEEDING

Patients who present with an acquired bleeding disorder and in whom an inhibitor is demonstrated most often have antibodies to a specific clotting factor. Subsequent laboratory evaluation should attempt to demonstrate the specific coagulation factor to which the antibody is directed and to determine the specificity of the antibody. The former is done using a specific assay for the coagulation factor suspected of being affected, and the latter is done using a specific assay for the coagulation factor of a mixture of various dilutions of patients plasma (antibody) and normal plasma (antigen) over time. If the inhibitor is specific for a single clotting factor, procoagulant activity of that coagulation factor is neutralized over time, whereas other clotting factor assays are unaffected. For example, if an acquired inhibitor of factor VIII is suspected and the factor VIII assay is low, a factor VIII assay of a mixture of the patients plasma and normal plasma should demonstrate a progressive decrease in factor VIII activity from immediately after the mixture was made to 12 hours later. By contrast, if factor IX and XI assays were done on the same mixture, factors IX and XI would be unaffected.

Rarely, a spontaneously acquired autoantibody reacts with a noncoagulant epitope of a specific hemostatic factor (e.g., prothrombin in the lupus anticoagulant-hypoprothrombinemia syndrome) or a specific clotting factor is adsorbed to cellular surfaces (e.g., vWF) or to amyloid (e.g., factor X). In these patients, the addition of normal plasma to the patients plasma results in correction of the abnormality. In these patients, the in vivo half-life of the affected hemostatic factor is shortened significantly because of rapid clearance of the antigenantibody complex or by adsorption of the clotting factor to a pathologic surface.

Spontaneously acquired heparin-like anticoagulants differ from the aforementioned inhibitors in that they are not immunoglobulins, and they do not specifically affect one specific clotting factor. These anticoagulants are easily recognized because their major effect is on the thrombin time, but the Reptilase time is normal.

APPROACH TO INHIBITORS NOT ASSOCIATED WITH EXCESSIVE BLEEDING

If the patient has a history of thrombotic disease or repeated episodes of fetal loss, he or she should be evaluated for the presence of a lupus anticoagulant or elevated levels of anticardiolipin antibody. Most commonly, patients with the former have a prolonged PTT and a normal or slightly prolonged PT. However, on occasion, the PT may be more prolonged than usual, even in the absence of an associated prothrombin deficiency. If the patient is suspected of having a lupus anticoagulant, several relatively simple tests can be used to confirm the diagnosis. For sensitivity, the kaolin clotting time as modified by Exner, the dRVVT, or the Staclot lupus anticoagulant test are excellent tests with very good sensitivity. Some believe that more than one test should be done if a lupus anticoagulant is suspected. Correction of a prolonged clotting time by the addition of phospholipid as described by Rosove or Triplett is specific for the lupus anticoagulant. In the presence of a lupus anticoagulant with a prolonged PTT, specific intrinsic clotting factor assays are frequently low but increase with increasing dilution of test plasma. For example, assays for factor IX would be 5%, factor XI 8%, factor XI 9%, and factor XII 10%, and all would progressively increase with increasing dilution of the test plasma. In some cases, the factor XI assay is more affected than the other assays. Thus, the lupus anticoagulant may affect all the specific assays, in contrast to an antibody to a specific clotting factor, for which a single assay shows irreversible inactivation of that clotting factor. In the latter case, dilution would not result in an increase in the level of that clotting factor.

mixtures amplifies the effect of the inhibitor. Thus, the most sensitive tests for detecting the inhibitor contain only limited amounts of procoagulant phospholipid: the recalcification time of platelet-free plasma, [234] the kaolin clotting time of platelet-poor plasma, [219] [235] [236] the dilute Russell viper venom time (dRVVT), [237] and the PT performed with very dilute tissue factor (the tissue thromboplastin inhibition [TTI] test). [191] [236] Adding liposomes containing phosphatidylserine, [238] rabbit brain phospholipid, [239] freeze-thawed platelets [240] [241] or hexagonal phospholipids [242] [243] markedly shortens the prolonged PTT of plasma containing the lupus anticoagulant and is used as a confirmatory test to increase specificity for presence of a lupus anticoagulant when there is a prolonged clotting test.

Patients with the lupus anticoagulant also frequently have evidence of plasma immunoglobulin reacting with the phospholipid, cardiolipin. This was first recognized as a high prevalence of an associated chronic biologic false-positive test for syphilis, [188] [234] [244] a test in which cardiolipin is the antigen. Anti-cardiolipin antibody assays are measured by an ELISA using microtiter plates coated with cardiolipin. [245] Bovine serum is added to block nonspecific antibody binding and to provide a source of $_2$ -GPI. Assay results are usually reported as either MPL units for IgM anti-cardiolipin antibody or GPL units for IgG anti-cardiolipin antibody, which are derived from a standard curve. Because of assay variability and a non-Gaussian distribution in normal people, the distinction between normal and abnormal is not clear. With the use of this sensitive assay for anti-cardiolipin antibodies, most patients with lupus anticoagulant have elevated levels of anti-cardiolipin antibodies in their plasma.

Although most patients with elevated levels of anti-cardiolipin antibodies also test positive for lupus anticoagulant activity, considerable data support lupus anticoagulant activity and anti-cardiolipin antibodies as distinct subgroups of antibodies that can be separated by affinity or physicochemical methods and have different antigenic specificities. [246] [247] Moreover, antibodies to $_2$ -GPI can be further separated into those that have anticoagulant activity and those that do not. [248] [249] In addition, lupus anticoagulants and anti-cardiolipin antibodies occur concurrently in only approximately 5075% of patients, and thus a patient may have no anticoagulant activity simultaneously with a markedly elevated anti-cardiolipin antibody titer by ELISA, and vice versa. Thus, patients who are being evaluated for a possible antiphospholipid antibody syndrome must have

tests for lupus anticoagulant activity in a clotting assay and anti-cardiolipin antibody activity by ELISA.

The mechanism by which the different antiphospholipid antibodies interfere with coagulation in vitro is not clear. However, phospholipid participates in coagulation at several known steps: as a component of the prothrombinase complex, as a co-factor for factor VIIIa and factor IXa in the tenase complex, and as a co-factor for activation of factor X by factor VIIa. The lupus anticoagulant may impede each of these reactions of blood coagulation, and it can inhibit the binding of both factor X and prothrombin to negatively charged surfaces. [219] [250] [251] Because $_2$ -GPI also binds tightly to phospholipid, it is possible that antibodies directed to epitopes on $_2$ -GPI could also interfere with phospholipid-dependent clotting reactions, particularly the tenase and prothrombinase complexes, accounting for the anticoagulant effect in vitro.

Mechanism of Hypoprothrombinemia in the Hypoprothrombinemia-Lupus Anticoagulant Syndrome

A subset of patients with the lupus anticoagulant also have a selective deficiency of prothrombin. The plasma of such patients does not contain an antibody that neutralizes prothrombin activity, [252] and the plasma prothrombin antigen is decreased to the same extent as prothrombin activity. [253] [254] Bajaj et al [255] demonstrated that the plasma from patients with the hypoprothrombinemia-lupus anticoagulant syndrome contains antibodies that bind prothrombin without neutralizing its in vitro coagulant activity. The decreased concentration of plasma prothrombin in patients with this syndrome results from the rapid removal of the prothrombinprothrombin antibody complexes. In addition, altered mobility of prothrombin antigen on crossed immunoelectrophoresis, indicative of the presence of plasma prothrombin antigenantibody complexes, has been demonstrated in 6675% of patients with the lupus anticoagulant in whom plasma prothrombin activity was not substantially decreased. [256] It is probable that these antibodies are the same antibodies to which the lupus anticoagulant is directed, and that prothrombin deficiency stems from an excess of antibody causing very rapid clearance of antigen.

Laboratory Evaluation

The results of coagulation tests usually found in patients with the lupus anticoagulant include a prolonged PTT, which is prolonged when the patients plasma is mixed with equal parts of normal plasma. The PT is minimally to moderately prolonged (0.53 seconds), and occasionally it is normal. However, the PT is prolonged more than normal plasma when diluted tissue factor is used, as in the TTI test. [191] [257] The thrombin time is normal. The sensitivity of the PTT for lupus anticoagulant detection varies with different commercial reagents used for the test, [258] [259] [260] probably reflecting, at least in part, variation in the phospholipid composition of these

reagents.[260] Moreover, some commercial PTT reagents have been created to be very sensitive to the presence of lupus anticoagulants. The prevention of platelet activation in plasma samples is crucial because procoagulant phospholipid, either in the patient plasma or in the normal plasma used for mixing studies, may neutralize weak lupus coagulant activity. [261] [262] It is therefore recommended that test plasmas and normal plasma be initially centrifuged at 10,00015,000 × g for 1015 minutes or filtered through 0.22-m screens to remove platelets before freezing. [262]

Confirmation of the Diagnosis

The pattern of abnormality of the lupus anticoagulant is often indistinguishable from that of an anticoagulant directed against any one of the several clotting factors that influence the result of the PTT, but not the PT. Therefore, further tests are needed to confirm that the prolonged PTT of a mixture of the patients plasma and normal plasma results from the lupus anticoagulant. It is particularly important to rule out a factor VIII anticoagulant, which, in contrast to the lupus anticoagulant, frequently causes serious bleeding.

Various tests have been devised to increase the sensitivity to lupus anticoagulants, including examination of clotting time in systems containing reduced phospholipid such as the kaolin clotting time,[219] the dRVVT,[237] and the dilute phospholipid time (dilute PTT). [263] [264] Some believe that the kaolin clotting time is the most sensitive, whereas the dRVVT is the most specific. By contrast, the TTI test is less sensitive and specific, [235] [236] [239] [257] but recent modifications using recombinant tissue factor have significantly improved its sensitivity. [265] However, there is evidence that to maximize the number of patients with lupus anticoagulant identified, multiple tests should be done.[209] [217] [266] Mixing studies are important in distinguishing factor deficiencies from inhibitors (deficiencies caused by warfarin are corrected by the addition of normal plasma, whereas plasma from patients taking oral anticoagulants and containing lupus anticoagulants will not be completely corrected). A recent study provides evidence that $_2$ -GPIdependent antibodies (i.e., anti-cardiolipin antibodies) prolong the dRVVT more than the kaolin clotting time, and the prothrombin-dependent antibodies prolong the kaolin clotting time to a greater extent than the dRVVT. [267] [268]

Tests based on the observation that excess phospholipid substantially shortens the prolonged PTT of lupus anticoagulant plasma are important as a means of differentiating the lupus anticoagulant from other inhibitors. The excess phospholipid is added as either freeze-thawed platelets, [241] liposomes containing phosphatidylserine,[238] platelet-derived microvesicles, [269] rabbit brain phospholipid,[239] or hexagonal phase phospholipids. [243] Correction of prolonged clotting times by excess phospholipid significantly increases specificity, and false-positive results are encountered only for heparinized patients or extremely high-titer inhibitors to other clotting factors. However, no positive results are obtained from patients with low-titer clotting factor inhibitors, congenital factor deficiencies, hepatic insufficiency, or in patients receiving warfarin therapy.

Another novel test for the detection of lupus anticoagulants uses two different snake venoms, one of which depends on the presence of phospholipid and one of which does not.[270]

One diagnostic approach that is helpful in making the diagnosis is to perform several of the specific one-stage clotting

METHODS FOR ESTABLISHING THE PRESENCE OF A LUPUS ANTICOAGULANT

1. Platelets and platelet debris must be removed from both the patients plasma and the normal plasma used for mixed studies before any testing is carried out.
2. If sensitivity is important, a screening test with very high sensitivity (e.g., kaolin clotting time, dilute phospholipid PTT, or dRVVT) should be used.
3. The clotting time of a mixture of test and normal plasma should be significantly longer than that of the normal plasma mixed with various non-lupus anticoagulant plasmas.
4. To increase specificity there should be a relative correction of the defect by the addition of lysed washed platelets, phospholipid liposomes containing phosphatidylserine, or hexagonal-phase phospholipids.
5. Testing must be repeated 24 months apart to establish the presence of a persistent abnormality.[268]

factor assays based on the PTT technique. The following pattern of results is frequently found: (1) low values for several clotting factors (artifactually decreased values reflecting the ability of the lupus anticoagulant in the test sample to impair the reactivity of the phospholipid reagent common to each assay system); and (2) increasing values for each clotting factor with increasing dilution of the test plasma in the assay system (reflecting a decreased carryover of the lupus anticoagulant into the assay system with a higher dilution of the patients plasma). Thus, inhibitors affecting more than one clotting factor using the PTT technique are usually lupus anticoagulants. In addition, for reasons that are not clear, the assay for factor XI is frequently affected more than other intrinsic assays. A comprehensive review of laboratory testing for lupus anticoagulants has been published. [271]

Laboratory Recognition of the Hypoprothrombinemia-Lupus Anticoagulant Syndrome

Although minimal to moderate prolongation of the PT, up to approximately 3 seconds beyond a control value, can be accounted for by the lupus anticoagulant, the finding of a substantially prolonged PT (e.g., 1820 seconds) represents presumptive evidence of an associated specific prothrombin deficiency. Unlike the specific clotting factors assayed in modified PTT test systems, the specific clotting factors affecting the prothrombin time test, factor VII, factor X, and factor V are assayed in clotting systems that are affected only by rare, high-titer lupus anticoagulants. Therefore, the finding of a low value in a specific prothrombin assay may be taken as convincing evidence of an associated prothrombin deficiency. If, however, further evidence is desired, three additional findings may be demonstrated: (1) a mixture of equal parts of the patients plasma and normal plasma gives the expected value calculated from the mean of the levels in individual plasmas; (2) prothrombin activity and prothrombin antigen are concordantly decreased; or (3) prothrombin has abnormal mobility on crossed immunoelectrophoresis. [272] [273]

Clinical Relationships of Lupus Anticoagulant and Anti-cardiolipin Antibodies

Both lupus anticoagulant and anti-cardiolipin antibodies are associated with thrombosis, fetal wastage, or thrombocytopenia with or without autoimmune disorders. This clinical entity is known as the antiphospholipid syndrome. [274] [275] The primary antiphospholipid syndrome is defined as venous or arterial thrombotic disease, or both, or as recurrent fetal wastage associated with elevated levels of antiphospholipid antibodies in the absence of any definite autoimmune disease. [275] These patients do not demonstrate any other clinical or serologic evidence of autoimmune disease, except for occasional low-titer (<1:160) anti-nuclear antibodies. In contrast, the secondary antiphospholipid antibody syndrome is associated with SLE and related disorders. Some patients have some evidence of a systemic autoimmune disorder but insufficient criteria to make the diagnosis of SLE (overlap syndrome). An occasional patient with high-titer anti-cardiolipin antibodies can present with fulminant disease with multiorgan system involvement (e.g., lung, kidney, brain), hypertension, and microvascular and macrovascular thrombosis. [276] [277] [278] Because these patients have a high mortality rate, they require aggressive treatment.

Most patients who test positive for the lupus anticoagulant have elevated levels of anti-cardiolipin antibody. However, although the correlation between the two is significant, many patients showing positivity for lupus anticoagulant activity do not have elevated levels of anti-cardiolipin antibody or other antiphospholipid antibodies, and vice versa.[279] [280] [281] [282]

Because anti-cardiolipin antibody levels can fluctuate significantly, [283] a negative test for both the lupus anticoagulant and anti-cardiolipin antibody does not completely rule out the presence of phospholipid antibodies. This is particularly true during an acute thrombotic episode, when antibody titers may transiently decline

to normal.[284]

Several studies[209] [266] suggest that when tests for the lupus anticoagulant and anti-cardiolipin antibodies are performed at two separate time intervals (816 weeks), a statistically significant association can be shown between persistently positive tests and prior thromboembolic events and fetal loss. The strength of the association is much reduced when transiently positive patients are included. These studies also showed that a combination of tests for detecting lupus anticoagulant activity is superior to a single test. However, the number of patients who tested positive for lupus anticoagulant activity was small, and tests were considered negative when they were <2 SD above normal.[208]

A false-positive Venereal Disease Research Laboratory (VDRL) test in low-titer (1:41:8) can be demonstrated in 30% of patients with the lupus anticoagulant or anti-cardiolipin antibodies. These cross-reacting antibodies differ from reagin, the antibody responsible for the Wasserman reaction in patients with syphilis, and do not require the presence of $_2$ -GPI for their detection. The detergent, Tween 20, can be used in the anti-cardiolipin antibody assay to distinguish $_2$ -GPIdependent and independent antibodies.[285]

Relationship of Lupus Anticoagulant and Anti-cardiolipin Antibodies to Other Antibodies

In some subjects with lupus anticoagulant and anti-cardiolipin antibody, antibodies that react to other anionic phospholipids such as phosphatidylserine, phosphatidylinositol, and phosphotidic acid have been demonstrated. [250] [282] Recently, in some patients with lupus anticoagulant or anti-cardiolipin antibody, antibodies to neutral phospholipids (phosphatidylethanolamine or phosphatidylcholine) have been demonstrated. [286] Sugi et al[287] have demonstrated that autoantibodies to phosphatidylethanolamine recognize a kininogenphosphatidylethanolamine complex. In addition, Smimov et al [288] have shown that inhibition of activated protein C is antibody and phosphatidyl-ethanolamine dependent.

Correlation Between Clinical Findings and Antiphospholipid Antibodies

Bleeding

Most patients with the lupus anticoagulant do not have a bleeding phenotype. Patients with the lupus anticoagulant have undergone needle biopsy of the kidney and the severe hemostatic challenges of major surgery,[188] [194] [289] including prostatectomy[188] and open heart surgery, [188] without excessive postoperative bleeding.

Nevertheless, patients with the lupus inhibitor may have clinically significant bleeding. In all but a few, the bleeding can be attributed to some abnormality other than the lupus inhibitor,[6] [234] such as depressed prothrombin activity. [233] [254] [290] The combination of the lupus anticoagulant and a prothrombin coagulant activity below approximately 20% of normal has resulted in severe and even fatal bleeding. In other patients, thrombocytopenia, alone or in combination with moderate prothrombin deficiency, accounted for the bleeding tendency. The hemorrhagic manifestations may be related to severe uremia. [291]

Evaluation of the risk of abnormal bleeding in patients with the lupus anticoagulant includes establishing the presence or absence of prothrombin deficiency, thrombocytopenia, or uremia. Occasionally a patient may have only a prolonged bleeding

---

time associated with excessive bleeding.[292] In the absence of these coexisting risk factors, abnormal bleeding is minimal even after trauma or surgery. [194] [216] [293] [294] In summary, most patients with the isolated finding of lupus anticoagulant do not experience abnormal bleeding. Nevertheless, excessive postoperative bleeding has been attributed to the lupus anticoagulant on rare occasions. [295] [296]

Thrombosis

Since the initial observation of Bowie et al [291] in 1963, it has become clear that thrombosis is a major concern in patients with the lupus anticoagulant. The incidence has varied from 17 to 71%, averaging approximately 3040%. [192] [194] [220] [294] [297] In addition, in patients with an elevated level of anti-cardiolipin antibody, a high incidence (40%) of thrombotic disease has been reported in such patients. [220] [274] [298] Thrombosis (and fetal loss and thrombocytopenia) are more frequent as the level of anti-cardiolipin antibody increases, and very high titers (>7 SD above the normal mean) are more frequently associated with thrombotic events. In addition, although some investigators believe that elevated levels of IgG or IgA isotypes are more common than IgM in patients with thrombotic complications, [299] [300] this has not been clearly established. Moreover, the lupus anticoagulant or increased levels of anti-cardiolipin antibody must be persistently present on more than one occasion because the incidence of thrombotic complications is almost the same in patients with transiently positive tests as in patients with negative tests at two different time intervals.[208] [209] [266] In addition, the persistent presence of elevated levels of anti-cardiolipin antibody has been shown to be associated with indices of in vivo coagulation activation. In a study of patients with SLE [301] who were either persistently anti-cardiolipin antibody positive versus patients who were transiently positive or persistently negative, anti-cardiolipin antibody-positive patients had a higher mean level of F1·2 and fibrinopeptide A than patients who were transiently positive, persistently negative, or on warfarin therapy. The differences remained significant even if patients with prior thromboembolism were excluded from the analysis. These results suggest that the presence of persistently elevated levels of anti-cardiolipin antibody in SLE patients is associated with an ongoing prothrombotic state. Most recent studies suggest that the presence of lupus anticoagulants was more strongly associated with both venous and arterial thrombosis than the presence of anti-cardiolipin antibody. [302] [303] [304] Moreover, Galli et al[268] have suggestive evidence that $_2$ -GPI antibodies that prolong the dRVVT more than the kaolin clotting time (dRVVT phenotype) are associated with a higher incidence of thrombosis than the prothrombin-dependent antibodies, which prolong the kaolin clotting time more than the dRVVT (kaolin clotting time phenotype). However, either antibody may be associated with the antiphospholipid antibody syndrome.

Thrombosis may be either venous or arterial,[274] with events occurring nearly equally in the arterial and venous circulation, [305] [306] although in some series the incidence of venous thrombosis is greater (70%) than the incidence of arterial thrombosis. [303] [307] Venous thrombosis is usually manifested as deep venous thrombosis of the lower extremities with or without pulmonary emboli. In addition, unusual sites of venous thrombosis, such as hepatic veins, inferior vena cava, mesenteric veins, renal veins, cerebral venous sinuses, retinal veins, and axillary veins, have occasionally been reported. [274] Arterial thrombosis is manifested as stroke[216] [274] [308] or transient ischemic attacks.[309] The association of antiphospholipid antibodies and coronary artery disease is controversial. Hamsten et al [310] reported that young survivors of myocardial infarction had a high incidence of anti-cardiolipin antibody, and those patients with a persistently elevated anti-cardiolipin antibody had a higher incidence of recurrent events. Similar findings were reported in another prospective study of 133 patients who had a significant number of subsequent events compared with matched control subjects.[311] In contrast, other studies did not find either elevated anti-cardiolipin antibody or subsequent events in patients with an acute myocardial infarction.[312] [313] Patients admitted for peripheral vascular surgical procedures also have a high incidence of phospholipid antibodies. [314] Unusual presentations such as gangrene of the extremities and digits, multi-infarct dementia, and bowel infarction have also been reported. [315] Thromboembolic pulmonary hypertension with or without SLE can occur in association with the lupus anticoagulant or elevated levels of anti-cardiolipin antibody, or both. [274] [316] [317]

Nonbacterial mitral and aortic endocardial valve lesions, with or without SLE, accompanied by thromboembolic transient ischemic attacks and strokes associated with lupus anticoagulant activity or elevated levels of anti-cardiolipin antibody have also been reported. [318] Livedo reticularis and cerebrovascular disease (Sneddon syndrome)[275] and giant cell arteritis[319] have also been associated with the presence of these antibodies.

Although thrombosis is supposedly not associated with the lupus anticoagulant or anti-cardiolipin antibody induced by infection or drugs, there have been several reports of human immunodeficiency virus- or drug-associated thrombosis.[194] [320] In a report of the treatment of patients with melanoma with immunotherapy, 5 of 12 patients receiving interferon- had lupus anticoagulants and anti-cardiolipin antibodies within 428 days, and deep vein thrombosis developed in 4 of these 5 patients.[321] In addition, in patients with infections, anti-cardiolipin antibodies bind cardiolipin directly and do not require the presence of $_2$ -GPI. [216] [321]

Patients who are persistently positive for the lupus anticoagulant or who have persistently elevated levels of anti-cardiolipin antibody and suffer a thromboembolic event have a recurrence rate of approximately 50% within 2 years. [305] [306] [322] [323] Although one study suggested that the recurrence rate of venous thromboembolism in patients with antiphospholipid antibodies is not greater than in patients without such antibodies, [324] the average follow-up of these patients was short (8.5 months). In addition, recurrences tend to occur (90%) on the same side of the circulation as the initial eventvenous recurrences after an initial venous event and arterial recurrences after an initial arterial event. [305]

Fetal Loss, Thrombocytopenia, and Other Associations

Another major clinical manifestation associated with the lupus anticoagulant or anti-cardiolipin antibody is fetal loss. [192] [208] [209] [211] [212] [213] [214] [215] [274] [294] [300] [325] Fetal wastage may occur at any time during pregnancy.[213] [214] [274] Any patient with a history of recurrent first-trimester abortion, second- or third-trimester intrauterine death, or intrauterine growth retardation should be tested for the lupus anticoagulant and anti-cardiolipin antibody. This syndrome occurs in patients with or without SLE; thrombosis of placental vessels and placental infarction are thought to be the mechanisms by which fetal loss occurs. [212] [215] [274] The high incidence of thrombotic disease in these patients lends further support to this hypothesis.

Thrombocytopenia is a frequent finding in patients with the lupus anticoagulant or anti-cardiolipin antibody. Patients with SLE or related autoimmune disorders show an increased incidence of thrombocytopenia associated with these antiphospholipid antibodies. [326] Moreover, the incidence of these antibodies is increased (3040%) in patients with idiopathic immune thrombocytopenic purpura.[325] [327]

Coombs-positive hemolytic anemia has also been associated with lupus anticoagulants or anti-cardiolipin antibodies in patients with or without SLE. [328] Other occasional associations with antiphospholipid antibodies include migraine, chorea, transverse myelopathy, Guillain-Barré syndrome, [274] and epilepsy.[329]

Pathophysiologic Mechanism(s) of Thrombosis

The nature of the association between thrombosis and antiphospholipid antibodies such as the lupus anticoagulant and anti-cardiolipin antibody is uncertain. Because many people with antiphospholipid antibodies never experience thrombosis, it is not clear whether antiphospholipid antibodies are direct causative factors for thrombosis, or rather represent secondary consequences of thrombosis with no direct pathophysiologic role. Because we know that many of these antibodies perturb hemostasis in vitro, we have assumed to a certain degree that they also directly affect the hemostatic system in vivo so that the prothromboticantithrombotic equilibrium is perturbed enough that it becomes imbalanced, thus favoring thrombosis or placental ischemia. There is evidence substantiating this in patients with SLE and elevated anti-cardiolipin antibodies, in whom elevated levels of fibrinopeptide A [330] and the prothrombin fragment F1·2 have been demonstrated.[330] [331] In the study by Ferro et al,[331] F1·2 was elevated in patients with SLE who were lupus anticoagulant positive, but patients who were positive only for anti-cardiolipin antibody did not have elevated levels of F1·2. In other studies of patients who were lupus anticoagulant positive, the mean level of thrombinantithrombin III complexes was higher than in control subjects.[332] [333]

Antiphospholipid Antibodies as Direct Causative Factors for Thrombosis

There are a few experimental animal models that suggest that antiphospholipid antibodies directly cause thrombosis. The antiphospholipid syndrome has been produced in normal mice by passive transfer of human immunoglobulin with anti-cardiolipin activity [334] or by active immunization with a human monoclonal anti-cardiolipin antibody [335] or with $_2$ -GPI.[336] [337] In addition, pregnant mice passively [334] or actively immunized with anti-cardiolipin antibody IgG have increased fetal loss.[334] [338] In another experimental model,[339] mice injected with purified anti-cardiolipin antibody from patients with antiphospholipid syndrome followed by a pinch injury to their femoral vein had significantly larger thrombi that persisted for a longer period of time than in appropriate control animals. All of these experimental models strongly suggest that antiphospholipid antibodies have a direct pathophysiologic role in thrombosis.

Mechanism of Thrombosis

Antiphospholipid antibodies could directly contribute to thrombosis by altering platelet activity, procoagulant or anticoagulant pathways, or vascular endothelial function. Several considerations support a possible role for platelet activation in the pathogenesis of antiphospholipid antibody-associated thrombosis. First, many subjects with antiphospholipid antibody-associated thrombosis have some degree of thrombocytopenia, [194] [196] [293] [294] presumably immune in origin. Second, there is an association between antiphospholipid antibodies and antiplatelet antibodies. [325] [326] Indeed, antiphospholipid antibodies may directly cross-react with platelets. [340] [341] The third consideration is the occurrence of arterial as well as venous thrombotic episodes. Platelet activation is thought to play a role in the pathogenesis of arterial thrombotic disease, whereas other causes of increased thrombotic risk, such as deficiencies of antithrombin III, protein C, protein S, or factor V Leiden predispose primarily to increased venous thrombotic risk. Increased levels of a urinary metabolite of thromboxane A $_2$ have been demonstrated in patients with antiphospholipid antibodies.[342] However, in contrast, another study showed that although antiphospholipid antibodies could bind to circulating platelets, no evidence of measurable platelet activation was found.[340] Fourth, serum or purified IgG from subjects with antiphospholipid antibodies inhibits the release of the platelet inhibitor, prostacyclin, from vascular segments or cultured vascular endothelial cells. [343] [344] [345] [346] This finding suggests that in some subjects with antiphospholipid antibodies, impaired prostacyclin release might lead to excessive platelet activity, resulting in thrombosis. Platelets from subjects with antiphospholipid antibody-associated thrombosis are more resistant to in vitro inhibition by the inhibitory prostaglandin, PGE $_1$, than normal platelets. However, except for one study,[347] the correlation between in vitro inhibition of prostacyclin release and thrombosis in subjects with antiphospholipid antibodies has been poor. [344] [346] In addition, Shi et al[348] showed that purified IgG from patients with lupus anticoagulants and anti-cardiolipin antibodies bound to thrombin-activated but not resting platelets, and antibody binding did not produce any evidence of platelet activation. Thus, there is little evidence that lupus anticoagulants or anti-cardiolipin antibodies directly cause platelet activation. However, Arvieux et al [349] showed that murine monoclonal antibodies to $_2$ -GPI with lupus anticoagulant activity could activate platelets when there were subthreshold concentrations of epinephrine or adenosine diphosphate in the presence of $_2$ -GPI. Subsequent platelet activation was shown to depend on binding to the platelet Fc receptor, similar to the pathophysiologic process occurring in heparin-induced thrombocytopenia.

Several abnormalities of natural anticoagulant pathways have also been reported in patients with antiphospholipid antibody-associated thrombosis. In one study, thrombomodulin antibodies were found in 30% of patients with lupus anticoagulant, in 10% of patients with unexplained thromboembolism, and in 10% of control subjects.[350] However, in another study, inhibition of thrombomodulin activity was found in only 2 of 46 patients with lupus anticoagulants. [351] In that same study, plasma from 24 of 33 patients with thrombosis showed significant inhibition of activated protein C, whereas plasma from 13 patients with thrombosis showed no inhibition. In other studies, [352] [353] [354] serum and purified IgG impaired activation of protein C by thrombin complexed to the endothelial co-factor, thrombomodulin, [355] and impaired the phospholipid-dependent anticoagulant action of activated protein C and its co-factor, protein S. [352] In addition, two studies of patients with antiphospholipid antibodies have shown a higher incidence of factor V Leiden than in patients without antiphospholipid antibodies. [356] [357] Reduced plasma levels of free protein S have also been observed in subjects with antiphospholipid antibody-associated thrombosis. [320] [343] [358] In another study, purified IgG from seven patients with antiphospholipid antibodies reacted with the disaccharide present in the heparin-heparan pentasaccharide that binds antithrombin III, and these antibodies inhibited formation of thrombinantithrombin complexes.[359] Thus, it appears that plasma from some patients with antiphospholipid antibodies inhibits several natural anticoagulant pathways, and whether this inhibition stems from other antibodies has not yet been established. However, although several abnormalities of the natural anticoagulant pathway have been demonstrated in patients with antiphospholipid antibodies, a close correlation between abnormalities of these pathways and thrombosis in patients with antiphospholipid antibodies has not been consistently demonstrated. Moreover, a defect in natural anticoagulant pathways could not by itself explain the presence of arterial thromboembolism.

Because anti-cardiolipin antibodies are antibodies directed against $_2$ -GPI, [246] [247] it suggests that possibly the antihemostatic effect is due to inhibition of $_2$ -GPI function. Although patients with severe $_2$ -GPI deficiency do not have thromboembolic disease, [360] the presence of anti-$_2$ -GPI antibodies is associated with lupus anticoagulant activity, anti-cardiolipin antibodies, and thromboembolic complications in patients with SLE. [361]

Impaired fibrinolysis may contribute to thrombosis in patients with antiphospholipid antibodies. [362] [363] However, active SLE[363] [364] is independently associated with impaired fibrinolysis.[365]

More recent studies of patients with antiphospholipid antibody-associated thrombosis without SLE have failed to document either impaired fibrinolysis in vivo [366] or any effect of plasma containing antiphospholipid antibodies on in vitro endothelial secretion of either tissue plasminogen activator or plasminogen activator inhibitor-1.[367]

Antibodies against endothelial cells have been reported in some patients with antiphospholipid antibody-associated thrombosis. [368] These antibodies might cause thrombosis by directly damaging endothelial cells; by impairing endothelial, antiplatelet, or anticoagulant activities; or by bringing about procoagulant changes in endothelial function such as expression of tissue factor. [369] [370] Antiphospholipid antibody-containing sera from patients with SLE and thrombosis induced a small but significant increase of endothelial cell tissue factor activity. When added in combination with a low dose of tumor necrosis factor, a synergistic enhancement of tissue factor activity was found.[371] In addition, these antiphospholipid antibody-containing sera led to enhanced thrombosis formation in an in vitro thrombosis model. In contrast, nonantiphospholipid antibody-containing sera from patients with SLE did not generate tissue factor activity, nor did the sera produce enhanced thrombus formation.[370]

Recently, Simantov et al[371] showed that purified IgG from SLE patients with elevated anti-cardiolipin antibody and the antiphospholipid antibody syndrome causes increased monocyte adhesion when reacted with endothelial cells in vitro. Moreover, monocyte adhesion depended on the presence of $_2$ -GPI. These data strongly suggest that anti-cardiolipin antibody is capable of binding to and activating vascular endothelial cells.

Horkko et al[372] found that apolipoprotein E-deficient mice who had active atherogenesis developed high titers of autoantibodies to epitopes of oxidized low-density lipoproteins (LDL) and to cardiolipin, and sera or anti-cardiolipin antibody-IgG from patients with antiphospholipid syndrome bind to cardiolipin as it is oxidized but do not bind to reduced cardiolipin. Thus, antiphospholipid antibodies are directed at neoepitopes of oxidized lipoproteins. Moreover, it had been previously shown by Vaarla et al[373] that binding of anti-cardiolipin antibody to solid-phase cardiolipin was inhibited by oxidized LDL but not by native LDL, suggesting cross-reactivity between antiphospholipid antibodies and antibodies to oxidized LDL. These data suggest that antiphospholipid antibodies may be pathogenic in the formation of atherosclerotic lesions.

A recent study of the pathogenic mechanism of recurrent fetal loss in patients with antiphospholipid antibodies implicated annexin V, a potent anticoagulant protein found on placental trophoblast cells.[374] IgG fractions from three patients with the antiphospholipid antibody syndrome incubated with a trophoblast cell line and endothelial cells resulted in reduced levels of annexin V. Plasma overlayed on these cells had faster clotting times than controls. Thus, the results of this study suggest that antiphospholipid antibody inhibits the anticoagulant effect of annexin V, causing a prothrombotic surface.

Therapy for Patients with Lupus Anticoagulant

The lupus anticoagulant usually persists in the untreated adult patient. However, it frequently disappears spontaneously when it occurs in children in whom the anticoagulant develops after a viral infection, and may be transient in adult patients without SLE, thromboembolic disorders, or fetal loss.

When either the lupus anticoagulant or anti-cardiolipin antibody, or both, is found in patients with underlying autoimmune disease, treatment of the underlying disease with immunosuppressive therapy frequently results in reduction or disappearance of the antibody. [244] [252] [290] [375] When the anticoagulant is found in association with severe prothrombin deficiency or severe thrombocytopenia (<20,000/l), treatment with corticosteroids is indicated. There has been one case report of a patient with a lupus anticoagulant and hypoprothrombinemia who was resistant to corticosteroids but responsive to IVIG. [376] However, when the lupus anticoagulant or anti-cardiolipin antibody is discovered as an isolated finding not associated with thrombosis or fetal loss, treatment is not indicated. Nevertheless, it is very important to inform patients so that they can be educated about the symptoms of, and prophylaxis for, venous thrombosis, about the symptoms of stroke, and about the possibility of fetal loss.

Therapy for thrombosis associated with the lupus anticoagulant or anti-cardiolipin antibody should be guided by the knowledge that recurrence is common. [305] [306] [323] In one study, patients who had discontinued oral anticoagulation had a 50% probability of recurrence in two years and a 78% recurrence in eight years. [377] Similar results have been published by others.[305] [306] [323] Venous recurrence usually occurs in patients who have an initial venous event, whereas arterial recurrences occur in patients who sustain an initial arterial event. [305] However, treatment with warfarin with a target international normalized ratio (INR) of 3.0 has been associated with a significant decrease in recurrences. [305] [306] Although aspirin added to warfarin may be helpful, aspirin alone is not efficacious in preventing thrombotic events. [305] Thus, it is recommended that patients with venous or arterial thrombosis receive life-long anticoagulation with oral anticoagulants. Because of the efficacy of warfarin therapy in preventing recurrences, the use of corticosteroids and other immunosuppressive agents to suppress antibody production in the absence of autoimmune disease is not recommended.

Monitoring anticoagulant therapy may be difficult in patients with lupus anticoagulants and a prolonged PTT. Thus, it is mandatory when using heparin to monitor therapy using a specific heparin assay such as the one dependent on factor Xa inhibition (therapeutic range, 0.30.7). When using warfarin, the optimal INR for patients with lupus anticoagulants is controversial [305] [306] [324] [378] [379] because patients with lupus anticoagulants may have a variably prolonged prothrombin time [378] [380] [381] [382] and various thromboplastins have a different sensitivity in the presence of a lupus anticoagulant. [378] Therefore, it is possible that in various studies of therapy in patients with lupus anticoagulants that the degree of anticoagulation is overestimated, and the target INR of 3.0 noted earlier might be an overestimate because of the presence of the lupus anticoagulant. This hypothesis is substantiated by the report by Moll and Ortel, [378] in which the prothrombin time done by the prothrombin-proconvertin test and a chromogenic factor X level correlated well with established therapeutic ranges. Thus, if either of the latter two assays are available, they would be preferable in monitoring oral anticoagulant therapy in patients with lupus anticoagulants.

A pregnant patient with or without SLE with the lupus anticoagulant or anti-cardiolipin antibody associated with a history of recurrent fetal wastage should be treated. However, the precise regimen to be followed has not been clearly established. Lubbe et al [383] described a successful pregnancy outcome in a patient with the lupus anticoagulant and fetal wastage who was treated with prednisone and low-dose aspirin. Subsequently, the same regimen led to successful pregnancy outcomes in 10 of 16 pregnancies in 12 patients, some of whom had SLE.[384] Other investigators, using a similar regimen in patients without SLE, also reported a decrease in fetal wastage in a significant number of patients. [341] [375] However, long-term, high-dose corticosteroids during pregnancy may be associated with significant side effects, including hypertension, gestational diabetes, and premature labor and delivery. In a study by Silveira et al, [375] however, prednisone and low-dose aspirin given to 11 patients with recurrent fetal wastage (32 previous fetal losses and 5 live-born infants) resulted in 100% live-born infants (12 pregnancies and 12 live-born infants), and no significant adverse effects to either

THERAPY FOR PATIENTS WITH THE LUPUS ANTICOAGULANT OR AN INCREASED LEVEL OF ANTI-CARDIOLIPIN ANTIBODIES

The lupus anticoagulant persists in most untreated adults. Often it disappears spontaneously when it occurs in children in whom the anticoagulant is acquired after a viral infection, and it may be transient in adult patients without SLE, thromboembolic disorders, or fetal loss.

When the lupus anticoagulant or increased level of anti-cardiolipin antibodies is found in patients with underlying autoimmune disease, treatment of the underlying disease with immunosuppressive therapy frequently results in reduction or disappearance of the antibody. When the lupus anticoagulant is found in association with severe prothrombin deficiency or severe thrombocytopenia (<20,000/l), treatment with adrenal corticosteroids is indicated, beginning with a dose of 6080 mg of prednisone. However, when the lupus anticoagulant or increased level of anti-cardiolipin antibodies is discovered as an isolated finding and not associated with thrombosis or fetal loss, treatment is not indicated.

Therapy for thrombosis associated with the lupus anticoagulant or anti-cardiolipin antibodies should be guided by the knowledge that recurrence is common. The site of the first event (arterial or venous) tends to predict the site of subsequent events. It is recommended that patients with venous thrombosis receive intravenous unfractionated heparin in the usual therapeutic doses to achieve a plasma heparin level of 0.30.7 units using a factor Xa inhibition assay. Long-term anticoagulation with warfarin can be started simultaneously with a dose to maintain the INR between 2.53.5. Long-term oral anticoagulation at the same INR is also efficacious in preventing arterial thrombosis. If arterial events recur at a therapeutic INR, then low-dose aspirin (80 mg) can be added. Because of the high recurrence rate, oral anticoagulants should be given for life except during pregnancy (see later). Because of the efficacy of warfarin therapy in preventing recurrence, the use of corticosteroids and other immunosuppressive agents to suppress antibody production in the absence of autoimmune disease is not recommended.

A pregnant patient with or without SLE with the lupus anticoagulant or anti-cardiolipin antibodies associated with a history of recurrent fetal wastage should be treated either with heparin (5,000 units bid) plus low-dose aspirin (80 mg) or intermediate-dose heparin (enough to prolong to PTT by 1.21.5 times control) plus low-dose aspirin. If fetal loss recurs on this regimen, then full therapeutic doses of unfractionated heparin or, alternatively, a therapeutic dose of lowmolecular-weight heparin should be tried.

For the patient who becomes pregnant for the first time and who has not had prior thromboembolic events, no treatment is indicated. However, the patient should be educated regarding the possibility of fetal loss, the potential side effects of therapy, and the lack of controlled trials in such patients. If the patient desires therapy, it should be given. If the patient has suffered only one fetal loss, particularly in the second and third trimester, with no evidence of placental infarction, the patient should be treated with prophylactic doses of heparin and low-dose aspirin as noted previously. If the patient has the persistent presence of anti-cardiolipin antibody or the lupus anticoagulant, or both, but has not had any clinical problems and requires a major surgical procedure, prophylactic heparin and intermittent pneumatic compression should be used.

For the patient who presents with the catastrophic antiphospholipid syndrome, the favored regimen consists of aggressive therapy with daily plasmapheresis, heparin anticoagulation, pulsed high-dose methylprednisolone 2 g/day IV × 3 days, and cyclophosphamide 750 mg/m ^{2} on day 1.

mother or infants. The prednisone regimen consisted of a starting dose of 40 mg/day for 4 weeks, with the dose tapered by 10 mg/day every 4 weeks to a final maintenance dose of 5 mg/day. The levels of anti-cardiolipin antibody decreased in most patients. However, in a recent, large, randomized trial in 202 patients with autoantibodies (either lupus anticoagulant, anti-cardiolipin antibody, anti-nuclear antibody, anti-DNA, or antilymphocytic IgM) and unexplained loss of at least two fetuses, corticosteroids plus low-dose aspirin resulted in 65% viable infants, compared with 57% in the placebo group. [385]

Wallenberg and Rotmans[386] used low-dose aspirin and dipyridamole in 37 patients with obstetric histories similar to those with antiphospholipid antibodies, with a 93% success rate. Unfortunately, these patients were not systematically examined for the presence of antiphospholipid antibodies. Similarly, Elder et al [387] reported similar success using low-dose aspirin alone in 42 patients, of whom 16 had SLE (13 with antiphospholipid antibodies). However, Lockshin et al [388] have cast significant doubt regarding the efficacy of aspirin with or without corticosteroids in high-risk patients with high-titer anti-cardiolipin antibodies. In 11 pregnancies receiving corticosteroids and low-dose aspirin, there were 9 fetal losses, whereas in 10 pregnancies receiving aspirin alone or no therapy, there were 5 fetal losses.

In a recent, small, randomized trial,[389] 50 patients with at least three consecutive episodes of spontaneous pregnancy loss and positive antiphospholipid antibody were assigned either low-dose aspirin alone or low-dose aspirin plus heparin with increasing doses throughout pregnancy to achieve a PTT between 1.21.5. Viable infants were delivered by 11 of 25 (44%) women receiving aspirin alone, whereas 20 of 25 women (80%) receiving aspirin plus heparin delivered viable fetuses (r < 0.05).

In another recent randomized trial[390] in patients with persistently positive antiphospholipid antibodies and three or more fetal losses, low-dose aspirin (75 mg) plus unfractionated heparin (5,000 units bid) resulted in live births in 32 of 45 (71%) pregnancies, compared with 19 of 45 (42%) live births in patients receiving low-dose aspirin alone.

Rosove et al[391] reported 14 successful outcomes in 15 pregnancies in 14 patients (5 with lupus) using adjusted full-dose heparin therapy throughout pregnancy. None of the patients was treated with aspirin, and only one patient received a short course of corticosteroids for a lupus flare.

Thus, different therapeutic regimens in uncontrolled and controlled clinical trials have resulted in a decrease in fetal wastage. The most efficacious regimens appear to be either low- or intermediate-dose heparin plus low-dose aspirin, or adjusted-dose heparin without aspirin. Although most of the experience has been with unfractionated heparin, there is sufficient experience with lowmolecular-weight heparin to be confident that it is safe and efficacious in pregnancy. Thus, it is likely that lowmolecular-weight heparin will replace unfractionated heparin in the future. Whether it should be used in prophylactic or therapeutic

doses remains to be determined in clinical trials. Regimens containing corticosteroids appear in most studies to cause significant adverse events (hypertension, diabetes, and preterm labor and delivery).

Whether asymptomatic patients with antiphospholipid antibodies who desire pregnancy should be treated prophylactically is not clear. It is known that low-titer anti-cardiolipin antibody occurs in up to 24% of healthy young women and high-titer antibody in approximately 0.2%. [226] Thus, many young women with antiphospholipid antibody who wish to become pregnant may be referred for consultation. If the patient does have a high titer of IgG anti-cardiolipin antibody, the risk of fetal loss approximates 28%.[392] [393] If the patient has a positive lupus anticoagulant without an elevated anti-cardiolipin antibody, the risk has not been estimated. Thus, the patient should be educated regarding these data, the possibility of fetal loss, the potential side effects of therapy, and the lack of controlled trials in such patients.

Chapter 117 - Disseminated Intravascular Coagulation

David C. Calverley
Howard A. Liebman

Disseminated intravascular coagulation, frequently designated by its acronym DIC, is a pathologic syndrome arising from a heterogeneous group of medical disorders (Table 1171). It is characterized by laboratory evidence of consumption and proteolytic degradation of hemostatic components. The clinical expression varies and may be manifested by laboratory abnormalities alone or in combination with hemorrhagic and thrombotic complications. Because of the variable clinical manifestations and heterogeneity of primary disorders associated with the development of DIC, the syndrome has been characterized

TABLE 117-1 -- Underlying Conditions Associated with Disseminated Intravascular Coagulation

Acute and Subacute
Infection
Gram-negative bacteria
Encapsulated gram-positive bacteria
Viruses (e.g., varicella)
Obstetric complications
Abruptio placentae
Amniotic fluid embolism
Sepsis
Saline-induced abortion
Malignancies
Leukemia, lymphoma
Tissue injury
Burns
Heat stroke
Chronic
Malignancies
Solid tumors
Obstetric complications
Dead fetus syndrome
Localized intravascular coagulation
Aortic aneurysm
Hemangiomas (Kasabach-Merritt syndrome)
Advanced liver disease
LeVeen shunt
Fatty liver of pregnancy

under a number of designations, including *defibrination syndromes*, *consumptive coagulopathies*, or *consumptive thrombohemorrhagic disorders*.[1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] Significant controversies exist in regard to the pathophysiology, diagnosis, and treatment of DIC. However, certain generally accepted clinical and laboratory observations regarding this syndrome can provide a model to assist the clinician in the diagnosis and therapy of these patients.

GENERAL PATHOGENESIS

Central to the pathogenesis of DIC is the unregulated and excessive generation of thrombin. This overexpression of thrombin results in the consumption of coagulation factors that are the natural substrates of this protease, such as fibrinogen, factor V, and factor VIII. Thrombin, acting as a ligand, binds to thrombin receptors on platelets and endothelial cells, [16] [17] and is a potent agonist inducing platelet activation and aggregation. [18] Thrombin also induces the endothelial release of tissue plasminogen activator (t-PA). [19] In the presence of the newly formed fibrin monomer,[20] plasmin is proteolytically formed from plasminogen. This results in an aggressive secondary fibrinolysis. Therefore, the clinical and laboratory manifestations of DIC result from generation of these two proteases, thrombin and plasmin. The overexpression of thrombin with relatively reduced expression of plasmin may result in either large-vessel thrombosis or microvascular fibrin deposition leading to organ dysfunction and ischemic necrosis. Excessive thrombin generation with a vigorous secondary fibrinolysis may result in increased consumption of hemostatic components and bleeding. Both the bleeding and thrombotic manifestations of DIC are well documented in autopsy studies. [11] [21] [22] [23] Although this model is overly simplistic, it can provide a hypothetical basis by which the clinician can approach the diagnosis and treatment of DIC.

INITIATION OF PHYSIOLOGIC AND PATHOLOGIC THROMBIN GENERATION

The physiologic formation of the hemostatic plug requires the localized and limited generation of thrombin at the site of vessel injury. DIC results from a failure of the mechanisms that limit

the regulation of blood clotting and thrombin generation. This site-specific generation of thrombin is accomplished by a combination of regulatory mechanisms (Fig. 1171). Tissue factor is exposed or expressed at the site of vessel injury. This is followed by the sequential proteolytic conversion of proenzymes (zymogens) to enzymes by a mechanism that involves the formation of macromolecular complexes of enzymes and co-factors on specific receptors present on the surface of endothelial cells and platelets. [24] [25] [26] [27] [28]

The excessive generation of thrombin is limited by several natural inhibitory mechanisms. Tissue factor pathway inhibitor modulates the local effects of tissue factorfactor VIIa expression.[29] [30] The protease inhibitors antithrombin III and heparin co-factor II are bound to endothelial- and subendothelial-associated proteoglycans.[31] [32] When bound to these endothelial-associated, heparin-like molecules, they become potent inhibitors of factors IXa and Xa and thrombin. Thrombomodulin, a thrombin-specific receptor present on the surface of endothelial cells, binds thrombin and modifies its substrate specificity. Thrombin bound to thrombomodulin can no longer act as a procoagulant enzyme[33] [34] and becomes the primary protease for the activation of protein C. [35] The resulting activated protein C, along with its co-factor protein S, degrades factors Va and VIIIa, destroying their coagulant activity. [36] Finally, the fibrinplatelet hemostatic plug is limited by a highly regulated fibrinolytic system. Plasmin, the mediator of fibrinolysis, is produced by the proteolysis of plasminogen by t-PA. Plasmin rapidly degrades newly formed fibrin, reducing the size of the clot and initiating events that lead to vascular repair. DIC arises from an overwhelming of these regulatory mechanisms that leads to excessive generation of thrombin and a failure of the normal inhibitory pathways to prevent the systemic effects of the enzyme.

Although a wide variety of disorders are associated with the development of DIC, initiation most often involves a common pathway (Fig. 1171). Initiation of DIC usually involves one or both of two mechanisms: mechanical tissue injury and endothelial activation and injury. Primary to both initiating pathways is the exposure of blood to excessive amounts of tissue factor. Mechanical injury of organs rich in tissue factor, such as brain or placenta, may result in fulminant consumption, as observed in gunshot wounds to the brain[37] or abruptio placentae. [38] A variation of tissue injury is observed in patients with malignancy-associated DIC. Malignant tissues disrupt the normal vascular hemostatic regulatory mechanisms and expose blood to tumor-associated procoagulant activity. Malignant tissues have been shown to express tissue factor-like activity,[39] and some tumors have been shown to produce a cysteine protease capable of directly activating factor X. [40] [41] An extreme example of malignancy-associated DIC is observed in patients with acute promyelocytic leukemia. The coagulopathy persists while the tissue factor-rich leukemic blasts are present in blood and bone marrow. [42] [43] The down-regulation of tissue factor expression in the leukemic blasts by all-trans retinoic acid, resulting in the correction of the coagulopathy, is an excellent demonstration of the importance of tissue factor in the initiation of DIC in this disease. [44] [45] Studies using sepsis or endotoxin models of DIC have clearly demonstrated the primary role of tissue factor. [46] [47] [48] In addition, these studies have shown that the contact-phase proteins of the classic intrinsic pathway are not directly linked to the initiation of DIC and have only an ancillary role in the coagulopathy of sepsis. [48]

Resting endothelium does not express tissue factor. [49] Endothelial cells activated by cytokines, such as interleukin-1 and tumor necrosis factor, or injured by endotoxin express tissue factor activity. [50] [51] Viruses and other pathogens capable of infecting

Figure 117-1 Regulatory pathways of hemostasis and pathophysiology of DIC. endothelium are also capable of inducing increased tissue factor expression. [52] In conjunction with this enhanced endothelial procoagulant activity, there is a suppression of endothelial anticoagulant properties as reflected in decreased thrombomodulin expression. [47] [52] [53] In addition, there is increased plasminogen activator inhibitor synthesis and secretion, resulting in suppression of t-PAmediated activation of fibrinolysis. [54] [55] In these circumstances, even without mechanical injury or cell death, blood is exposed to a potent procoagulant surface.

Monocytes and neutrophils play an important ancillary role in the initiation of DIC. Monocytes activated by endotoxin or antibodyantigen complexes can express tissue factor activity and assemble the prothrombinase complex on their membranes.[56] [57] Activated monocytes also secrete the inflammatory cytokines, interleukin-1 and tumor necrosis factor,[58] [59] which modulate endothelial procoagulant activity. [50] [51] Platelet-activating factor, another monocyte-derived cytokine, induces platelet activation and aggregation[60] and increases vascular permeability. [61] Activated neutrophils release a number of cellular enzymes that can injure endothelium and degrade subendothelial matrix.[62] Neutrophil elastase has been shown to degrade and inactivate a number of coagulation proteins and inhibitors, including factor V, factor VIII, antithrombin III, tissue factor pathway inhibitor, and plasminogen activator inhibitor. [63] [64] [65] [66] [67]

The coagulation inhibitors antithrombin III, heparin co-factor II, and thrombomodulin, although highly effective in regulating the localized generation of thrombin, are overwhelmed in DIC by the more potent systemic generation of thrombin and its precursor enzymes. Significant acquired deficiencies of antithrombin III are rarely observed except in cases of overwhelming acute DIC or cases complicated by significant hepatic dysfunction. [12] [68] [69] [70] Interleukin-1 and tumor necrosis factor, which are elevated in sepsis, have been shown to decrease thrombomodulin expression on endothelium. [47] [52] [53] Levels of protein C also appear to decrease significantly in patients with sepsis-induced DIC. [71] [72] [73] In addition, inherited deficiencies of both protein C or protein S may be associated with microvascular thrombosis and intravascular consumption, as observed in purpura fulminans of the newborn or Coumadin necrosis in deficient adults. [74] [75] [76] [77]

The variable clinical expressions of DIC result from this complex interaction of thrombin, plasmin, proteolytic inhibitors, platelets, endothelium, monocytes, and neutrophils. The underlying disorders that initiate DIC, such as sepsis, malignancy, or mechanical tissue injury, may trigger different hemostatic and cellular pathways for thrombin and plasmin generation, resulting in a clinical pathologic process that favors either thrombosis or consumption with bleeding. Furthermore, the intensity and duration of hemostatic activation can result in a fulminant (acute), subacute, or chronic presentation. Fulminant DIC is usually characterized by coagulation factor consumption and bleeding. The chronic forms of DIC are more frequently characterized by thrombotic manifestations. However, in a significant number of cases, there are few or no clinical manifestations of DIC exclusive of the abnormal laboratory findings. Morbidity and mortality in these patients predominantly result from the

underlying disease, and no specific treatment for the DIC is indicated.

DIAGNOSIS OF DIC: CLINICAL AND LABORATORY FINDINGS

Clinical Features

The clinical manifestations of DIC are frequently obscured by the clinical features associated with the primary initiating illness (see Table 1171). There is considerable variation in the frequency of specific clinical findings described in different case series, which probably reflects differences in the underlying primary disorders reported in each study.[9] [11] [12] [78] [79] Many of the clinical findings ascribed to DIC in early case series, such as the adult respiratory distress syndrome (ARDS) or acute tubular necrosis, are probably a direct result of the primary illness, shock, and hypoperfusion. Their onset frequently has no direct relationship to the initiation of DIC, and may precede its appearance. However, the microvascular thrombosis associated with DIC may aggravate multiorgan dysfunction, and less frequent pathologic features such as pulmonary hemorrhage and renal cortical necrosis may be directly linked to the development of DIC. [9] [11] [12] [21] [23] [78]

Bleeding is the predominant clinical manifestation observed in DIC and is reported in 7090% of patients. [9] [11] [12] [78] [79] Cutaneous, gastrointestinal, genitourinary, and pulmonary bleeding, along with bleeding at surgical sites, are the most frequently reported. However, in earlier case series, the definition of DIC was based primarily on laboratory studies that clearly defined a patient population with severe consumption of hemostatic components, including fibrinogen and platelets. Studies that use laboratory criteria of DIC based primarily on markers of thrombin generation, find many more cases of DIC without clinical evidence of bleeding then previously reported.[80] [81]

Overt thromboembolic manifestations have been less frequently observed in DIC and have been reported in 1040% of patients. [9] [11] [12] [78] [79] In patients with cancer, laboratory evidence of thrombin generation is frequently present without evidence of severe coagulation factor or platelet consumption. [82] [83] [84] [85] However, activation of coagulation pathways in the patient with cancer usually results in thromboembolic manifestations. [86] [87] [88]

Laboratory Features

Laboratory studies used in the diagnosis and evaluation of patients with DIC can be characterized as tests of thrombin and plasmin generation and screening tests for hemostatic function that delineate the severity of coagulation factor consumption (Table 1172). Although abnormalities in the screening assays such as the prothrombin time (PT), partial thromboplastin time (PTT), or platelet count may provide important corroborative evidence of hemostatic component consumption, the diagnosis of DIC should not be made without at least one positive test indicative of excessive thrombin generation. The two most readily available studies that document the excess activity of thrombin are immunoassays for D-dimers and the protamine paracoagulation assay for fibrin monomer. [80] [89] [90] [91] D-dimers are

the proteolytic by-products of plasmin degradation of cross-linked fibrin monomers. In contrast to the older assays for fibrin/fibrinogen degradation products (FDPs), which do not distinguish between the plasmin degradation by-product of either fibrin or fibrinogen, the formation of D-dimers requires prior formation of fibrin monomer, which is cross-linked by factor XIIIa. Both the formation of fibrin monomer and the generation of factor XIIIa from its zymogen require thrombin. When using the D-dimer assay as the only laboratory marker of thrombin generation, caution must be exercised in interpreting abnormal results in patients who have had recent surgery, bleeding into tissues, cirrhotic liver disease, or renal failure. In each of these clinical circumstances, D-dimers can be moderately elevated without DIC. Therefore, patients with D-dimer levels <2,000 ng/ml should not be diagnosed as having DIC unless there is other corroborating evidence. [80] [89] [90] [92]

The protamine paracoagulation test detects the presence of excess soluble fibrin monomer, which is associated with fibrinogen in plasma. The presence of fibrin monomer documents prior action of thrombin on fibrinogen. This assay can be particularly helpful in clinical circumstances when there may be other disorders that could contribute to elevations in D-dimers. However, the assay is difficult and is most reliable when the laboratory has extensive experience with the assay. Additional

assays of thrombin generation that have been used in the evaluation of patients with DIC include the ethanol gel assay for fibrin monomer, [93] immunoassays for fibrinopeptide A, [94] thrombinantithrombin complexes,[95] and prothrombin fragment 1·2. [96] However, the routine clinical use of these assays is limited by their cost and complexity for simple and rapid laboratory screening. In addition, the latter three immunoassays have an excessive degree of sensitivity to thrombin generation, and positive results may not reflect clinically significant DIC.

Laboratory studies that delineate the severity of hemostatic component consumption in the patient with DIC include quantitative platelet counts and screening assays for plasma coagulation function. The screening tests include the PT, PTT, and thrombin time. Prolongations of the PT, PTT, and thrombin time assays result from the combined primary and secondary consumption of coagulation factors. Plasmin generated by secondary fibrinolysis results in the proteolytic degradation of factors, including fibrinogen and factors V, VIII, and XII. The intermediate plasmin degradation products of fibrin inhibit fibrin polymerization, which further contributes to the prolongations observed in these assays. [97] The results from these screening assays provide the information necessary for appropriate decisions regarding replacement treatment. These screening tests direct the clinician toward a diagnosis of acute DIC.

In five case studies of acute DIC, combining over 900 patients, the most frequent laboratory abnormalities reported, in decreasing order of frequency, were thrombocytopenia, elevated FDPs, prolonged PT, prolonged thrombin time, prolonged PTT, and a low fibrinogen. [9] [11] [12] [78] [79] Although deficiencies of nearly every coagulation factor have been reported, acquired deficiencies of factor V and fibrinogen are the most frequently observed in patients with acute DIC. A fibrinogen <100 mg/dl, in the absence of severe liver disease, is invariably associated with acute DIC, usually associated with bleeding manifestations, and denotes a poor prognosis. [9] [11] [12]

In chronic DIC syndromes, the degree of factor consumption may be limited and can be balanced by enhanced hepatic synthesis of coagulation factors, resulting in only minor abnormalities in the screening assays. Platelet counts may be at low normal levels and fibrinogen levels can be normal because hepatic synthesis of fibrinogen can be significantly up-regulated by inflammatory cytokines. [98] In these circumstances, the presence of high levels of the markers of thrombin generation, in the appropriate clinical settings, may be sufficient to make the diagnosis of DIC.

Despite the presence of a significant secondary fibrinolysis, screening assays for increased fibrinolysis, such as the dilute whole-blood clot lysis test or euglobulin clot lysis test, usually give normal results in patients with DIC. [9] [12] However, the use of these screening assays should be considered in clinical circumstances such as DIC in association with severe liver disease, [99] in acute promyelocytic leukemia, [100] [101] heat stroke, [102] amniotic fluid embolism, [103] or metastatic prostate carcinoma. [104] The clinician should be aware that there can be false-positive studies if these screening tests are performed in patients with fibrinogens <100 mg/dl.

The presence of thrombocytopenia, the most frequent laboratory abnormality observed in patients with DIC, should always direct the clinician to a review of the peripheral blood film. Fragmented red blood cells, although reported in patients with DIC, rarely constitute >10% of the red cells. [12] However, in some cases of chronic DIC with elevated D-dimers but normal coagulation screening assay results, the presence of fragmented red cells can provide confirmatory evidence. In contrast, disorders such as acute leukemia, sepsis, and thrombotic thrombocytopenic purpura can result in significant thrombocytopenia and a markedly abnormal blood film without laboratory evidence of DIC.

Several systems combining clinical and laboratory data have been devised to assist in the diagnosis and determination of the prognosis of patients with DIC. When these scoring systems were proposed, they were highly predictive of patient mortality. [9] [105] However, it is uncertain whether they are as predictive of patient outcome, in view of the respiratory, cardiovascular, and hemostatic support systems available today. A diagnosis of DIC should never be made based on laboratory abnormalities, but must include consideration for the underlying primary initiating illness and the patients clinical presentation.

DIFFERENTIAL DIAGNOSIS OF DIC

A number of clinical disorders not associated with DIC can result in an acquired bleeding diathesis and significant laboratory hemostatic laboratory abnormalities. Thrombocytopenia can result from primary bone marrow failure, an infiltrative marrow process such as leukemia, endothelial-mediated platelet activation such as in vasculitis or thrombotic thrombocytopenic purpura, or immunologic destruction. A difficult clinical problem occurs in the patient with sepsis. [104] Sepsis without DIC can be associated with a variable degree of thrombocytopenia; however, sepsis with platelet counts <50,000 are most often associated with DIC. [106]

A rare syndrome of primary fibrinolysis occurs with the independent generation of plasmin without concomitant thrombin generation. [107] Such patients can have low fibrinogen, prolonged screening assays, and elevated FDPs. In addition, patients with liver disease and primary fibrinolysis with portal hypertension may have thrombocytopenia secondary to splenic sequestration. Therefore, the differential diagnosis in these patients may prove difficult. However, in these patients, the dilute whole-blood clot lysis and euglobulin clot lysis tests are significantly shortened, and the protamine paracoagulation assay is negative for fibrin monomer. Also, despite significantly elevated FDPs, the D-dimer assay results are normal or only minimally elevated. [108]

CLINICAL PRESENTATIONS

Acute and Subacute DIC

Infection

Bacterial sepsis is a common cause of acute DIC. Thrombin generation results from bacterial or endotoxin-associated endothelial cell perturbation and monocyte activation, leading to

---

enhanced tissue factor activity and inflammatory cytokine secretion. [25] [46] [47] [50] [51] [53] Gram-negative organisms are more commonly associated with sepsis and DIC, although cases are associated with gram-positive sepsis. [109] Infection with viruses such as varicella, rubella, rubeola, and influenza, along with intracellular pathogens such as *Mycobacterium tuberculosis*, can also lead to DIC through enhanced endothelial and monocyte tissue factor activity. [110] [111] [112] [113] [114] Both fungal infections and malaria have similarly been complicated by DIC. [115] [116] [117]

There is a wide range of clinical manifestations of sepsis-associated DIC. Many cases are characterized by laboratory changes without bleeding or clinical evidence of microthrombus formation. Examples of clinical entities at the other end of the spectrum include Waterhouse-Friderichsen syndrome and purpura fulminans. The Waterhouse-Friderichsen syndrome is rare and most often seen in association with fulminant meningococcal sepsis. [118] [119] It is characterized by widespread intravascular fibrin deposition and platelet thrombi that lead to microvascular obstruction of vital organs along with hemorrhagic necrosis of the adrenal glands. The latter leads to significant, often irreversible shock associated with a high mortality rate.

Virtually any gram-negative organism can cause DIC. The gram-positive bacterial infections associated with DIC often involve encapsulated organisms such as pneumococci. The overwhelming infection observed in those with diminished circulatory clearance due to functional or anatomic asplenia is frequently implicated. [120] Clostridial species are also associated with severe DIC due to septic abortion, which carries a very high mortality rate. [121] [122]

Purpura Fulminans

Purpura fulminans is a rare, severe skin disorder associated with DIC that primarily affects children and infants. Extensive areas of skin develop blue-black hemorrhagic necrosis, and biopsy typically reveals small-vessel microthrombi and vasculitis. Distribution of necrotic areas typically depends on the clinical setting. Patients are acutely ill with fever and hemorrhage from multiple sites, are hypotensive, and manifest typical laboratory signs of DIC. [123] [124] The pathogenesis of purpura fulminans is unknown, but histologic findings have been likened to the animal model of consumptive coagulopathy, the local Swartzman reaction. [125] It has also been suggested that the development of purpura fulminans in meningococcemia may result from acquired defects in the protein C pathway because similar lesions are seen in two other protein C deficiency states, namely, neonatal purpura fulminans and Coumadin-induced skin necrosis. [126]

Purpura fulminans occurs in three clinical settings. [127] In acute sepsis-associated or secondary purpura fulminans, the initial presentation is one of overwhelming infection that is most commonly meningococcemia, but has been reported with many other gram-positive and gram-negative organisms. [127] [128] [129] [130] [131] Patients are hypotensive with reduced peripheral perfusion contributing to skin necrosis on distal extremities; alternatively, skin necrosis can occur in a patchy distribution. [132] [133] Idiopathic purpura fulminans can present within 10 days of an antecedent illness, most commonly scarlet fever and varicella in children. Most skin lesions are localized to the breasts or lower half of the body. Third, purpura fulminans can be seen in association with homozygous protein C deficiency in affected neonates, in whom massive intravascular thrombosis and abdominal wall gangrene can also develop. [75] [76] [134] Acquired inhibitors of the protein C pathway can also be associated with this presentation. [135] Patients with Coumadin-induced skin necrosis may present with a similar but usually less severe form of purpura fulminans, and thus warrant consideration of protein C or protein S deficiency. [76] [136] [137]

The mortality rate has recently been significantly reduced in purpura fulminans, largely because of more widespread use of therapeutic heparinization in these patients and aggressive red cell and clotting factor replacement. [125] [127] [138]

Obstetric Complications

Pregnancy predisposes patients to DIC through the generation of a hypercoagulable state manifested by increased levels of most coagulation factors along with reduced fibrinolytic activity due to decreased t-PA production and increased plasmin activator inhibitor levels. [139] Overt clinical DIC manifestations occur when these baseline conditions are complemented by the occurrence of any of a number of acute obstetric complications that lead to the release of tissue factor or endothelial cell perturbation, followed by consumption of clotting factors and enhanced fibrinolysis.

The manifestations of DIC associated with obstetric complications are varied, with different grades of severity noted depending on the degree of hypofibrinogenemia and depletion of other clotting factors seen in each case. Because of this variation and baseline pregnancy-associated coagulation abnormalities, it is prudent to consider serial assessment of coagulation parameters when DIC is suspected to detect progressive alterations over time. Similarly, the coagulopathy may be localized to the uterus or disseminated through the blood.

Abruptio placentae, or placental detachment, has a wide range of clinical presentations, from incidental detection on pathologic examination of the placenta, to vaginal bleeding, to pronounced DIC with accompanying shock, bleeding, severe abdominal pain due to uterine contractions, and fetal death. [139] Both the exact causes of placental abruption, outside of trauma, and the subsequent processes leading to DIC remain unclear. Placenta is rich in tissue factor activity, which likely comprises an important component of the DIC pathophysiologic process. [140] [141] Hypofibrinogenemia has been documented in 38% of abruptio placentae cases, which implies that potentially serious and life-threatening DIC is present in a significant number of patients. [38]

Amniotic fluid embolism is a rare, usually fatal catastrophe occurring in 1 in 8,000 to 1 in 80,000 deliveries. Amniotic fluid is introduced into the circulation of multiparous, postmature women with large-for-dates fetuses and in those undergoing long and vigorous labor after induction. [142] [143] DIC is triggered by amniotic fluid tissue factor and an activator of factor X. [144] [145] [146] The extensive occlusion of the pulmonary arteries that causes sudden dyspnea, cor pulmonale, shock, and seizures is due to blockage with fetal debris and meconium. This in turn enhances local plateletfibrin thrombus formation. There can be secondary fibrinolysis, further contributing to defibrination and bleeding. This is followed after a latent period of up to 3 hours by severe bleeding in 37% of cases. [145] The mortality rate associated with this condition, primarily due to respiratory failure, is >80%. [140] As with abruptio placentae, the pathogenetic mechanism for the clinical manifestations is unclear.

Because of the rapid course of this complication and its infrequency, specific treatment modalities such as heparin and fibrinolysis inhibitors have not been adequately assessed, but may be considered in individual cases. Blood and coagulation factor replacement therapy warrants consideration in patients with active bleeding, along with pulmonary and hemodynamic support.

Sepsis during pregnancy is often caused by gram-negative bacteria and *Clostridium* sp., with the patient being particularly susceptible to DIC under these circumstances. Septic abortions are often associated with severe DIC accompanied by endotoxin-mediated shock and a high mortality rate. [140] [147] Virtually any organism can be associated with septic abortion. In addition, saline-induced abortion during the second trimester without sepsis also has a clear association with hypofibrinogenemia, thrombocytopenia, and increased FDPs. [148] [149]

Malignancies

Cancer can be associated with both acute or chronic DIC, depending primarily on the type of cancer. Malignancy-associated chronic DIC associated with solid tumors is reviewed later in the chapter, whereas acute DIC associated with leukemia is discussed here. DIC has been associated with acute myelocytic and lymphocytic leukemia, chronic myeloid and myelomonocytic leukemia, hairy cell leukemia, and angioimmunoblastic lymphadenopathy. [150] [151] [152] [153] [154] [155] [156] [157] [158] [159] Among these diagnostic entities, acute promyelocytic leukemia is most commonly associated with life-threatening hemorrhage secondary to DIC and other hemostatic abnormalities.

The pathogenesis of DIC associated with acute promyelocytic leukemia has remained controversial, and consequently the optimal therapeutic approach associated with this condition remains unclear. Leukemic cells from patients with acute promyelocytic leukemia have been found to harbor tissue factor, a factor X-activating protease, and produce interleukin-1. [160] [161] [162] [163] Increased levels of prothrombin fragment 1·2 and thrombinantithrombin III complexes have also been described in these patients, and document the excessive generation of thrombin in this leukemia. [164]

Investigators have also provided evidence for primary fibrino(geno)lysis as a contributing factor associated with serious bleeding seen in patients with acute promyelocytic leukemia. In this respect, urokinase-type plasminogen activator and t-PA have been found in acute promyelocytic leukemia cells along with reduced plasma activity of plasminogen activator inhibitor and reduced $_2$ -antiplasmin plasma levels. [101] [165] [166] [167] [168] [169] [170] [171] [172] In reality, it is likely both DIC and primary fibrino(geno)lysis contribute to bleeding in the patient with acute promyelocytic leukemia.

Although bleeding predominates in acute promyelocytic leukemia, thromboembolic complications have been noted in up to 5% of patients and 1525% of autopsy results. [173] [174] One study suggested acute promyelocytic leukemia cells from a patient with coagulopathy did not in fact have procoagulant activity, but rather were capable of elaborating interleukin-1 that induced endothelial tissue factor activity when mixed with endothelial cells. [169]

Acute promyelocytic leukemia-associated bleeding due to DIC is further exacerbated by thrombocytopenia due to marrow suppression. Furthermore, once treatment is initiated, subclinical DIC often becomes clinically apparent because of chemotherapy-induced acute promyelocytic leukemia cell lysis. [175] The incidence of coagulopathy- and hemorrhage-related mortality associated with acute promyelocytic leukemia has significantly decreased since the recent introduction of the differentiating agent all-trans retinoic acid into induction regimens, with bleeding frequently abating within 48 hours of treatment initiation. [44] [176]

Tissue Injury, Burns, and Heat Stroke

Extensive trauma and burns are often associated with both localized and disseminated intravascular coagulation. This is particularly true if there is a component of head injury associated with multiple trauma because brain parenchyma is rich in tissue factor. In this respect, laboratory-based DIC scores have been shown to have prognostic value in patients with head injury. [177] [178] [179] Studies have demonstrated a high mortality rate when head injuries are accompanied by bleeding and laboratory evidence of DIC, along with a correlation between time to treatment after trauma and the development and extent of DIC. [179] [180]

Extensive exposure of circulating blood to tissue factor is probably the most prevalent causative factor in trauma-associated DIC. Other possible contributions to this clinical picture may relate to dilutional coagulopathy due to blood loss or replacement with crystalloid solutions and packed red cells alone; ischemic or trauma-associated hepatic dysfunction with reduced clotting factor and natural inhibitor synthesis; and ARDS.

Massive trauma is often accompanied by ARDS, to which hypotension followed by aggressive fluid replacement contribute. Obstruction of the pulmonary circulation secondary to multiple thrombi may also contribute to ARDS. [181] One study noted that among 30 patients with ARDS, 7 had evidence of additional thrombotic microangiopathy in the skin and kidneys, whereas an additional 12 had thrombocytopenia and 4 had pulmonary vessel fibrin deposition on postmortem examination. [182]

Serious trauma cases, usually but not always involving multiple fractures, can lead to fat embolism within the first 48 hours. [183] [184] This is associated with respiratory distress and neurologic impairment secondary to marrow fat emboli from associated fractures. If the pulmonary picture is complicated by ARDS, laboratory evidence of DIC may also be present because of endothelial perturbation, tissue factor expression, and inhibition of fibrinolysis. [184]

Burns can be associated with DIC through release into the circulation of tissue factor from damaged tissues along with associated hypovolemic shock and infection, which occur later in the clinical course. In addition to DIC, significant local consumption of clotting factors has also been associated with burns. [185]

Both DIC and primary fibrinogenolysis have been demonstrated in association with heat stroke, a syndrome defined as a body temperature >42°C due to collapse of thermoregulatory mechanisms. [186] [187] Pathophysiologic mechanisms associated with the disorder include tissue factor expression from damaged tissues and endothelial cell perturbation. [188] Extensive fibrin deposition with subsequent increased release of plasminogen activators and secondary fibrinolysis has been associated with the generalized bleeding and multiorgan failure accompanying fatal cases of heat stroke. [189]

Chronic DIC

Malignancies

The association between solid tumors and thrombotic and bleeding symptoms was initially described by Trousseau in 1865. *Trousseau syndrome* refers to either spontaneous recurrent or migratory venous thrombosis, or arterial emboli due to nonbacterial thrombotic endocarditis, or both, occurring in the setting of malignancy. [190] There is a spectrum of thrombohemorrhagic diagnostic entities seen in association with solid tumors, including low-grade DIC, venous thromboembolic disease, primary fibrino(geno)lysis, microangiopathic hemolytic anemia, and nonthrombotic valvular endocarditis. [191] These different disorders can present singly or multiply at any location and with any degree of acuteness or chronicity.

Disseminated intravascular coagulation associated with solid tumors demonstrates pathophysiologic mechanisms similar to those of the DIC seen with acute promyelocytic leukemia. These include tissue factor secreted by tumor cells and activated monocytes. [192] [193] A factor X-activating cysteine protease has been described in human carcinoma tissue. [39] [40] [41] Tumor cells or media conditioned by these cells induce platelet aggregation both in vitro and in vivo. [194] [195] [196]

Chronic DIC is classically associated with thrombosis. Among the many studies done in the area of thrombosis and bleeding in association with solid tumors, one group documented deep venous thrombosis in 113 of 182 (62%) patients with cancer. Ninety-six of the 182 (53%) manifested migratory thrombophlebitis, 41 (23%) demonstrated nonbacterial thrombotic endocarditis, a disorder classically associated with mucin-producing carcinomas, whereas 75 (41%) had bleeding manifestations. [197]

Classic laboratory findings associated with chronic DIC and

---

solid tumors include thrombocytopenia and circulating FDPs. Hypofibrinogenemia also occurs, but is less common. Microangiopathic hemolytic anemia may occur in the absence of other DIC laboratory abnormalities, usually in association with disseminated mucin-secreting adenocarcinoma. Laboratory manifestations of increased thrombin generation are seen in patients with solid tumors and may not be accompanied by clinical thrombosis or bleeding.

Primary fibrino(geno)lysis is primarily seen in patients with prostate cancer and acute promyelocytic leukemia. These tumors are capable of producing activators of plasminogen and thrombin.[104] [198] Biopsy of prostate tumors is sometimes accompanied by prolonged postoperative bleeding as a result of this phenomenon, and hemorrhagic manifestations can dominate the clinical picture. [199]

Dead Fetus Syndrome

The dead fetus syndrome occurs several weeks after intrauterine fetal death and can be accompanied by DIC. [200] [201] The clinical syndrome is usually one of insidious-onset DIC mediated by tissue factor from the placenta or dead fetus entering the maternal circulation over the ensuing days, eventually causing bleeding. Serial laboratory monitoring of the mother after diagnosis of intrauterine fetal death is warranted to detect possible progressive coagulopathy; in this event immediate evacuation of uterine contents is indicated.

Localized Intravascular Coagulation

Aortic Aneurysm

Extensive aortic aneurysms have been associated with significant laboratory abnormalities and bleeding secondary to platelet and fibrinogen consumption. [202] These complications are characteristically associated with extensions and enlargements of the dissecting aneurysm, which in turn are often accompanied by sudden onset of severe pain. In one series of patients with aortic aneurysms, 40% had chronically elevated levels of fibrin split products, with 4% showing evidence of significant bleeding and laboratory findings of DIC. [203] Management of DIC in association with aortic aneurysms is outlined in the section on treatment (see later).

Hemangiomas

Kasabach and Merritt were the first to report localized intravascular coagulation in association with hemangiomas. [204] These are usually benign tumors seen mostly in infants and children that typically enlarge over time. They are associated with consumption of platelets and fibrinogen as demonstrated by radiolabeling studies showing intravascular clotting and excessive fibrinogenolysis (the latter due to t-PA release from abnormal endothelium of tumor vessels). [205] [206] [207] Microangiopathic hemolytic anemia has also been observed in this setting along with laboratory evidence of DIC. [208] [209] Clinical DIC and emboli to other organs, however, usually are not seen in association with hemangiomas. Severe bleeding is normally noted only after surgery or other invasive procedures associated with the hemangioma. [209]

Liver Disease and DIC

Patients with advanced liver disease are prone to a plethora of hemostatic and thrombotic derangements that are often very difficult to classify and hence successfully manage on a pathophysiologic basis. Alterations in hepatic synthesis and both hepatic and renal clearance of activated coagulation, fibrinolytic, and natural inhibitor proteins, along with the thrombocytopenia and the deranged hemodynamics typically seen in this patient population, collectively contribute to the difficulties encountered.

In those with advanced or acute, severe liver disease, the clinician may expect to find decreased hepatic synthesis of most coagulation proteins, protein C, protein S, antithrombin III, and plasminogen, along with $_2$ -antiplasmin. The liver also demonstrates defective clearance of activated clotting proteins under these circumstances.[210] [211] Portal hypertension leads to splenomegaly with enhanced platelet sequestration and thrombocytopenia.

Given these circumstances, the issue of whether DIC is directly associated with liver disease, as opposed to the observation that these patients may simply be more sensitive to DIC, is an unsettled one. Experimental observations exist either suggesting the existence of an association [212] [213] [214] [215] [216] [217] [218] or supporting the hypothesis these hemostatic derangements may stem from disorders other than DIC.[219] [220] [221] [222]

As is the case with the pregnancy-associated disorders, the diagnosis of DIC in patients with liver disease and generalized bleeding not due to a local source is most readily appreciated by following serial hemostatic parameters and noting a significant reduction in these values over a short period of time. If available, tests reflecting thrombin generation, such as the protamine paracoagulation assay, the prothrombin fragment 1·2 or thrombinantithrombin III complex levels, along with D-dimer levels, can also contribute to establishing the diagnosis.

Disseminated intravascular coagulation is also seen after the placement of peritoneovenous (LeVeen) shunts for complications associated with massive ascites. The incidence is variously quoted in different studies as ranging from 3 to 91%, and may depend on whether the primary disease is peritoneal or hepatic in origin. [223] [224] [225] [226] Ascitic fluid possesses both tissue factor activity in association with monocytes and thrombin activity, which likely contribute to the DIC. [227] Clamping the shunt is the only effective treatment in severe cases because heparin and antithrombin-III concentrates have not proven efficacious. [228] [229]

Fatty liver of pregnancy has also been associated with DIC on the basis of labor-induced clotting factor and platelet consumption in the presence of decreased synthesis of the clotting factors and natural inhibitors. [230] The clinical and laboratory features have been attributed to low plasma antithrombin-III levels, and in this respect patients have responded to antithrombin-III concentrate. [231]

TREATMENT OF DIC

General Measures and Replacement Therapy

Given the heterogeneity of the underlying disorders with which DIC is associated, the difficulties often encountered with determining the extent of consumption of clotting factors and fibrino(geno)lysis in each case, and the relative lack of well controlled studies of treatment of homogeneous subgroups with DIC, it is not surprising that many aspects of treatment of DIC are controversial. Part of the problem resides with the fact that studies are very difficult to perform in view of the variety of pathophysiologic triggers and clinical presentations associated with DIC. Thus, DIC is one disorder in which management has to be individualized, with careful attention to variables such as the initiating illness and the presence of bleeding or thrombosis.

The cornerstones of management of DIC include aggressive basic support measures, paying close attention to circulatory volume status, gas exchange, and electrolyte balance, along with prompt, vigorous treatment of the underlying cause of the DIC. This includes, for example, intravenous antibiotics for gram-negative septicemia, prompt uterine evacuation for abruptio placentae, and restoration of hemodynamic stability for hypovolemic shock. The other management components of the disorder include determining whether replacement of

REPLACEMENT THERAPY FOR DIC

The symptoms and abnormal laboratory findings associated with DIC are most readily addressed through the prompt recognition and treatment of the underlying disorder. Until the underlying cause can be definitively managed, blood product replacement therapy warrants consideration in the patient with significant bleeding or a planned procedure and coagulation parameters compatible with DIC. Replacement folate and vitamin K therapy also warrant consideration in any patient with prolonged DIC.

Platelet transfusions should be considered to maintain the count >2030 × 10^9 /L in a bleeding patient, while aiming for higher values if concurrent functional impairment is present, a procedure is planned, or blood loss is significant. DIC-associated thrombocytopenia does not usually reach levels of 20 × 10^9 /L, however, without concurrent contributing factors such as sepsis. One unit of donor platelets is expected to contain at least 5.5 × 10^9 platelets and raises the count 68 × 10^9 /L, assuming normal splenic pooling. The platelet count should be repeated 1060 minutes after the first transfusion to confirm the expected increment, and every 6 hours after that. Poor postplatelet transfusion increments are often seen in consumptive thrombocytopenia, making transfusion support difficult under these circumstances.

Cryoprecipitate administration is considered in a symptomatic patient to maintain plasma fibrinogen over 100 mg/dl. The fibrinogen content of each cryoprecipitate unit varies from 100 to 250 mg, depending on variable storage volumes and pooling methods. Thus, from 1 to 4 units/10 kg can be given, with the postinfusion increment checked 3060 minutes later and followed by repeat determinations every 6 hours.

Fresh frozen plasma is given if significant DIC-associated bleeding is accompanied by a prolonged PT and PTT. The aim is to reduce the PT, with the target in each case dependent on the nature and extent of bleeding, the presence and extent of co-existing hemostatic defects, and whether a procedure is planned, and its attendant bleeding risk. This is accomplished through administration of 1015 ml/kg of plasma.[265] Each milliliter of plasma contains 0.71 unit of activity of each clotting factor and 12 mg of fibrinogen, so an alternative formula to 1015 ml/kg incorporates estimated plasma volume, desired factor level increment, and the half-life of the factor being replaced into the equation. The PT and PTT should be checked every 6 hours and plasma given as needed based on the patients clinical response. Depending on clinical circumstances, bleeding patients with DIC given plasma transfusions can exhibit poor clinical and laboratory responses, particularly if advanced liver disease with co-existent diminished clotting factor synthesis and altered hemodynamics complicates the picture.

depleted platelets or clotting factors is necessary and whether attempted abrogation of the DIC with heparin or natural inhibitors should be considered.

The idea that blood replacement therapy may be fueling the fire of DIC has never been proven. Transfusion of platelets, cryoprecipitate, and fresh frozen plasma should be reserved for those with both clear laboratory evidence of DIC and either bleeding or a pending invasive procedure. It is typically most effective in those with very low platelet and fibrinogen levels in whom DIC is self-limited or concluded.

Patients with head injury-associated brain tissue destruction are particularly prone to acute, limited defibrination (hypofibrinogenemia, elevated levels of serum fibrinogen-related or fibrin-related split products, and low levels of factors V and VIII or platelets), in which laboratory abnormalities often return toward normal within hours.[37] These patients benefit from rapid, optimal correction of hemostatic deficiencies to minimize the neurologic consequences of intracranial bleeding, whereas heparin therapy to prevent ongoing intravascular coagulation is not helpful because of its short-lived course and associated intracranial bleeding risk.

Platelets should ideally be maintained at over 2030 × 10^9 /L in a bleeding patient, whereas those undergoing procedures or who have concurrent functional impairment or significant blood loss should have higher counts. Cryoprecipitate should be given to maintain plasma fibrinogen >100 mg/dl, whereas fresh frozen plasma is indicated to correct a prolonged PT and PTT in appropriate clinical circumstances. To determine the efficacy of transfusion, platelet and fibrinogen levels should be checked 3060 minutes after the transfusion and every 6 hours after that. Replacement therapy may be required every 8 hours while the underlying cause of the DIC is being addressed. Transfusions can be discontinued when the coagulation parameters are almost or fully normalized and symptoms have abated. If laboratory parameters fail to improve with transfusions because of DIC-associated bleeding, a concurrent heparin infusion may warrant consideration.

The Role of Heparin in DIC Management

Heparin should be considered in the management of DIC if (1) a patient has strong clinical and laboratory evidence of DIC and thromboembolic manifestations predominate (e.g., purpura fulminans, dead fetus syndrome before induction, aortic aneurysm prior to surgery); or (2) intensive blood replacement therapy fails to alleviate excessive bleeding and increase the level of clotting factors. These circumstances notwithstanding, it is important to consider that heparin is less likely to lead to clinical improvement in DIC once it is established and ongoing, which is usually the case by the time it is diagnosed. Heparin is also capable of exacerbating DIC-associated bleeding in these populations and should be used very cautiously. For these reasons, heparin usually has a limited role, if any, in acute DIC.

In chronic DIC associated with solid tumors, the dead fetus syndrome, or hemangiomas, continuous heparin infusion without a loading bolus can be given with blood products if the clinical picture warrants treatment (e.g., deteriorating coagulation parameters in dead fetus syndrome, thrombosis, before chemotherapy). Once symptoms have resolved, patients with solid tumors can be given long-term, adjusted-dose subcutaneous heparin or lowmolecular-weight heparin rather than oral anticoagulants, which are frequently ineffective under these circumstances. [232] Because the baseline PTT is often prolonged in these patients, the antithrombotic effect of heparin may be monitored by serial heparin or anti-factor Xa levels.

The role of heparin in treatment of acute promyelocytic leukemia remains controversial, with evidence supporting [160] [161] [162] [163] [164] [233] [234] [235] and refuting[236] [237] [238] its use in the complex coagulopathy associated with this disorder. Any role it plays may decline in the future in light of preliminary data suggesting the incidence of acute promyelocytic leukemia-associated coagulopathy is diminished when all-trans retinoic acid is included in induction regimens. [44] [45] [176] Similarly, the use of heparin in DIC associated with advanced liver disease is controversial. [239] [240] [241] [242] It is contraindicated in abruptio placentae because of bleeding complications associated with delivery and hysterectomy, if

HEPARIN IN THE MANAGEMENT OF DIC

The circumstances under which a trial of heparin should be considered in the management of a patient with clinical and laboratory evidence of DIC are outlined in the text. In general, if the clinical setting is more compatible with chronic DIC (e.g., secondary to solid tumor), the picture is more likely to be complicated by thromboembolic phenomena rather than bleeding, which in turn necessitates consideration of heparin.

If an initial heparin bolus is indicated, one nomogram suggests 80 U/kg intravenously (IV) can be given, followed by an 18 U/kg/hr infusion. [266] Heparin has variable sensitivity to different thromboplastin reagents incorporated in individual laboratory PTT assays. Therefore, any laboratory nomogram used in heparin dosing needs to have its dosing recommendations based on the therapeutic range for the local PTT reagent tailored to corresponding heparin levels of 0.20.4 U/ml by protamine titration or anti-factor Xa levels of 0.30.7 U/ml. If no bolus is indicated, patients can be started on an 18 U/kg/hr infusion. The PTT, heparin level, or anti-factor Xa level should be checked 6 hours after the start of therapy, and dosage adjustments made accordingly.[266]
