It has been reported that a new derivative of doxorubicin, 4-iodo-4-deoxydoxorubicin (I-DOX) may be effective in AL amyloidosis. [174] [175] The precise mode of action of this compound is not known; however, it has a very high affinity for amyloid fibrils of any sort, which likely plays a key role in its mechanism of action. [176] It has also been reported that treatment with I-DOX significantly delayed the clinical signs of disease and prolonged survival time in Syrian hamsters with experimental prion infection. [177] The results of a phase I trial showed that 5 of 8 patients treated with 16 administrations of I-DOX at dosages of 15100 mg/m ^{2} obtained clinical improvement, concomitant with evidence of amyloid resorption. [175] The benefits appeared some weeks after treatment and persisted for a median of 6 months. The efficacy of I-DOX was not related to cytotoxicity since no significant or persistent reduction of the serum or urinary concentrations of the monoclonal protein was noticed in any of the patients. The results observed in 14 more patients treated with I-DOX at our institution (GM) and in 28 patients treated on a compassionate basis in several European countries have been recently reported. [178] Six of the 13 evaluable patients treated at our institution were responsive and four showed stable disease. Median duration of clinical benefit was 7 months. Best results were obtained in patients with soft tissue involvement, while those with heart, kidney, or liver involvement did not experience recovery of organ function. Of the 28 patients treated on a compassionate basis a response was observed in 5 patients, in 11 patients I-DOX stabilized the disease, 11 patients did not respond and the disease progressed to death in most of them. Serious adverse events were reported in three patients: two sudden deaths and an onset of acute renal failure. These data indicate that only a minor proportion of all patients responded to I-DOX as used and that clinical effects were transient and insufficient to affect the course of the disease. Further clinical investigation is necessary to define the role of I-DOX in the treatment of AL amyloidosis. At present, it appears that this drug should be used as an adjunct to more specific and effective therapy for AL amyloidosis.

Prognostic Factors

In most patients, AL amyloidosis is a fatal disease, with median survivals ranging from 1 to 3 years. [51] [142] In 171 patients seen at our institution, the median survival is 34 months (range, 1149 months; 5-year survival rate of 15%; Fig. 773A). In L/HCDD, the overall survival rate is quite variable, ranging at 5 years from 20 to 70%. [21] [158] [159] The primary determinant of prognosis in both disorders is the extent of dysfunction of a vital organ. Thus, the prognosis depends on the clinical syndrome at presentation, and the number of organ systems involved. In a series of patients with AL amyloidosis, patients with congestive heart failure had a median survival of 8 months (5-year survival rate, 2.5%), whereas those with peripheral neuropathy as the sole manifestation had the best outcome (median survival, 40 months; 5-year survival rate, 32%). [61] In a multivariate analysis of 168 patients with AL amyloidosis, the presence of congestive heart failure, urinary light chain, hepatomegaly, and

multiple myeloma adversely affected survival during the first year, whereas after the first year, increased serum creatinine, presence of myeloma, orthostatic hypotension, and serum M protein were predictors of poor survival. [179] In our experience using high-dose therapy, however, the survival of patients with myeloma and AL amyloidosis appears to be quite comparable to

Figure 77-3 (A) Overall survival of 171 patients with primary amyloidosis (dotted lines denote 95% confidence intervals). **(B)**

that of myeloma patients without amyloidosis. [53] In a large cohort of patients with AL amyloidosis followed at our institution, the presence of congestive heart failure was one of the major prognostic determinants (Fig. 773). Few studies have specifically addressed the prognostic variables in a large cohort of patients with L/HCDD, but the extent of renal and cardiac dysfunction appears similarly to affect the survival rates of these patients. [158] In approximately half the patients with AL amyloidosis, the cause of death is cardiac related. [164]

FUTURE DIRECTIONS

Amyloidosis causes progressive organ damage that is ultimately fatal. Early diagnosis is of paramount importance to establish timely therapy and recover the function of the organs involved by the disease. The hematologist should maintain a high level of alertness, in particular in patients with known M protein. Diagnosis is now rapid and reliable; traditional and ultrastructural immunohistochemistry allow rapid typing of the amyloid, which is necessary to choose the appropriate treatment. The management of these patients is and will be increasingly articulated. Supportive therapy should be applied with full intensity, and specific therapy will become more comprehensive as the unraveling of the complex pathogenesis discloses new potential therapeutic targets. The recent advances in our understanding of the nature of the different amyloid forms have been remarkable. The genetic defects of the hereditary amyloidoses have been identified, thus allowing patients with these diseases to benefit from diagnostic testing, genetic counseling, prenatal testing, and treatments, such as liver transplantation. The molecular mechanisms involved in the transformation of a native protein into a polymeric and fibrillar structure, and the clarification of the role of other tissue components in the formation and persistence of amyloid deposits, offer potential for the development of novel approaches to therapy.

Chapter 78 - Atypical Immune Lymphoproliferations

Timothy C. Greiner
Thomas G. Gross

INTRODUCTION

Development of modern classification systems for hematologic malignancies resulted from the recognition that specific histologic and cytologic patterns correlated with prognosis.[1] [2] [3] [4] The Working Formulation for Clinical Usage predicts prognosis in many of the subtypes of lymphoma, but is limited by the lack of immunophenotype and molecular data that the Revised European and American classification proposal provides. [1] [2] The Rye classification scheme for Hodgkins disease correlates prognosis with histologic features such as the number of Reed-Sternberg cells, the composition of the background lymphoid cells, and the degree and type of sclerosis.[3] The French-American-British (FAB) scheme for leukemias relies on cytologic features for lymphocytic leukemias and a combination of cytologic and cytochemical features for myeloid leukemias.[4] These classification systems can be reliably applied to most clinically relevant neoplastic lesions, but some lymphoproliferations are not addressed because they do not meet the pathologic definition of malignancy. No unifying system exists for classifying atypical or preneoplastic lymphoproliferations that provides prognostic information to predict whether a patient will have a self-limited illness or progress to lymphoma or death.

WHAT CONSTITUTES AN ATYPICAL LYMPHOPROLIFERATION?

The tremendous complexity of the immune system and its variable responses to challenges has led to recognition of certain hyperplastic responses that are clearly benign and manifest specific histologic patterns when biopsied. [5] Examples of benign hyperplastic immune responses include follicular hyperplasia, in which B-cell areas of the lymph node increase in size and number. As a nonspecific diagnosis, follicular hyperplasia may be seen in a wide range of clinical presentations, from bacterial infections to generalized lymphadenopathy of acquired immunodeficiency syndrome (AIDS). Sinus histiocytosis, in which benign histiocytes distend lymph node sinuses, [5] is seen in reaction to particulates and organisms in hilar lymph nodes and in lymphoid drainage sites of carcinomas. Clearly benign or malignant lesions can be easily diagnosed by biopsy, clinicopathologic correlation, and the exclusion or establishment of clonal rearrangements.

A significant group of patients present with unusual clinical features, and their biopsies result in pathologic diagnoses that prompt use of terms such as atypical or suspicious for malignant lymphoma, leaving the physician with incomplete information

on how to treat the condition. Some disorders present with clinical features that suggest a malignant process but show characteristic histologic features that correlate with a benign outcome. The majority of these processes are related to an abnormal immune response to some inciting stimulus. Others may sometimes result in the death of the patient, either by progression to malignancy or by damage to the immune system. Accurate diagnosis requires careful correlation of immunohistologic, karyotypic, virologic, and genotypic analyses with the clinical findings. The more commonly encountered atypical lymphoproliferations related to viruses, drugs, genetic abnormalities, and unknown causes will be discussed.

VIRUS-ASSOCIATED ATYPICAL LYMPHOPROLIFERATIONS

Epstein-Barr Virus: Fatal Infectious Mononucleosis

Biological Aspects

The prototypical cause of atypical lymphoproliferations is the ubiquitous Epstein-Barr virus (EBV). [6] A knowledge of the mechanisms by which EBV induces lymphoproliferation provides a model for understanding other virus-associated lymphoproliferations. [6] [7] EBV causes the well-characterized clinical syndrome of infectious mononucleosis (IM) discussed in Chapter 45 . This disscussion will not specifically address IM but will cover those lesions that fall outside the usual clinical spectrum of self-limited IM.

EBV, a large herpesvirus (172,000 base pairs), preferentially infects B cells in humans and causes lifelong infection. [6] [8] The key to understanding atypical responses to EBV involves the relationship that is established between the virus and the immune system after primary infection. [6] [8] Primary infection by EBV results in two main responses, depending on the age of the individual or the maturity of the immune system. [6] [8] If the primary infection occurs in early childhood, the immune response and clinical symptoms are almost always silent, but about two-thirds of infected older children and adults develop IM. [6] [8] Once infected by EBV, an individual maintains a lifelong relationship with the virus in which a virus-driven B-cell proliferation is kept in check by the host immune surveillance. A low level of virus production occurs in the oropharyngeal region by unknown mechanisms; about 1 in 10^6 B cells in peripheral blood carries EBV. [6] [8] The intimate association of oropharyngeal epithelium with oropharyngeal lymphoid tissue results in a constant cycle of circulating infected B cells. Disease results when the immune system is depressed, either by iatrogenic means or by concurrent infections with other agents (Fig. 781).[6] The resulting immune suppresion allows escape of EBV-infected B cells and resultant lymphoproliferation. [6] [7] [8] [9] [10] [11] The self-limited course of IM contrasts with the atypical responses that can occur, such as fulminant infectious mononucleosis (FIM).[6] FIM is characterized by extensive infiltration of lymphoid and parenchymal organs by polyclonal T and B cells in varying degrees of transformation, resulting in a polymorphous pattern (Plate 78-1A), which contrasts with the monomorphic pattern of malignant lymphoma (Plate 78-1B).[6] [8] [9] [10] [11] The extent of T-cell and histiocytic reaction in FIM is often dramatic. Hemophagocytosis is common. [7]

Epidemiology

FIM occurs in approximately 1 in 3,000 IM cases, or about 40 cases annually in the United States. [6] [7] [8] [10] [11] The explosive lymphoproliferation that occurs in FIM mimics that in certain hematologic neoplasms, such as lymphoid leukemia, and can obscure recognition of FIM as a cause of death. [6] [7] [10] [11] The median age at presentation is 13 years, with a 1:1 male/female ratio. [10]

Clinical Manifestations

Patients who progress to FIM initially present with the usual signs and symptoms of IM, including fever, sore throat, malaise, anorexia, nausea, vomiting, and a maculopapular rash, but

Figure 78-1 The EBV-immune system relationship and the development of lymphoproliferations associated with various immune deficits or diseases.

these symptoms are usually more extensive than those of IM.[10] Patients initially manifest an atypical lymphocytosis but subsequently develop severe, persistent pancytopenia, hepatic dysfunction resulting in fulminant hepatitis, meningoencephalitis, and varying degrees of myocarditis. [6] [7] [8] [9] [10] [12]

Laboratory Diagnosis

The diagnosis of EBV-associated atypical lymphoproliferations and of FIM can be difficult because the usual EBV antibody responses may be lacking or unusually high, and the clinical picture may resemble an acute leukemia, another malignancy, or overwhelming sepsis. [6] [10] [11] [12] [13] [14] Reactive lymphocytes may be seen in the peripheral blood. An accurate diagnosis may require performing serologic studies of the EBV-specific antibodies to the viral capsid antigen (VCA), early antigen (EA), and EBV nuclear-associated antigen (EBNA); staining of lymphoid tissue for latent membrane protein (LMP)-1; establishment of lymphoblastoid cell lines; and in some cases, molecular analyses including in situ and Southern blot hybridization or polymerase chain reaction studies. [6] [10] [11] [12] [13] [14] (Table 781). Because FIM is rare, a search for a heritable immune deficiency in family members is mandatory. [6] [10] [11] [12] [13] [14] Although FIM is the most common manifestation of males affected with X-linked lymphoproliferative disease (XLP), FIM can occur outside the context of XLP. [6] [8] [10] [11] [12] [15] Clinically, FIM is indistinguishable from other viral associated hemophagocytic syndromes (VAHS), familial hemophagocytic lymphohistiocytosis (HLH), and the accelerated phase of Chediak-Higashi disease. [7] [16]

TABLE 78-1 -- EBV Diagnostic Procedures

Parameter Assayed	Method
Infectious (viable) EBV virions	
EBV cytopathic effect	Conventional tissue culture
EBV early antigen (EA) detection	Centrifugation culture and direct immunofluorescence
Establishment of EBNA and/or EBV genome-positive lymphoblastoid cell lines	Culture of lymphocytes from peripheral blood or biopsy material; cord-blood lymphocyte transformation by throat washings
Circulating EBV antibodies	
VCA: IgG, IgM, IgA	Indirect immunofluorescence
EA-D: IgG, IgA	Indirect immunofluorescence
EA-R: IgG	Indirect immunofluorescence

EBNA: IgG	Anticomplement immunofluorescence; enzyme-linked immunoabsorbent assay
Heterophil: IgM	Paul-Bunnell-Davidson test
Monospot	Rapid slide test
EBV protein(s) in tissue	
EBNA	Anticomplement immunofluorescence; Western blot analysis
LMP-1	Immunoperoxidase
EBV-specific cytotoxic T-cell functions	Lymphocytotoxicity assay; regression assay
EBV nucleic acid analysis	
EBV DNA	Dot blot hybridization; Southern blot analysis; in situ hybridization; polymerase chain reaction
EBV RNA	Dot blot hybridization; Northern blot analysis; in situ hybridization
EBV terminal repeat (clonal marker)	Southern blot analysis

EBV, Epstein-Barr virus; EBNA, Epstein-Barr nuclear antigen; VCA, viral capsid antigen; EA, early antigen; LMP-1, latent membrane protein-1.

A GENERAL APPROACH TO THE DIAGNOSIS OF ATYPICAL LYMPHOID HYPERPLASIAS

Accurate diagnosis of atypical lymphoproliferations requires a systematic approach. The patients history and physical examination often suggest a malignant process, which requires a biopsy for confirmation. If the clinical features and biopsy findings are suggestive of a viral process, serology and virologic assays may be confirmatory, and the patient can be observed without further workup. If the family history and clinical features suggest a heritable immune defect, then pedigree and immunologic analysis of the patient and family members is mandatory. Conditions that have a characteristic histologic appearance (e.g., Castlemans disease) can be accurately diagnosed with histologic examination alone, but most patients will require application of more sophisticated diagnostic procedures on appropriately prepared specimens.

To obtain optimum results from a lymph node biopsy in the settings described in this chapter, close cooperation between the referring physician, surgeon, and pathologist is required. In our practice within the Nebraska Lymphoma Study Group, we sometimes see patients who have had one or more biopsies that have had improper handling of the tissue, negating the opportunity to perform adjunctive studies. These procedures require fresh tissue. Thus the practice of placing the entire lymph node biopsy specimen in formalin is to be condemned, for it is a frequent cause of a second biopsy. Therefore, a protocol to handle lymphoid tissue is mandatory to evaluate these difficult lesions. It is imperative for the referring physician to communicate the differential diagnosis of lymphoma, atypical immune response, transplant status, and recent drug history to the surgeon and pathologist so that fresh tissue is appropriately partitioned. At the Nebraska Lymphoma Study Group, fresh lymph node tissue is routinely frozen for possible immunohistochemical studies and molecular gene rearrangement analyses after routine histology. Other laboratories choose to form cell suspensions for flow cytometry. In addition, cytogenetic analysis is performed on a portion of the fresh tissue. Case records are maintained for each patient in our lymphoma, XLP, and PTLD registries. In situ hybridization for EBV is performed in all cases of suspected immune deficiency. After a diagnosis of EBV-positive lymphoproliferation, new masses are biopsied to rule out transformation to non-Hodgkins lymphoma.

Therapy

All these diseases are characterized by uncontrolled T lymphocytes and macrophages, and immunosuppression with corticosteroids, cyclosporin A, and/or anti-thymocyte globulin (ATG) has been effective. The use of etoposide (VP-16) to quench macrophage activation and to down-regulate T-cells, in conjunction with immunosuppression, can be effective even in the most severe cases. Occasionally, the central nervous system is involved and intrathecal chemotherapy is required to resolve the symptoms.[7] [17] [18]

Prognosis

Patients who develop FIM succumb to severe and progressive multiorgan failure, apparently brought on by anomalous cytotoxic T-cell and natural killer cell activity, which nonselectively destroys uninfected hepatocytes, bone marrow elements, skin,

and other organs during the unrestricted polyclonal immune response initiated by the EBV infection. [6] [7] [8] [9] [10] [17] The median survival time is approximately 4 weeks, and splenic rupture is conspicuously rare as a cause of death in these patients. [6] [10]

Other Presentations of EBV Lymphoproliferations

Rarely, elderly patients, malnourished patients, and those with cancer also develop EBV-associated atypical lymphoproliferation. [6] [11] [13] These patients have a secondary immunodeficiency. The majority of them will have had a prior infection with EBV and will have achieved a virusimmune system balance prior to acquiring an immune deficiency, which then allows the virus to escape the defective immune surveillance mechanisms. Lymphoproliferations ranging from IM to FIM to overt lymphoma (Plate 781A & B) can then occur.[6] [10] [11] [13]

Patients with the acquired immunodeficiency syndrome also experience virus reactivation because the T-cell arm of the immune system is selectively attacked by the AIDS virus, resulting in loss of control over the persistent EBV infection. [6] Various lesions, including explosive follicular hyperplasia, hair leukoplakia of the tongue, and lymphoma have all been associated with EBV.[13] [14] Children with AIDS often develop lymphoid interstitial pneumonitis resulting from EBV-induced polyclonal B-cell proliferation.[19] Adults with AIDS have a 1,000-fold increased risk of developing malignant lymphomas, most of which probably begin as polyclonal EBV-associated (50%) lymphoproliferations and progress to monoclonal lymphomas. [6] [14] This is secondary to the development of cytogenetic events that occur

during the lack of adequate control of EBV by the damaged T-cell systems. [6] [11] [14]

Cytomegalovirus

Cytomegalovirus (CMV), also a herpesvirus, can cause the mononucleosis syndrome but is usually latent until unmasked by immune deficiency, pregnancy, multiple drug exposures, or immune suppression. CMV causes less of a lymphoproliferative response than EBV, and activation often results in more extensive inflammation and tissue necrosis. [20] Diagnosis is made by appropriate serologic studies, by identification of characteristic nuclear inclusions in cytologic or tissue biopsy specimens (Plate 78-2A), immunoperoxidase studies (Plate 78-2B), or by molecular techniques, including in situ hybridization and polymerase chain reaction (PCR). [20] [21] Therapy includes the use of current antiviral agents such as acyclovir and gancyclovir.

Virus-Associated Hemophagocytic Syndrome

Introduction and Epidemiology

Virus-associated hemophagocytic syndrome (VAHS) is also included in the spectrum of atypical lymphoproliferations and usually occurs in the setting of immunodeficiency. The syndrome was originally described in patients with viral infections but has subsequently been encountered in patients with fungal, bacterial, and parasitic infections; in immunodeficient patients; and in patients with T-cell lymphomas. [22] VAHS has now been classified as a secondary form of type II histiocytic diseases, termed histiocytic lymphohistiocytosis (HLH). [16] A familial form of HLH (FHLH) also occurs, called familial erythrophagocytic lymphohistiocytosis (FEL), which is an autosomal recessive condition, that usually presents before 5 years of age with hepatosplenomegaly and fever. [23] [24] Patients exhibit multiple defects in cellular immunity. [25] [26]

Clinical Manifestations

Approximately 80% of patients with FIM exhibit clinicopathologic findings consistent with VAHS. [15] [17] [27] [28] Patients with VAHS present with hepatosplenomegaly, abnormal liver function tests, fever, rashes, lymphadenopathy, coagulopathy, and pancytopenia, but may also present with central nervous system and pulmonary abnormalities. [7] [16] [22] [27]

Laboratory Diagnosis

Early in the course of VAHS the bone marrow appears normal, but myeloid hyperplasia, lymphocytic infiltration, cellular necrosis, and increased macrophages subsequently appear. [22] [27] Marked sinus histiocytosis with prominent erythrophagocytosis [22] [27] (Plate 783) is evident throughout the reticuloendothelial system of affected patients, and hyperplasia of the spleen can result in splenic weights in excess of 1 kg. [27] Histologic examination of lymph nodes, especially in FEL, shows lymphoid proliferation early in the disease, which is followed by lymphoid depletion at later stages. At necropsy activated macrophages, exhibiting phagocytosis, can be seen infiltrating areas of hemorrhagic necrosis. [15] [16] [27] The disease often terminates in a hemophagocytic syndrome with pancytopenia, jaundice, and marked erythrophagocytosis.

RETROVIRUSES AND LYMPHOPROLIFERATION

Human Immunodeficiency Virus

During the recent decade, the RNA retroviruses have been implicated in a spectrum of lymphoproliferations. [29] The AIDS retrovirus, human immunodeficiency virus (HIV), does not transform lymphocytes but selectively destroys helper T cells. [29] During acute HIV infection, a mononucleosis-like syndrome often occurs, and the virus can cause chronic persistent lymphadenopathy. [29] [30] In situ hybridization of lymph nodes will demonstrate HIV sequences. Often EBV positive cells will be increased 5- to 10-fold in lymphoid tissues of HIV-infected patients compared to those non-HIV-infected patients. The T-cell immunodeficiency caused by HIV permits opportunistic viral, bacterial, protozoal, and fungal infections.

Human T-Cell Leukemia/Lymphoma Virus Type I

The most extensively studied transforming retrovirus is the human T-cell leukemia/lymphoma virus type I (HTLV-I), which is implicated in the endemic form of adult acute T-cell leukemia/lymphoma (ATL) in Japan and the Caribbean basin. [29] This virus has the capacity to selectively immortalize T cells in vitro, but HTLV-I infection alone is insufficient to cause malignancy, as only one in 2,500 chronic viral carriers develop the T-cell malignancies after a long latent period. [29] HTLV-I infection is transmitted during sexual intercourse or by blood transfusion. The viral infection probably increases the likelihood of further cytogenetic events by stimulating T-cell lymphoproliferation. [29] Seropositive asymptomatic carriers of the virus exhibit subtle signs of immunodeficiency. [29] Those who progress to ATL have HTLV-I-positive serology, generalized lymphadenopathy, hepatosplenomegaly, skin lesions, and distinct involvement of peripheral blood by a spectrum of malignant T cells ranging from small lymphocytes to bizarre hyperlobulated forms. [29] Not all patients manifest a leukemic phase. The prognosis is poor, as patients tend to present with stage IV disease; the median survival is less than 6 months. [29] Of the many HTLV-infected patients who do not develop ATL, most are asymptomatic, but a small group develops an early benign transient lymphocytosis; if subacute or chronic lymphocytosis persists, the risk of progression to ATL increases.

DRUG-ASSOCIATED LYMPHOPROLIFERATIONS

While some drugs permit activation of latent viral infections such as EBV by causing immunosuppression, other drugs cause

TABLE 78-2 -- Drug-Associated Lymphadenopathy

Unknown mechanism
Dilantin
Carbamazepine

atypical lymphoid responses by unknown mechanisms (Table 782). Diphenylhydantoin (Dilantin) is a rare but well-documented cause of such responses. [31] [32] The clinical presentation is similar to that of a viral infection and includes fever, rash, lymphadenopathy, and eosinophilia. [31] [32] Acquired immunoglobulin A deficiency may develop. The symptoms usually abate when the drug is stopped. [31] [32] The lymph node pathology is similar to that in infectious mononucleosis, with a florid follicular hyperplasia or paracortical expansion by a polymorphous immunoblastic infiltrate that is sometimes mistaken for lymphoma. [31] [32] Focal necrosis and Reed-Sternberg-like cells may be evident. Hodgkins disease and non-Hodgkins lymphoma have both been reported in association with diphenylhydantoin therapy. [32] Other hyperplastic lymphoid responses to drugs have been reported, including pseudoperipheral T-cell lymphoma in association with carbamazepine. [33] The immunosuppressive drugs, including cyclosporine, steroids, antilymphocyte globulin, tacrolimus, and cytotoxic agents usually unmask latent viral infections.

POST-TRANSPLANT LYMPHOPROLIFERATIVE DISORDERS

Introduction

Bone marrow and solid organ transplant recipients are exposed to a variety of immunosuppressive agents, including azathioprine, prednisone, cyclophosphamide, antilymphocyte globulin, anti-T-cell monoclonal antibodies, cyclosporine, and tacrolimus FK506. These patients are prone to developing a post-transplant lymphoproliferative disorder (PTLD), which includes predominantly atypical B-cell lymphoproliferations and, rarely, Hodgkins disease and T-cell lymphomas. [34] [35] [36] [37] [38] [39] [40] This discussion will be largely confined to the EBV-positive B-cell PTLDs.

Epidemiology

Over 90% of early (<6 months post-transplantation) PTLDs are EBV-positive, whereas late (>2 years) PTLDs tend to be EBV-negtive. [40] [41] The incidence of PTLD is highest in the first year after transplantation. The prevalence and the post-transplantation interval that precedes development of PTLD vary with the type of organ transplanted and the immunosuppressive agents administered. [37] Renal transplant patients have a low incidence (<2%) of PTLD. [34] [35] [36] [37] [42] The majority (78%) of cases are extranodal, with the brain and spinal cord being involved in 39% and the allograft itself in 15%. [37] The incidence of PTLD in heart transplant recipients ranges from 513% and in heart-lung recipients is 9%. [42] [43] [44] The organ transplant group at greatest risk for PTLD is the liver/small bowel transplant group in children treated with FK506, with up to a 22% incidence. [45] This is partially due to the low incidence of prior EBV infection in these young children. The use of FK506 appears to have increased the risk of PTLD, due to the enhanced immune suppression achievable with less toxicity. [45]

Among bone marrow transplant recipients, those receiving T-cell-depleted bone marrow allografts appear to be at particularly high risk for EBV-associated lymphoproliferation. [46] [47] [48] [49] EBV-genome-positive lymphomas have occurred after intervals of 249 months and do not respond well to acyclovir or conventional chemotherapy. [47] [48]

Biology and Molecular Aspects

These atypical lymphoproliferations can be aggressive with continued immunosuppression, even when polyclonal or oligoclonal, as defined by immunoperoxidase and gene rearrangement studies. The clonal ambiguity has led to difficulties in diagnosis, nomenclature, and therapy. [36] [50] [51] The most recent classification of PTLD, by Knowles, describes three main subgroups: plasmacytic hyperplasias, polymorphous PTLDs (Fig. 78-2), and monomorphous PTLDs, which include lymphoma and multiple myeloma. The monomorphous PTLDs have a higher incidence of clonal heavy chain or light chain immunoglobulin gene rearrangements. This subgroup also has a low incidence of translocations and mutations in p53. [52]

The pathogenesis of PTLD is related to a disruption of the hosts EBV immune surveillance by immunosuppression (Fig. 78-1). Impairment of T-cell-mediated responses to EBV leads to a serologic pattern of acute infection, and increased oropharyngeal shedding of the peripheral blood. During the first 6 months after transplant, cytotoxic T-lymphocyte response to EBV is often absent. [53] In addition, patients on immunosuppressants such as cyclosporine have an imbalance of T-cell-secreted cytokines, favoring B-cell proliferation. [54] Therefore, if immunosuppression is continued, EBV-infected B cells proliferate explosively, resulting in multiple independent, or oligoclonal, EBV-driven B-cell proliferations. Subsequent additional cytogenetic events then allow a dominant clonal population of B lymphocytes to emerge, resulting in the development of lymphoma. [52] The B-cell of origin appears to be predominantly host cells in solid organ transplant patients, but may be of donor origin in bone marrow transplant patients. [47] [48] [55] Donor and host sources of EBV both occur. [56] [57]

Clinical Manifestations

Patients with PTLD present several ways: single mass lesions like lymphoma, infectious mononucleosis with tonsillar enlargement, cervical lymphadenopathy and/or hepatitis, or a

Figure 78-2 Post-transplant lymphoproliferative disorder, polymorphous, expanding the perivascular space (hematoxylin and eosin × 200).

septic appearance with fevers but no radiologically detectable mass. [34] [35] [36] [37] [38] [39] [40] [41] [42] [43] [44] [45] [46] [47] [48] [49] [50] [51] [52] [53] [58]

Laboratory Evaluation

Radiology studies may reveal a mass, a miliary pattern if PTLD is in the lungs, or no lesion at all. Peripheral blood will sometimes reveal circulating plasmacytoid lymphocytes or plasma cells. Quantitative measurements of EBV load in the peripheral blood often rise prior to the rapid development of PTLD lesions. [59] Tissue biopsy should be performed for immunophenotyping and in situ hybridization for EBV sequences as LMP-1 protein will be negative in 25% of cases. [60] Typically, the lymphoid tissue is composed of plasmacytoid B cells, with few T cells, and often regional areas of necrosis. Distinguishing between a polyclonal and a monoclonal PTLD often requires lymphoid receptor gene analysis, since up to 50% of PTLDs do not express surface immunoglobulin.

Therapy and Prognosis

Mortality among patients with PTLD is as high as 5090%. [36] [37] [42] [47] [48] [49] [50] [51] [55] [61] [62] [63] [64] Successful treatment of PTLD is a therapeutic challenge, in part because of the patients increased toxicity from chemotherapy, increased susceptibility to life-threatening infections, and the necessity to maintain the allograft, especially with vital organs (heart, lung, or liver). Reduction of immunosuppression is the most widely used approach. [65] Many times this is sufficient in controlling the disease, especially in localized, polyclonal cases or cases that present like infectious mononucleosis. Patients who do not tolerate reduction of immunosuppression (i.e., graft rejection), or do not respond to immunosuppression reduction, require more aggressive therapy and have a much poorer prognosis. Anti-viral agents (acyclovir or ganciclovir), and/or intravenous immunoglobulin (IVIG) have been used extensively for prophylaxis and treatment of PTLD. The efficacy of anti-virals and IVIG is difficult to assess because reduction of immune suppression is almost always initiated simultaneously.

Surgery or radiotherapy are very effective in curing localized disease, but this represents only a small percentage of patients. [42] [61] [62] [64] Non-cytotoxic approaches

such as interferon-alpha (-IFN) and anti-B-cell monoclonal antibodies have been attempted. Responses are often seen using -IFN (83%), but these responses are often not durable. In the largest reported series (18 patients) using -IFN, in addition to relapse, infection and rejection were significant problems and the median survival was 6 months.[63] Response rates with anti-B-cell monoclonal antibodies were also good (73%), but no response was observed in monoclonal disease. Again, death resulting from progressive disease, infection, and rejection was significant with a 50% 1-year survival. [64]

Because virus-specific cytotoxic T cells (CTL) are critical in the control of EBV-driven B-cell proliferations, donor leukocyte infusion (DLI) has been used to treat PTLD.[66] DLI has been successful in the treatment of PTLD following T-cell-depleted bone marrow transplantation (BMT), but has been associated with severe graft-vs.-host disease (GvHD) and a lethal shock-like syndrome. [67] [68] The use of EBV-specific CTLs generated ex vivo has been very successful in preventing and treating PTLD following BMT without significant GvHD. [69] [70] However, the issue of using DLI in solid organ transplant patients with PTLD is complex. First, cadaveric organs are most widely utilized; therefore, donor leukocytes are often not available, and the use of closely matched relatives leukocytes runs the risk of both rejection and GvHD.

The use of chemotherapy for PTLD does not require waiting for the progression to the standard pathologic criteria for diagnosis of lymphoma, as the polymorphous hyperplasias subgroup of PTLD can be equally lethal. Chemotherapy has been efficacious in treating PTLD in some patients. The intensive, multi-drug (i.e., anthracycline-based) regimens traditionally used to treat high-grade lymphomas are usually immunosuppressive enough to maintain the organ graft, but death resulting from toxicity and infection has been a significant problem and 1-year survival is only 4045%. [61] [62] [71] AIDS patients with non-Hodgkins lymphoma also have increased toxicity to chemotherapy and susceptibility to life-threatening infections. Because it has been shown that the overall survival is improved with less aggressive therapy in AIDS patients treated for non-Hodgkins lymphoma,[72] a similar approach using low-dose chemotherapy may be more efficacious for treating PTLD patients.[71] [73]

ATYPICAL LYMPHOPROLIFERATIVE DISEASE IN PATIENTS WITH AUTOIMMUNE DISORDERS

Other disorders of immune regulation have an increased prevalence of lymphoid neoplasia. Patients with autoimmune collagen-vascular disease (i.e., rheumatoid arthritis) can develop non-Hodgkins lymphomas, which often arise in the setting of reactive lymphadenopathy. [74] [75] Rheumatoid arthritis patients have a specific defect in T-cell inhibition of EBV-induced lymphocyte proliferation and a five-fold increase in the rate of spontaneously transforming B-cell clones in vitro. [76] These patients develop atypical lymphoid hyperplasia and non-Hodgkins lymphoma while on methotrexate or azathioprine therapy. [77] [78] [79] Case reports describe spontaneous resolution upon discontinuation of methotrexate. [78] [79] Individuals with Sjögrens syndrome also show a progression of lymphoid hyperplasia to frank neoplasia, with a risk 44 times that observed in the general population. [80] Patients treated for Hodgkins disease have an increased prevalence of secondary lymphoid malignancies.[81] These lymphomas show a predilection for extranodular involvement, particularly of the gastrointestinal tract. [81]

GENETICALLY LINKED IMMUNODEFICIENCY AND LYMPHOPROLIFERATIONS

Introduction

In 1952 Burton recognized that recurrent and persistent pyogenic infections in a young male patient were due to lack of antibodies. [14] Subsequently, the triad of autoimmunity, immunodeficiency, and lymphoproliferation has been defined in an increasingly large group of patients with inherited and acquired immunodeficiency disorders.[6] [11] [14] About six well-defined X-linked immunodeficiency disorders are known, and many persons with uncontrolled lymphoproliferations other than these well-defined disorders probably have subclinical or undefined inherited immunodeficiencies. [11] [14] The prevalence of lymphoproliferations ranges from about 2% in patients with Burtons agammaglobulinemia to 25% in males with the X-linked lymphoproliferative (XLP) disease. [11] [14] [15] [28]

The X-Linked Lymphoproliferative Disease

Introduction

XLP disease illustrates the spectrum of lymphoproliferations that can occur in hereditary immune deficiencies, ranging from benign or fatal IM to non-Hodgkins lymphoma.[6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [28] Following EBV infection, chronic or fatal IM, acquired hypogammaglobulinemia or agammaglobulinemia, pure red cell aplasia, necrotizing lymphoid vasculitis, and/or non-Hodgkins lymphoma ensues. [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] [28]

Biological and Molecular Aspects

The mutation responsible for the XLP syndrome is genetically linked to a restriction fragment length polymorphism detectable

with the DXS42 probe on chromosome Xq25.[82] The XLP gene has been identified and sequenced, and the mutational pattern in an SH2DIA domain of the gene in numerous XLP families has been characterized. Current research is focused on analyzing the protein and its function. [83]

Clinical Manifestations

The disease should be suspected in families in which maternally related boys develop FIM, acquired hypogammaglobulinemia, agammaglobulinemia, or malignant lymphoma (Fig. 78-3).[6] [7] [8] [9] [10] [11] [13] [14] [15] [28] [84] The main differential diagnosis in these patients involves lymphoma versus florid IM. Patients who develop malignant lymphoma usually present with discrete mass(es), often extranodal, with or without dissemination at the time of diagnosis. [28] [84] In contrast, patients with severe or fatal IM have a disseminated lymphoproliferation involving generalized lymphadenopathy, as well as multiple organ sites, including skin, liver, spleen, lung, bone marrow, and brain.[7] [12] [15] [28] [84] Males with XLP do not usually have clinical evidence of immunodeficiency prior to EBV infection, though approximately 10% will have manifestations, including lymphoma, without evidence of EBV infection, and they are not unduly vulnerable to other infectious agents. [15] [28] [84] [85]

Laboratory Evaluation

Though affected males can be identified by DNA linkage analysis, a definitive diagnosis of XLP in the family must be present, i.e., two or more maternally related males manifest phenotypes of XLP.[15] [28] Once linkage is established identification of carrier females and prenatal diagnosis may be performed. The defect gene was localized to the Xq24-26 region of the X chromosome in 1987. [82] A 2-megabase pair deletion was found in 1989. [83] This region has been mapped and a small deletion (100 kilobases) has been found, which led to the discovery of the XLP gene. [83] [87] Identification of the gene now allows direct mutational analysis for definitive diagnosis in families in which a single male has symptoms consistent with XLP, and promises to provide us with a much greater insight on the control of EBV infections and the immune system in general.

Therapy and Prognosis

Complete remissions (CR) at rates as high as 80% can be achieved in XLP boys presenting with lymphoma utilizing standard lymphoma protocols; however, relapses or other manifestations,

Figure 78-3 Frequency of phenotypes in X-linked lymphoproliferative disease. FIM, fulminant infectious mononucleosis; Dysgam, dysgammaglobulinemia; AA, aplastic anemia; LYG, lymphoid granulomatosis/vasculitis.

i.e., hypogammaglobulinemia, are very common.[28] Boys with dysgammaglobulinemia receive monthly IgG injections, but this does not prevent EBV infection and its sequelae. Several boys have developed FIM and died while receiving IgG supplementation. [15] [28] Many treatments have been used to treat FIM of XLP, including antibiotics, steroids, intravenous IgG, plasma infusions, acyclovir, interferon (both and), chemotherapy, and/or cyclosporin A. Because FIM is essentially indistinguishable from other hemophagocytic syndromes, i.e., hemophagocytic lymphohistiocytosis (HLH) and the accelerated phase of Chediak-Higashi, it is now recommended that boys receive aggressive chemotherapy to quell the immunologic anarchy of uncontrolled T lymphocytes and macrophages, with etoposide (VP-16) to quench macrophage activation and steroids and/or cyclosporin A to down-regulate T cells. [7] [17] [28] Eight of 10 boys treated in this fashion have had complete response. Again, relapse is common (50%); therefore, the recommended therapy for FIM is now aggressive intervention with etoposide and immunosuppression, and initiation of a search for a suitable bone marrow donor, with transplantation performed once the patient is stabilized.

Allogeneic hematopoietic stem cell transplantation (HSCT) remains the only curative therapy for XLP. [88] [89] Data from the XLP Registry show 13 boys having undergone HSCT; the only non-survivors were all over 15 years of age. This survival advantage observed in younger patients is reflective of the findings regarding the use of HSCT in other immunodeficiencies, especially with alternative donor sources. [88] [89]

Other Heritable Immunodeficiency Diseases with Lymphoproliferations

Clinical Manifestations

A complete review of genetically linked diseases manifesting lymphoproliferation is beyond the scope of this discussion, but certain conditions have been sufficiently characterized to allow recognition. Wiskott-Aldrich syndrome, also X-linked in inheritance, is characterized by chronic eczema, chronic suppurative otitis media, anemia, and thrombocytopenic purpura.[14] Patients have defective cell-mediated immunity and poor antibody responses to polysaccharide antigens. Males with Wiskott-Aldrich syndrome are more immunocompetent than males with XLP, and FIM has not been reported in association with this syndrome. [14] EBV-specific antibody responses are less commonly abnormal in Wiskott-Aldrich patients; however, these patients are more likely to develop widely disseminated malignant lymphoma (50%) than XLP males with the malignant phenotype.[6] [14]

Ataxia-telangiectasia is an autosomal recessive trait characterized by severe progressive cerebellar ataxia associated with oculocutaneous telangiectasia, sinopulmonary infections, and abnormal eye movements.[6] [14] The immune defects involve both T and B cells, and decreased levels of IgA and IgG are frequent. [6] [14] EBV reactivation occurs in ataxia-telangiectasia patients but has not been extensively studied. Lymphocytosis associated with chromosome abnormalities may persist for years.[14] Chromosome 14 abnormalities in these patients are associated with a high incidence of chronic T-cell leukemia, and preleukemic clonal expansions of cells and full-blown leukemias in these patients often demonstrate the inv(14q)(q11q32) or the t(14;14)(q11;q32) translocation. [90] [91] Molecular analysis has shown that the cytogenetic breakpoint at 14q11 occurs in the joining region of the T-cell receptor chain. [90] [91] Hybrid recombinations between T-cell receptor and occur, indicating genome instability.[92] The 14q32 breakpoints appear to be more heterogenous and include breaks near the immunogobulin heavy chain locus and at 14q32.1, the site of TCL1, an oncogene. [90] [91] Identical cytogenetic and molecular findings have been detected in T-cell

neoplasms not associated with ataxia-telangiectasia. [90] [91] The chromosome 14 abnormality involves both the immunoglobulin heavy chain locus and the T-cell receptor chain locus.[90] [91] The chromosomal location of many of the gene defects in these hereditary illnesses will be mapped in the future and will provide further molecular evidence of the etiology of these diseases.

Epidemiology

Many genetically linked diseases can manifest with lymphoproliferations. An increased incidence of lymphoproliferative disease is observed in individuals with antibody deficiencies, i.e., X-linked agammaglobulinemia, IgA deficiency, as well as cellular or combined deficiencies, i.e., severe combined immunodeficiency (SCID), XLP, Wiskott-Aldrich syndrome, ataxia-telangiectasia, hyper Ig-M (CD40 ligand deficiency), common variable immunodeficiency (CVID), and autoimmune lymphoproliferative syndrome (fas deficiency). [93] [94] [95] [96] [97] Data from the Immunodeficiency Cancer Registry show that 50% of all cancer seen were non-Hodgkins lymphoma, but Hodgkins disease (8.6%), leukemia (12.6%), adenocarcinomas, mainly gastric carcinomas (9.2%), and others (19.2%) have also been observed.

Laboratory Evaluation

Diagnosis of lymphoma can be difficult in these patients, who frequently have reactive lymphoid hyperplasia or chronic granulomatous inflammation. Demonstration of EBV in lesions is helpful in evaluating a lymphoid lesion, but is not synonymous with lymphoma. EBV-positive cells can be found in greater than normal numbers in benign nodes, and EBV is not found in all the lymphomas. [94] [96]

Therapy and Prognosis

Although complete remissions can be achieved in these patients, the outcome for patients with primary immunodeficiencies and lymphoma compared to that for immunocompetent patients with lymphoma has been poor. One reason is death due to chemotherapy toxicities, especially in ataxia-telangiectasia. Death due to infections and sepsis is also frequent, and relapses are common. [94] [96] Therefore, induction of remission with low-dose or standard-dose chemotherapy and correction of the underlying immune defect (i.e., allogeneic stem cell transplant, if a suitable donor can be identified) offers the greatest chance of long-term survival.

ATYPICAL LYMPHOPROLIFERATIONS OF UNKNOWN CAUSE

Angiofollicular Lymph Node Hyperplasia (Castlemans Disease)

Introduction and Epidemiology

Angiofollicular lymph node hyperplasia (AFH), or Castlemans disease, has many other names, including giant lymph node hyperplasia, angiomatous lymphoid hamartoma, lymph nodal hamartoma, and lymph node hyperplasia of Castleman.[98] There is no sex or age preference, and most patients present with asymptomatic mediastinal masses, which are discovered on routine chest radiographic examination. There are two types of localized AFH, the more common hyaline-vascular (90%) and the plasma cell type (10%).[98]

Multicentric lesions have been identified in a subgroup of patients and may herald a higher risk of subsequent development of overt lymphoma. [98] [99] Most reports in the literature favor the concept that the hyaline vascular type of AFH is a reactive chronic lymphoid hyperplasia. [100] [101] The plasma cell type is considered to have an inflammatory pathogenesis, either through chronic antigenic stimulation (i.e., infection) or via an autoimmune mechanism. The plasma cell group tends to affect younger persons and has a higher rate of mesenteric and retroperitoneal tumors. [98]

Clinical Manifestations

When symptomatic, the hyaline vascular subgroup presents with mass-related symptoms such as pain, chronic cough, and obstruction. Clinical symptoms associated with the plasma cell type include fever, sweats, weight loss, and fatigue. Patients with multicentric disease can be extremely ill, with malaise and cytopenias. [98] [99]

Laboratory Evaluation

Associated abnormalities include anemia, an elevated erythrocyte sedimentation rate, hypergammaglobulinemia, hypoalbuminemia, hyperferremia, and hypertransferrinemia.[98] The hyaline-vascular type has a histologic pattern characterized by follicular hyperplasia distributed evenly thoughout the lymph node. [98] The follicles are unusually small, and their germinal centers are often penetrated by radial capillaries, which are surrounded by collagen or hyaline material, hence the name (Plate 78-4). [98] [99] The germinal centers are surrounded by multiple concentric layers of lymphocytes (Plate 78-4A). [98] [100] In the plasma cell type, which is less common (10%) and may represent an earlier stage of the lesion, [98] the germinal centers are larger, the peripheral cuffs of mature lymphocytes are not as prominent, and their interfollicular areas are occupied by extensive sheets of plasma cells, occasionally including some atypical forms (Plate 78-4B). Immunohistochemical and gene rearrangement studies have recently identified clonal cell populations in some cases of multicentric AFH. [102] [103] The human herpesvirus-8 (HHV-8), also called Kaposis sarcoma herpesvirus (KSHV), has been associated with the multicentric form of Castlemans disease in 25% of cases, but not with the more common subtypes.[104]

Therapy

Localized Castlemans disease is a self-limited process, curable with local therapy. [98] [105] [106] Following local excision, there is frequently total disappearance of systemic symptoms with only rare local recurrences. Multicentric Castlemans disease is a systemic disease associated with an aggressive, usually fatal course associated with infectious complications, and a risk of developing malignancies such as lymphoma or Kaposis sarcoma. Experimental and clinical data indicate that IL-6 plays a pivotal role in the biogenesis of multicentric Castlemans disease. [107] The hyperplastic germinal centers of these patients have been shown to produce excessive quantities of IL-6, and transient alleviations of the systemic manifestations of this disorder have been achieved with an anti-IL-6 monoclonal antibody. [107] [108] The median survival of patients with multicentric Castlemans disease has been reported to be 29 months. [106] Twenty-six patients in one series died within the first year of diagnosis. A limited body of information is available regarding the treatment of multicentric Castlemans disease. [104] [106] [108] [109] A reduction in the quantity of involved tissue either surgically or by means of radiation therapy may be an effective strategy to control the systemic signs and symptoms. [106] High doses of corticosteroids have been reported to result in sustained unmaintained remissions, although continuous high-dose prednisone therapy is frequently required. [106] Chemotherapy with single agents or combination therapy used to treat non-Hodgkins lymphoma has resulted in partial responses although occcasionally patients may enjoy durable complete remissions.[106] [105] Occasionally, patients may enjoy spontaneous remissions and not require any therapeutic interventions. [105] [106]

Angioimmunoblastic Lymphadenopathy with Dysproteinemia

Clinical Manifestations

Angioimmunoblastic lymphadenopathy with dysproteinemia (AILD) is the preferred term for a condition that occurs more often in elderly patients and is characterized by generalized lymphadenopathy, hepatosplenomegaly, fever, night sweats, weight loss, anemia frequently due to antibody mediated hemolysis, and hypergammaglobulinemia and pruritic skin rashes. [110] [111] Other terms for AILD include immunologic aberrations in idiopathic reticuloses, atypical lymph node hyperplasia with fatal outcome (immunodysplastic disease), diffuse plasmacytic sarcomatosis, chronic pluripotential immunoproliferative syndrome, immunoblastic lymphadenopathy, and lymphogranulomatosis X.[110] [111]

Laboratory Evaluation

Biopsies of lymph nodes affected by AILD show complete effacement of the architecture, a prominent vascular proliferation, a florid immunoblastic proliferation, abundant plasma cells in clusters or sheets, burned-out germinal centers, focal necrosis, eosinophilic material, a background of mature lymphocytes, and, occasionally, eosinophils and neutrophils [110] [111] (Plate 78-5). Serum protein electrophoresis reveals a polyclonal hypergammaglobulinemia, and a complete blood count shows mild to moderate anemia. The Coombs test is frequently positive. Clonal T-cell gene rearrangements are present in many cases. Trisomy 3, trisomy 5, and an additional X chromosome are the most frequent chromosomal aberrations in AILD. Although AILD is considered a malignancy, a large number of cytogenetically unrelated clones exist that cannot originate from a common cell of origin because of their completely different karyotypes. There unrelated clones have been hypothesized to be the consequence of increased genetic instability and an immune defect resulting in impaired clearing of damaged cells. [112] [113]

Therapy

The median survival of patients with AILD is 30 months.[110] Most patients are treated with prednisone or combination chemotherapy.[111] [114] [115] [116] [117] [118] The most important prognostic factor in AILD is achievement of complete remission.[114] [115] [116] [117] [118] Randomized prospective treatment trials are needed to determine optimum treatment.

Although aggressive courses are observed in most patients, some patients experience a more indolent course or even spontaneous remissions. A prospective evaluation of standardized treatment in patients with AILD has been reported.[118] In this study patients initially received prednisone therapy followed by five cycles of COPBLAM (cyclophosphamide, vincristine, prednisone, bleomycin, doxorubicin, procarbazine) followed by 2 cycles of ifosfamide methotrexate (IM)VP-16. The combination chemotherapy was administered to patients who did not achieve a complete remission with prednisone or relapsed after prednisone therapy. Prednisone therapy was skipped in patients who presented with rapidly progressive life-threatening disease. Initial prednisone therapy led to resolution of B symptoms and reduction in tumor load in most patients.[118] The complete remission rate with prednisone only was 20%, and over 60% of these patients eventually relapsed. In contrast, the complete remission rates after primary and secondary chemotherapy were 56% and 64%, respectively. Siegert et al. have concluded that primary chemotherapy is superior to sequential therapy with prednisone with or without chemotherapy. In their series, the projected event-free survival was 35% at 36 months, and no relapses occurred after 12 months.[118] Because of the high rate of death resulting from *Pneumocystis carinii* and aspergillosis during treatment with prednisone or combination chemotherapy, strong consideration should be given to prophylactic therapy with trimethoprim-sulfamethoxasole and oral antifungal agents.[118]

Prognosis

AILD progresses to malignant T-cell lymphoma. It is defined by the presence of clusters, islands, or diffuse infiltrates of monomorphic immunoblasts and has a much graver prognosis than AILD alone.[111] [119] [120] Many apparent cases of AILD may actually represent early T-cell lymphomas; clonal populations of T cells have been identified in several cases studied by Southern blot analysis and PCR.[121] Cytogenetic analysis and fluorescent hybridization demonstrate the clonal nature in many instances.[112] [122]

Histiocytic Necrotizing Lymphadenopathy

Histiocytic necrotizing lymphadenitis (Kikuchis disease) is a pseudolymphomatous lesion, which presents as cervical lymphadenopathy and occurs predominantly in young women. Patients usually present with a cervical mass, but are otherwise asymptomatic and do not show evidence of IM.[123] [124] [125] The process usually resolves spontaneously in 1 to 4 months without further therapy.[123] [124] [125] These patients do not have an increased risk of lymphoma, and surgical excision is curative. Although the etiology of histiocytic necrotizing lymphadenitis is unknown, its histologic and clinical features are similar to those of systemic lupus erythematosus,[126] and the disease may, in fact, reflect a self-limited autoimmune condition resembling systemic lupus erythematosus. Therefore, an autoimmune disorder such as lupus must be ruled out when a diagnosis of Kikuchis disease is received.

Sinus Histiocytosis with Massive Lymphadenopathy

Clinical Manifestations

Patients with sinus histiocytosis with massive lymphadenopathy (Rosai-Dorfman disease) usually present with bilateral lymphadenopathy predominantly affecting the cervical region, and they usually exhibit some systemic symptoms, including fever, polyclonal hypergammaglobulinemia, and increased erythrocyte sedimentation rate.[127] [128] The disease occurs most commonly in black children.[127] [128] The etiology of the disease remains obscure. A relationship to an underlying immunodeficiency has been postulated.[129]

Laboratory Evaluation

Biopsies reveal pericapsular fibrosis, dilation of sinuses, numerous intrasinusoidal histiocytes, and abundant plasma cells. The most striking histologic feature is the presence of lymphocytes and other hematopoietic cells within the cytoplasm of the sinus histiocytes, called emperipoiesis.

Therapy and Prognosis

Clinically most of the patients are thought to have a non-Hodgkins lymphoma. However, the disease has a protracted but benign course; spontaneous regression of the lymphadenopathy and total recovery will occur in most cases.[126] [127] Administration of antibiotics, radiation, antituberculin therapy, and/or steroids does not have a major impact on the course of the disease.[126] [127]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

CONCLUSION

Atypical lymphoproliferations occur in a variety of clinical settings in response to a variety of stimuli. Accurate diagnosis of these processes is made by careful clinicopathologic correlation and in some cases by genetic, immunologic, virologic, and molecular techniques. In many of these conditions emphasis should not be placed on determining whether this is a malignant lymphoma but, rather, whether it is a lethal clinical condition requiring optimally staged therapy.

Chapter 79 - Clinical Approaches to Infections in the Compromised Host

Alison G. Freifeld
Thomas J. Walsh
Philip A. Pizzo

INTRODUCTION

Patients with hematologic disease may be predisposed to the development of infections as a result of a wide array of potential defects in host defenses. Just as the clinical spectrum of hematologic diseases is broad, so is the range of associated abnormalities in host defense. Accordingly, the types of infection encountered in this population as well as their relative severity will vary dramatically.

Good medical care of immunocompromised patients demands a broad base of factual knowledge, but optimal management mandates evaluation of each patient on an individual basis. Although it is useful, and often appropriate, to establish general guidelines for the diagnosis and treatment of infectious complications, decisions should always reflect each patients specific, often unique, clinical setting.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

TYPES AND SOURCES OF PATHOGENS ENCOUNTERED IN COMPROMISED PATIENTS

The list of predominant pathogens encountered in the compromised host is extensive and includes bacteria, fungi, viruses, and protozoa. The range of potential pathogens in any given patient will depend on the specific perturbations in host defense present in that individual, which in turn will vary according to the underlying disease and its management (Table 79-1). For example, the bacterial pathogens encountered in neutropenic patients with acute myeloid leukemia (AML) will differ dramatically from those commonly encountered in a patient with sickle cell anemia and splenic dysfunction. This chapter presents a detailed analysis of the pathogens associated with specific hematologic disorders.

The epidemiology of most pathogens is well established, but it is often difficult to determine the precise environmental or endogenous origin of organisms isolated from individual infectious episodes. It is clear, however, that most pathogens have colonized a body site at some point before causing infection in compromised patients. Many of these, such as the enteric gram-negative bacteria or *Candida albicans*, may be found in the normal flora of healthy individuals. Others, such as *Pseudomonas aeruginosa* or *Aspergillus* spp., are usually acquired from exogenous sources but cause transient colonization before the development of invasive disease. Still others, such as varicella-zoster virus and *Pneumocystis carinii*, may be present in a latent or subclinical stage for years before significant infection develops. Ultimately the presence or absence of serious invasive disease will be determined both by the relative virulence of the resident or colonizing organism and by the severity and type of host impairment (Fig. 79-1). Clinically, it is crucial that potential sources of infection and mechanisms of colonization be identified in order to develop rational strategies for infection prevention in high-risk populations.

Bacteria

Bacteria are responsible for most infections encountered in compromised patients, accounting for the greatest morbidity and mortality. The predominant bacterial pathogens encountered will vary substantially, depending on the population at risk. Patients with neutropenia are at high risk of serious infections due to gram-negative pathogens such as *Escherichia coli* and *Klebsiella pneumoniae. E. coli* and *K. pneumoniae* are Enterobacteriaceae present in the normal gastrointestinal (GI) flora, while *P. aeruginosa* is more often acquired from exogenous sources. Encapsulated gram-negative bacteria, such as *Hemophilus influenzae and Neisseria* spp., are more often encountered in patients who have undergone splenectomy. *Salmonella* spp. infections occur with increased frequency in those with dysgammaglobulinemia or AIDS. Gram-negative bacteria of increasing importance include other Enterobacteriaceae (e.g., *Citrobacter* spp., *Enterobacter* spp., or *Serratia marcescens*), *Acinetobacter* spp., non-*aeruginosa Pseudomonas*-like organisms (e.g., *Stenotrophomonas maltophilia*, *Burkholderia cepacia*), and *Legionella* spp.

Patients with serious illness may show a dramatic change in the pattern of their colonizing microbial flora after admission to the hospital. Indeed, the most consistent and clinically important change observed is a relative decrease in the organisms making up the normal flora and a concomitant increase in potentially pathogenic aerobic gram-negative bacteria. These changes have been observed in the noncancer population [1] as well as in patients with leukemia. [2] In the study by Fainstein et al.,[2] the oropharyngeal and fecal flora of 33 leukemic patients was examined serially during the course of hospitalization for intensive chemotherapy. Although most patients had a

Figure 79-1 Sources of nosocomial infection in high-risk patients. Interactions between colonization and infection.

normal pattern of microbial flora on admission, by the completion of the hospital stay 68% of the initial throat isolates and 57% of the fecal isolates had changed. The main shift was in the acquisition or increasing prominence of aerobic gram-negative bacilli (mostly *E. coli*, *K. pneumoniae*, *Enterobacter* spp., and *P. aeruginosa*). Although these changes were initially seen even before antibiotics were administered, they were clearly accentuated after courses of antibacterial therapy.

In another study addressing this issue, 48 patients with leukemia were followed for 2.5 years with extensive microbiologic surveillance. [3] Again, the culture data and clinical observations indicated that most infections caused by gram-negative bacteria originated in the endogenous flora. However, 47% of infections were caused by organisms that had colonized the patients only after admission to the hospital. Studies have also suggested that differences may exist among the gram-negative bacteria, not only in their propensity to colonize but also in their ability to produce invasive infection after colonization. For example, certain biotypes of Enterobacteriaceae species have been associated with a particularly high incidence of both colonization and infection in leukemic patients. [4] Nevertheless, most patients who become colonized with enteric gram-negative rods do not develop clinically significant infections. By contrast, other organisms such as *P. aeruginosa* appear to be intrinsically more virulent and are much more likely to cause invasive infection after colonization, especially during periods of severe host impairment such as profound granulocytopenia. [5]

Over the past 15 years, the incidence of infections due to gram-positive organisms has increased significantly in both compromised and noncompromised patients. [6] [7] [8] [9] [10] [11] [12] [13] The most common gram-positive organisms causing infection in almost all groups of immunocompromised patients are the coagulase-positive and coagulase-negative staphylococci (usually *Staphylococcus aureus* and *S. epidermidis*, respectively), streptococcal species, and enterococci, including vancomycin-resistant enterococci. Although relatively uncommon overall, *Streptococcus pneumoniae* is seen with increased frequency in dysgammaglobulinemia or splenectomy patients. Serious infections due to -hemolytic streptococci may be seen more commonly in patients who have received high doses of cytosine arabinoside (Ara-C) and who have mucositis. Streptococcal bacteremia in these patients may be complicated by pulmonary involvement, including adult respiratory distress syndrome.[14] The use of prophylactic fluoroquinolones appears to be associated with an increased incidence of staphylococcal and streptococcal infection. [15] [16] Other potentially important gram-positive bacteria that are encountered less frequently include *Corynebacterium* spp., *Bacillus* spp., and *Listeria monocytogenes*. Some of these organisms, such as *S. pneumoniae*, enterococci, and *S. epidermidis*, are found in almost all healthy individuals as part of the normal GI or skin flora. Others, such as methicillin-resistant *S. aureus* or *Corynebacterium jeikeium*, are not commonly found as part of the normal flora but are more often acquired from exogenous sources, particularly in hospitalized patients. [17] [18] The increase in bacteremias due to organisms that colonize the skin (e.g., *C. jeikeium* and *S. epidermidis*) is often attributed to the increased use of indwelling intravenous catheters, although not all studies have corroborated this finding. [12] [19] One study by Khabbaz and co-workers[20] has suggested that GI tract colonization with *S. epidermidis* may correlate better with subsequent bacteremia than does skin colonization.

The major anaerobic bacteria causing infection in compromised patients are *Clostridium* spp. (both *C. perfringens* and non-*perfringens* clostridia), *Bacteroides fragilis*, and other *Bacteroides* spp. In addition, a variety of other anaerobic organisms have been reported, including *Fusobacterium* spp., *Peptostreptococcus*, *Peptococcus*, *Eubacterium*, *Veillonella*, and *Bifidobacterium*. [21] [22] [23] [24] Most of these anaerobic organisms are normal residents of the human GI tract, with anaerobes accounting for 90% of fecal organisms. Infections due to these anaerobes are most often seen in patients with disruption of GI mucosal barriers, often as a result of chemotherapy or tumor invasion. Anaerobic infections are relatively uncommon, accounting for only 510% of bacteremias, even in profoundly neutropenic patients. [25] Clearly, they play a more prominent role in localized intra-abdominal infections or in certain soft tissue infections such as perirectal cellulitis.

From an epidemiologic perspective, infection due to *C. difficile* may differ from infection caused by most other anaerobic organisms. *C. difficile*-related disease (ranging from mild GI symptoms to pseudomembranous colitis) often develops as a result of overgrowth of endogenous toxin-producing organisms that have colonized the GI tract, particularly after surgical procedures or exposure to antibiotics. Studies addressing epidemiologic issues have suggested an important role for nosocomial acquisition and transmission of this organism. McFarland and colleagues [26] reported that one of five patients with stool cultures positive for *C. difficile* acquired the organism while hospitalized, having been culture negative on admission. Of these patients with newly acquired positive stool cultures, approximately one-third developed a diarrheal illness, while two-thirds remained asymptomatic. Patient-to-patient transmission of *C. difficile* was strongly suggested by the temporal and spatial clustering of incident cases with identical immunoblot types and by the significantly more frequent and earlier acquisition of *C. difficile* among patients exposed to roommates with positive cultures. Almost two-thirds of the hospital personnel caring for these patients had positive cultures for *C. difficile* isolated from

their hands, and significant contamination of the rooms of both symptomatic and asymptomatic patients was found. Clearly, these data may have important implications for the prevention of *C. difficile*-related disease.

Anaerobic bacteria of the GI tract may assist in protecting against infections caused by other organisms. This theory of colonization resistance suggests that the large quantity of anaerobic bacteria normally present in the gut produces unfavorable conditions for colonization or overgrowth by other more pathogenic organisms, such as the Enterobacteriaceae or *P. aeruginosa*.[27] Indeed, this concept has been supported by a number of preclinical studies. For example, Van der Waaij and colleagues[28] showed that GI colonization could be established in germ-free mice by oral administration of small inocula (approximately 10^3 organisms) of gram-negative bacteria. By contrast, >10[7] organisms were required to establish colonization in mice with their normal flora intact. Accordingly, recent antibiotic prophylaxis regimens have been designed to suppress aerobic gram-negative organisms while preserving endogenous anaerobic flora. Antibiotics such as trimethoprim-sulfamethoxazole and the fluoroquinolones have antimicrobial activity that is almost exclusively against aerobic organisms, and so these agents have been widely employed for prophylaxis.

In the past, mycobacterial infections were relatively uncommon in most immunocompromised populations. A striking increase has been documented in the number of infections due to *Mycobacterium tuberculosis*, and a particular concern is the emergence of multi-drug-resistant tuberculosis in the United States. [29] [30] Infections due to *M. tuberculosis* as well as *M. avium-intracellulare* complex are seen primarily in patients with human immunodeficiency virus-1 (HIV-1) infection. Patients with hairy cell leukemia appear to be at increased risk for the development of infection with atypical mycobacteria such as *M. kansasii*, *M. fortuitum*, *M. chelonei*, and *M. avium-intracellulare*. [31] [32] [33] In rare cases, certain rapid growers, such as *M. fortuitum* and *M. chelonei*, cause significant infections around exit sites of indwelling intravenous catheters.

The community and the hospital environment have many exogenous sources that can lead to colonization or infection, or both. In addition to patient-to-patient and staff-to-patient transmission,

exogenous sources include food, air, water, and specialized equipment such as catheters, respirators, and humidifiers; as well, contamination may result from a variety of invasive procedures.[34] [35] For example, *P. aeruginosa* is not part of the normal GI flora but flourishes in moist environments, particularly in soil or on certain fruits and vegetables. Accordingly, it might be prudent for certain patients at risk, particularly those receiving antibiotics, to restrict direct contact with potential sources such as potted plants or uncooked foods.[36] [37] [38] Knowledge of the common sources of certain organisms can also help prevent the spread of infection or prevent an outbreak. For example, a clustering of infections due to *Legionella pneumophila* should direct attention to potential water sources such as air-conditioning cooling towers,[39] [40] an outbreak of infection due to *Burkholderia cepacia* in an intensive care unit should raise the possibility of contamination of equipment used for respiratory care,[41] and a clustering of infection due to *C. difficile* or methicillin-resistant *S. aureus* should raise suspicion of a staff or patient carrier or might point to the need for more rigorous hand washing by patient care staff.

Fungi

The major fungal species that cause serious infection in compromised patients are *Candida* spp., *Aspergillus* spp., and *Cryptococcus neoformans*. Other less frequently encountered but nevertheless potentially important fungal pathogens include the Zygomycetes (e.g., *Mucor* spp. or *Rhizopus* spp.), *Fusarium* spp., *Trichosporon beigelii*, *Coccidioides immitis*, *Histoplasma capsulatum*, *Malassezia furfur*, and the dematiaceous fungi, such as *Bipolaris* species.[42] [43] [44] [45] [46] [47] The predominant fungal pathogens will vary according to the nature of host impairment in any given patient. For example, invasive infections due to *Candida* or *Aspergillus* are most commonly encountered in patients with prolonged episodes of neutropenia. Infections due to *C. neoformans*, *H. capsulatum*, or *C. immitis* are more often seen in patients having an underlying disease (e.g., lymphoma, HIV infection) or receiving a therapeutic intervention (e.g., corticosteroid treatment) associated with impaired cell-mediated immunity.

Overall, *Candida* spp. represent the most common fungal pathogens responsible for serious infection in immunocompromised patients. *C. albicans* may be found as part of the normal human GI and cutaneous flora,[48] but certain factors may predispose patients to a change in the patterns of colonization with this fungus. This change is often marked in those receiving broad-spectrum antibiotics, requiring extensive hospitalization, or receiving immunosuppressive agents. Indeed, widespread and even visibly apparent GI overgrowth can occur in these settings. [49] GI colonization and overgrowth can then provide an ideal setting for the development of invasive disease, which often occurs secondary to intercurrent mucosal disruption as a result of surgery, tumor invasion, or chemotherapy. Certain fungal species appear to be intrinsically more pathogenic than others; colonization with these organisms is more frequently associated with invasive infection. For example, in one series, 16% of cancer patients colonized with *Candida* (*Torulopsis*) *glabrata* developed serious invasive infection. [50] In another study, 14 of 25 patients colonized by *Candida tropicalis* developed an infection with this organism. [51]

Aspergillus spp. constitute the second most common fungal pathogens in immunocompromised hosts. *Aspergillus* spp. are not part of the normal human flora but are usually acquired from exogenous sources in the hospital setting, such as unfiltered air, contaminated ventilation systems, sites of renovation or construction, food, and ornamental plants.[44] [52] Air is the principal route of transmission of *Aspergillus* spp. within the hospital environment, and the respiratory tract is the most common entry portal. Upper airway colonization with *Aspergillus* probably precedes most cases of invasive infection; some authorities believe that documentation of nasal carriage of *Aspergillus* may predict the development of aspergillosis in certain high-risk settings. [53] Also, smokers appear to have an increased incidence of colonization with *Aspergillus* spp., but in some studies they do not appear to have an increased incidence of invasive *Aspergillus*, even in the setting of severe immunosuppression.[54] [55]

C. neoformans, the third most common pathogenic fungus in the compromised population, is an encapsulated yeast that is ubiquitous in nature. Although pigeon excreta are the classically implicated environmental source, this fungus can be found widely in many types of soil. [56] [57] *C. neoformans* does not normally colonize humans. Primary infection is usually not hospital acquired and is often subclinical. Disseminated infection in high-risk patients usually represents reactivation of latent infection.

Viruses

The most significant viral infections seen in immunocompromised patients belong to the herpes group and include herpes simplex virus (HSV), varicella-zoster virus (VZV), and cytomegalovirus (CMV). Serious infections due to these viruses are seen with increasing frequency in certain subgroups of immunosuppressed patients, particularly those with impaired cell-mediated immunity. Infection due to HSV, VZV, or CMV can result either from primary infection or from reactivation of latent infection. Most serious infections in adults occur as a result of reactivation of infection initially acquired before the onset of impaired immune function.

Other viruses can cause serious infection in this population, but their incidence does not appear to be substantially increased compared to a normal population. These include Epstein-Barr virus (EBV), human herpesvirus type 6 (HHV-6), influenza and parainfluenza viruses, respiratory syncytial virus (RSV), measles virus, adenoviruses, and the enteroviruses. Infection with some viruses, such as parvovirus or HIV-1, may, in certain hosts, result in secondary hematologic abnormalities that further compromise immune function.[58]

Both HSV-1 and HSV-2 can lead to significant morbidity in the compromised host. As in immunocompetent individuals, HSV-1 is encountered with greater frequency. Primary infection with HSV-1 usually occurs in childhood between the ages of 2 and 10 years and is most often transmitted by contact with oral secretions. HSV-2 infection is usually spread by genital contact and is generally acquired after puberty. In adults, the incidence of antibodies to HSV (presumably reflective of prior infection) has been 30100% in various studies and appears to be higher in groups of lower socioeconomic status. [59] [60] [61] [62] In a retrospective review of sera from patients with hematologic diseases presenting for bone marrow transplantation, 51 of 93 had elevated titers of anti-HSV antibody. [63] High titers of anti-HSV-1 have been correlated with the development of subsequent infections in immunocompromised patients. [64] [65] In addition to reactivation of latent disease, seronegative individuals may acquire primary infection from contact with either asymptomatic execretors or overtly infected persons, although virus titers are higher and transmissibility is greater in the latter group. [59]

In the healthy population, VZV is a highly contagious virus that causes primary infection predominantly in children. Primary varicella infection, or chickenpox, occurs in 50% of children before they enter school, and >90% of adults have VZV antibodies as a result of prior clinical or subclinical infection. In immunocompromised patients, both primary disease and reactivation of latent virus are clinically important. In accordance with its prevalence in the healthy population, primary varicella in compromised patients tends to affect children and is responsible for most serious infections in those with hematologic malignancies. [66] [67] Adult patients who are

seronegative are also at risk.

Person-to-person transmission to other patients at risk of

primary varicella infection can occur after close contacts both in and out of the hospital. Primary varicella is transmitted predominantly by the respiratory route. Secondary varicella infection, or herpes zoster (also known as shingles), can occur in otherwise healthy patients, particularly in the aged, but it is more common and usually more severe in immunosuppressed patients.[68] [69] [70] [71] In virtually all cases, herpes zoster represents reactivation of latent disease. Little concrete evidence has been found to support its acquisition by exposure to other patients with either primary varicella infection or zoster. [71] [72] However, patients at risk of the development of primary varicella infection may acquire the infection through contact with people who have zoster or chickenpox.

CMV can cause serious infection in a variety of immunocompromised populations, but most notably in the HIV-infected population and in those undergoing allogeneic bone marrow transplantation. Most studies indicate a 6070% prevalence of antibody to CMV by adulthood in both compromised and noncompromised patients. [73] [74] [75] [76] As with HSV, the prevalence of antibodies will vary with the socioeconomic condition, geography, and age of the population studied. A study from Houston found that only 25% of healthy white subjects aged 1822 had positive titers, compared with 50% of nonwhite individuals. [77]

In the compromised host, serious CMV infection can occur either by reactivation of latent disease as a result of immunosuppression or through primary infection. Among patients undergoing bone marrow transplantation, the incidence of significant CMV infection (usually pulmonary) is substantially higher for patients who are initially seropositive for anti-CMV antibody than for those who are seronegative. Meyers et al. [74] found that 69% of seropositive patients developed CMV, compared with 36% of seronegative patients. Presumably, most of the seropositive patients experienced reactivation of latent disease, while the seronegative patients acquired a primary infection. For this latter group, it was subsequently established that the source of virus was often transfused blood products or bone marrow from seropositive donors. The exclusive use of seronegative blood products for seronegative patients has nearly eliminated serious CMV infection in these patients. [78]

Increasing age may be associated with reactivation of CMV. McVoy and Adler [79] used IgM positivity as a marker of reactivation in patients with known positivity for IgG and found an increase in positivity from 15% for those <20 years old to 63% for those >60 years old. Consequently, older patients with hematologic diseases could be at higher risk than younger patients for the development of CMV infection.

The development of CMV in high-risk seropositive patients has been assumed to occur largely as a result of reactivation of endogenous previously acquired virus. Accordingly, blood products for patients who are already seropositive have generally not been screened. However, studies using restriction enzyme digest profiles and strain-specific neutralizing antibody measurements indicate that even seropositive patients can develop symptomatic CMV as a result of reinfection with different donor strains.[80] [81] [82] In light of these findings, further studies may be warranted to address the value of exclusive use of seronegative blood products even for seropositive patients.

The respiratory viruses, including RSV, influenza, parainfluenza, and adenovirus, have been increasingly recognized as pathogens in immunocompromised patients over the past decade. RSV is the leading cause of pneumonia and bronchiolitis in young children and is an important cause of nosocomial infection in childrens hospitals. A study by Hall et al.[83] found a higher incidence of nosocomial acquisition of RSV, of RSV pneumonia, and of deaths due to RSV in children with cancer than in children with normal immune function.[83] Another study has described severe RSV pneumonia in adults with lymphoma and in adults who underwent bone marrow or solid organ transplantation.[84] Prompt identification and isolation of infected patients are mandatory to prevent nosocomial transmission of RSV infection.

Parasites

With the exception of *P. carinii*, parasites are relatively uncommon causes of infection in compromised patients with non-HIV-related diseases. The parasitic infections most commonly encountered include those due to *P. carinii*, *Toxoplasma gondii*, *Cryptosporidium*, and *Strongyloides stercoralis* and occur most commonly in patients with altered cell-mediated immunity. When infection develops as a result of these organisms, it usually represents the reactivation of a latent or asymptomatic infection previously acquired outside the hospital setting. Gastroenteritis due to *Cryptosporidium* is an exception, with person-to-person transmission (both in and out of the hospital) and large water-source outbreaks having been clearly documented. [85] [86] [87] [88] [89] [90]

Symptomatic infection due to *P. carinii* likely results from reactivation of latent cysts acquired early in life rather than from new acquisition of disease. One study supporting this concept evaluated serum from 600 normal volunteers and used an indirect fluorescent antibody test for detection of anti- *P. carinii* IgG.[91] Of the children tested in this series, significant titers were found in nearly all by the age of 2 years, which implies asymptomatic infection early in life. In addition, the largest published study of a so-called institutional clustering of *P. carinii* infection, which occurred at St. Jude Childrens Cancer Research Hospital, failed to corroborate, or even suggest, any patient-to-patient spread.[92]

By contrast, studies of clusters of *P. carinii* pneumonia have suggested the possibility of person-to-person transmission. [93] [94] [95] In a study from Memorial Hospital, 11 cases of *P. carinii* pneumonia were seen in a 3-month period, 10 of them involving patients with leukemia or lymphoma. Epidemiologic analysis indicated that most of the patients either had had extensive contact with each other or had been treated by the same physician before the onset of disease. [94] In a study by Ruebush et al.,[93] 10 cases of *P. carinii* pneumonia were seen in a 10-month period, all in children with acute lymphocytic leukemia (ALL). Although their risk of infection appeared to be related to the intensity of chemotherapy, members of the hospital staff who had close contact with these children had significantly higher titers of anti- *P. carinii* antibody than other staff members or the parents of the children, suggesting that transmission could have occurred within the hospital environment. In addition, animal data suggest airborne transmission from infected to uninfected rats.[96] Although these studies are suggestive, person-to-person transmission of *Pneumocystis* has not been clearly documented, even in centers with a large number of cases.

ALTERATIONS IN HOST DEFENSE-ASSOCIATED PATHOGENS AND MAJOR CLINICAL CORRELATES

The range of abnormalities in host defense that can occur in patients with hematologic diseases and the major associated pathogens are listed in Table 79-2 . For any given patient, only rarely is a specific defect in host defense seen in isolation. Nevertheless, certain types or patterns of defects are more often associated with specific underlying diseases or particular therapeutic interventions.

Anatomic Alterations

The skin and mucosal surfaces represent an important primary defense against both endogenous and exogenous sources of infections.

Compromised patients frequently have alterations in integumentary and mucosal barriers. Disruption of skin and mucosa may result from invasion by malignant cells, from the effects of chemotherapy or radiation therapy, from the use of invasive diagnostic or therapeutic procedures (e.g., intravenous catheters), and from the effects of locally disruptive infections such as oral HSV. Such mucosal alterations may provide a nidus for microbial colonization, a focus for localized infection, and a portal of entry for systemic invasion.

The types of organisms associated with specific alterations in skin or mucosal surfaces will depend on the site of breakdown as well as the presence or absence of other associated factors. For example, isolated disruption of the skin associated with insertion of an indwelling intravenous catheter primarily increases the risk of infection with certain gram-positive organisms, usually coagulase-negative staphylococci. However, in patients who have been hospitalized, who are neutropenic, or who have previously received broad-spectrum antibiotics, the normal flora of the skin can change, and serious catheter-related infections due to a variety of other organisms can occur. These organisms include other gram-positive bacteria, such as *C. jeikeium* or *Bacillus* spp.;[18] [97] [98] a variety of gram-negative organisms, including *P. aeruginosa*, non-*aeruginosa Pseudomonas*-like organisms, or enteric gram-negative rods; [99] [100] [101] [102] fungi such as *C. albicans* or *Aspergillus* spp.;[103] [104] [105] and atypical *Mycobacterium* spp. such as *M. chelonei* or *M. fortuitum*.

Because the GI tract is normally colonized by a wide array of aerobic and anaerobic bacteria as well as by some fungi, disruption of its mucosa can lead to infection by a variety of pathogens, and sometimes to polymicrobial infection. Identification of a specific site of mucosal damage in the GI tract may help predict which pathogens play a role, based on a knowledge of normal flora in that area. Oral ulceration, for example, not only will suggest the possibility of HSV reactivation but may also predict bloodstream infection with -hemolytic streptococci. Alternatively, isolation of certain organisms in blood cultures can help direct diagnostic or therapeutic intervention toward specific sites, even in the absence of clinically evident disease. For example, isolation from the blood of organisms normally found in the mouth, such as *Peptococcus* or *Capnocytophaga*, should focus attention on the oral cavity, while cultures yielding *B. fragilis* or *Streptococcus bovis* can be clues to pathology originating in the lower GI tract. [22] [106] [107] [108]

One of the most common causes of disruption of the GI mucosal integrity is administration of chemotherapeutic agents to patients with malignancy. Those that lead to the most serious problems include Ara-C, the anthracyclines (daunorubicin and doxorubicin), methotrexate, mercaptopurine, and fluorouracil. Although stomatitis is usually the most clinically recognizable manifestation of GI toxicity, the clinician should remember that significant oral mucositis is often only the tip of the iceberg and that diffuse GI involvement is likely present.

The urinary tract may also be affected by tumor, invasive procedures, or cytotoxic therapy, with subsequent colonization and the potential for local or invasive infection. The urinary tract pathogens most commonly encountered in these settings are the enteric gram-negative rods, enterococci, and *C. albicans*.

In addition to actual mucosal breakdown, other anatomic alterations can occur in compromised patients, increasing their risk of infection. Mechanical obstruction of body passages by tumor, for example, can greatly increase the risk of serious localized infection. This may be due in part to stasis of local body fluids, with resultant overgrowth of potentially pathogenic colonizing organisms. Common sites of secondary infection due to obstruction include the lung, urinary tract, biliary tract, and auditory tube. An obstructive process should be considered when infection at any of these sites fails to respond to appropriate antibiotics.

Anatomic alteration can also predispose to infection simply by providing a nidus for growth of organisms. It is likely that most healthy individuals experience periodic but uneventful episodes of transient bacteremia (e.g., secondary to toothbrushing). In the setting of altered anatomy or foreign bodies such as prosthetic devices, however, even transient bacteremia can lead to persistent localized infection. Important examples of hematologic diseases associated with such anatomic alterations include sickle cell anemia and hemophilia. In patients with sickle cell disease, macrophage and splenic dysfunction predispose to the development of certain bacteremias, especially caused by *S. pneumoniae* and *Salmonella* spp.[109] [110] [111] Many of these patients have underlying anatomic abnormalities of bones and joints as a result of vaso-occlusive crises causing infarction of bone marrow, bony cortex, or synovium. In turn, these changes may predispose to the development of infection at the sites of anatomic alteration, such as osteomyelitis or arthritis. [112] [113] Decreased blood flow to these areas and increased adherence of organisms may be additional contributing factors. Similarly, hemophiliacs may develop anatomic alterations of joints as a result of repeated episodes of hemarthrosis. Although suppurative arthritis has been less frequently described in hemophiliacs than in patients with sickle cell disease, it can occur and should be considered in the differential diagnosis of any hemophiliac whose articular signs and symptoms fail to improve quickly after administration of appropriate coagulation factors. [114] Patients with chronic hemolytic states may develop gallstones, which can also provide a nidus for infection.

Phagocyte Defects

Quantitative and qualitative defects affecting polymorphonuclear leukocytes (PMNs) and monocytes can occur in compromised patients. Although both cell types are important, the contribution of granulocyte abnormalities to the pathogenesis of infectious diseases has been better described and more completely elucidated, primarily because isolated defects in monocytes are relatively rare.

Quantitative Abnormalities

Significance of Neutropenia in Predisposing to Infection

Of the many abnormalities in host defense that potentially affect compromised patients, granulocytopenia is perhaps the most important, for two reasons: (1) it predisposes patients to a wide array of pathogenic organisms, and (2) it may be associated with rapid progression of infection, often in the absence of classic signs

and symptoms.

Most clinicians associate granulocytopenia with malignant disease, with which it can occur as a result of either a myelophthisic process or, more commonly, cytotoxic therapy. Indeed, cancer patients account for most cases of neutropenia encountered in the clinical setting. However, it is important to recognize that many other pathologic processes may be associated with granulocytopenia. Unfortunately, very few data specifically address the relative risks, types, or management of infections in neutropenic patients with nonmalignant diseases. In the absence of these data, the clinician is often forced to extrapolate from studies in the cancer population.

For cancer patients receiving cytotoxic therapy, the relationship between the development of granulocytopenia and serious infection has been established unequivocally. Bodey et al.[115] followed the course of 34 patients with ALL and 29 patients with AML (age range, 177 years) and correlated the development of infection with granulocyte counts over the course of treatment (Table 79-3). The salient findings of this study were as follows. First, the incidence of proven infection and the absolute granulocyte level showed a definite relationship. The risk of infection

TABLE 79-2 -- Selected Hematologic Diseases, Associated Host Defense Impairment, and Common Pathogens

Disease/Condition	Factors Contributing to Infection						Most Common Pathogens
	Neutropenia	Phagocyte Dysfunction	Abnormal Cell-Mediated Immunity	Abnormal Humoral Immunity	Anatomic Disruption	Splenic Dysfunction	
Acute myeloid leukemia	Major factor	Abnormalities described	May result from therapy (e.g., bone marrow transplantion)	May result from therapy	Often significant, may be caused by therapy, tumor invasion, localized infection	Not prominent	Bacteria Gram-positive (staphylococci, streptococci) Gram-negative (enteric organisms, *P. aeruginosa*) Fungi *Candida* *Aspergillus* Viruses Herpes simplex Varicella-zoster Other *P. carinii*
Acute lymphocytic leukemia	Major factor	Abnormalities described	May result from disease or therapy	May result from therapy	Often significant (see AML)	Not prominent	See AML. *P. carinii* more common in some centers
Hairy cell leukemia	Major factor (also monocytopenia)	Probably contributes	Probably contributes	Not prominent	Not prominent unless aggressive therapy	Major factor if therapeutic splenectomy	Gram-positive and gram-negative bacteria Atypical mycobacteria
Chronic lymphocytic leukemia	Not prominent unless aggressive therapy or end stage	Not prominent	May result from therapy (e.g., steroids)	Major factor	Not prominent unless aggressive therapy	Not prominent	Bacteria *S. pneumoniae* *H. influenzae* *Neisseria* spp.
Chronic myeloid leukemia	Not prominent unless aggressive therapy or end stage	Abnormalities described	Not prominent	Not prominent	Not prominent unless aggressive therapy	Not prominent	Few infections in stable chronic phase Blast crisis (see AML)
Multiple myeloma	Not prominent unless aggressive therapy or end stage	Abnormalities described	Not prominent	Major factor	Not prominent	Not prominent	Bacteria *S. pneumoniae* *H. influenzae* *Neisseria* spp. Enteric gram-negative
Hodgkin disease	May be major factor, depending on therapy	Abnormalities described	Major factor	May result from therapy	May be significant, depending on therapy	Major factor if diagnostic splenectomy or radiation to splenic bed	See AMLviral and parasitic infections may occur with higher frequency
Myelodysplastic syndromes	Variable	Abnormalities described	Not prominent	Not prominent	Not prominent	Major factor if therapeutic splenectomy	Gram-positive and gram-negative bacteria
Aplastic anemia	Major factor	Abnormalities described	May result from therapy (e.g., steroids, antithymocyte globulin, cyclosporine, bone marrow transplantation)	Not prominent	Not prominent unless aggressive therapy	Not prominent	Gram-positive and gram-negative bacteria*Candida, Aspergillus* Other depends on therapy
Chronic granulomatous disease	Not prominent	Major factordefective oxidative metabolism	Not prominent	Not prominent	Not prominent	Not prominent	Catalase-positive organisms*S. aureus,* enteric gram-negative bacteria, *P. cepacia, Nocardia, Aspergillus*
G6PD deficiency	Not prominent	Major factor if severe	Not prominent	Not prominent	Not prominent	Not prominent	Catalase-positive organisms if severe

Myeloperoxidase deficiency	Not prominent	Major factor (usually with few clinical manifestations)	Not prominent	Not prominent	Not prominent	Not prominent	Infections rare; possible increase in *Candida* infections
Paroxysmal nocturnal hemoglobinuria	May contribute	Potentially contributorydeficient Fc receptor	Not prominent	Not prominent	Thromboembolic disease may contribute (intra-abdominal infections)	Not prominent	Bacterial infections

began to increase significantly when granulocyte counts fell to <1,000/mm ^{3} and was most marked when the counts were 100/mm^3 . Second, in addition to the absolute granulocyte count, an important factor in predicting the risk of infection at any level was the duration of granulocytopenia. Thus, counts in the range of 1,000/mm ^{3} for a short duration (e.g., <1 week) were associated with little risk of infection, compared with a significant risk if the counts stayed within that range for 14 weeks. By contrast, neutropenia in the range of 100/mm^3 , even for a few days, was associated with a significant risk. Third, the incidence of infection was also related to a falling granulocyte count, but the magnitude of the fall was less important than the final granulocyte levels. Fourth, at any granulocyte level, the severe infectious episodes occurred more frequently during relapse than during remission, suggesting that other factors played a role in predisposing to infection.

For practical purposes, granulocytopenia is usually defined as a cell count of <500 PMNs/mm ^{3} and band forms/mm^3 . The absolute granulocyte count, the duration of granulocytopenia, and whether the neutrophil count is falling or rising must all be considered when assessing the risk to any individual patient. Granulocytopenia primarily predisposes to the development of bacterial and fungal infection but does not per se appear to increase the incidence or severity of viral and parasitic infections.

Types of Bacterial Infections in Neutropenic Patients

General trends in the frequency of infection caused by certain types of organisms have occurred since the 1950s and 1960s, when aggressive cytotoxic regimens were in early development. In those years, gram-positive bacteria were encountered most commonly. [116] [117] [118] However, by the 1970s, gram-negative organisms had emerged as the predominant pathogens isolated in neutropenic patients. Interestingly, during the 1980s and 1990s,

TABLE 79-3 -- Association of Granulocyte Level and the Chance of Developing Significant Infection

Granulocyte Level (per mm^3)		Percentage of Serious Infections for Different Durations of Granulocytopenia (in wk)							
Initial	**Change**	**1**	**2**	**3**	**4**	**6**	**10**	**12**	**14**
Any level	Any fall	12							
Any level	Fall to 2,000	2							
Any level	Fall to 1,500	5							
Any level	Fall to 1,000	10	30	45	50	65	70	85	100
Any level	Fall to 500	19

gram-positive organisms re-emerged as common bacterial isolates at many centers; at some centers they are now the most frequently encountered organisms. [8] [10] [119] [120] [121] Although an appreciation of these fluctuations can be helpful for the clinician, the potential for institutional variation in the patterns of infection cannot be overemphasized. Accordingly, clinicians treating granulocytopenic patients should have a working knowledge of the specific bacterial isolates encountered at their own facility.

Gram-Negative Bacteria.

The relative frequency of infections due to gram-negative organisms has decreased over the past 15 years. [120] In particular, the National Cancer Institute (NCI) has reported a dramatic decrease in infections due to *P. aeruginosa*, often an extremely virulent pathogen in neutropenic hosts. [120] *E. coli* and *K. pneumoniae* are now the most common gram-negative isolates at most centers. These organisms are frequently isolated from the blood; the most common endogenous source is the GI tract. Other common sources include the urinary tract and the respiratory tract, although a precise source of gram-negative bacteremia is identified in only a few cases. In neutropenic patients, gram-negative organisms may be isolated from cultures done on specimens obtained at the onset of fever or may cause breakthrough secondary infections in patients already receiving antibiotics. *Enterobacter* spp., *Citrobacter* spp., and *S. marcescens* are increasingly encountered Enterobacteriaceae that can rapidly become resistant to a broad range of -lactam antibiotics through the induction of chromosomally mediated -lactamases. [122] Other less common gram-negative organisms include *Acinetobacter* spp., *Hemophilus* spp. (usually nontypable *H. influenzae*),[123] and non-*aeruginosa Pseudomonas*-like organisms (often catheter related and antibiotic resistant). [101]

Gram-Positive Bacteria.

The gram-positive organisms most frequently encountered are the coagulase-negative staphylococci (most commonly *S. epidermidis*), coagulase-positive staphylococci (*S. aureus*), enterococci (most commonly *E. faecalis*), and -hemolytic streptococci (e.g., *S. mutans* or *S. viridans*). They can cause either primary or secondary infection in neutropenic patients. Both coagulase-positive and coagulase-negative staphylococci are most commonly isolated from the blood, and often from patients with indwelling intravenous catheters or skin breakdown from other causes. In addition, both have been well documented to cause infections around catheter sites or foreign bodies, such as prosthetic heart valves or orthopedic implants. *S. aureus* tends to be significantly more virulent and may cause a picture of rapidly developing septic shock as well as serious deep-seated infections. Most infections due to coagulase-negative staphylococci tend to be relatively indolent compared with *S. aureus* infection. A picture of septic shock is rarely, if ever, seen with most coagulase-negative staphylococcal bacteremias, and it has been debated whether these organisms can cause invasive visceral infections (e.g., pneumonia). Enterococci are part of the normal GI flora, are frequent components of intra-abdominal infections, and are a relatively common cause of urinary tract infections (second to the enteric gram-negative rods). Compared with streptococci, they are relatively -lactam resistant. Of additional concern, isolates of *Enterococcus* that are resistant to vancomycin have become a significant problem at some centers. Vancomycin-resistant enterococci are frequently resistant to aminoglycosides and -lactam drugs as well, posing a serious therapeutic dilemma. [124] Most -hemolytic

streptococci are part of the normal oral flora and may be seen with increased frequency after chemotherapy that produces significant oral mucosal disruption (e.g., high-dose Ara-C).[125] [126] Most -hemolytic streptococci are sensitive to a variety of -lactam antibiotics. However, recent reports have documented particularly virulent strains of -hemolytic streptococci that do not respond to -lactam antibiotics. Other gram-positive bacteria encountered in neutropenic patients include *Bacillus* spp. (often catheter related), *Corynebacterium jeikeium* (often catheter related and relatively antibiotic resistant), *Enterococcus faecium*, which may be resistant to vancomycin and other antibiotics, and *Lactobacillus,* which may also be resistant to vancomycin.

Anaerobic Bacteria.

Infections due to anaerobic bacteria may also be encountered in neutropenic patients, although less commonly than those due to aerobic organisms. [127] [128] [129] The anaerobic organisms most frequently encountered are *B. fragilis* and *Clostridium* spp., both normal inhabitants of the human GI tract. Infections caused by these organisms are often associated with a concomitant abnormality in GI mucosal integrity. Although bacteremia may occur, only rarely are anaerobes isolated from cultures done on specimens obtained at the discovery of initial fever in neutropenic patients. More commonly they present as secondary infections. Bacteremia due to *C. perfringens* can be a particularly fulminant and rapidly lethal process. [125] By contrast, when bacteremia due to *B. fragilis* occurs, it is often relatively indolent. [129] These anaerobes are most commonly isolated as components of necrotizing gingivitis or of intra-abdominal infections, including peritonitis, intra-abdominal abscesses, and perirectal cellulitis or abscesses. [129] Although *B. fragilis* and *C. perfringens* are the most common infecting organisms, other species may be clinically important. These include other species of *Bacteroides* [22] and *Clostridia* (e.g., *C. tertium* or *C. septicum*, which are often clindamycin resistant).[24] *C. difficile* is also a common cause of morbidity in neutropenic patients. It is not associated with bacteremia or invasive disease; rather, it produces a wide range of GI pathology due to elaboration of toxins.

Mycobacteria.

Infections attributable to *Mycobacterium* spp. are only rarely encountered in neutropenic patients and for the most part are not seen with increased frequency in this population. With the emergence of *M. tuberculosis* in a number of American cities, however, it seems likely that an increase in this infection will be observed in cancer patients. Patients with hairy cell leukemia appear to have an increased risk of developing infections with certain atypical mycobacteria. Hairy cell leukemia is often associated not only with neutropenia but also with profound monocytopenia, which may be an important risk factor for these infections. [130] Dysfunction of cell-mediated immunity may also be a contributing factor. In addition to the more common bacterial infections seen in other neutropenic hosts, patients with hairy cell leukemia may develop significant infections due to *M. kansasii*, *M. fortuitum*, *M. chelonei*, and *M. avium-intracellulare* complex.[31] [32] [33] Fast-growing mycobacteria (*M. fortuitum* and *M. chelonei*) may also cause persistent exit-site or tunnel infections in patients with indwelling intravenous catheters or wound infections after surgery.

Types of Fungal Infection Seen in Neutropenic Patients

The next most common type of organism encountered in neutropenic patients is fungus. Although neutropenia per se may predispose to the development of fungal infection, certain subsets of neutropenic patients appear to be at heightened risk,

most notably (1) those with prolonged neutropenia (>2 weeks) and (2) those receiving broad-spectrum antibacterial therapy. In contrast to the bacterial infections often associated with the onset of fever in neutropenic patients, fungal infections only rarely cause primary infection (i.e., initial infection in patients not yet receiving antibiotics). More commonly, fungal infections occur as secondary processes in patients receiving antibacterial drugs. Although a variety of fungal infections can be encountered in the neutropenic host, *Candida* spp. and *Aspergillus* spp. predominate. Emerging pathogens, such as azole-resistant *Candida* spp., *Fusarium* spp., Zygomycetes, *Trichosporon* spp., and dematiaceous molds, pose new threats to immunocompromised hosts, particularly those with neutropenia. Patients treated with glucocorticosteroids, particularly for postengraftment graft-versus-host disease (GvHD), are also at high risk for the development of invasive aspergillosis.

Qualitative Abnormalities

A variety of hematologic diseases may be associated with pronounced functional defects in effector cells, which in turn may contribute to the development of infectious complications. The microbicidal activity of granulocytes and monocytes involves complex interactions between the cell and the organism or inflammatory site. Some of the major functions important for microbicidal activity that have been elucidated include migration of the cell to the inflammatory site (chemotaxis), cell activation, phagocytosis, and intra- or extracellular killing by both the oxygen-dependent and oxygen-independent pathways. Clinically important defects in granulocyte function have been more completely delineated than have abnormalities in monocytes, with specific abnormalities described in nearly every measurable function of neutrophils. Problematic are patients with borderline granulocyte counts (e.g., absolute granulocyte counts in the range of 5002,000/mm ^{3} that are not falling precipitously), which occur most commonly with the myelodysplastic syndromes or newly diagnosed leukemias.

Previously it was thought that only cells less mature than the metamyelocyte were deficient in microbicidal activity, whereas more mature cells were fully competent. This supposition was based on early data on white blood cells (WBCs) obtained from healthy individuals. Subsequently, however, a number of studies documented significant functional defects in mature PMNs from patients with AML. [131] [132] [133] [134] In addition, one study initiated in patients with AML before treatment found a correlation between abnormalities in myeloperoxidase activity of the PMNs and the subsequent development of infectious complications. [135] Although fewer data are available addressing this issue for patients with ALL, studies have shown evidence of functional deficits in PMNs from these patients. [136] [137] Accordingly, it is prudent to approach all patients with acute leukemia and borderline granulocyte counts as if they had an absolute neutropenia.

Significant defects in granulocyte function have also been found in PMNs from patients with myelodysplastic syndromes and preleukemic states; [138] [139] [140] in some studies, these have correlated with infectious complications. [141] Although it is likely that these functional defects contribute to the increased infections seen in these populations, their effects per se are difficult to establish. The clinician should probably assume that neutrophils from patients with myelodysplastic syndromes or preleukemia are functionally defective. As in the case of AML or ALL, from a clinical perspective, patients with borderline granulocyte counts should be approached as if they had an absolute neutropenia.

Phagocyte dysfunction can also be due to the therapeutic use of pharmacologic agents and radiation for the treatment of the underlying hematologic disease. Again, because most patients receiving these therapies have multiple defects in host defense, the clinical significance of these in vitro findings is often difficult to establish. In addition to pronounced effects on phagocyte function, many of the drugs themselves (e.g., cyclophosphamide) can impair other immune parameters, including the production of quantitative defects, and can cause abnormalities in humoral responses and cell-mediated immunity.

In vitro studies have demonstrated inhibition of a variety of functional granulocyte parameters by antineoplastic agents, including inhibition of hexose monophosphate shunt activity, superoxide production, phagocytosis, chemotaxis, expression of Fc receptors, and microbicidal activity. The implicated agents have included methotrexate, 6-mercaptopurine, vincristine, vinblastine, the anthracyclines, cyclophosphamide, carmustine, and platinum compounds. [142] [143] [144] [145] [146] [147] [148] [149] [150] [151] [152]

It is widely accepted that exogenous administration of glucocorticoids leads to increased susceptibility to infection. Glucocorticoid therapy has been associated with the development of fulminant varicella infections in cancer patients and has been correlated with an increased risk for deep fungal infections in immunocompromised hosts.[153] [154] The major effect of steroids on in vitro measurement of granulocyte function appears to be confined to a decrease in chemotactic activity, which inhibits accumulation of PMNs at the site of infection and decreases the localized inflammatory response. [155] This may in large part account for the clinical observation that the signs and symptoms of even severe infections may be masked or greatly reduced in patients receiving steroids. In vitro, steroids may also impair PMN phagocytosis, microbicidal activity, and antibody-dependent cytotoxicity. [156] [157] In addition to their effects on granulocytes, corticosteroids may have important effects on the function of circulating monocytes, although the available data are limited. Documented effects have included in vivo monocytopenia as well as in vitro defects in monocyte chemotaxis, phagocytosis, and killing of bacteria and fungi. [158] In addition to their action on granulocytes and monocytes, steroids may enhance susceptibility to infection through other mechanisms, including negative effects on wound healing, skin fragility, lymphocyte function, production of cytokines, and humoral immune responses. The use of recombinant cytokines may reverse or prevent the corticosteroid-induced immunosuppression of phagocytic cell function against pathogenic fungi. For example, granulocyte colony-stimulating factor (G-CSF) and interferon- (IFN-) prevent corticosteroid-induced suppression of human PMN-induced damage of *Aspergillus fumigatus* hyphae.[159]

Various biologic agents are increasingly employed in the management of hematologic disorders, among which the colony-stimulating factors (predominantly

granulocyte-macrophage colony-stimulating factor [GM-CSF] and G-CSF) and interleukin-2 (IL-2) are most notable. A number of functional parameters may be enhanced by GM-CSF or G-CSF, including oxidative metabolism, phagocytosis, microbicidal activity, and antibody-dependent cytotoxicity. In vitro, recombinant human G-CSF has been shown to partially restore respiratory burst and bactericidal activity in neutrophils from patients treated with chemotherapy. [160] However, several pieces of data underscore the potential for inhibition of cell function as well. For example, in patients undergoing autologous bone marrow transplantation, impaired in vivo migration of granulocytes during GM-CSF administration has been documented. [161] Additionally, G-CSF has been shown to significantly decrease motility and bacteria-induced chemotaxis of neutrophils from patients undergoing cancer chemotherapy. [162] Impaired granulocyte function has been noted in some patients receiving high doses of IL-2. Patients receiving high-dose IL-2 therapy appear to have an increased incidence of significant infections due to *S. aureus*.[163] [164] Granulocyte function studies in patients receiving IL-2 demonstrated decreased production of superoxide, decreased chemotaxis, and decreased Fc receptor gamma-III expression.[164] Although the clinical significance of any of these effects on functional parameters has yet to be established, one

must keep an open mind to their potential to impair, as well as improve, cell function.

Many other commonly employed drugs have had documented in vitro or in vivo effects on phagocyte function, including nonsteroidal anti-inflammatory drugs, [165] [166] [167] [168] [169] opiates and other narcotic analogues, [170] [171] [172] ethanol,[173] benzodiazepines,[174] methylxanthines,[175] -blocking agents, [176] phenytoin,[177] [178] inhaled and intravenous anesthetics,[179] [180] nicotine,[181] allopurinol,[182] cyclosporine,[183] [184] heparin,[185] and calcium channel-blocking agents. [186] Even antibiotics, such as the tetracyclines, macrolides, and amphotericin B, have been shown to inhibit neutrophil function in vitro. [187] [188] [189]

Radiation therapy has also been associated with granulocyte dysfunction both in animal studies and in humans. Baehner and colleagues [190] studied granulocyte function in children with ALL. They found significant impairment of bactericidal activity when the cells were obtained during periods of craniospinal irradiation as compared with values before radiation therapy. The effect was transient, and cell function returned to normal 24 weeks after completion of radiation therapy.

Defects in Cell-Mediated Immunity

Cellular immune dysfunction may either be primary, as in a number of congenital immunodeficiency states, or secondary to other disorders or therapeutic interventions. Secondary deficiency in cell-mediated immunity is most commonly seen in patients with lymphoid malignancies, those with acquired immunodeficiency syndrome (AIDS), recipients of organ transplants, and patients receiving steroids or radiation therapy. The specific pathogens encountered and the spectrum of clinical findings in patients with defects in cell-mediated immunity vary with the underlying disease, the degree of immunosuppression, and the presence or absence of other host defense abnormalities. Defective cell-mediated immunity can lead to infections caused by bacteria, fungi, viruses, and protozoa. For the most part, however, the organisms are distinct from those that cause serious infection in patients with phagocyte abnormalities (Table 79-1). The most frequently encountered pathogens are often characterized as intracellular organisms because they can survive and even replicate inside macrophages in a nonimmune individual or in the absence of T-cell immunity. T-cell function appears to be required for macrophage activation and subsequent microbicidal activity. [191] Among the pathogens are (1) bacteria, including mycobacteria (both *M. tuberculosis* and atypical mycobacteria), *Legionella*, *Nocardia asteroides*, and *Salmonella* spp.; (2) fungi, including *C. neoformans*, *H. capsulatum*, and *C. immitis*; (3) viruses, including VZV, HSV, CMV, and EBV; and (4) parasites, including *P. carinii*, *T. gondii*, *Cryptosporidium*, and *S. stercoralis*. Patients with a deficiency in cell-mediated immunity are also at risk for the development of disseminated infection due to live vaccines, even with attenuated organisms. Accordingly, these patients should not receive bacillus Calmette-Guérin (BCG), vaccinia, measles, rubella, mumps, yellow fever, or live polio vaccines. The one exception is that all HIV-infected children, regardless of symptoms, should receive the measles vaccine. Although severe measles infection with high mortality does occur rarely, little morbidity from the measles vaccine has been reported in this patient population. [192]

Hodgkin disease, followed by the non-Hodgkin lymphomas, is the best-characterized and most commonly encountered malignant disorder associated with impaired cell-mediated immunity.[193] [194] [195] While the degree of immune impairment may correlate with the extent of disease and is often compounded by the administration of immunosuppressive therapy, both Hodgkin disease and non-Hodgkin lymphoma are associated with an intrinsic impairment of cell-mediated immunity that can persist even after apparent cure. Patients in remission are still at increased risk for the development of certain infections, particularly disseminated VZV infection; the identification of primary chickenpox or even localized zoster in these patients mandates prompt therapy with intravenous acyclovir (see the discussion under Clinical Approach to Viral Infections in Immunocompromised Patients).

Clinically significant intrinsic impairment of cell-mediated immunity has not been well established for other malignancies. Defects in cell-mediated immunity have been postulated to help explain the incidence of atypical mycobacterial infections in patients with hairy cell leukemia and also occur in patients with the relatively rare T-cell malignancies such as mycosis fungoides or T-cell chronic lymphocytic leukemia (CLL). Defects in cell-mediated immunity clearly exist in children with ALL, as evidenced by their increased susceptibility to the development of *P. carinii* or disseminated VZV infection, but it is likely that concurrent therapy plays a major role. Similarly, while defects in cell-mediated immunity may occur in patients with a variety of other malignancies, they are often explained by the use of therapeutic agents or by concomitant nutritional deficiencies.

Impaired cell-mediated immunity is not a prominent feature of nonmalignant hematologic disorders unless it is associated with therapy or the acquisition of HIV-1 infection. Abnormalities in cell-mediated immunity have been described in patients with hemophilia who have received factor VIII concentrates. [196] [197] Clearly, hemophiliacs who have acquired infection with HIV-1 from factor replacement therapy may have severe impairment of cell-mediated immunity. However, some studies have shown that HIV-1-seronegative hemophiliacs who have received factor VIII concentrates, as well as previously untreated hemophiliacs, have immune impairment.[198] Patients with sickle cell anemia have been found to have anergy in association with zinc deficiency and decreased nucleoside phosphorylase activity;[199] cell-mediated immunity defects have been described in patients with thalassemia. [200] Overall, however, the clinical significance of these findings is uncertain.

Pharmacologic agents and irradiation are major causes of impaired cell-mediated immunity. Corticosteroids are the pharmacologic agents most often associated with abnormalities in cell-mediated immunity, although they may also cause immune suppression through their effects on other host defense mechanisms. [201] The degree of immunosuppression and the relative risk of infection will depend on the dose and duration of corticosteroids as well as on the underlying disease. Even when these factors are known, however, infectious complications in patients receiving corticosteroids may be highly variable and difficult to predict on an individual basis. [155] Nevertheless, whether corticosteroid therapy is being used should always be taken into account when one is confronted with potentially infected patients. Those patients about to embark on corticosteroid-containing treatment regimens who have a known history of tuberculosis or positive purified protein derivative (PPD) should be treated with prophylactic isoniazid (INH) to prevent reactivation and potential dissemination of disease.

A number of cytotoxic agents may also be associated with impaired cell-mediated immunity, notably methotrexate, cyclophosphamide, 6-mercaptopurine, and azathioprine.[202] [203] Infections due to impaired cell-mediated immunity, such as *P. carinii* pneumonia, have also been associated with certain combination chemotherapeutic regimens more often than with others.[204] In patients with hematologic malignancies, cytotoxic agents are frequently administered in combination with other immunosuppressive therapies, such as corticosteroids or radiation therapy, which may further impair cell-mediated immunity and increase infection risk for diseases such as *P. carinii* pneumonia.

Cyclosporine is an immunosuppressant used to suppress transplant rejection and also as a therapeutic modality in aplastic

anemia. It is associated with alterations in T-helper cells, effector T cells, and natural killer (NK) cells. It has not been established, however, that the use of cyclosporine is associated per se with an increased risk of infection. Although there are anecdotal reports of unusual infections in patients receiving cyclosporine, evidence shows that its use can decrease certain infections as compared with other immunosuppressive regimens used for allograft recipients. [205] [206]

Radiation therapy can result in impaired cell-mediated immunity, especially when used in combination with other immunosuppressive agents or for the treatment of patients with underlying diseases associated with intrinsic cell-mediated immunity defects (e.g., as a component of the preparatory regimen for bone marrow transplantation or for the treatment of Hodgkin disease). Defects in cell-mediated immunity may persist for >1 year after intensive radiation therapy or after bone

marrow transplantation.[207] Accordingly, patients should be considered at risk for the development of certain infections during this period.

A number of infections may themselves result in impaired cell-mediated immunity. Viral infections may affect cell-mediated immunity either directly (e.g., by infecting crucial cellular components such as T lymphocytes or macrophages) or by affecting other immunoregulatory mechanisms.[208] The key viral infection associated with impaired cell-mediated immunity is HIV-1. Patients with AIDS have profound defects in cell-mediated immunity and are susceptible to a wide array of infectious complications. Other viral infections associated with cell-mediated immunity defects include CMV, EBV, RSV, HBV, and influenza. Other nonviral infections that have been variably associated with impaired cell-mediated immunity by in vitro testing have included tuberculosis, leprosy, bacterial pneumonia, *Brucella*, typhoid fever, coccidioidomycosis, syphilis, and a variety of parasitic diseases.[209]

Noninfectious disorders linked to abnormal cell-mediated immunity include chronic protein-calorie malnutrition, uremia, diabetes mellitus, sarcoidosis, cystic fibrosis, and other conditions resulting from surgery and the administration of anesthesia.

Abnormalities of Humoral Defense MechanismsImmunoglobulins and Complement

Immunoglobulins and complement are among the most important components of the humoral immune system; defects or deficiencies in either may be associated with serious infections. Other proteins classified as part of the humoral defense system include lysozyme and lactoferrin, tuftsin, and fibronectin. Abnormalities in these proteins have been variably associated with infectious complications. Immunoglobulins and complement each have associated opsonic, lytic, and neutralizing activities and function predominantly against bacterial infection. Patients with either primary or secondary defects or deficiencies in these proteins are at highest risk for the development of serious infection from the encapsulated bacteria and, to a lesser extent, from the enteroviruses and *Giardia lamblia*.

Multiple myeloma is frequently associated with a defect in humoral immunity.[210] The degree of humoral impairment in multiple myeloma is related to the stage of the disease. Malignant plasma cells induce the production of a protein that is synthesized by macrophages and that selectively suppresses B-cell function. Cell-mediated immunity remains intact unless patients are treated with corticosteroids or cytotoxic therapy. In addition, myeloma patients with IgG paraprotein have an increased rate of catabolism of both normal and clonal IgG.

Patients with myeloma are most susceptible to recurrent pyogenic infections from high-grade polysaccharide-encapsulated bacteria such as *S. pneumoniae*, *H. influenzae*, or *Neisseria* spp. However, infections due to enteric gram-negative rods and staphylococci are also frequently encountered. In the series reported by Doughney et al.,[211] gram-negative bacilli accounted for most isolates. Savage et al.[212] found a biphasic pattern of infection, with infections due to *S. pneumoniae* and *H. influenzae* occurring earlier in the course of disease (i.e., within the first 8 months of diagnosis) or in patients responsive to therapy, and those due to gram-negative bacilli occurring more frequently in patients with refractory or advanced disease. The sites of recurrent infection are most often the upper respiratory tract, urinary tract, or skin. Repetitive bouts of infection may herald the diagnosis of multiple myeloma; infection is the major cause of death.

Because pneumococcal infections are frequent, some studies have explored the potential role of pneumococcal vaccine administration to these patients. In patients with multiple myeloma antibody titers may rise after administration of pneumococcal vaccine but, because preimmunization titers are frequently low, postimmunization titers often fail to reach a protective level.[210] In addition, postimmunization antibody levels fall rapidly in this population, in part because of the increased catabolism of immunoglobulins.[207] This is of practical importance, because revaccination with pneumococcal vaccine may be associated with Arthus reactions or systemic reactions.[213] Nevertheless, it is currently recommended that patients with multiple myeloma receive pneumococcal vaccine and that revaccination be considered in patients sustaining a rapid decline in pneumococcal antibody levels.[214] Revaccination should be done no sooner than 6 years after administration of the initial vaccine.[215] [216] The efficacy of prophylaxis with passive administration of immunoglobulins has not been established and cannot be recommended.

Patients with B-cell CLL also appear to have an intrinsic defect in the clonal B cells that leads to unbalanced immunoglobulin chain synthesis and resultant hypogammaglobulinemia. The incidence of infection correlates with the duration and stage of the disease as well as with the serum levels of immunoglobulins (particularly IgG). Infection is a major cause of morbidity and mortality and may account for as much as 60% of deaths in certain series.[217] The organisms causing serious infection are often the encapsulated bacteria, although patients are also at risk of infection due to staphylococci and enteric gram-negative bacilli.[218] Upper and lower respiratory tract infections are encountered most commonly, although septicemia and other sites such as the urinary tract and skin are frequently involved. Therapeutic administration of corticosteroids or cytotoxic drugs will increase the risk of infection and may dramatically expand the list of potential pathogens.[218] [219] It is recommended that patients with CLL receive polyvalent pneumococcal vaccine, although its efficacy in this population has not been demonstrated unequivocally. A multicenter trial demonstrated that prophylaxis with pooled intravenous immunoglobulin (IVIG) decreased the incidence of bacterial infection; however, the decrease was primarily seen in minor or moderately severe infections.[218] In addition, the cost-effectiveness of immunoglobulin prophylaxis and its effect on the quality of life are questionable.[220]

The precise role of abnormalities in humoral defenses in other malignancies has not been well defined. Observed defects may be due in part to the components of therapy, as opposed to intrinsic defects associated with the underlying disease. Patients with acute leukemia have been found to have lower levels of antibody to the core glycolipid of the Enterobacteriaceae than noncancer patients, and their antibody levels fall after cytotoxic therapy.[221] Theoretically, this decrease in antibody levels could contribute to an increased risk of infection with enteric gram-negative bacteria, but this has not been established. Cytotoxic chemotherapy, radiation therapy, and steroids all adversely affect B-cell as well as T-cell functions, which may result in diminished opsonizing activity, inadequate agglutination and lysis

of bacteria, and deficient neutralization of bacterial toxins. Cytotoxic therapy can blunt the humoral response to vaccine administration,[222] [223] but adequate responses have also been documented for patients in remission on maintenance chemotherapy.[224]

Role of Splenectomy and Splenic Dysfunction

Abnormalities in splenic function may be a prominent part of a number of hematologic disorders owing to either intrinsic impairment or to therapeutic or diagnostic splenectomy. Splenic dysfunction in the absence of splenectomy is crucial in patients with sickle cell disease, who lose function presumably as a result of repeated infarctions. Splenectomy can be performed either as a part of staging or as a therapeutic intervention.

The precise reason for enhanced susceptibility to infection in asplenic patients or patients with splenic dysfunction is not entirely clear. The spleen probably plays an adjunctive role in fighting infection in a number of ways. First, it appears to function as a sieve, removing organisms from the blood that have been ineffectively opsonized by complement. In addition, it participates in the primary immunoglobulin response and is involved in the regulation of the alternate complement pathway, with low levels of immunoglobulins and properdin reported in patients after splenectomy.[225] [226] A decrease in the opsonic peptide tuftsin has also been reported after splenectomy,[227] and alternate pathway defects may be important in patients with sickle cell disease and splenic dysfunction.[228]

The risk of the development of serious infection and the type of infections that develop vary somewhat, depending on the cause of the abnormal splenic function and the presence or absence of other immunologic abnormalities. For example, patients who have undergone splenectomy after trauma may be at lower risk of infection than other groups. Overwhelming infection after splenectomy occurs in 6.9% of post-splenectomy patients, with 50% of infection-related deaths occurring in the first 3 months.[229] An increased risk for *Salmonella* infection appears to be unique for the sickle cell population. In general, however, most asplenic patients or splenectomized patients are at increased risk of serious bacterial infection, primarily infection due to *S. pneumoniae* and *H. influenzae* as well as *Neisseria* spp. and *Capnocytophaga canimorsus*. The initial presentation of even overwhelming infection can be deceptively subtle, with fever often the only sign. Accordingly, all asplenic patients with underlying hematologic disease who present with fever should be managed initially as potentially septic. In addition to a detailed physical examination, the evaluation should routinely include at least two blood cultures and a urine culture, a culture of any other potentially infected site, and chest radiography. For all such patients we first give empirical intravenous antibiotics (even for those who are non-neutropenic) and continue a course of antibiotics for a minimum of 72 hours until the preantibiotic culture results are known. If the cultures are found to be negative and the patient is clinically stable, we often discontinue antibiotics and observe. We do not recommend routine prophylactic antibiotics for asplenic patients. However, most authorities do recommend penicillin prophylaxis for small children or for those with increased immune impairment from malignant disease.

Because asplenism predisposes to the development of pneumococcal infection, pneumococcal vaccine should be administered l2 weeks before elective splenectomy.[230] The rationale for this timing of vaccination is twofold. First, evidence shows that splenectomized patients respond less well to pneumococcal polysaccharides than do patients with intact splenic function.[231] However, a 1986 study in patients with Hodgkin disease showed that the antibody response to

pneumococcal vaccine was not affected by the timing of immunization relative to splenectomy.[222] Second, and perhaps more important, presplenectomy immunization can result in protective titers immediately after splenectomy. Finally, it should be remembered that, although pneumococcal vaccine is effective in these patients, it does not eliminate the risk of serious pneumococcal disease, the possibility of which should be kept in the forefront even in vaccinated patients. Because asplenic patients are at risk of infection with all encapsulated bacteria, they should also be immunized with *H. influenzae* b and the meningococcal vaccines, which can be given with pneumococcal vaccine.[232]

PROPHYLAXIS OF INFECTIONS IN HIGH-RISK PATIENTS

Prophylaxis of Bacterial Infections

With bacterial organisms accounting for most infections in compromised patients, trials designed to assess prophylactic strategies have appropriately focused on these pathogens. Strategies assessed fall into four major categories: (1) the use of mechanical techniques to prevent acquisition of new pathogens; (2) the use of various absorbable or nonabsorbable oral antibiotic regimens either to prevent acquisition or to decrease the number of potentially pathogenic colonizing organisms; (3) the use of passive or active immunization; and (4) the use of prophylactic granulocyte transfusions (Tables 79-4 and 79-5). In addition, a number of biologic agents (e.g., the CSFs) are under evaluation for the prevention of infection.

However, the single strategy that is applicable in every setting involving immunocompromised patients is hand washing. Although stressing the need for rigorous hand washing may appear somewhat trivial and seems intuitively obvious to many, its importance cannot be overemphasized, particularly in the hospital setting. Organisms of all types can be transmitted on the hands of health care workers or patients. If questioned, most health care workers avidly affirm the importance of hand

TABLE 79-4 -- Methods for Preventing Infection in High-Risk Patients

Prevent Acquisition and/or Suppress or Eliminate Microbial Flora	Methods to Improve or Modify Host Defenses
Isolation	Immunization
Simple or reverse isolation	Active
Isolation with HEPA air filtration	*Hemophilus influenzae*
Prophylactic antibiotics	*Pseudomonas*
Nonabsorbable antibiotics	*Pneumococcus*
Trimethoprim-sulfamethoxazole, erythromycin	VZV
Selective decontamination	Passive
Quinolones	J-5 core glycolipid
Prophylactic antivirals	Pooled immunoglobulins
Acyclovir	Hyperimmune globulins
Amantadine	Monoclonal antibodies
Prophylactic antifungals	Cell component replacement
Nystatin	Leukocyte transfusions
Imidazoles	Accelerate granulocyte recovery
Triazoles	Lithium
Amphotericin B	CSF-G
Prophylactic antiparasitics	CSF-GM
Thiabendazole	
Trimethoprim-sulfamethoxazole	
Combination-comprehensive	
Total protective isolation

Reducing need for hospitalization or for drugs	No	No	No	±	?

washing, yet only a few adhere to a strict policy. In one study of an intensive care unit, health care personnel washed their hands after fewer than one-half of patient contacts, and physicians specifically did so after fewer than one-third of contacts. [233] In the high-risk setting, all health care personnel should wash their hands immediately after every patient contact, no matter how brief the contact. In addition, high-risk patients (or their parents or guardians) should be instructed in the importance of hand washing and urged to remind health care workers who inadvertently forget. Physicians, nurses, and other health care workers should not be embarrassed or intimidated by gentle but firm reminders from patients or colleagues that hand washing has been overlooked.

Methods

Mechanical Techniques

A number of so-called mechanical techniques or intervention strategies to prevent infections have been assessed in granulocytopenic patients. Typical reverse isolation, after the onset of neutropenia, has no documented efficacy in preventing infection. First, colonization by potential pathogens is likely to have already occurred by the time granulocytopenia develops. In addition, requiring patients to wear a surgical mask outside of their own rooms will do little to protect against subsequent infection. Likewise, perhaps the only value to having medical personnel gown, glove, and mask before entering a patients room is to heighten their awareness of the importance of other less expensive and more effective measures, such as hand washing. [234] On mostly theoretical grounds, some authorities have recommended that all foods be thoroughly cooked and that fresh fruits or vegetables be avoided to avoid transmission of gram-negative bacteria, which can colonize raw or unprocessed food.[36] [37] However, the actual value of these measures in preventing infection is unproved.

A total protective environment is a comprehensive anti-infective regimen designed to reduce the patients endogenous microbial burden while preventing the acquisition of new organisms. A sterile environment is created in a clean-air room with constant positive air flow and is maintained by an aggressive hygiene program, including surface decontamination, sterilization of all objects that enter the room, and an intensive regimen to disinfect the patient that includes the use of oral nonabsorbable antibiotics, skin antiseptics, antibiotic sprays and ointments, and a low microbial diet. A number of studies have documented that a total protective environment can reduce infections in profoundly granulocytopenic individuals. [235] However, a total protective environment is expensive and, because of improvements in treating established infections and in shortening the duration of neutropenia, it does not offer a survival advantage to most patients. Thus, a total protective environment is not necessary for the routine care of most granulocytopenic patients.

Oral Antibiotic Regimens

The value of oral antibiotic regimens designed to protect the patient against the development of bacterial infections during the course of granulocytopenia has been subject to ongoing debate. The rationale for this approach is based on the observation that most organisms ultimately implicated in infection (particularly the gram-negative bacteria) can be isolated from the patients own flora. [3] Since the mid-1970s, numerous studies have evaluated a variety of prophylactic oral regimens. These have included nonabsorbable antibiotics (e.g., gentamicin, vancomycin, polymyxin, and colistin), [235] [236] [237] [238] [239] [240] [241] [242] as well as antibiotics absorbed from the GI tract (e.g., trimethoprim-sulfamethoxazole, erythromycin, or quinolones). [237] [243] [244] [245] [246] [247] [248] [249] [250] [251] [252] [253] [254] [255] [256] The goal of many of the earlier studies employing nonabsorbable agents was total decontamination of the alimentary tract, which met with only marginal success in the absence of strict isolation procedures. [236] The agents often tasted bad and noncompliance was a major problem, potentially leading to rebound overgrowth of pathogenic organisms. [236]

The use of trimethoprim-sulfamethoxazole and the fluoroquinolones for the prophylaxis of bacterial infections is meant primarily to result in selective decontamination of the GI tract, i.e., to eliminate the potentially pathogenic aerobic flora (mostly the enteric gram-negative bacteria) while preserving most anaerobic organisms.

Despite the voluminous literature on the subject, a final answer on the efficacy of trimethoprim-sulfamethoxazole in this setting has not been established, and debate as to its value continues. [244] [250] [257] [258] [259] Potential pitfalls associated with the use of trimethoprim-sulfamethoxazole include bone marrow suppression,

[244] [250] [257] [258] [259] the development of resistant organisms,[236] [260] rash,[261] and an increase in fungal colonization. [250]

Fluoroquinolones offer the advantage of gram-negative coverage, including coverage of *Pseudomonas aeruginosa*, with preservation of the anaerobic flora. In clinical trials of immunocompromised patients, fluoroquinolones have shown better efficacy in the prevention of gram-negative bacteremia than either placebo [261] or trimethoprim-sulfamethoxazole;[260] [262] they have also been well tolerated. However, studies have demonstrated colonization with resistant gram-negative organisms during the prophylactic use of fluoroquinolones. [263] [264] In addition, there has been an increase in gram-positive infections in patients receiving prophylactic fluoroquinolones.[16] [262] [265] [266] [267] Kotilainen et al.[266] documented a small outbreak of ciprofloxacin-resistant coagulase-negative staphylococcal infections in neutropenic patients after the introduction of ciprofloxacin prophylaxis onto their ward. In another study, Cruciani et al. [262] compared 21 children given prophylactic norfloxacin to 23 given trimethoprim-sulfamethoxazole; there were four documented streptococcal infections in those treated with norfloxacin, compared to only one gram-positive infection in the trimethoprim-sulfamethoxazole group. The multicenter Italian GIMEMA study is one of the few studies comparing the different fluoroquinolones.[264] In this study, 619 patients were randomized to receive either ciprofloxacin or norfloxacin. Although more benefits were seen with ciprofloxacin, that was true only for those patients who were severely neutropenic for <1 week. Because current information does not definitively support the use of prophylactic antimicrobial agents and because of the disastrous consequences of bacterial resistance, we do not support the routine use of prophylactic antimicrobial agents.

In the bone marrow transplant setting, fluoroquinolone prophylaxis is widely employed, particularly for those undergoing allogeneic transplantation, although there are few data to solidly support this practice. A large randomized study comparing ciprofloxacin with trimethoprim-sulfamethoxazole prophylaxis was performed in transplant patients at the Dana-Farber Cancer Center. [265] Among 145 evaluable patients there were no gram-negative bacillary infections in those receiving ciprofloxacin, versus four gram-negative infections in trimethoprim-sulfamethoxazole recipients. This difference was not statistically significant. However, of the ten documented bacteremias in patients taking ciprofloxacin, nine were due to *Streptococcus viridans*, an organism that may cause shock and adult respiratory distress syndrome in neutropenic patients. In contrast, only four patients in the trimethoprim-sulfamethoxazole group developed bacteremia due to *S. viridans*. Again, these data underscore the trend toward an increased rate of gram-positive infections in patients who receive fluoroquinolone prophylaxis.

Growth Factors and Immune Mediators

The development of cytokines in the past decade is allowing clinicians both to influence the most critical factor in susceptibility of infection and neutropenia and to manipulate the hematopoietic and immune systems. The cytokines that have been most intensively studied and widely employed are G-CSF and GM-CSF, which stimulate the proliferation and maturation of bone marrow progenitor cells. Although G-CSF and GM-CSF do not prevent neutropenia, multiple studies have demonstrated an increase in the neutrophil count and a decrease in the duration of neutropenia after their use. [268] [269] [270] [271] There are many reports of G-CSF and GM-CSF use, but these studies have used multiple doses and schedules, patients have had varied underlying malignancies and received different chemotherapeutic regimens, and few studies have been randomized or placebo controlled. Crawford et al. [269] randomized 104 patients to receive placebo and 95 patients to receive G-CSF at 230 g/m^2 /day after chemotherapy for small cell lung cancer, prior to the onset of neutropenia. Patients treated with G-CSF had a significant decrease in the number of days with a neutrophil count of <500 cellsmm^3 (3 days, compared to 6 for placebo patients) and in depth of neutropenia. G-CSF-treated patients also had significantly fewer episodes of fever and neutropenia, and the treatment group had 51% fewer culture-confirmed infections. Other advantages were a 45% reduction in days of hospitalization and a 47% decrease in days of intravenous antibiotic use for the G-CSF cohort. Other studies have shown fewer significant differences with the addition of G-CSF or GM-CSF. Accordingly, the American Society of Clinical Oncology has published guidelines for the use of cytokines, indicating that they should be employed prophylactically only if there is an expectation of a >40% incidence of febrile neutropenia. [272]

More recently (1997), a large randomized double-blind placebo-controlled trial of G-CSF in afebrile outpatients with severe chemotherapy-induced neutropenia showed that although adjunctive G-CSF significantly accelerated recovery from neutropenia, it did not result in a decreased rate of hospitalization for febrile neutropenia or in fewer documented infections.[273] Based on these data, there is no current recommendation to initiate G-CSF once a patient has developed deep neutropenia but is still afebrile. It appears that the greatest benefit of cytokine prophylaxis occurs when the CSF is started immediately after chemotherapy, when the

patients peripheral neutrophil count has not yet decreased.

A randomized double-blind placebo-controlled trial of GM-CSF was performed by Nemunaitis et al. [274] in patients with leukemia and lymphoma undergoing autologous bone marrow transplantation. Sixty-five patients were treated with GM-CSF (250 g/m^2 /day), while 63 were given placebo. The neutrophil count of GM-CSF-treated patients rose more rapidly to 500 cells/mm^3 . Although no difference was noted between the two groups in number of days with fever or percentage of patients with fever, patients receiving GM-CSF did have a decrease in number of days of antibiotic therapy and number of days of hospitalization.

Because of their stimulation of neutrophil and macrophage function, these growth factors may also have a role in the treatment of fungal infection; a study conducted by Roilides et al.[275] found that incubation of neutrophils with G-CSF in vitro produced an increase in the oxidative burst of the neutrophils in response to *C. albicans*.

G-CSF has also been demonstrated to be of benefit in patients with aplastic anemia, [276] congenital or acquired neutropenia, [277] and HIV infection.[278] However, in addition to their expense, side effects are noted with both agents. [279] Either drug can cause bone pain or an increase in hepatic transaminases. The use of G-CSF may rarely result in Sweet syndrome, while the use of GM-CSF has been more often complicated by fever, chills, hypoxia, skin rash, fluid retention, and pericarditis.

Other cytokines currently being studied include M-CSF, which stimulates macrophage and monocyte cell lines and augments the immune response to *C. albicans* in vitro. IL-1 affects the immune system at multiple levels, including the stimulation of other cytokines and increasing the number of polymorphonuclear leukocytes. [279] Animal models have shown an increase in survival in mice infected with *Pseudomonas* or *Klebsiella* and then treated with IL-1.[280] IL-3 not only stimulates all cell lines but also enhances the effect of monocytes and eosinophils. [281] IFN- enhances the activity of macrophages against intracellular organisms and protozoa and increases the activity of monocytes and PMNs against some bacteria and fungi.[279] [282] It has been shown to decrease the frequency of infection and the need for antibiotics in patients with chronic granulomatous disease.[283] These cytokines are promising agents for future use in bone marrow recovery and in the treatment of bacterial or fungal infection.

Prophylaxis of Fungal Infections

Because of the increasing incidence of invasive mycoses in immunocompromised patients, antifungal prophylaxis has been studied fairly extensively (Table 79-4). The most frequently evaluated antifungal agents have included nystatin, miconazole, clotrimazole, ketoconazole, fluconazole, and orally administered amphotericin B. Prophylactic regimens have generally been aimed at reducing invasive infections due to *Candida* spp. and by virtue of the antifungal activity of the aforementioned agents, they have a significant impact on *Aspergillus* infections or mucormycoses. Strategies designed to prevent infection by *Aspergillus* have largely concentrated on preventing its acquisition from environmental sources.

Until recently, several problems with antifungal prophylaxis were noted. First, when an adequate dose of an antifungal agent such as amphotericin B, ketoconazole, or clotrimazole was administered, there was a consistent decrease in fungal colonization but not necessarily a concomitant decrease in invasive fungal infections. [260] Second, several studies employing prophylactic and empirical antifungal regimens reported a shift in the colonization pattern of fungal organisms. In general, these drifts were toward more resistant fungi. Thus, prophylactic regimens can successfully eradicate the susceptible fungi (particularly *C. albicans*) but can lead to overgrowth and ultimately invasion by more resistant species, especially non- *albicans Candida* species. However, a double-blind randomized study of bone marrow transplant recipients reported by Goodman et al. [284] found a decrease in both fungal colonization and infection rates after antifungal prophylaxis with fluconazole. One hundred seventy-nine patients were treated with fluconazole, 400 mg/day, from initiation of chemotherapy until neutrophil counts of 1,000 cells/mm ^{3} were achieved or until drug toxicity or an invasive fungal infection was suspected. Compared with patients given placebo, fluconazole-treated patients had a significant decrease in rates of fungal colonization (67.2% vs. 29.6%), superficial fungal infection (33.3% vs. 8.4%), and systemic fungal infection (15.8% vs. 2.8%). In addition, the number of deaths due to invasive fungal disease in the fluconazole-treated group showed a significant decrease. Although the number of fluconazole-treated patients eliminated from the study because of hepatotoxicity was not significant, the mean increase in alanine aminotransferase level was significantly higher in the fluconazole-treated group. Although this study showed no significant increase in *C. krusei* infection in the fluconazole-treated group as compared with the placebo group, Wingard et al.[285] subsequently revealed a sevenfold increased risk of *C. krusei* infection after fluconazole prophylaxis in marrow transplant recipients and acute leukemia patients. During the time that Wingard et al. used fluconazole as antifungal prophylaxis, *C. krusei* became the most commonly isolated fungal pathogen in patients receiving fluconazole. The topic of antifungal prophylaxis is extensive and has been reviewed in depth elsewhere. [286]

Overall, the potential benefits of prophylactic antifungal therapy must be balanced against the toxicity and relative efficacy of the regimen employed, as well as epidemiologic considerations. Although the data are clear that antifungal prophylaxis with fluconazole reduces the frequency of disseminated candidiasis in allogeneic bone marrow transplant recipients, the use of this strategy in other populations is not recommended. Until a clear benefit can be proved, widespread chemoprophylaxis against fungi should not be attempted.

Prophylaxis of Viral Infections

Herpes Simplex Virus

HSV can be a frequent cause of morbidity in compromised patients, particularly those undergoing bone marrow or renal transplantation or intensive chemotherapy for acute leukemia. In these settings the incidence of reactivation is high (80%) in seropositive patients not receiving prophylaxis. [64] [65] [287] Higher antibody titers (1:16) appear to be most predictive of subsequent development of clinical infection. Studies employing prophylactic intravenous acyclovir [64] [65] [288] or oral acyclovir[289] [290] in these settings have demonstrated nearly 100% efficacy in the prevention of clinically significant reactivation of HSV. The placebo-controlled study by Saral and co-workers[64] in bone marrow recipients used intravenous acyclovir at a dose of 250 mgm^2 t.i.d. beginning 3 days before the transplant. None of ten patients receiving acyclovir developed HSV infection, whereas seven of ten patients receiving placebo did. In the study by Wade et al., [289] oral acyclovir (400 mg five times per day) was begun 1 week before bone marrow transplantation. Among patients who had a minimum of 40% compliance with the prescribed dose, the prophylaxis was 100% clinically effective. The study by Gluckman and colleagues [290] also showed complete clinical efficacy, but at a lower dose of oral acyclovir (200 mgm^2 q.i.d.). All the studies employing prophylactic acyclovir have demonstrated the absence of significant toxic effects in these settings.

Studies of the prevention of CMV disease with ganciclovir in recipients of allogeneic marrow transplants have also addressed the prophylaxis of HSV infection. [291] [292] In one study, high-dose acyclovir was given to patients until marrow engraftment, after which the regimen was changed to ganciclovir. [292] None of the ganciclovir recipients excreted HSV, compared to 14 of 31 controls. In the study by Winston et al., [291] ganciclovir (2.5 mg/kg t.i.d.) was begun before transplantation and continued until day 120 after transplantation but held during periods in which the neutrophil count was <1.0 × 10^9 /L. In this study, acyclovir was not given. Only 5% of ganciclovir recipients excreted HSV compared with 29% of those receiving a placebo; however, there were cases of localized, clinically evident HSV disease. No trials have been conducted to compare acyclovir versus ganciclovir in the prevention of both HSV and CMV in marrow transplant recipients. It seems prudent to use either oral or intravenous acyclovir in a prophylactic regimen for several subgroups of high-risk patients: (1) those who are seropositive (with titers of 1:16 or higher) undergoing bone marrow transplantation (on engraftment, these patients may be changed to ganciclovir if CMV positive); (2) those who are seropositive and receiving intensive therapy for acute leukemia; and (3) those with a previous clinical history of HSV infection undergoing these therapies. In addition, it is reasonable to consider prophylactic acyclovir in conjunction with cytoreductive therapy of any type if previous cycles of similar therapy have resulted in clinically significant HSV infection.

Varicella-Zoster Virus

One of the most important and simple methods of preventing VZV infection is isolation of infectious individuals from other high-risk immunosuppressed patients. Infectious patients include any with a diagnosis of either primary VZV (chickenpox) or secondary VZV (zoster). Of these groups, those with chickenpox are more highly infectious, the respiratory route being the major mode of transmission. In addition to those with diagnosed VZV infection (i.e., the presence of characteristic lesions), individuals at risk of chickenpox who have had known exposure to the virus (mostly young children) should be considered potentially infectious and kept away from susceptible immunosuppressed patients. The incubation period for chickenpox is 1021 days, and patients may spread the infection from 2 days before the appearance of lesions until the time of crusting of all lesions. Therefore, any individual who has not had chickenpox but who has been exposed should not be allowed contact with

susceptible immunosuppressed patients from 1 week after the initial exposure until at least 3 weeks after the exposure or until complete crusting of any lesions that appear.

Passive immunization with zoster immunoglobulin (ZIG) has been shown to reduce the incidence of pneumonitis and encephalitis and decrease the mortality of chickenpox from 7% to 0.5% in immunocompromised patients. Immunosuppressed children or adults who are seronegative or possess low-titer antivaricella antibody should receive ZIG (1 vial/10 kg) within 72 hours after exposure to a potentially infectious source. One dose should be protective for about 4 weeks.

A live attenuated varicella vaccine is commercially available, although it is not currently licensed for use in immunocompromised children. [293] Although 95% of normal children seroconvert after receiving the vaccine, 80% of immunosuppressed children will produce antibodies to VZV and 25% will be antibody negative at 1 year. [294] The vaccine has been shown to prevent transmission of chickenpox from normal children to children with leukemia in 85% of cases. [295] Varicella vaccine has also been given to healthy siblings of children with malignancies; of 30 children vaccinated, six contracted chickenpox and only four transmitted it to their immunocompromised siblings.[296] Despite the effectiveness of the varicella vaccine, there are still concerns about its use. Most immunocompromised patients have had their chemotherapy interrupted for 1 week before and after vaccine administration. Little data regarding the efficacy and safety of vaccine administration during chemotherapy exist. Arbeter et al.[297] compared results in 24 children who continued to receive 6-mercaptopurine while the vaccine was administrated with 20 children whose chemotherapy was suspended. Although the number of patients studied was small, there was no difference in antibody response or in vitro lymphocyte proliferation, no difference in side effects, and no difference in breakthrough infection. Approximately 40% of immunocompromised children develop a rash at the vaccine site after immunization. The child is contagious with this rash, and may require isolation and therapy with acyclovir. Additionally, rash, viremia, and elevated hepatic transaminase levels were documented in a vaccinated 4-year-old child with leukemia. [298] Because the clinical picture of varicella is milder in breakthrough infection, there is some concern that vaccine recipients may have an asymptomatic infection and may be infectious without exhibiting physical signs of varicella. The concern that VZV vaccine would increase the risk of the development of herpes zoster infection in immunocompromised patients has been dismissed by Hardy et al., who demonstrated a lower incidence of zoster in vaccinated children with leukemia (13 children with zoster of 548 vaccinated) than in children who have had natural infection (15 of 96).[299] The varicella vaccine seems better suited to providing herd immunity in the normal population than in protecting those who are immunocompromised.

Cytomegalovirus Infection

Because of the high morbidity and mortality of CMV disease, especially in recipients of marrow and solid organ transplants, attention has focused on its prevention. CMV infection develops either from exogenous sources (i.e., transfused blood or transplanted organs) or from reactivation of endogenous, latent virus. The seroprevalence of CMV is >50% in the United States, and because reactivation disease occurs in most latently infected patients, there is a large population at risk for the manifestations of CMV infection. The three preventive strategies that have been most successful in preventing CMV disease are (1) the use of seronegative blood products, (2) passive immunization with IVIG, and (3) chemoprophylaxis with acyclovir or ganciclovir.

Transplantation of bone marrow and solid organs from seronegative donors into seronegative recipients results in a markedly decreased incidence of CMV infection post-transplant. Furthermore, the sole use of seronegative blood products in seronegative recipients can virtually eliminate primary CMV infection. [78] However, blood product screening is not effective in preventing CMV infection in seronegative patients if the organ or marrow donor is seropositive. [300] The efficacy of immunoglobulin is somewhat more controversial. In a number of studies,[301] IVIG prophylactically, usually on a weekly basis, had little effect on the incidence of CMV infection (as measured by viremia or virus shedding) in CMV allogeneic marrow transplant recipients. However, two studies have shown a dramatic decrease in the incidence of CMV interstitial pneumonitis in those patients given IVIG prophylactically, despite the lack of a significant reduction in CMV infection rates. [302] [303] [304] Consequently, IVIG is generally given in the allogeneic marrow transplant setting from about 1 week prior to transplantation to approximately day 100, on a weekly or biweekly basis. It is thought that the immunoglobulin may act by reducing the incidence of GvHD. [304] Prophylactic high-dose acyclovir also appears to decrease the occurrence of CMV disease and significantly lowers patient mortality in some studies. [305] It is now widely used to prevent CMV disease as well as for HSV prophylaxis in this population, at 500 mg/m^2 every 8 hours. Ganciclovir given prophylactically can also decrease the incidence of interstitial pneumonitis, but bone marrow toxicity limits its utility.[306] The primary adverse event associated with ganciclovir use has been neutropenia. In one study, over half of the marrow transplant patients who received prophylactic ganciclovir had to have the drug interrupted owing to the development of neutropenia. Others have noted an increased rate of bacterial infection during periods of ganciclovir-induced neutropenia.

The preemptive use of ganciclovir is an interesting strategy that has been developed to specifically target ganciclovir therapy to those asymptomatic patients who are at highest risk for CMV disease following bone marrow transplantation. Seropositive post-transplant patients are screened periodically for CMV antigenemia, or for positive CMV cultures from urine, throat, or bronchoalveolar lavage washings. Ganciclovir preemptive therapy of patients with evidence of active CMV replication has been shown to prevent serious CMV disease, which decreased from 43% in patients without prophylaxis to only 3% in those who did receive preemptive ganciclovir.[307] Early ganciclovir use in a preemptive fashion was also shown to markedly decrease mortality in bone marrow transplant recipients, from 17% in untreated patients who were shedding CMV to 2.7% in treated patients. [307] However, this approach does not prevent CMV infection in the small number of patients in whom CMV reactivation is not detected until the onset of severe symptoms.

Weekly screening for CMV antigenemia through day 100 is now routine in most allogeneic bone marrow recipients. Detection of the CMV coat protein, pp65, by a specific monoclonal antibody yields a positive test, indicating active replication of CMV. A positive antigenemia test is clearly predictive for the development of CMV invasive disease and is more sensitive than routine culture because it typically becomes positive approximately 710 days before shell-vial culture detection of CMV. One problem with this approach is the tremendous variability in the performance and interpretation of the antigenemia test. Polymerase chain reaction (PCR) tests are becoming increasingly common as the assay of choice for detection of CMV replication following transplantation, and as a cue to initiate preemptive ganciclovir therapy.

Amantadine and rimantadine, antivirals with activity against influenza A virus, can prevent illness in 7090% exposed to the virus. They can also reduce the severity of symptoms if begun within the first 48 hours of influenza A illness. [308] The use of amantadine or rimantadine should be considered in persons at high risk of severe influenza infection during a

community outbreak. However, amantadine causes mild central nervous system (CNS) disturbances that may be more severe in the elderly or in those with diminished renal function. Rimantadine has slightly fewer neurologic side effects. Neither drug has activity against influenza B virus. [308]

Prophylaxis of Parasitic Infections

Strategies aimed at preventing parasitic diseases in immunosuppressed patients have primarily targeted *P. carinii* (Table 79-4). The agent studied most extensively has been trimethoprim-sulfamethoxazole, which has proved effective in preventing *P. carinii* infection in children with leukemia, in patients undergoing bone marrow transplantation, and in AIDS patients. An intermittent (i.e., two or three times weekly) dosage schedule is both effective and less toxic. [309] Although trimethoprim-sulfamethoxazole is the drug of choice for *P. carinii* prophylaxis in AIDS patients, up to 65% of adults with AIDS have adverse reactions (primarily dermatologic and hematologic) to this drug combination. [310] [311] Recent studies have shown aerosolized pentamidine to be less effective but better tolerated. [312] Dapsone may be a useful alternative in preventing *P. carinii* infection, but only small numbers of patients have been studied. [313] [314] Other agents given for prophylaxis include atovaquone, pyrimethamine with sulfadoxime, and pyrimethamine with dapsone, but data on their efficacy are limited. [311] The value of these agents in high-risk groups other than AIDS patients is only speculative at present.

Active and Passive Immunization for the Prevention of Infections in High-Risk Groups

Active Immunization

In the United States, few eligible adults are actually immunized. Shapiro et al. [315] conducted an investigation which showed that only 21% of those with an indication for the pneumococcal vaccine received it, despite the increasing incidence and severity of pneumococcal infection due to (1) the AIDS epidemic, (2) the growing

population that is >65 years of age, and (3) the increase in penicillin-resistant *S. pneumoniae*. The pneumococcal vaccine contains 23 of the serotypes responsible for >88% of pneumococcal bacteremias in the United States; however, it provides effective protection in only 61% of immunocompetent recipients and is less protective in immunocompromised hosts.[316] Despite its varying efficacy, the pneumococcal vaccine is recommended for patients who are asplenic, undergoing transplantation, have certain malignancies (Hodgkin disease, lymphoma, multiple myeloma), or are infected with HIV. [232] Another inactivated vaccine against encapsulated bacteria is the *H. influenzae* b vaccine. Although few data are available in adults, it is recommended for patients with anatomic or functional asplenia and its use should be considered in HIV-infected patients. [232] Yearly vaccination with the influenza vaccine, an inactivated viral vaccine, is recommended for those at increased risk of severe disease with influenza infection, including the elderly, persons with chronic cardiac or pulmonary disease, persons immunosuppressed through malignancy or drug therapy, and those with symptomatic HIV infection, although the protective value in severely immunocompromised patients is suboptimal.[192] [308] It is important for health care workers and family members of immunocompromised persons to receive the influenza vaccine in order to prevent transmission to those at risk of severe disease.

As a general rule, live attenuated viral or bacterial vaccines should not be administered to patients who are immunosuppressed as a result of leukemia, lymphoma, generalized malignancy, symptomatic HIV infection, or therapy with alkylating agents, antimetabolites, radiation, or large amounts of corticosteroids. [216] The only live bacterial vaccine currently available in the United States is BCG. The live viral vaccines that are available include varicella, measles, mumps, and rubella vaccines, oral poliovirus vaccine, and yellow fever vaccine. The latest recommendations of the Centers for Disease Control (CDC) state that patients with leukemia in remission whose chemotherapy has been terminated for 3 months may be given live virus vaccines. With respect to corticosteroid usage, low- to moderate-dose short-term systemic corticosteroid therapy (<2 weeks), topical steroid therapy, long-term alternate-day treatment with low to moderate doses of short-acting systemic steroids, and intra-articular, bursal, or tendon injection of corticosteroids should not be considered contraindications to live viral vaccine administration. [216] A 1989 study in bone marrow transplant recipients documented the safety and efficacy of administering measles-mumps-rubella (MMR) vaccine to patients in remission 2 years after transplantation who do not have active GvHD.[317] Live vaccines should generally be avoided in patients with HIV infection. The CDC recommends that MMR vaccine be administered to all HIV-infected children, even if they have symptomatic HIV infection, because of the recent resurgence of measles and the potential severity of measles in this population.[192] In general, varicella and oral polio vaccines should not be given to severely immunocompromised patients.

Passive Immunization

Passive immunization involves administration of preformed antibodies to high-risk patients, with the goal of either replacing qualitatively or quantitatively defective immunoglobulins or of attenuating the virulence of pathogenic organisms or their toxic components. Studies have examined the use of a variety of antibody preparations, including pooled immunoglobulins, immunoglobulins collected from individuals with high titers of specific antibodies (hyperimmune preparations), and monoclonal antibodies.

Passive immunization with VZIG is effective in preventing infection and decreasing the morbidity and mortality associated with primary chickenpox in susceptible hosts. Another hyperimmune preparation that has been investigated in high-risk patients consists of the so-called J-5 antisera collected from patients with high titers of antibody directed against the core glycolipid of Enterobacteriaceae. In a clinical trial, J-5 antiserum was not shown to reduce the mortality of neutropenic patients with gram-negative infections.[318] A randomized double-blind trial of HA-1A, a human monoclonal IgM antibody to the lipid component of endotoxin, demonstrated improved survival in patients with gram-negative bacteremia.[319] However, subsequent follow-up data showed unanticipated toxic effects in the HA-1A-treated patients, precluding its current use.

Immunoglobulin preparations with high titers against CMV have been used as adjuncts in the prevention and treatment of CMV-associated disease in bone marrow transplant recipients.[78] [301] [302] [303] [320] [321] Prophylactic CMV-enriched immunoglobulin has been shown to reduce the incidence of CMV clinical disease in renal transplant recipients by 5060%.[301] Immunoglobulin that has not been made from CMV hyperimmune plasma has also been shown to decrease CMV disease in bone marrow transplant recipients.[302]

Pooled immunoglobulin preparations have also been assessed in a number of immunocompromised populations. Both intramuscular and intravenous routes have been studied. In patients with hypo- or dysgammaglobulinemia not associated with malignancy or cytotoxic therapy, administration of pooled immunoglobulins has been effective in preventing infections due to encapsulated bacteria and in the treatment of certain enteroviral infections. [322] In patients with malignancy, the effects of immunoglobulin preparations have been less compelling, with one large randomized trial in allogeneic bone marrow transplant recipients showing a marginal benefit of IVIG in reducing bacterial sepsis.[302] A randomized placebo-controlled

trial of IVIG in patients with CLL showed that it was effective in decreasing the incidence of bacterial infections. [219] Although some early reports suggest a potential benefit of IVIG in patients with multiple myeloma, its value in this population remains controversial, and further studies will be needed before firm conclusions can be drawn.[322]

MANAGEMENT OF FEVER AND INFECTION IN NEUTROPENIC PATIENTS

Initial Evaluation of the Febrile Neutropenic Patient

The goal of the initial evaluation of a newly febrile neutropenic patient is to identify potential sources of infection in order to optimize therapy. Ideally we would like to be able to distinguish at the outset those febrile patients with an infection from those who are infection free. In a prospective study from the NCI evaluating >1,000 consecutive episodes of fever and neutropenia, there were no features identified on presentation that reliably distinguished bacteremic patients from those with unexplained fever.[323] Physical examination was helpful only if a specific site of infection (e.g., cellulitis or abscess) was readily detectable. Other measurements that might be predictive in noncompromised patients, including the degree of fever, the presence of chills or rigors, or a toxic appearance, were not helpful in this population. Indeed, significant and potentially life-threatening bacteremias were not infrequently present, even in the absence of any symptoms or signs on physical examination. Of the patients with proven bacteremia, 55% had no evidence of infection on physical examination aside from fever.

For neutropenic patients with a new fever, the standard initial evaluation should include the following:

1. *Careful physical examination*. Particular attention should be devoted to areas that may hide a site of infection unless closely examined, notably the oral cavity and the perianal area. There is some debate as to whether neutropenic patients should have an initial rectal examination because manipulation in this area may lead to bacteremia. It is our policy to first perform a complete external examination of the perirectal area, including deep palpation. Then, only if there are findings suggestive of a localized inflammatory site (e.g., pain or fluctuance) do we perform a careful digital examination. We have found that virtually all perianal or perirectal sites of infection can be detected with this approach.
2. *Blood cultures*. A minimum of two sets of blood samples should be obtained for cultures. If the patient has an indwelling intravenous catheter, at least one set should be drawn through the catheter and another drawn from a peripheral vein. For patients with multilumen intravenous catheters, a sample should be drawn through each lumen, as well as from the specific lumen clearly identified on the culture bottle. This is important because catheter infection may be limited to a single lumen. It must be emphasized that a peripheral culture is essential in addition to catheter cultures, in order to make the diagnosis of a catheter infection.
3. *Urine culture*. Because of the absence of granulocytes, microscopic examination of the urine may be normal even in the presence of a urinary tract infection. Nonetheless, a urine culture should be performed, and the urine may be considered a source of infection in the neutropenic patient even if pure growth is <10 [5] of a single organism.
4. *Chest radiography*.
5. In addition, accessible sites of potential infection should be aspirated or biopsied and appropriate material sent for Gram stain, culture, and histologic examination. Other diagnostic tests directed at certain sites, such as cranial computed tomography (CT) or lumbar puncture, should be reserved for patients who have symptoms or signs referable to those areas.

Even with a comprehensive evaluation, an infectious cause of the initial fever is demonstrated in only 3050% of patients. Moreover, the definitive diagnosis may take days, presumably because of the relatively low microbial inoculum. This probably reflects the short period that elapses between the onset of fever and the evaluation and initiation of empirical therapy. Even subtle inflammation must be considered as indicating a site of infection in the presence of granulocytopenia. For example, minimal perirectal erythema and tenderness may be the harbinger of a perirectal cellulitis. Minimal erythema or discharge at the exit site of an indwelling intravenous catheter may signal a tunnel or exit-site infection.

Colonization with microorganisms often precedes the development of significant infection. Logic has dictated that identification of a specific pathogen during the colonization phase might help guide the clinician toward earlier use of appropriate antimicrobial therapy at the first signs of infection. Accordingly, some investigators have recommended routine serial surveillance culturing in neutropenic patients. To evaluate the clinical value of this concept, an NCI study of 652 febrile granulocytopenic episodes was conducted.[45] Nose, throat, urine, and stool specimens were cultured serially during the neutropenic episode. Of those patients who became septic and from whose blood a specific causative pathogen was isolated, 62% were found to be colonized with the infecting organism. However, the results of the surveillance cultures provided little clinically useful information, for the following reasons: (1) no single body site was predictive; (2) other potential pathogens were usually isolated in addition to the organism responsible for infection; and (3) the actual pathogens isolated from the blood cultures were usually known prior to their isolation from the surveillance cultures. Furthermore, the cost of routine surveillance is enormous, and knowledge of the colonizing flora is unlikely to have a significant impact on initial antibiotic management, because most clinicians routinely employ broad-spectrum antibiotics for the empirical treatment of febrile granulocytopenic patients. For these reasons, we do not recommend routine surveillance cultures in neutropenic patients. They can be helpful, however, in certain subgroups of patients, such as those with protracted neutropenia (>34 weeks) and those treated at centers that have a high incidence of particularly virulent or resistant organisms, such as *P. aeruginosa* or *Aspergillus* spp.

Antibiotic Strategies

Empirical Antibiotics

The management of neutropenic cancer patients as compared with nonimmunocompromised patients more frequently involves the empirical use of antibiotics directed against a wide array of potential pathogens. It is now well accepted that when a neutropenic patient develops a new fever (fever is usually defined as one oral temperature reading of 38.8°C or two successive readings of 38°C during a 4-hour period), an empirical antibacterial regimen should be started expeditiously. This holds true even in patients with no clinically evident source of infection. The rationale for this approach evolved from the observation that bacteremias in neutropenic patients are often rapidly lethal, especially those due to gram-negative organisms. [5] [324] [325] [326] [327] A delay of even 2448 hours for the results of initial blood cultures to become available can substantially increase morbidity and mortality. In addition, no reliable way has been found to determine whether an isolated fever in a neutropenic patient is due to an underlying infection. Within that context, even fevers that are temporally associated with the administration of blood products or with fever-producing antineoplastic drugs should be considered potentially infectious in origin and treated as such. In sum, virtually all new fevers in the neutropenic population warrant careful clinical and microbiologic

Box 79-1. APPROACH TO THE NEUTROPENIC PATIENT WITH FEVER AND INFECTION

We define clinically relevant neutropenia as <500 polymorphonuclear leukocytes and band forms per microliter or any count that is falling and expected to be <500 l within 24 hours. Any fever in this population should be interpreted as potentially indicating serious infection (including fevers following administration of blood products). Conversely, even in the absence of fever, any subtle indication of infection should be considered potentially serious and treated as such. Fever is defined as one oral temperature reading >38.5°C or more than two successive readings of >38°C in a 12-hour period.

Routine workup should include a complete history and physical examination, with particular attention directed toward sites that may hide infection, such as the mouth and perirectal area. At least two sets of blood samples should be obtained (including one from a peripheral vein) for culture, with samples drawn through each lumen of any multilumen intravenous access device. A urine sample for culture and a chest radiograph should be obtained. Further workup is determined by the patients clinical presentation.

Empirical antibacterial therapy should be administered to all neutropenic patients with fever of new onset or clinical evidence of infection even in the absence of fever. There is no single best regimen; however, there are many inappropriate regimens. At a minimum, regimens should have broad-spectrum activity against gram-positive and gram-negative organisms (including *P. aeruginosa*). Aminoglycosides or extended-spectrum penicillins (e.g., ticarcillin, mezlocillin, piperacillin, azlocillin) should never be used as single agents or as the only agents with anti-gram-negative activity.

For most patients, we initiate single-agent empirical therapy (monotherapy). Of the antibiotics that are potentially useful for monotherapy, ceftazidime has been studied most extensively and has the longest track record of efficacy. The development of resistance to these agents, although not reported frequently, must be monitored if they are used alone. Imipenem appears to be equally efficacious but is often associated with intolerance or toxic effects. Nausea and vomiting with higher doses and seizures in susceptible patients have been reported. Cefepime is also effective.

The monobactam aztreonam is useful for patients with significant -lactam allergies who still require the use of an antipseudomonal antibiotic in addition to an aminoglycoside. Accordingly, for patients with significant -lactam allergies who present with fever and neutropenia, we begin a combination of aztreonam plus an aminoglycoside plus vancomycin. Further study is warranted to see if aztreonam can suffice as the only anti-gram-negative component of empirical regimens (thus avoiding the use of an aminoglycoside).

Because the incidence of infection due to gram-positive organisms is increasing, the question of whether vancomycin should be included in the initial empirical regimen has been the subject of considerable debate. Because of the emerging resistance to vancomycin and the relatively lower morbidity with a number of gram-positive organisms, empirical vancomycin is not recommended for routine use.

For certain patients who present with a defined site of infection, the standard regimen should be individually modified. For example, for a neutropenic patient presenting with a perirectal abscess, coverage might be extended to include an antianaerobic agent (e.g., metronidazole or clindamycin) as well as an agent active against enterococci. For a neutropenic patient with Hickman catheter exit site infection, vancomycin might be added to extend gram-positive coverage.

For most neutropenic patients who present with fever, a microbiologically or clinically documented infectious source is not identified (i.e., they have unexplained fever). For this group we prefer to continue empirical antibiotics until the neutropenia resolves. However, this is not always practical, especially for those with prolonged neutropenia. Therefore, for persistently neutropenic patients with unexplained fever who undergo defervescence and remain afebrile from days 7 to 14 (i.e., they do not need empirical amphotericin B or other modifications), we discontinue antibiotics on day 14 and carefully observe. Depending on the amount of additional time they remain neutropenic, a substantial number may experience recrudescence and require prompt resumption of empirical therapy. In patients with hematologic evidence of recovery, antibiotics can be discontinued sooner.

For patients who present with a documented infection, we continue therapy for a minimum of 1014 days, even if the granulocytopenia resolves before this time. If the infection has been identified microbiologically, we switch to narrow-spectrum therapy or oral therapy to complete the course at the resolution of granulocytopenia.

Common modifications in antibacterial regimens include changes in gram-negative coverage for potentially resistant organisms and the addition of intravenous vancomycin for improved gram-positive coverage or of oral vancomycin for *C. difficile*, and the addition of clindamycin or metronidazole to improve anaerobic coverage.

For patients with a persistent or new fever after >17 days of empirical antibacterial therapy, we begin empirical amphotericin B and continue it along with the antibacterial agents until the neutropenia resolves. Following an initial test dose of 1 mg given over 1 hour, we proceed directly to 0.5 mg/kg/day (without dose escalation). Adequate hydration and diuresis (saliuresis) are important in limiting the resultant azotemia. However, patients needing long courses of amphotericin B will invariably have some rise in BUN and creatinine levels, which usually stabilize.

Acyclovir is the most common antiviral agent added to regimens for neutropenic patients and may be directed toward HSV or VZV. Ganciclovir provides activity for the treatment or prevention of CMV. Trimethoprim-sulfamethoxazole is the most common antiparasitic agent added, with activity directed primarily against *P. carinii*.

Although gram-positive organisms will cause most infections associated with central venous catheters, gram-negative organisms are not infrequently encountered. Neutropenic patients who present with even a mild exit-site infection should receive broad-spectrum coverage directed at gram-positive and gram-negative organisms, including *P. aeruginosa*.

More than 90% of catheter-related bacteremias can be successfully treated with antibiotics alone without the need for catheter removal. Initial specimens for culture should be drawn through all lumina or any multilumen device, and antibiotic administration should be rotated among the ports. Persistently positive cultures or the progression of infection after 2448 hours of appropriate antibiotics mandates prompt catheter removal. Other indications for initial catheter removal are infection caused by *Bacillus* spp. or *Corynebacterium jeikeium*, any tunnel infection (extending to >2 cm from the exit site), and candidemia.

evaluation, followed by prompt initiation of empirical antibiotic therapy. Conversely, any clinically evident site of potential infection mandates expeditious broad-spectrum therapy, even in the absence of fever.

The goal of empirical antibiotic therapy is to protect against the early morbidity and mortality that result from untreated bacterial infections. Accordingly, regimens have been formulated to maximize activity against organisms that are commonly encountered or particularly virulent. One must remember that empirical regimens cannot realistically be designed to cover every potential bacterial pathogen. Likewise, no regimen is capable of completely eliminating the risk of subsequent development of infections in persistently neutropenic patients. Empirical antibiotic regimens should be individualized at each institution to cover organisms seen at

that hospital and to cover organisms associated with certain chemotherapeutic regimens.

Traditionally, gram-negative bacteria have been the most frequently isolated pathogens in the neutropenic population, with *E. coli*, *K. pneumoniae*, and *P. aeruginosa* the most common. Although gram-negative bacteria may still predominate at some institutions, the trend in the past 20 years has been toward more gram-positive infections, which now account for most isolates at many centers.[8] [10] [119] [328] [329] [330] [331] [332] [333] In general, gram-negative infections tend to be more virulent; early empirical regimens were formulated to provide protection primarily from these organisms while maintaining a broad spectrum of activity against other potential pathogens. Indeed, adequate coverage of these gram-negative organisms is still an essential property of any empirical regimen (Table 79-6).

In order to achieve the desired properties of empirical therapy, it has been necessary to employ combinations of antibiotics. Early experience combining aminoglycosides and an expanded-spectrum penicillin such as carbenicillin resulted in an improved clinical outcome.[334] This combination appeared to obviate both the poor clinical efficacy of aminoglycosides when used alone and the emergence of resistance to the expanded-spectrum penicillins often encountered when used as single agents. In addition, a body of in vitro data emerged showing a synergistic effect of such combinations against the gram-negative bacilli, particularly *P. aeruginosa*.[211] [335] [336] [337] [338] [339] [340] [341] [342] [343] [344] Such combination regimens are still widely used and represent a standard against which newer regimens are tested.

Many variations of the initial gentamicin-carbenicillin combination have been studied (Table 79-7). These consist of an aminoglycoside at the core, usually in combination with an extended-spectrum (or antipseudomonal) penicillin and often with an antistaphylococcal -lactam antibiotic (e.g., nafcillin or a first-generation cephalosporin). Third-generation cephalosporins can also be combined with aminoglycosides, provided that the third-generation cephalosporin has good antipseudomonal activity (e.g., ceftazidime or cefoperazone).[345] In general, no specific combination has been shown to have consistently superior efficacy. If an aminoglycoside-containing combination regimen is to be employed, the choice of specific antibiotics should be based primarily on the institutions antibiotic sensitivity patterns and secondarily on toxicity and cost differences.

In order to avoid the use of aminoglycosides yet retain the theoretical advantages of combination antibiotics, various non-aminoglycoside-containing combination regimens have been devised and studied. For the most part these have consisted of combinations of two -lactam antibiotics (so-called double -lactam regimens), usually consisting of an expanded-spectrum carboxy- or ureidopenicillin and a third-generation cephalosporin (e.g., piperacillin and ceftazidime).[346] [347] Although double -lactam combinations may offer some of the potential advantages of other combinations, they also have some of the inherent disadvantages of any combination regimen (see later). In addition, increased -lactamase induction is a theoretical disadvantage when certain of these agents are combined (thus accelerating the development of resistant organisms).[347]

Single-agent coverage with an aminoglycoside or an extended-spectrum penicillin is not a viable option because of the rapid emergence of pathogens when either of these agents are used alone. The combination of an aminoglycoside and a -lactam antibiotic has demonstrable efficacy, but in the past decade, a number of potent cephalosporins and carbapenems have been developed that offer the option of effective antibiotic monotherapy for the febrile neutropenic patient. Ceftazidime has been the most extensively studied of the third-generation cephalosporins; most other agents in this class exhibit inadequate activity against *P. aeruginosa* for use as monotherapy (*P. aeruginosa* is among the most virulent of the gram-negative organisms).[348] [349] Cefoperazone also has activity against *P. aeruginosa*, but its clinical value in this setting has not been as extensively evaluated. In the carbapenem class, imipenem and meropenem are the currently available agents; several trials support the efficacy of both drugs as monotherapy.[350] [351] [352]

Ceftazidime has a broad spectrum of activity that encompasses the vast majority of bacterial pathogens encountered in neutropenic hosts, including *P. aeruginosa* (Table 79-8). Standard dosing results in serum and tissue levels that are bactericidal for these organisms, and the toxicity profile is similar to that of most -lactams.

TABLE 79-7 -- Aminoglycoside-Based Combination Regimens

Aminoglycoside +	Antipseudomonal -Lactam ±	Additional Anti-Gram-Positive
Gentamicin Tobramycin Amikacin	Extended-spectrum penicillin Carbenicillin Ticarcillin Azlocillin Mezlocillin Piperacillin OR Third-generation cephalosporin Ceftazidime Cefoperazone OR Aztreonam	Isoxozolyl-penicillin Nafcillin Oxacillin OR First-generation cephalosporin Cephalothin Cefazolin OR Vancomycin

TABLE 79-8 -- Activity of Newer Antibiotics Against Pathogens Commonly Encountered in Cancer Patients

Antibiotic	Enteric Gram-Negative	*P. aeruginosa*	Coagulase-Positive Staphylococci	Coagulase-Negative Staphylococci	Enterococci	Streptococci	Anaerobes
Ceftazidime	Good	Good	Moderate (poor against methicillin-resistant strains)	Poor against the majority (most are methicillin-resistant)	Poor	Good	Poor
Cefepime	Good	Moderate to good	Moderate (poor against methicillin-resistant strains)	Poor against the majority	Poor	Good	Poor
Other third-generation cephalosporins	Good	Poor to moderate	Moderate (poor against methicillin-resistant strains)	Poor against the majority	Poor	Good	Poor to moderate (moxalactam and ceftizoxime have some activity)
Imipenem	Good	Good	Good (poor against methicillin-resistant strains)	Poor against the majority	Good	Good	Good
Quinolones	Good	Good	Good (including some methicillin-resistant strains)	Good (limited clinical experience)	Poor to moderate	Poor to moderate	Poor
Aztreonam	Good	Good	Poor	Poor	Poor	Poor	Poor

A large randomized study evaluating 550 consecutive episodes of fever and neutropenia conducted at the NCI compared a combination of antibiotics (i.e., cephalothin, gentamicin, and carbenicillin) with ceftazidime as a single agent.[349] The overall results showed that monotherapy compared favorably with a standard combination regimen (Table 79-9 (Table Not Available)). Approximately two-thirds of the episodes in both groups were successfully treated for the entire duration of the granulocytopenia without requiring any changes in the initial regimen. Another one-third of the episodes required some change or modification (e.g., addition of an antibacterial, antifungal, or antiviral drug) to ensure a successful outcome (Table 79-10) (see also discussion under Modifications of Antibiotic Therapy During the

Course of Granulocytopenia), and an equally low number in both groups (5%) died of infection. None of the deaths was attributable to

TABLE 79-9 -- Outcome of 550 Febrile Neutropenic Episodes Randomized to Monotherapy or to Combination Antibiotic Therapy

(Not Available)

Modified from Pizzo et al.,[323] with permission.

a specific deficiency in one regimen that was not present in the other (i.e., an organism sensitive to one regimen but resistant to the other). In addition, the average time to initial defervescence was equivalent for those receiving monotherapy and those treated with combination antibiotics.

Two subgroups of patients identified in this study appeared to need more frequent modifications of the initial regimen in order to achieve a successful outcome: (1) those presenting with a documented source of infection to account for the initial fever, and (2) those having relatively protracted periods of granulocytopenia (>1 week). However, the need for modification in these subgroups was identical for those episodes treated with monotherapy and those treated with combination therapy. In this study, these modifications did not represent a failure of either regimen per se but instead reflected the limitations of any regimen in treating patients at high risk for the development of subsequent infections.

In a 1991 review of 12 randomized, controlled trials comparing ceftazidime as single-agent therapy for febrile, neutropenic patients with combination therapy, Sanders et al.[353] studied 1,077 episodes of fever and neutropenia and 248 episodes of bacteremia. In this meta-analysis, no advantage of combination therapy over monotherapy with ceftazidime could be detected.

Cefepime is a new extended-spectrum cephalosporin with excellent activity against gram-negative and gram-positive bacteria. It is comparable in efficacy to ceftazidime against *P. aeruginosa* but it has greater stability against degradation by certain -lactamases, particularly those produced by *Enterobacter* and *Serratia* spp. Additionally, it has better in vitro activity than ceftazidime against gram-positive organisms such as methicillin-sensitive staphylococci and viridans streptococci. Despite its improved antimicrobial profile, cefepime was found to be equivalent to either ceftazidime monotherapy or the combination of piperacillin plus gentamicin for the empirical coverage of febrile neutropenia in cancer patients. [353A] In a randomized study, 109 patients received cefepime and 107 received either of the comparator regimens. In 75% of febrile episodes, patients

TABLE 79-10 -- Modifications of Therapy During the Course of Granulocytopenia

Clinical Event	Possible Modifications of Therapy
Breakthrough bacteremia	If gram-positive isolate (e.g., *S. epidermidis*), add vancomycin If gram-negative isolate (i.e., presumably resistant), switch to regimen containing non-cross-resistant antibiotics (e.g., aminoglycoside plus a carbapenem or extended-spectrum penicillin)
Catheter-associated infection	Add vancomycin (as well as gram-negative coverage if not already being given)
Severe oral mucositis or necrotizing gingivitis	Add specific antianaerobic agent (e.g., clindamycin or metronidazole) or change to antibiotic with improved anaerobic coverage (e.g., imipenem)
Esophagitis	Trial of oral clotrimazole, fluconazole, IV amphotericin B, or acyclovir
Pneumonitis, diffuse or interstitial	Trial of trimethoprim-sulfamethoxazole and erythromycin (plus broad-spectrum antibiotics, if patient is granulocytopenic)
New infiltrate in a granulocytopenic patient also receiving antibiotics	If granulocyte count is rising, watch and wait If granulocyte count is not recovering, biopsy to establish diagnosis, add amphotericin B empirically
Perianal tenderness	If patient is already receiving broad-spectrum antibiotics, add a specific antianaerobic agent If patient is not on antibiotics, begin broad-spectrum therapy with anaerobic coverage
Persistent fever and neutropenia	Continue antibiotics after 1 week of persistent fever and neutropenia; add systemic antifungal therapy empirically

had a satisfactory response at the completion of therapy and eradication rates were similar for all pathogens treated by the three regimens. In an era of increasing antibiotic resistance, however, cefepime may assume a more important role in populations in whom -lactamase-producing gram-negative rods are a particular problem.

Imipenem is a member of the carbapenem class of antibiotics and offers another option for empirical monotherapy. Overall it has the broadest spectrum of activity of any available antibiotic (Table 79-8). Of note is its good in vitro activity against many enterococci, staphylococci, and many anaerobes, in addition to its excellent gram-negative activity. A large randomized study from the NCI compared monotherapy with ceftazidime to monotherapy with imipenem.[350] Both drugs showed success without modification in slightly >60% of episodes of fever without a known source. In patients with a documented infection, the majority of patients in both groups required antibiotic changes or additions. Among those receiving imipenem, 70% needed antibiotic modification, while 83% of those receiving ceftazidime needed a change in antibiotics. Often the anaerobic coverage was added to the regimen of patients on ceftazidime. However, more side effects were seen in patients on imipenem, most notably nausea (21% vs 3% in ceftazidime recipients) and *C. difficile* colitis (11% vs 4% in ceftazidime recipients). In addition, imipenem could not be used in patients with brain tumors or with a decreased creatinine clearance rate because of the increased risk of seizures. [354]

Several authorities have raised concerns regarding the use of single-agent therapy for fever and neutropenia. Some of these concerns are purely theoretical; others are based on unique experiences limited to specific centers. However, these issues underscore the appropriateness of maintaining a flexible approach with regard to selection of an empirical regimen, which should be based on individual and institutional experience. Also, regardless of the specific regimen chosen, the clinician must be acutely aware of the potential need for changes in that regimen during the course of granulocytopenia (Table 79-10). This mandates frequent and meticulous clinical evaluation by an experienced supportive care team.

During the late 1980s, gram-positive organisms re-emerged as the most frequently encountered isolates at many centers. [331] [332] [333] Although the precise reason for this shift is unclear, it is evident that many of these gram-positive bacteria (e.g., the enterococci and the coagulase-negative staphylococci) are either resistant to, or poorly covered by, most standard empirical regimens. Some authorities have therefore recommended the addition of vancomycin to empirical regimens. Conversely, it has been argued that because many of these organisms are of relatively low virulence and are often inhibited by the antibiotics (even suboptimal antibiotics), vancomycin may be safely withheld until the gram-positive isolate has been identified microbiologically.

In a randomized study of a vancomycin-containing versus a non-vancomycin-containing regimen conducted by Karp et al., [119] the incidence of secondary gram-positive infections was reduced in the vancomycin-containing group. However, no difference in morbidity was related to gram-positive infections between the two groups, and all the gram-positive infections in the non-vancomycin-treated group were successfully treated by its addition after the organism had been identified and reported by the microbiology laboratory. There also appeared to be less need for amphotericin B in the group that did not receive vancomycin initially. Subsequently, a study conducted by the European Organization for Research and Treatment of Cancer (EORTC) looked at results in 747 patients who were randomly assigned to receive ceftazidime and amikacin or ceftazidime, amikacin, and vancomycin.[355] No difference was found in the number of febrile days between the two groups. The group receiving ceftazidime and amikacin did need more antimicrobial modifications, most commonly the addition of vancomycin, but the group receiving the vancomycin-containing regimen required the addition of antifungal therapy more frequently than those without vancomycin in the initial regimen. Notably, no deaths due to gram-positive infection occurred in the first 3 days of therapy, regardless of the antibiotic regimen.

In addition, a retrospective analysis from the NCI indicated that no excess morbidity resulted when the institution of vancomycin was delayed by waiting for either a microbiologic or clinical indication for its use (i.e., a positive culture for a resistant gram-positive organism or a clinical infection developing in the presence of other antibiotics).[8] All the primary infections with gram-positive isolates (from cultures done before the empirical institution of therapy) and 82% of the secondary infections with gram-positive isolates (from cultures done after the institution of antibiotics) were treated successfully with this pathogen-directed approach. These data strongly

support the practice of not including vancomycin in the initial empirical regimen. However, the most compelling reason to avoid routine vancomycin use is the emergence of vancomycin-resistant enterococci (VRE) in recent years. Between 1989, when VRE were first identified in the United States, and 1993 there was a 20-fold rise in the proportion of nosocomial isolates of enterococci showing resistance to vancomycin. [356] The severe infections that are caused by VRE frequently occur in patients with cancer, and there is an attributable mortality of nearly 40% due to VRE bacteremia in this population. [357] Because the emergence and spread of VRE in hospitals are related to the use and overuse of vancomycin, the CDC has published guidelines for prudent vancomycin

use. Specifically, these guidelines indicate that vancomycin should not be used for empirical antimicrobial therapy for febrile neutropenia and should not be used prophylactically to prevent indwelling catheter infections. [358]

The development of newer broad-spectrum antibiotics has expanded the available options for the empirical treatment of fever and neutropenia; both aztreonam and ciprofloxacin are useful additions to the antibiotic armamentarium. Aztreonam, a monobactam active against gram-negative aerobes, including *P. aeruginosa*, should not be used as monotherapy because of its limited spectrum. At the NCI, aztreonam is used in combination with vancomycin in patients with allergies to -lactam antibiotics. Ciprofloxacin, the most commonly used quinolone, has a distinctive mechanism of action: inhibition of bacterial DNA gyrase. Its spectrum of activity includes some staphylococci and gram-negative organisms, including multiply resistant *P. aeruginosa*, *Enterobacter*, *Serratia*, and *Klebsiella*. However, it has poor streptococcal coverage and is inactive against anaerobes. The use of ciprofloxacin as monotherapy for fever and neutropenia has been complicated by an increase in breakthrough bacteremias with streptococci. [359] [360] Although ciprofloxacin can be combined with vancomycin or a penicillin as empirical therapy, we prefer to reserve its use for multiply resistant gram-negative infections.

Approach to the Low-risk Patient with Fever and Neutropenia

The excellent bioavailability and broad spectrum of the oral fluoroquinolones, particularly ciprofloxacin and ofloxacin, make them attractive for use in the management of low-risk patients with fever and neutropenia. Low-risk patients may be defined as those who have fever in the setting of an anticipated short duration of neutropenia (e.g., <10 days) and no medical comorbid conditions (e.g., hypotension, abdominal pain, vomiting, mental status changes, respiratory compromise) on presentation. To explore the use of oral antibiotic therapy, Rubenstein et al. randomized 83 episodes of low-risk febrile neutropenia to treatment with either oral ciprofloxacin plus clindamycin or intravenous therapy consisting of aztreonam plus clindamycin, with both regimens administered in an outpatient setting. [361] Overall responses were good in both groups, with no mortality. All therapy was accomplished in the outpatient setting, following a 24- to 36-hour initial treatment and observation period in the clinic. However, six patients in the oral regimen cohort were readmitted for persistent fever or for nephrotoxicity that appeared to be associated with ciprofloxacin use in dehydrated patients. This study was relatively small and did not include a comparison group managed as inpatients, but it does suggest that outpatient therapy is a feasible alternative for low-risk patients with febrile neutropenia.

In a larger study performed in Pakistan (n = 122 patients), Malik et al. found that ofloxacin monotherapy, 400 mg given orally every 12 hours, appeared to be comparable in efficacy to combination parental antibiotics for the management of low-risk fever and neutropenia in adults. There were no differences in rates of successful therapy, either with or without modifications of the initial regimen, between the two treatment groups. The overall success rate for patients in each cohort was 75%. [362] Significantly lower response rates were seen in both groups in patients with prolonged and profound neutropenia, and in those with documented infections compared to those with fever of unknown origin. Two *P. aeruginosa* bacteremias were treated with ofloxacin in this trial, although the outcomes were not specifically reported. As the antimicrobial activity of ofloxacin is less potent than that of ciprofloxacin against *P. aeruginosa*, ofloxacin is theoretically less reliable for empirical therapy in cancer centers where this organism is more prevalent. However, ofloxacin may be more potent than ciprofloxacin against *S. aureus* and less prone to breakthrough drug-resistant isolates. These features may amount to an overall benefit as gram-positive organisms are increasingly isolated in the setting of febrile neutropenia. The same investigators also reported a prospective, randomized trial comparing inpatient and outpatient management of low-risk patients with fever and neutropenia with oral ofloxacin. [363] There were no differences in overall outcome, and most patients were treated without modifications of the empirically employed oral fluoroquinolone. However, 21% of those originally assigned to outpatient therapy were readmitted for persistent fever or unresolved infection. Mortality was very low and was comparable in both groups (2% for inpatients vs 4% for outpatients). However, a single early death in an outpatient who developed vomiting and difficulty with oral intake and who subsequently refused to be admitted to the hospital emphasizes the need for good patient compliance as well as close patient contact and strict vigilance by health care workers when treating even low-risk patients outside of the hospital setting.

The importance of these studies was the demonstration of efficacy, excellent tolerability, decreased expense, and low toxicity of oral fluoroquinolone therapy when compared with parental combination antibiotics for the management of fever and neutropenia in low-risk patients. At the NCI, we have paired oral ciprofloxacin with amoxicillin/clavulanate in a double-blind randomized comparison of this oral combination with intravenous ceftazidime monotherapy among low-risk febrile neutropenic inpatients. We have found no difference in overall efficacy between the oral regimen and intravenous ceftazidime in patients hospitalized with fever and short-duration (<10 days) neutropenia (unpublished observations). The use of oral empirical antibiotic therapy in the outpatient setting is becoming more acceptable for low-risk patients. However, patients must be monitored frequently in the outpatient setting and be taught to return to the hospital when any signs of decompensation emerge.

Approach to the Patient with Prolonged Granulocytopenia

Length of Antibiotic Therapy

A question of practical importance is the length of time antibiotics should be continued in persistently neutropenic patients. Should they always be continued until the granulocyte count recovers, or can they be safely discontinued before that time? Our overall approach is illustrated in Figure 79-2 .

Operationally, it is easiest to approach the question of duration of therapy by placing patients in two categories: (1) those whose initial workup did not reveal the source of infection (i.e., patients with fever of undetermined origin), and (2) those whose initial workup revealed a documented infection to account for the fever. Most patients (60%) at most centers will fall into the former category, although this will vary with the institution, therapy, and patient population.

Limited data specifically address the issue of duration of empirical therapy in neutropenic patients presenting with fever of undetermined origin. In a randomized NCI study, patients with fever of undetermined origin and persistent granulocytopenia were assigned either to discontinue antibiotics on day 7 of therapy or to continue them until the resolution of the neutropenia (Table 79-11). [364] A large percentage of afebrile patients who stopped taking antibiotics developed recurrent fever, and an alarmingly high percentage of persistently febrile patients whose antibiotics were discontinued had hypotensive episodes. It was concluded that day 7 was too early to discontinue antibiotics in this group.

In a subsequent randomized study conducted at the NCI, persistently neutropenic afebrile patients were assigned either to continue or to discontinue antibiotics on day 14. Analysis

Figure 79-2 Algorithm for antibiotic management in febrile neutropenic patients. F+ N+, febrile, neutropenic; F N+, afebrile, neutropenic; FUO, no source of fever on preantibiotic evaluation; AMPHO B, amphotericin B.

TABLE 79-11 -- Outcome of Patients with Unexplained Fever Who Were Randomized Either to Continue or to Discontinue Empirical Antibiotics When They Remained Persistently Granulocytopenic

	Continue Antibiotics		Discontinue Antibiotics	
	F G+ (%)	F+ G+ (%)	F G+ (%)	F+ G+ (%)
Remained afebrile or improved	100	62	59	44
Became febrile or worsened	0	38	41	56
Became hypotensive	0	0	12	38

Abbreviations: F, reduction of fever; G+, granulocytopenia; F+, continuation of fever.

showed no difference between the two groups; approximately one-third of patients became febrile again, regardless of whether they stopped or continued taking antibiotics. However, those whose fevers recurred after discontinuation of antibiotics responded to a re-institution of their initial regimen, while those remaining on antibiotics required the addition of amphotericin B. Currently, for patients with fever of unknown origin who are predicted to have a long duration of neutropenia and who have remained afebrile at day 14, we discontinue antibiotics and cautiously observe. Additional studies have suggested that antibiotics can also be safely discontinued in afebrile patients who have evidence of bone marrow recovery, even though their neutrophil count is still <500 cells/mm ^{3} . [365] [366]

In addition, for persistently neutropenic patients who have had clinical and microbiologic resolution of their infection and who are afebrile at day 14 we consider discontinuing antibiotics. The final decision as to whether to continue or discontinue antibiotics rests on a number of clinical parameters, such as the degree of or potential for antibiotic toxicity, the predicted duration of neutropenia, the seriousness of the initial infection, and the presence or absence of other factors predisposing to subsequent infection. It should be emphasized that any neutropenic patient whose antibiotics are discontinued requires meticulous follow-up evaluation so that any new fevers or infection can be quickly detected.

Modifications of Antibiotic Therapy During the Course of Granulocytopenia

Empirical antibiotics have their greatest impact early in the course of neutropenia. It is during these early days, after the initial febrile episode and before results of the initial cultures are known, that the antibiotic regimen is truly empirical. One must not assume that the efficacy of an empirical regimen implies that it will suffice as the sole antimicrobial therapy throughout a protracted course of neutropenia. Indeed, it is during a prolonged granulocytopenic episode that the patient is at highest risk for multiple types of secondary infections or superinfections, as well as for changing clinical parameters, many of which dictate specific types of modifications of the initial regimen to ensure a successful outcome. Only a few secondary infections actually represent a true failure of the initial antibiotic regimen. Rather, they should be viewed as part of the natural history of most patients with prolonged neutropenia, and the need for modifications of the initial regimen should be expected and planned for.

Modifications for Resistant Bacterial Isolates.

Bacterial isolates resistant to the initial empirical regimen are invariably encountered when one is managing neutropenic patients. Although their occurrence can be minimized if the initial regimen is selected on the basis of regional sensitivity patterns, the overall incidence of resistant organisms will vary dramatically, depending on the institution, characteristics of the patient population, selection of antibiotics, and unexplained ecologic fluctuations. Clinically, it is important to distinguish between organisms in the environment with intrinsic or de novo antibiotic resistance (primary resistance) and organisms that develop resistance while the patient is receiving antibiotics (secondary resistance). Organisms with primary resistance may cause either initial infection or breakthrough infections, while organisms developing secondary resistance cause infections in patients already being treated with antibiotics.

Primary resistance is predominantly dependent on the institution and/or location and is reflective of a regional pool of organisms with similar sensitivity patterns. In addition, individual patients may be colonized with resistant organisms in the absence of an environmental reservoir. For a patient whose site of infection is believed likely to harbor a resistant organism (e.g., coagulase-negative staphylococci from a catheter exit-site infection) or for a patient with a prior history of recurrent infections due to a rare but resistant organism, appropriate modifications of the initial empirical regimen are warranted.

Organisms with intrinsic resistance to most components of standard empirical regimens may also cause secondary or breakthrough infection. Commonly encountered examples include breakthrough infections caused by methicillin-resistant coagulase-negative staphylococci, enterococci, or anaerobes in patients whose initial regimens do not include antibiotics active against these organisms. Rarer examples include secondary infections due to non- *aeruginosa Pseudomonas*-like organisms, *C. jeikeium*, or atypical mycobacteria. For patients receiving non-vancomycin-containing empirical regimens, reports from the microbiology laboratory of gram-positive cocci growing from a culture should prompt the addition of vancomycin, with subsequent modifications made on the basis of a final sensitivity determination. If anaerobes are reported, clindamycin or metronidazole should be added.

The appearance of secondary resistance is seen more frequently with certain organisms. For example, *Enterobacter* spp., *Citrobacter* spp., and *Serratia* spp. harbor inducible -lactamases; a 1989 report noted the appearance of a clinically significant clustering of resistant *Enterobacter* in a neutropenic population.[367] Accordingly, when these organisms are isolated from a patient, careful observation for the emergence of resistance is warranted, and an aminoglycoside should be added to the regimen of patients receiving monotherapy with a broad-spectrum -lactam. *P. aeruginosa* may become resistant to imipenem through a relatively novel mechanism involving a change in porins. Hence, for patients receiving single-agent therapy with imipenem who have a documented infection with *P. aeruginosa*, an aminoglycoside should be added to their regimen. Secondary development of resistance among the gram-positive organisms is somewhat rarer, although it has been described. Most notable is the increasing incidence of highly resistant enterococci in patients receiving vancomycin. [356] [357] [367]

Modifications Based on Changing Clinical Parameters.

For neutropenic patients receiving antibiotics, the appearance of a new clinically documented infection (e.g., cellulitis, pneumonia) or the progression of a previously documented infection should raise suspicion of the presence of resistant organisms. Attempts should be made to obtain microbiologic confirmation with appropriate tissue samples. In addition, the empirical regimen should be changed to cover the potential for resistant bacteria. The site of infection can be helpful in guiding certain antibiotic choices (Table 79-10).

The development of marginal or necrotizing gingivitis is relatively common in patients who have received intensive cytotoxic therapy (Fig. 79-3). Anaerobic organisms contribute to this process, and an antianaerobic agent such as clindamycin or metronidazole should be added to the empirical regimen if gingivitis is diagnosed.

Figure 79-3 Marginal gingivitis. Note well-demarcated red (dark) border on gingiva.

The most common pathogens contributing to perianal cellulitis (which may manifest only with localized pain) are the aerobic gram-negative bacilli, enterococci, and bowel anaerobes.[129] Therefore, the appearance of this infection in a patient already receiving broad-spectrum antibiotics mandates the addition of antianaerobic agents as well as a change in broad-spectrum coverage. Similarly, any suspected intra-abdominal site of infection should prompt the addition or inclusion of antibiotics active against aerobic gram-negative bacilli, enterococci, and bowel anaerobes.

In febrile and neutropenic patients with abdominal pain, the possible development of typhlitis or pseudomembranous colitis should be considered. Typhlitis, a necrotizing inflammation of the cecum, presents as right lower quadrant pain and fullness but may progress to an acute abdomen with decreased bowel sounds, abdominal distention, and rebound.[369] Mortality is high, and the optimal therapy is controversial, but all patients should receive broad-spectrum antibiotics, specifically with coverage of *Enterococcus*, anaerobes, and gram-negative bacteria. Antibiotic-associated colitis has long been associated with the administration of a variety of antibiotics; the risk of its development may also be increased by antineoplastic agents. Consequently, neutropenic patients receiving broad-spectrum antibiotics are at high risk. Most cases are thought to be caused by a toxin produced by *C. difficile*.[370] The spectrum of disease caused by *C. difficile* may range from asymptomatic colonization or mild diarrhea to overt pseudomembranous colitis with peritoneal signs and extensive mucosal erosion. [371] The diagnosis should be made by

documenting toxin production, and therapy should be instituted with either oral vancomycin (125 mg q.i.d.) or oral metronidazole (250 mg q.i.d.). The treatment of *C. difficile*-associated disease in patients who cannot take oral medications is problematic. Intravenous vancomycin does not achieve sufficient levels within the colon to be effective, but intravenous metronidazole does achieve such concentrations, and successes with the latter approach have been reported. [372]

The development of an exit-site infection or cellulitis around an indwelling intravenous catheter is often caused by a gram-positive organism; if such an infection is noted, vancomycin should be added to the regimen, if not already included. However, one must remember that neutropenic patients may be infected at any site by atypical organisms. Accordingly, for most new or progressive clinically documented infections, empirical changes should usually include modification of the components directed at the gram-positive as well as those directed at the gram-negative bacteria.

The development of a new site of infection may also warrant the addition of other antibiotics directed at fungi, viruses, or parasites. Burning retrosternal pain is frequently an indication of esophagitis, most often caused by cytotoxic therapy, *Candida* infection, or HSV infection. Accordingly, empirical therapy with amphotericin B or acyclovir, or both, may be indicated (see the sections on herpes simplex and *Candida* infections). The development of pulmonary infiltrates might raise suspicion not only of resistant bacteria but also of *P. carinii*, fungi, or a viral pneumonia. In a neutropenic patient receiving broad-spectrum antibiotics who has a new localized infiltrate, perhaps the first question to ask is whether the granulocyte count is rising. If so, the appearance of the new infiltrate may simply represent an inflammatory reaction at a previously unrecognized site of infection, and close observation without any modification may be appropriate. [373] If the granulocyte count is not rising and the patient has been neutropenic for only a short time (i.e., <1 week), a bacterial process is most likely, and changes in the antibacterial coverage should be considered. If the patient has been persistently neutropenic for a more prolonged period, a fungal pneumonia should also be strongly considered and amphotericin B added while a diagnostic workup is initiated. The development of an interstitial infiltrate in a neutropenic patient should raise suspicion of a variety of infectious and noninfectious diagnoses. The most likely infectious causes of interstitial infiltrates are *P. carinii* and CMV, although a variety of other organisms, including bacteria (e.g., *Legionella*), other viruses, and fungi, should be considered. Appropriate modifications of therapy will depend on the presence or absence of other risk factors (e.g., bone marrow transplantation or administration of corticosteroids) and on the availability and feasibility of diagnostic tests such as sputum induction, bronchoalveolar lavage, or open lung biopsy (see Fig. 79-4 for approach to the cancer patient with pulmonary infiltrates).

Patients in whom hypotension develops while they are receiving broad-spectrum antibiotics should be presumed septic

Figure 79-4 Algorithm for the management of the cancer patient with a pulmonary infiltrate.

with a resistant organism or breakthrough infection. In these cases, changes in the empirical regimen should be made expeditiously and continued for the duration of treatment if an organism is not recovered. So-called culture-negative sepsis may occur when the growth of resistant organisms is suppressed by marginally effective antibiotics or when the specimens for culture are not drawn during the bacteremic episode. In addition, it is likely that a variety of endogenous mediators (e.g., tumor necrosis factor) play a role in the associated cardiovascular changes, which often persist in the absence of identifiable bacteremia.

Empirical Antifungal Therapy

The rationale for empirical utilization of antifungal compounds is based on several observations. First, the diagnosis of even a disseminated fungal infection is difficult in an immunocompromised patient. Withholding antifungal therapy until a definitive clinical or microbiologic diagnosis is established frequently permits widespread dissemination. Second, it is now possible to identify subgroups of immunosuppressed patients who are at greatest risk of mycotic disease. Thus, neutropenic patients who remain persistently febrile despite a 5- to 7-day trial of broad-spectrum antibacterial therapy are particularly susceptible to fungal infection. [374] [375] [376] Finally, an accumulating body of data suggests that the early institution of effective antifungal agents will improve the therapeutic outcome in immunocompromised patients with established mycoses.[377] Thus, use of an empirically based antifungal regimen might be expected to have a dual effect: suppression of the fungal overgrowth that inevitably accompanies the administration of broad-spectrum antibacterial agents, and early treatment of subclinical localized mycotic disease before locally invasive infection or dissemination develops.

Two prospective randomized studies were the first to demonstrate the efficacy of empirical amphotericin B in persistently febrile neutropenic patients. [374] [378] In the NCI study,[374] patients who were granulocytopenic and persistently febrile without an identifiable infectious source were randomly assigned after 7 days of broad-spectrum antibacterial therapy to three study arms. In group I, all antibiotic therapy was discontinued; in group II, the broad-spectrum antibacterial agents were continued; and in group III, the antibacterial agents were continued and amphotericin B was added (at a dosage of 0.5 mg/kg/day). Clinically or microbiologically proved infections (bacterial and fungal) occurred in six of the 16 patients in group I, in six of the 16 patients in group II, but in only two of the 18 patients in group III. Documented fungal infections occurred in one patient in group I (esophageal candidiasis), in five patients in group II (invasive candidiasis in three, disseminated aspergillosis in one, and a disseminated mixed *Candida* and *Aspergillus* infection in one), and in one patient in group III (a fatal pulmonary infection with *Petriellidium boydii*, an amphotericin B-resistant organism). Further confirmation of the beneficial role of empirical antifungal therapy was provided by consideration of the mean time to defervescence after day 7 randomization. Patients receiving empirical amphotericin B (group III) defervesced within 35 days. Patients remaining on antibiotics alone (group II) required 78 days to defervescence, while those randomized to discontinue all therapy (group I) required 1112 days. Thus, this trial strongly suggested a beneficial role for empirical amphotericin B among high-risk patients.

The other randomized trial of empirical amphotericin B was performed by the European International Antimicrobial Therapy Cooperative Group. [378] This randomized multicenter trial examined the use of empirically administered amphotericin B in granulocytopenic patients who remained persistently febrile for 4 days despite administration of antibacterial antibiotics. Patients were divided into two groups: 68 were randomly assigned to receive empirical amphotericin B and 64 were assigned to continue the protocol antibiotics. Amphotericin B was administered at 0.6 mg/kg/day or 1.2 mg/kg every other day. Abatement of fever occurred in 69% of the amphotericin B-treated group and in 53% of the other group ($P = 0.09$). Six documented fungal infections, four of which were deemed severe, occurred in the 64 patients randomized not to receive empirical amphotericin B, in comparison with only 1 patient with fungemia among the 68 treated empirically with amphotericin B ($P = 0.01$). No deaths occurred as a result of fungal infections in those receiving empirical amphotericin B, whereas four deaths due to fungal infections occurred in those not receiving it ($P = 0.05$). Although the mortality from fungal infections was reduced, no difference in overall survival between the two groups was observed. These studies are consistent with retrospective evaluations, which have also reported a benefit for amphotericin B. [375] [379]

Other strategies for empirical antifungal therapy using antifungal azoles have been studied. A study at the NCI attempted to avoid the toxicity of amphotericin B yet provide empirical antifungal therapy with ketoconazole. [380] Seventy-two patients who remained neutropenic and febrile after 7 days of antimicrobial therapy were randomized to receive amphotericin B (0.5 mg/kg/day) or ketoconazole (800 mg/kg/day). The results were similar in terms of duration of fever after antifungal randomization, number of documented fungal infections, number of patients requiring crossover to the alternate regimen due to intolerance, and overall outcome scored as success (i.e., survival) or failure (i.e., death due to fungal disease). However, almost one-third of patients eligible for this study could not be enrolled because of their inability to tolerate oral medications, including ketoconazole. The use of ketoconazole was also complicated by its erratic absorption; only eight of 12 patients with ketoconazole peaks measured had adequate levels. Once the diagnosis of an invasive fungal infection was made, however, disease progression was likely unless the patient received amphotericin B. In a similar randomized prospective study from the M.D. Anderson Hospital, 172 neutropenic patients received either amphotericin B (at a dose of 0.61.0 mg/kg/day) or ketoconazole (200 mg PO q.i.d.); these patients had remained febrile for 7296 hours after institution of empirical antibiotic therapy.[381] Overall, these investigators also reported equivalent efficacy for both regimens. However, the frequency of aspergillosis was too low in this study to permit evaluation of the impact on this infection. Thus, conventional amphotericin B desoxycholate has remained the first-line agent of choice for empirical antifungal therapy.

Unfortunately, the current use of conventional amphotericin B is complicated by nephrotoxicity and infusion-related toxicity. Moreover, breakthrough fungal infections continue to occur despite the use of conventional amphotericin B. Despite further support and clinical evidence for the efficacy of empirical therapy with amphotericin B,[376] [380] [382] some clinicians remain reluctant to administer a potentially toxic agent to patients in whom a definitive diagnosis of a fungal infection has not been made. Fever, nephrotoxic effects, chilling reactions, and electrolyte imbalances (especially hypokalemia) are frequently associated with amphotericin B; anemia,

thrombocytopenia, and anaphylaxis have been noted less frequently.

Lipid formulations of amphotericin B may provide an effective avenue by which to reduce the nephrotoxicity and infusion-related toxicity of the parent compound. In order to test this hypothesis, liposomal amphotericin B was compared to conventional amphotericin B for empirical antifungal therapy in a randomized, double-blind, multicenter trial. This study, which enrolled 687 patients and was powered to a delta of 10%, found that liposomal amphotericin B was equivalent to conventional amphotericin B in overall therapeutic success and was superior in reducing proven breakthrough fungal infections, infusion-related

toxicity, and nephrotoxicity.[383] We therefore now recommend liposomal amphotericin B for empirical antifungal therapy in persistently febrile neutropenic patients, particulalrly bone marrow transplant recipients and patients with acute leukemia.

Management of Indwelling Intravenous Catheters

While infections due to gram-positive bacterial infections (especially staphylococci) are the most frequent in patients with indwelling catheters, other bacterial and nonbacterial species are also encountered, particularly in the neutropenic patient. These include resistant *Corynebacterium* spp., *Bacillus* spp., gram-negative bacteria, mycobacteria, and fungi. In approaching management issues for the patient with a catheter-related infection, it is important to process several key pieces of information: (1) the specific type of infection, (2) the location (i.e., bacteremia versus exit site versus tunnel), (3) the duration of infection, (4) any history of recurrent or previous infections and responses to antibiotics, and (5) overall clinical status.

The vast majority of simple catheter-related bacteremias and exit-site infections can be cleared by using appropriate antibiotics and do not necessitate catheter removal (Table 79-12). This applies to both neutropenic and non-neutropenic patients. If multilumen devices are used, the antibiotics must be rotated among the ports when infusing the antibiotics, since infection may be limited to one lumen (failure to follow this procedure can cause persistent infection despite antibiotics). Specimens for diagnostic culture should also be drawn through all ports of any multilumen device. Persistent bacteremia after 48 hours of appropriate therapy warrants removal of the catheter. Failures of therapy are more common when the infections are due to such organisms as *Bacillus* spp., *C. albicans*, *Mycobacterium chelonei*, or *Mycobacterium fortuitum*; in these cases, we recommend prompt catheter removal as well as antibiotic therapy.

In addition, specific clinical parameters may dictate the approach to therapy. For example, infections that extend to involvement of the tunnel of a catheter usually mandate prompt removal of the device, as antibiotics alone rarely cure this closed-space infection, particularly in the granulocytopenic host. Likewise, infections around the reservoir of an implantable subcutaneous device can be difficult to eradicate if the catheter is still in place. Patients with recurrent catheter infections

TABLE 79-12 -- Recommended Approaches to Central Intravenous Catheter-Related Infections

Type of Infection	Management
Most bacteremias	Appropriate antibiotic(s), depending on cultures and granulocyte status Rotate antibiotics through all lumina of the catheter if multilumen device used Removal of catheter if persistent cultures after 48 hr of therapy, or sooner if clinical deterioration
Exit-site infections	Appropriate antibiotics; obtain cultures (remembering that not all exit-site infections are gram-positive) Catheter removal if no response or progression after 48 hr
Tunnel infections	Immediate removal of catheter and appropriate antibiotics
Bacillius spp. or *Corynebacterium jeikeium* infections	Removal of catheter and appropriate antibiotics
Fungemia	Removal of catheter and appropriate antibiotics

(despite a history of appropriate therapy) are also candidates for prompt catheter removal.

Another question of practical importance is how to approach a febrile non-neutropenic patient with a central intravenous catheter who has no identifiable source of infection on examination. Should empirical antibiotics be started? Our policy in this setting is to obtain material for culture and start appropriate antibiotics; stable patients are treated with intravenous ceftriaxone and followed daily as outpatients pending culture results. This approach protects against the progression of undetected yet virulent infections (e.g., *S. aureus*), can minimize the need for ultimate catheter removal, and decreases hospital costs while maximizing outpatient time. If by 72 hours the cultures are negative and the patient is stable, we discontinue antibiotics.

Granulocyte Transfusions

Since granulocytopenia is the predominant factor predisposing to infection in cancer patients, many investigators have hypothesized a therapeutic role for granulocyte transfusion in infected patients. Early data from small trials were encouraging, but they have not been corroborated in other studies, including prospective controlled trials.[384] [385] [386] [387] The efficacy of granulocyte transfusions has been hindered by the low yield of granulocytes obtained from donors and the resultant disappointing increase of white cells in the recipient. The result has been the need for multiple donors, increasing the risk of alloimmunization [388] and of transmission of infections (e.g., CMV,[389] [390] toxoplasmosis).[391] In a recent study by Bensinger et al.,[392] eight WBC donors were given subcutaneous G-CSF daily, and granulocytes were harvested on a mean of 7.6 occasions. Not only was the mean number of granulocytes collected (41.6×10^9) sixfold higher than in historical controls, but mean granulocyte levels in the bone marrow recipients receiving these cells were significantly higher than those seen in historical controls (0.95×10^9 at 24 hours post transfusion).[392] Although these data are preliminary, this method of collection could improve the efficacy of granulocyte transfusion and might permit more reliable and successful administration of cell component therapy to profoundly granulocytopenic patients. [393] [394]

CLINICAL APPROACH TO FUNGAL INFECTIONS IN IMMUNOCOMPROMISED PATIENTS

The most common fungal infections encountered in immunocompromised patients are those due to *Candida* spp., *Aspergillus* spp., and *C. neoformans*. Serious invasive *Candida* and *Aspergillus* infections are seen most often in granulocytopenic patients, although other populations may also be at risk. Infections due to *C. neoformans* are more common in patients with altered cellular immunity, and HIV-infected patients now constitute the largest group at significant risk for this infection.

Infections Due to *Candida* Species

Oropharyngeal Candidiasis

Of all *Candida* infections seen in the immunosuppressed population, oral candidiasis, or thrush, is most often encountered. Patients with cell-mediated immune deficits are particularly susceptible to the development of oropharyngeal and esophageal candidiasis. The clinical importance of oropharyngeal *Candida* infections in immunocompromised patients is threefold. First, locally invasive disease may be painful, especially when it occurs in association with mucositis or oral HSV infection. Second, oropharyngeal infection may be a harbinger of more serious mucosal disease affecting other sites, including the epiglottis, esophagus, or lower GI tract. Finally, it may serve as a nidus for the development of fungemia and disseminated

Box 79-2. APPROACH TO FUNGAL INFECTIONS

***CANDIDA* INFECTIONS**

In neutropenic patients we first treat symptomatic, proven oropharyngeal candidiasis with clotrimazole (usually clotrimazole troches, administered five times per day). If there is no improvement, we discontinue clotrimazole and begin fluconazole, 100200 mg/day. If there is still no improvement, we discontinue fluconazole and begin amphotericin B, 0.5 mg/kg/day. For suspected or diagnosed *Candida* esophagitis, we begin fluconazole. For patients with persistent fever and neutropenia with or without esophagitis, we begin liposomal amphotericin B, 3.0 mg/kg/day. Because of the risks associated with esophagoscopy and biopsy in the neutropenic population, we usually elect to treat empirically and not to perform this procedure.

Isolation of *Candida* from blood cultures has been increasingly achieved owing to changing characteristics of the neutropenic population and improved microbiologic techniques. In a neutropenic patient even a single colony of *Candida* isolated from the blood should be viewed as significant and not discarded as a contaminant. When candidemia occurs, we take the following approach: (1) begin amphotericin B; (2) remove and/or change all intravenous lines; and (3) begin a diagnostic workup to look for disseminated disease, which at a minimum should include follow-up evaluation of blood cultures, measurement of alkaline phosphatase levels, an ophthalmologic examination, and CT of the liver and spleen. Abnormalities on CT may not become apparent until the granulocytopenia resolves, and imaging studies should be repeated at this time if disseminated disease is suspected. Should the organism be germ-tube positive (*C. albicans*), we use fluconazole, 800 mg/day.

Hepatosplenic candidiasis is the most common manifestation of disseminated fungal disease in the neutropenic population. Patients with neutropenia of prolonged duration who are receiving broad-spectrum antibacterial agents are at highest risk. Clues to the diagnosis include abdominal pain, rebound leukocytosis and persistent fever following recovery from granulocytopenia, and elevated alkaline phosphatase levels. US, CT, and MRI may all be useful in making a presumptive diagnosis. The definitive diagnosis requires histologic and/or microbiologic demonstration of *Candida* in hepatic tissue. However, even when organisms are demonstrated histologically, they rarely grow in culture. We initiate therapy with a combination of amphotericin B (0.5 mg/kg/day) and 5-flucytosine (initially 100 mg/kg/day in four divided doses, assuming normal renal function), carefully monitoring 5-FC levels. Alternatively, patients can be successfully treated with liposomal amphotericin formulations, especially when there is evidence of impaired renal function. When the patient is stable, we change therapy from amphotericin B to fluconazole. Therapy should be continued until radiographic abnormalities resolve.

***ASPERGILLUS* INFECTIONS**

In most non-neutropenic patients with aspergillomas, we favor a conservative approach, reserving surgical resection for those with recurrent or significant hemoptysis. Surgery should also be considered for patients with isolated aspergillomas who are about to receive cytotoxic therapy that will place them at increased risk of bleeding.

Invasive aspergillosis occurs most commonly in patients with prolonged periods of granulocytopenia (average time of onset is 3 weeks in most studies). Fever, cough, and pleuritic chest pain are clues to the diagnosis and may have their onset before the appearance of pulmonary infiltrates. The lungs and sinuses are the sites most commonly affected, and lesions are often multifocal. When invasive aspergillosis is suspected, CT of the lungs and sinuses should be performed and may reveal widespread disease in the face of minimal findings on plain radiographs. In the appropriate clinical setting, positive sputum or nasal cultures are highly suggestive of the diagnosis. Surgery has little role in therapy because the disease is usually multifocal and because many patients have concomitant thrombocytopenia. In the absence of granulocyte recovery, invasive aspergillosis is nearly always fatal. The goal of therapy is to stabilize the disease and buy time until the granulocytopenia resolves. We treat patients with high-dose amphotericin B (1.01.5 mg/kg/day). Itraconazole, 600800 mg/day, with careful monitoring of levels to ensure bioavailability, may be used if patients have recovered from neutropenia and are afebrile, and lesions are resolving. Therapy should be continued until the radiographic abnormalities resolve.

disease, particularly in granulocytopenic patients with concurrent mucosal disruption.

The presumptive diagnosis of oropharyngeal candidiasis is often relatively easy to make by visual examination. In most cases, characteristic creamy white patches appear on the mucosal surfaces, which can be friable and which bleed easily when scraped. Wet-mount examination of scrapings will show typical yeast forms. However, the definitive diagnosis is often elusive because other local processes such as HSV or noninfectious mucositis may be clinically and visually indistinguishable. Oral swabs for microscopic examination or fungal culture should be performed to confirm mucosal candidiasis.

Therapeutic approaches include a number of options. First, for asymptomatic patients at relatively low risk for disseminated *Candida* (e.g., those who are nongranulocytopenic or who have a short expected duration of granulocytopenia), specific therapy may not be warranted. Many of these infections will clear spontaneously after the return of the granulocytes or discontinuation of antibiotic or immunosuppressive therapy, or both. Therapy should be considered for patients who are chronically immunosuppressed (e.g., AIDS patients), who have significant symptoms (usually pain), or who are at relatively high risk of dissemination (e.g., granulocytopenic). Potential therapeutic drugs include oral nonabsorbable antifungal agents (e.g., nystatin or clotrimazole), oral absorbable antifungal agents (e.g., fluconazole, ketoconazole), and amphotericin B. Both nystatin and clotrimazole can be effective in the treatment of thrush, although clotrimazole appears to be better tolerated, and prophylactic studies suggest its superior efficacy. [395] [396] [397] [398] Nystatin is usually administered in doses of 100,000 units three to six times per day, and clotrimazole troches are administered five times per day.

If no symptomatic response occurs after a trial of nonabsorbable agents, or if the condition of the patient precludes administration of oral nonabsorbable agents, treatment with systemic antifungal agents is warranted, depending on the severity of the symptoms and the degree of immunosuppression. In addition, failure to respond to nonabsorbable agents with symptomatic improvement should alert the clinician to the potential existence of more serious or more extensive *Candida* infection, as well as

to the possibility of nonfungal processes, such as HSV infection or mucositis induced by cytotoxic therapy. Accordingly, appropriate diagnostic studies, including culture of oral lesions for HSV, should be initiated (see the discussion under Clinical Approach to Viral Infections in Immunocompromised Patients). Certain cases may warrant concomitant empirical antiviral therapy with acyclovir.

Oropharyngeal candidiasis refractory to nonabsorbable agents may be treated with fluconazole or amphotericin B. Fluconazole at a dose of 100200 mg q.d. has been shown to be as effective as ketoconazole but has the advantages of absorption independent of gastric pH and of availability in oral and intravenous formulations. [399] For oropharyngeal candidiasis in granulocytopenic patients that is either severe or unresponsive to other agents, amphotericin B in relatively low doses (e.g., 0.3 mg/kg/day) may be effective. We prefer to administer 0.6 mg/kg/day in neutropenic patients and to continue therapy until the granulocyte count has resolved.

Esophageal Candidiasis

Esophageal candidiasis is a locally invasive infection of the esophagus caused by *Candida* spp. The infection usually remains localized in nongranulocytopenic patients.[400] Significant granulocytopenia may predispose patients with esophageal candidiasis to submucosal vascular invasion as disseminated disease. The most common site of infection is the distal third of the esophagus, perhaps because *Candida* grows especially well in acidic environments. Many of the principles of diagnosis and management of thrush apply to esophageal candidiasis.

The diagnosis of esophageal candidiasis requires a high index of suspicion in susceptible hosts. Burning pain localized to the retrosternal or epigastric areas is the most commonly reported symptom. Its presence in the appropriate host should alert the clinician to the possibility of this diagnosis. The pain is often aggravated by swallowing and may also be associated with dysphagia localized to the site of maximal involvement. However, even significant esophageal candidiasis may be asymptomatic.[401] [402] [403]

The physical examination is usually not helpful in establishing the diagnosis of esophageal candidiasis. Although patients often have either visibly apparent or symptomatic oropharyngeal involvement, or both, the absence of thrush does not rule out the diagnosis, since the distal esophagus may be the only focus of disease. Conversely, the presence of even severe thrush in a patient with burning retrosternal pain does not establish the diagnosis of esophageal candidiasis, since other processes could be operative. Signs suggestive of oral HSV infection or of chemotherapy-related mucositis may suggest other causes but are not diagnostic and do not rule out the presence of a mixed process. For example, patients may present with severe oral HSV infection and concomitant esophageal candidiasis, or vice versa.

In terms of diagnostic tests, oral smears or cultures for fungus or HSV may be suggestive but are not diagnostic. Mouth cultures for *Candida* are virtually never helpful because of the high rate of colonization even in the absence of infection. If oral lesions suggestive of HSV infection are apparent, cultures should be done. Importantly, oral cultures positive for HSV do not establish the diagnosis of HSV esophagitis, nor do negative cultures rule it out. A barium swallow examination or upper GI tract series may be helpful in establishing or ruling out certain noninfectious processes, such as gastroesophageal reflux or peptic ulcer disease. They may also reveal mucosal irregularities suggestive of *Candida* esophagitis (e.g., cobblestoning) but are not helpful in establishing the definitive diagnosis. [404]

Only endoscopic biopsy with culture of the specimen and histologic tissue examination can establish the diagnosis of esophageal candidiasis with certainty and at the same time rule in or out other processes. Endoscopic examination without biopsy may suggest a diagnosis on the basis of visual appearance and culture results. However, similarities in the visual appearance of different lesions, coupled with the nonspecificity of culture results from specimens obtained noninvasively, detract from the clinical value of this procedure. Unfortunately, not all patients are able to tolerate an endoscopic biopsy. The most clinically relevant complications of esophagoscopy with biopsy are bacteremia and bleeding. Both complications are more common in patients who have received cytotoxic therapy and who are granulocytopenic or thrombocytopenic, or both.

Accordingly, in granulocytopenic patients showing symptoms and signs consistent with esophageal candidiasis, we initiate empirical therapy directed at *Candida* or HSV (or both) and reserve endoscopic biopsy for patients whose disease is refractory to therapy or in whom empirical therapy with amphotericin B is relatively contraindicated (e.g., patients with renal insufficiency or amphotericin B intolerance). For noncytopenic patients, the decision to perform endoscopic esophageal biopsy should be predicated on the relative risks and benefits of the procedure within the context of the degree of immunosuppression, ease of empirical therapy, and response or lack of response to selected agents. Patients who are granulocytopenic, who are receiving other aggressive immunosuppressive regimens (e.g., corticosteroids, total body irradiation, antithymocyte globulin), or who otherwise have a high propensity for dissemination of *Candida* and who have documented esophageal candidiasis or have failed an initial empirical trial of oral nonabsorbable agents are candidates for therapy with intravenous amphotericin B. Amphotericin B should be administered intravenously at a dosage of 0.6 mg/kg/day. For neutropenic patients, it should be continued at least until the neutropenia resolves. In patients in whom the granulocytopenia is unlikely to resolve (e.g., patients with aplastic anemia who have not responded to therapy), we administer amphotericin B for 2 weeks (approximately 500 mg total dose for most adults or 10 mg/kg for children). If symptoms have resolved and the patient is afebrile and clinically stable, we discontinue amphotericin B and watch closely for the return of symptoms. In high-risk patients, particularly those with fever and granulocytopenia, the clinician should also consider the potential presence of clinically occult diffuse GI or disseminated candidiasis.

Granulocytopenic patients with clinical symptoms of infective esophagitis who are not candidates for endoscopy are often candidates for presumptive or empirical therapy. At the NCI, if such patients have only mild to moderate symptoms and are clinically stable, a 4-day trial of fluconazole, 400 mg/day, is initiated. In patients with more severe symptoms or symptoms that fail to respond to, or worsen with, clotrimazole, amphotericin B, 0.6 mg/kg/day, is initiated. In addition, in patients in whom definitive diagnostic procedures are not feasible, treatment with acyclovir is often initiated as a logical extension of empirical amphotericin B therapy. In patients with active herpetic stomatitis, we usually initiate acyclovir (250 mg/m ^{2} q.8h., intravenously) simultaneously with empirical antifungal therapy. For patients without clinical evidence of HSV infection, we begin acyclovir if there is no response to initial antifungal agents.

Nongranulocytopenic symptomatic patients who are clinically stable and who have no apparent foci of *Candida* beyond the esophageal mucosa may benefit from fluconazole, 200400 mg/day given intravenously. [405] For nongranulocytopenic symptomatic patients with organisms resistant to fluconazole, amphotericin B (0.6 mg/kg/day) may be used. Most patients can be treated successfully with 12 weeks of therapy.

Most ambulatory patients with AIDS, solid tumors, or other non-neoplastic diseases who have esophageal candidiasis respond favorably to fluconazole in oral dosages of 100200 mg once daily. [406] Nonabsorbable agents such as nystatin and clotrimazole

also may be effective for this indication, but they are not as effective and are best utilized for prevention of recurrent esophageal candidiasis. In AIDS patients,

esophageal candidiasis is often a chronically recurrent process, as are many of the fungal and protozoal infections. Accordingly, some form of chronic suppressive antifungal therapy is often desirable in this population. Suppressive regimens that can be effective in selected patients include oral fluconazole (100200 mg/day), nystatin suspension (500,0001.5 million units, 515 ml, orally q.i.d.), or clotrimazole troches (10 mg five times a day, dissolved slowly in the mouth). Relapse of esophageal candidiasis during maintenance oral therapy may require institution of intravenous amphotericin B and should prompt the physician to consider other causes of infective esophagitis. As the emergence of resistance to fluconazole may complicate such a chronic suppressive strategy, [407] we employ long-term fluconazole suppression only in those patients in whom recurrences are no longer tolerated or successfully treatable.

Approach to the Patient with Candidemia

Candidemia is associated with a high morbidity and mortality and may be a harbinger of disseminated *Candida* infection. Candidemia is seen almost exclusively in patients with significant impairment in host defenses. Those at highest risk are neutropenic patients receiving broad-spectrum antibacterial agents. Other populations in whom candidemia and disseminated candidiasis occur include transplant recipients, postsurgical patients, burn victims, low-birth-weight neonates, patients with indwelling intravenous catheters, and those receiving hyperalimentation. [408]

During the past two decades, there has been a progressive increase in the frequency of candidemia in most medical centers. [409] [410] [411] [412] For example, Beck-Sague and colleagues [410] analyzed secular trends in the incidence of nosocomial fungal infections in U.S. hospitals between 1980 and the end of 1990. The rate rose from 2.0 to 3.8 infections per 1,000 discharges. *C. albicans* was the most frequently isolated fungal pathogen (59.7%), followed by other *Candida* spp. (18.6%). Bloodstream infections due to *Candida* spp. increased nearly tenfold. Patients with bloodstream infections who had a central intravascular catheter were more likely to have a fungal pathogen isolated than were other patients with bloodstream infection (relative risk = 3.2; $P < .001$): 29% of fungemia patients and 17% of patients with bloodstream infection due to other pathogens died during hospitalization ($P < .001$). Fungi are emerging as important nosocomial pathogens, and control efforts should target fungal infections, especially fungemia. Additional studies found that *Candida* spp. are the third to fourth most common bloodstream isolates in hospitalized patients. Estimates from large teaching hospitals have been as high as 8.5 per 10,000 admissions, with candidemia accounting for up to 10% of nosocomial bloodstream infections.[411] The mortality attributable to candidemia has been 2152%. [411] [413] [414] Candidemia as an independent event directly increases the average length of hospital stay by 30 days. [411]

Candidemia usually occurs in patients who already have extended hospitalizations. In the study by Horn et al., [412] the average period of hospitalization before the onset of candidemia was 20 days. In addition, the first positive blood cultures were obtained after a mean of 11.7 days of neutropenia and a mean of 11.8 days of antibiotics. Fever is often the only sign; its presence in a susceptible host, in the absence of other causes, should always raise the possibility of fungal infection. Other signs that can occur with early candidemia include embolic skin lesions, which in some series have occurred more commonly with *C. tropicalis*, and diffuse myalgias, which may be indicative of *Candida* myositis.[412] [415] A large percentage of immunocompromised patients with candidemia will have disseminated candidiasis; signs referable to involvement of specific organ systems (e.g., eye, CNS, heart valves, liver, and spleen) should also be sought.

In an immunosuppressed patient in whom a blood culture is positive for *Candida* spp., the following clinical approach seems prudent on the basis of current knowledge. A positive blood culture should rarely, if ever, be considered due to a contaminant. Culture contamination probably occurs far less frequently than does true candidemia in a susceptible host. In addition, even viscerally disseminated candidiasis is associated with a low incidence of positive blood cultures. Accordingly, there is danger in waiting for a second confirmatory culture before taking action, as it can yield negative results in the face of significant disease.

Central venous catheters, arterial catheters for monitoring blood pressure, and hyperalimentation lines have all been associated with an increased risk of candidemia and may be considered independent risk factors for disseminated infection. [416] [417] [418] If the patient does not have a catheter in place, an endogenous source should be assumed, and the likelihood of disseminated disease can be even higher. These patients should receive antifungal therapy as outlined below. If the patient does have a catheter, it is difficult to determine whether a positive blood culture represents an infection limited to the lumen or to the surface of the catheter itself, or whether the organisms were drawn from the circulation. If quantitative culture techniques are available (e.g., the lysis-centrifugation method) and simultaneous specimens have been obtained peripherally and through the catheter, a higher number of colonies in blood obtained through the catheter (or a positive culture of blood drawn exclusively through the catheter) may indicate an infection localized to the catheter. However, because *Candida* adheres avidly to plastic surfaces, an infection that appears to be originating from the catheter could simply represent locally proliferating organisms that adhered to the catheter during a period of candidemia.

The decision as to whether to remove intravascular catheters from patients with candidemia is both difficult and controversial. Although some recommend catheter removal only in cases of thrombophlebitis or disseminated infection, the catheter may represent a nidus for infection and a source for dissemination. In one study, only 11 patients of 155 with fungemia and central intravascular lines were treated without removal of the line; of these, nine were treatment failures despite receiving >500 mg of amphotericin B.[414] In addition, it is difficult to predict which patients can be successfully treated with the catheter in place, and such treatment delays can be costly. Therefore, we favor prompt removal of all indwelling intravenous catheters in this setting. Another study found that in the subset of non-neutropenic patients with candidemia and a catheter in place at the time of their first positive blood culture, removal and replacement of all intravascular catheters without exchange over a guidewire from a preexisting line on or before the first day the study drug was administered was associated with a reduction in the subsequent mean duration (± SE) of candidemia, from 5.6 ± 0.8 days to 2.6 ± 0.5 days ($P < .001$).[416]

All patients with impaired host defenses and documented candidemia should undergo evaluation for dissemination of disease. Documentation of disseminated disease mandates aggressive and often protracted therapy. The most common sites of dissemination are the eye (endophthalmitis), skin, liver, and spleen. Evaluation for disseminated disease should include careful ophthalmologic examination, examination of the skin, and imaging studies of the liver and spleen. It is important to realize that in the neutropenic host, assessment of the eyes, liver, and spleen can show negative results, even in the face of widespread dissemination. [419] [420] This presumably reflects that the lesions visualized on direct examination or imaging studies largely represent an inflammatory reaction. Accordingly, meaningful assessment of disseminated disease in neutropenic patients

with candidemia is probably best accomplished after recovery of the granulocytes. There is a direct relationship between duration of persistent fungemia and the risk of disseminated candidiasis.

The next question to address is whether a patient with candidemia and an indwelling intravenous catheter (but without evidence of dissemination) should receive antifungal therapy after removal of the catheter or whether catheter removal alone will suffice. Most authorities recommend that all episodes of candidemia in this population be treated with a course of antifungal therapy. [421] [422] Data to support this rationale and approach have been reported in retrospective series that have documented an increased incidence of disseminated *Candida* infection at autopsy in patients with prior candidemia who were not treated with amphotericin B, as compared with those who were so treated.[414] In another study, four of 33 patients with candidemia that was believed to be catheter related and who were treated only by catheter removal (and not with amphotericin B) developed *Candida* endophthalmitis, diagnosed 866 days after the last positive blood culture.

Intravenous amphotericin B is effective in the treatment of candidemia due to most *Candida* spp. in neutropenic patients. In uncomplicated candidemia in neutropenic patients without evidence of disseminated disease, we initiate a dose of 0.6 mg/kg/day without a preceding test dose. If the organism is germ-tube positive, indicating *C. albicans*, we change to fluconazole, 800 mg/day in adults or 12 mg/kg/day in children. Uncomplicated candidemia due to *C. albicans* in non-neutropenic patients may be treated with fluconazole.[422] There are also compelling in vivo and clinical data to support the use of fluconazole for treatment of candidemia due to *C. albicans* in neutropenic hosts.[423] [424] Because *C. tropicalis* and *C. parapsilosis* may be more amphotericin B resistant than other *Candida* spp., if either is isolated we administer amphotericin B at a dose of 1 mg/kg/day and consider the addition of flucytosine. There is no evidence that a stepwise escalation of dose to the targeted daily dose decreases toxicity. Indeed, such an approach may delay the attainment of effective plasma and tissue concentrations that may otherwise be more readily achieved at full dosages. No data are available on the most appropriate duration of therapy. We currently administer a minimal course for a total of 10 mg/kg or 500 mg (2 weeks of therapy in most adults). If the patient is neutropenic at the time the isolate is obtained, we continue amphotericin B at least until recovery of the granulocyte count to >500mm^3 , even if the 500 mg total dose is achieved before that time. Neutropenic patients should also be evaluated for disseminated disease within 1 week after recovery of the granulocyte count. Persistent fever, localizing symptoms, or elevation on liver function tests (particularly of the alkaline phosphatase level) after recovery of the granulocyte count should suggest the possibility of disseminated *Candida* infection.

If candidemia continues despite amphotericin therapy, we add flucytosine (100 mg/kg/day) with careful monitoring of blood levels. [425] There is little evidence that the addition of an azole antifungal agent will be of benefit in this situation, but this may be considered after other treatment options have failed. However, fluconazole may

have a role as monotherapy in the treatment of patients with candidemia but with a low probability of disseminated *Candida* infection.

Candida Endophthalmitis

Candida endophthalmitis is a relatively common complication of candidemia. Montgomerie and Edwards[426] found that five of 25 patients receiving hyperalimentation developed ocular lesions clinically consistent with *Candida* endophthalmitis. The lesions of *Candida* endophthalmitis are white, resemble cotton balls in appearance, and involve the chorioretina, from which they rapidly extend into the vitreous. In the appropriate setting, they often indicate not only infection of the eye but also widespread dissemination to other organs, the number of ocular lesions observed funduscopically correlating with the extent of disseminated visceral infection. [427] It must be remembered that eye lesions may not be recognized in granulocytopenic patients until recovery from neutropenia. Of the various *Candida* species, *C. albicans* appears to have a predilection for eye involvement. [428] Recognition of these lesions mandates a search for other locations of disseminated disease and expeditious treatment with amphotericin B, since *Candida* endophthalmitis can cause irreversible loss of vision or complete blindness in the involved eye. In selected cases, partial vitrectomy may also be helpful both diagnostically and therapeutically. [408] Adult patients with *Candida* endophthalmitis should probably receive an amphotericin B dose of 0.751.0 mg/kg/day for 68 weeks, where possible, with continuation of therapy at least until resolution of the ophthalmologic findings. Strong consideration should be given to the addition of flucytosine, especially in cases with perimacular involvement. If coexisting disseminated disease is found at other sites, even more prolonged therapy may be required.

Hepatosplenic Candidiasis

Only since about 1980 has hepatosplenic candidiasis or chronic disseminated candidiasis been recognized as an important clinical entity in the immunosuppressed host.[429] [430] Although this disease may infect any organ site and is most appropriately designated as chronic disseminated candidiasis, the term hepatosplenic candidiasis has been used most extensively in the literature and will be used here. It is most commonly seen in patients who have had prolonged or recurrent episodes of neutropenia. Presumably it results from hematogenous dissemination, and therefore all patients with documented candidemia should be evaluated for hepatosplenic involvement. However, only a few patients with documented hepatosplenic candidiasis will have had preceding candidemia. One must be aware of the signs and symptoms suggestive of this diagnosis, even in the absence of positive fungal blood cultures.

Four findings should raise the suspicion of hepatosplenic candidiasis in patients who have, or have recently recovered from, episodes of neutropenia, whether seen alone or in concert: (1) persistent fever after recovery of the granulocyte count, which is unresponsive to standard antimicrobial therapy, (2) rebound leukocytosis, (3) elevated serum alkaline phosphatase levels, and (4) abdominal pain.

Thaler and colleagues[429] reviewed their experience with eight cases of hepatosplenic candidiasis seen at the NCI, as well as 65 other cases that were diagnosed ante mortem and reported in the literature. Of the 73 patients, 68 had been neutropenic. In 87%, the underlying diagnosis was acute leukemia, with only three patients having neutropenia due to aplastic anemia. The clinical findings and laboratory abnormalities became apparent only after recovery of the granulocytes to normal levels, and none of the patients was diagnosed while neutropenic. Fever was a presenting symptom in 85% of patients and abdominal pain in 57%. An elevated serum alkaline phosphatase concentration was the most consistent biochemical abnormality. Serum transaminase and bilirubin concentrations were usually normal. Leukocytosis was present in 31%, and 50% had received prior antifungal therapy. With regard to imaging studies, US and CT were both helpful in demonstrating the lesions, and there was a suggestion that CT might be more sensitive and US more specific (with the appearance of the characteristic bulls-eye pattern, Fig. 79-5). Magnetic resonance imaging (MRI) may prove more helpful, as even smaller lesions may be detectable.

The definitive diagnosis can be established only by histologic or microbiologic methods. Grossly, the liver and spleen are usually studded with white to yellow nodules of 12 cm. The earliest histologic appearance of the invasive *Candida* lesion is an

Figure 79-5 CT scan showing typical lesions of hepatic candidiasis.

abscess composed of a necrotic center surrounded by an intense acute inflammatory infiltrate. Because the yeast forms and pseudohyphae often are only in the center of the abscess, serial sections and special stains are frequently needed to show their presence. As the lesion ages, the polymorphonuclear inflammatory cells mix with mononuclear cells, and a peripheral fibrous proliferation begins to wall off the lesion. As healing occurs, this proliferation progresses to a well-defined granuloma with occasional giant cells. Because resolved or resolving lesions may coexist with more acute lesions, the absence of organisms on a liver biopsy section should not be considered evidence that invasive candidiasis has resolved if there is clinical evidence to the contrary. It is important to realize that the culture of the liver specimen will often be negative even if yeast and pseudohyphae are visualized. In the review by Thaler et al., [429] biopsy material was cultured in 45 patients and was negative in 26. Of the 26 patients who received antifungal therapy before the biopsy, cultures were negative in 18. Of the 18 patients who did not receive antecedent antifungal therapy, fungal cultures were negative in seven. Of the 31 *Candida* isolates in this review, 20 were *C. albicans*, six were *C. tropicalis*, one was *C. pseudotropicalis*, and one was *C. stellatoidea*, and in three patients the species of *Candida* isolate was not determined. The decision of whether to perform a liver biopsy depends on the ability of the patient to withstand the procedure safely and on the degree of clinical suspicion for the diagnosis of hepatosplenic candidiasis as opposed to other possible diagnoses. In general, we prefer to make a histologic or microbiologic diagnosis, if at all possible.

We treat all patients initially with amphotericin B with or without 5-fluorocytosine (5-FC), depending on the presence of renal lesions and severity of infection. Following a 2-week course and stabilization of the patient, we attempt to convert therapy to fluconazole. There are both experimental and clinical data to support the use of fluconazole for treatment of this infection. [422] [431] [432] Although experience is limited, fluconazole has been useful in the treatment of hepatosplenic candidiasis that was refractory to amphotericin B therapy. For example, six patients with leukemia and hepatosplenic candidiasis who had received more than 4 g of amphotericin without resolution of infection were treated with fluconazole (200400 mg/day). In all patients fever and other symptoms resolved within 28 weeks and CT showed improvement within 48 weeks. A second study of patients who either did not improve with or were intolerant of amphotericin demonstrated response to fluconazole in 14 of 16 cases. The most favorable outcome in the study of Anaissie et al. indicated that patients treated initially with amphotericin B followed by fluconazole had the best therapeutic response.[411] In the absence of clearly defined end points, we continue antifungal therapy until resolution of all radiographic evidence of disease, performing follow-up studies at monthly intervals or more frequently if clinically indicated. Fever, leukocytosis, and alkaline phosphatase levels can also be helpful in assessing response in individual cases. We routinely employ a daily dose of 0.51 mg/kg of amphotericin B, with the higher doses used for documented *C. tropicalis*, failure of response to lower doses, or cases in which amphotericin B is used as a single agent (i.e., without concomitant 5-FC). We routinely add 5-FC to the therapy for *C. tropicalis* infection at least during the first month, carefully monitoring serum levels. In patients with normal renal function, we begin with a total daily dose of 100 mg/kg and carefully monitor serum levels to avoid toxicity (aiming for a serum level in the range of 50100 g/ml). More recently, studies have suggested that the use of lipid formulations of amphotericin B may allow for delivery of larger doses with less toxicity. [433] [434] The lipid formulations of amphotericin B are indicated for patients who are intolerant of or refractory to conventional antifungal therapy. [435]

A practical question that often arises with many patients diagnosed as having hepatosplenic candidiasis is whether chemotherapy can be safely continued during the course of antifungal therapy. Recognizing the critical importance of treating the underlying neoplastic disease without delay of chemotherapy, we continue antifungal therapy and chemotherapy cycles simultaneously, watching closely for progression of fungal disease. This approach has resulted in no breakthrough fungemias or progression of hepatosplenic candidiasis during neutropenia. [436]

Candida Infections of the Urinary Tract

Candida infections of the urinary tract are classified as upper (involving the kidneys) and lower (involving the urinary bladder). This distinction has important pathophysiologic and therapeutic implications. Renal candidiasis in immunocompromised patients is usually due to hematogenous dissemination; ascending urinary candidiasis is unusual as a cause of renal candidiasis unless there are preexisting anatomic abnormalities of the collection system. The risk factors for hematogenous renal candidiasis are the same as those for candidemia and disseminated candidiasis. The kidney is the most frequently involved organ in most series of disseminated *Candida* infection,[437] and candiduria may be the harbinger of disseminated disease in neutropenic and other immunocompromised patients. Treatment consists of systemic antifungal chemotherapy directed toward deep visceral candidiasis. By comparison, the major risk factors for the development of *Candida* infection of the lower urinary tract are the presence of an indwelling urinary catheter, the administration of broad-spectrum antibiotics, and diabetes mellitus.

Successful management of candidiasis of the lower urinary tract is most readily accomplished by simple removal of the indwelling urethral catheter.

A commonly encountered clinical situation is a urinalysis showing yeast or a urine culture positive for *Candida*. In immunocompetent patients without predisposing conditions, this often represents contamination from *Candida* colonizing the external urogenital tract. In addition, *Candida* spp. were isolated from the urine of 8% of normal males and 12% of normal females in one series.[437] In patients with urinary tract symptoms, an indwelling catheter, or immune impairment, the finding of candiduria may be more significant. The most difficult problem is in differentiating between bladder or catheter colonization and true infection. As a general rule, pyuria in non-neutropenic patients or symptoms of urinary tract infection in the absence of other causes should indicate the potential for true infection due to *Candida*. Quantitative colony counts are of little value in determining the significance of candiduria.[438] There are few laboratory tests that definitively distinguish between upper and lower tract infection. The presence of renal *Candida* casts in a urinalysis is highly specific for renal candidiasis; however, they

are not reliably found in neutropenic hosts.[439] Abdominal CT, MRI, or US can be helpful and should be performed in patients with candiduria and at risk for disseminated disease.

The simplest and most effective means of eradicating the *Candida* from the lower urinary tract in patients who have indwelling urethral catheters is removal of the catheter. However, certain groups of non-neutropenic patients may benefit from additional therapy aimed at local eradication, including (1) those with symptoms that fail to resolve with catheter removal or for whom catheter removal is not feasible; (2) those with upper urinary tract abnormalities (e.g., history of papillary necrosis or ongoing urinary tract obstruction), in whom there is a more significant risk of the development of ascending infection; (3) those with candiduria who will require urinary tract procedures such as transurethral resection of the prostate or chemotherapy for bladder cancer; and (4) those with persistent candiduria who are about to receive aggressive systemic cytotoxic therapy for ensuing neutropenia. For these patients with disease believed to be confined to the lower urinary tract, several strategies may be effective: fluconazole; intravenous amphotericin B; and amphotericin B bladder irrigations. For amphotericin B bladder washes, doses of 100 mg in 500 ml of D_5 W or in sterile water may be instilled and removed once or twice daily. The potential use of a single intravenous dose of amphotericin B in these settings has been suggested, but there are insufficient data to support this approach. The use of 5-FC alone is not recommended because of the potential for the rapid emergence of resistance. Approximately 70% of a fluconazole dose is excreted unchanged into the urine and can provide a less toxic alternative to amphotericin in non-neutropenic patients. In addition, the ease of administration and relative lack of toxicity make fluconazole an attractive alternative for chronic suppression of candiduria; however, physicians must be alert for the potential for *C. glabrata* and *C. krusei* superinfection because of their resistance to fluconazole.

Other groups of patients may need systemic amphotericin B. Clearly, patients (usually neutropenic) with renal involvement attributed to hematogenous spread need treatment with intravenous amphotericin B or high-dose fluconazole, depending on the *Candida* species. Refractory cases of renal candidiasis may be effectively treated with the combination of amphotericin B plus 5-FC. Neutropenic patients with persistent or symptomatic candiduria should also be considered for systemic therapy. In granulocytopenic patients, persistent candiduria may pose a risk of subsequent dissemination or, rarely, may be the first sign of established visceral involvement.

Infections Due to *Aspergillus* Species

In non-HIV-infected immunocompromised patients, *Aspergillus* spp. are the second most commonly encountered fungal pathogens. *A. fumigatus* and *A. flavus* account for the vast majority of human infections, with infections due to *A. terreus*, *A. niger*, and other species reported infrequently. Serious invasive infections due to *Aspergillus* spp. occur most frequently in patients with prolonged granulocytopenia or patients receiving high doses of corticosteroids.[47] [52] [440] [441] [442] Aspergillosis may be classified as allergic, saprophytic (as exemplified by aspergilloma), and deeply invasive infection. The latter two conditions are most relevant to the immunocompromised patient.

Aspergillomas

The term aspergilloma refers to colonization of a pulmonary cavity by *Aspergillus* spp. Aspergillomas can be either primary or secondary. Primary aspergillomas tend to follow granulocyte recovery in patients who have had an episode of invasive pulmonary aspergillosis during a period of granulocytopenia. Pathophysiologically, this results from a walling off of the infection associated with the inflammatory response generated by PMNs.

The most common symptom encountered is hemoptysis, which occurs to some degree in up to 75% of patients.[443] It can range in severity from intermittent blood-tinged sputum to massive pulmonary hemorrhage with exsanguination. In most patients who have not developed the initial infection in the setting of granulocytopenia, the lesions are usually solitary, with radiographs typically demonstrating a round or oval mass overlaid by a crescent of air (Monads sign)[444] (Fig. 79-6). Sputum cultures may be positive for *Aspergillus* in 50% of cases and may be highly suggestive of the diagnosis in the appropriate setting, but they are neither sensitive nor specific. In patients suspected of having aspergilloma, serum should be sent for determination of *Aspergillus* precipitins, which were positive in 92% of 66 patients tested in one review of ten reported series.[443] However, serologic tests for the diagnosis of *Aspergillus* remain experimental and are not commercially available.

Available therapeutic options include conservative management (with no surgery and no medication), intracavitary installation of amphotericin B, systemic administration of amphotericin B, and surgical removal of the lesion. Currently, most authorities recommend a conservative approach, when possible.[443] [445] Several arguments support conservative management. First, life-threatening bleeding is relatively rare, especially with the first episode of hemoptysis.[446] Second, many patients have

Figure 79-6 Typical radiographic appearance of aspergilloma.

underlying diseases associated with significant pulmonary compromise, making them relatively poor operative risks. Third, many patients sustain relatively long asymptomatic periods. In addition, resolutions of aspergillomas without therapy have been reported.[439] Most authorities agree that surgery is indicated for significant recurrent hemoptysis or severe hemoptysis. Clearly, each patient must be approached on an individual basis, and the decision with respect to surgical intervention should be made within the context of the severity of the symptoms, the prognosis of the underlying disease, and the relative operative risks.

Because aspergillomas primarily represent colonization within a preexisting cavity, systemic administration of anti-fungal therapy is rarely effective.[447] However, in a small percentage of patients who have localized invasive disease surrounding the aspergilloma and also have systemic symptoms (so-called chronic necrotizing pulmonary aspergillosis), intravenous amphotericin B has reportedly been effective.[439] [448] Oral administration of itraconazole may be used for long-term ambulatory management. In order to further investigate the utility of itraconazole in the management of this infection, there is currently a randomized, placebo-controlled trial of itraconazole in non-neutropenic patients with aspergilloma. Intracavitary amphotericin B has been reported to be effective in stabilizing or improving radiographic findings in small series of patients, but more data will be needed to assess its ultimate value.[443] [449]

Invasive *Aspergillus* Infections

Of the infections encountered in compromised patients, invasive *Aspergillus* infections are among the most serious because they are often multifocal, are associated with extensive tissue invasion and destruction, and, in the absence of appropriate host defenses, respond poorly to available antimicrobial therapy. Among cancer patients, those with acute leukemia who are undergoing aggressive cytotoxic therapy appear to be at highest risk.[54] However, in a study by Weinberger et al.,[450] fungal infections were responsible for 72% of deaths from infection, and more than one-half of these fungal infections were due to *Aspergillus*. Overall, prolonged neutropenia is clearly the most important risk factor predisposing to invasive *Aspergillus* infection.[451]

With rare exception, *Aspergillus* infection is acquired by inhalation of *Aspergillus* conidia. Consequently, invasive infection occurs primarily in the lung, frequently with

upper respiratory sites (usually the sinuses) affected as well. [452] The disease is often multifocal, with many patients having concomitant involvement of sinuses as well as multiple lung sites. Within the respiratory tree *Aspergillus* has a predilection for invading blood vessels as well as tissue parenchyma. Tissue infarction and subsequent necrosis often occur and may lead to rapidly progressive extensive disease (Fig. 79-7). The process often behaves in a malignant fashion, extending predominantly by local invasion, with little respect for tissue planes and anatomic boundaries. Extension of primary disease in the sinus or orbit through bone to involve the roof of the mouth or the brain is not uncommon. Disease originating in the lung can extend through the pleura and even involve the chest wall. Hematogenous dissemination to distant organ sites such as the CNS, liver, and skin is relatively rare but has been reported. [453]

Since early diagnosis and prompt institution of therapy have been associated with improved outcome, [377] knowledge of the early signs and symptoms of invasive aspergillosis is critical for the clinician caring for patients with prolonged episodes of granulocytopenia. The most common symptom is pleuritic

Figure 79-7 (A) Autopsy specimen of lung from patient with invasive *Aspergillus*. **(B)** Histologic specimen from lung showing invasion of *Aspergillus* around blood vessels.

chest pain, which occurs in 100% of patients; in 50% of patients, it develops an average of 6 days before the appearance of pulmonary infiltrates. [449] Pathophysiologically, pleuritic pain probably occurs as a result of tissue infarction, which often extends to involve the pleural surfaces. Cough occurs in 93% of patients and shortness of breath in 27%. With respect to pulmonary signs, rales are most common and are heard in 100% of patients with invasive aspergillosis.

The sinuses are also frequently involved in invasive aspergillosis; they may be the initial or sole site of disease, or sinus involvement may occur concomitantly with pulmonary infection. Signs or symptoms include sinus pain, nasal ulceration or eschar, periorbital edema, epistaxis, and discharge. In a study by Gerson et al., [451] one-third of patients with invasive pulmonary aspergillosis had microbiologic or pathologic documentation of *Aspergillus* sinus infection. Accordingly, all granulocytopenic patients with suspected or proven invasive aspergillosis should undergo clinical and radiologic evaluation of the sinuses. In addition, *Aspergillus* infection in the maxillary sinuses may invade inferiorly into the roof of the hard palate, and initial symptoms may be minimal, even in the presence of bone destruction. A small ulceration of the hard palate may be the first sign of widespread disease (Fig. 79-8A). Sinus infection may also extend directly to involve the CNS or the orbit.[452]

A high index of suspicion is critical to the early diagnosis of aspergillosis; this infection should be considered with the appearance of any new abnormality in the chest radiograph of a persistently neutropenic patient with fever. The radiographic appearance of invasive pulmonary aspergillosis can range from discrete or multifocal nodular lesions to patchy densities to diffuse consolidation or even cavitation (Fig. 79-8).[451] [454] The appearance can vary dramatically from patient to patient or can change dramatically at granulocyte recoverythe ensuing inflammatory response can even give the appearance of worsening disease when in fact the condition is improving clinically. In our experience at the NCI, the most characteristic finding on chest radiography is a localized infiltrate extending toward the pleural surface. Standard chest radiographs often do not show the full extent of pulmonary disease, especially if obtained early in the course or while the patient is neutropenic. CT scans of the chest are more accurate at defining the extent of disease and often show multifocal lesions when single or no lesions are visible on plain chest radiographs (Figs. 79-8C & D).[455] The radiographic appearance of *Aspergillus* sinusitis can range from minimal mucosal thickening to sinus obliteration and extensive bony erosion or destruction.

The only way to achieve a definitive diagnosis of invasive aspergillosis is by biopsy of the involved area, with either histologic or microbiologic confirmation, or both. Unfortunately, invasive procedures such as open lung biopsy or even transbronchial biopsy or sinus aspiration are often impractical or contraindicated in patients with suspected aspergillosis, owing to thrombocytopenia, other bleeding abnormalities, or concurrent medical problems. Even a highly directed open biopsy may fail to disclose the fungal elements and yield only necrotic or infarcted tissue. [456] Therefore, a less invasive means of establishing the diagnosis would be of great practical value. Accordingly, the clinical value of culture material obtained noninvasively (from sputum or nares or from fiberoptic bronchoscopy with brushings or lavage) has been examined in a number of studies.[53] [55] [457] [458] [459] Cumulative data in these studies would suggest that, in a high-risk patient with signs or symptoms consistent with invasive *Aspergillus*, positive cultures of material from these sites are often predictive of invasive disease. In these patients, directed therapy is often indicated, even in the absence of a definitive diagnosis. However, these data also indicate that negative cultures do not rule out the diagnosis. False-negative culture results may occur in >50% of histopathologically proven cases, even when the specimens are obtained bronchoscopically. Conversely, because *Aspergillus* may colonize the respiratory tract, positive cultures in the absence of signs or symptoms should be interpreted with caution, and directed therapy should rarely be based solely on these results.

Blood cultures are rarely, if ever, positive in invasive aspergillosis. The growth of *Aspergillus* spp. in a blood culture is much more likely to represent a contaminant than a clinically significant isolate. Immunodiagnostic assays for the detection of *Aspergillus* antigens in serum and body fluids are promising but are not widely available and require further study.

For granulocytopenic patients with a diagnosis of invasive aspergillosis, therapy with amphotericin B should be initiated promptly, and a workup to determine the extent of disease should be begun simultaneously. This should include a careful physical examination, with special attention to the lungs, hard palate, nares, sinuses, and orbits. A minimal radiographic evaluation should include chest and sinus radiographs. Any suspicious findings or documented abnormalities should be followed by either CT or MRI in order to define the extent of disease more accurately and to provide better guidelines for assessment of subsequent therapeutic response. Aspergillosis may become evident as a focal neurologic deficit as the first manifestation of disseminated infection. Unlike CNS candidiasis or cryptococcosis, CNS aspergillosis has a high propensity for angioinvasion, infarction, and focal neurologic deficits. [460]

In order to detect invasive aspergillosis while still limited to the lung, the combined strategies of bronchalveolar lavage, CT, and galactomannan antigen detection may afford earlier detection in neutropenic patients. Illustrating this concept, Caillot et al. found that early CT coupled with galactomannan antigen detection by ELISA improved the diagnosis in these patients.[461] Among 23 histologically proven and 14 highly probable cases of invasive pulmonary aspergillosis, the most frequent clinical signs associated with invasive pulmonary aspergillosis were cough (92%), chest pain (76%), and hemoptysis (54%). The bronchoalveolar lavage fluid assay was positive for *Aspergillus* spp. in 22 (69%) of 32. Galactomannan antigen was positive in 83% of cases when tested on bronchoalveolar lavage fluid. Early CT scans routinely performed in febrile neutropenic patients with pulmonary infiltrates on chest radiograph suggested CT halo signs in 92% of patients. Using this strategy, the mean time to the diagnosis of invasive pulmonary aspergillosis was reduced from 7 to 1.9 days compared to historical controls. As increasing attention has been directed to the halo sign as a radiologic diagnostic marker for invasive aspergillosis, our laboratory studies have found that this finding correlates with a zone of reversible ischemia and organism-mediated pulmonary injury.[462]

Amphotericin B should be administered at a dose range of 0.51.5 mg/kg/day. Empirical treatment with amphotericin does not preclude the development of aspergillosis; 22 of 24 patients who were receiving amphotericin empirically developed progressive pulmonary infiltrates ultimately shown to be due to *Aspergillus*. If a persistently neutropenic patient is receiving empirical amphotericin B and has either a clinical picture compatible with aspergillosis or evidence of documented infection, the dosage of amphotericin should be increased to 1.01.5 mgkg.[463] Patients should continue amphotericin B until clinical and radiographic evidence of disease resolves. Itraconazole may be administered to patients who are stable but should be accompanied by careful monitoring of plasma levels in order to ensure bioavailability. Peak plasma levels of itraconazole by bioassay of >5 g/ml or by HPLC of >3 g/ml should be sought. The response to therapy and the ultimate survival of patients with invasive aspergillosis will be critically dependent on recovery from granulocytopenia, decreased dosage of any steroids, and removal of other immunologic deficits, and may be dependent on the dosage of amphotericin B administered.

Note subtle appearance of round densities in the right lung field. **(D)** CT scan of the chest from the patient whose chest radiograph is shown in B. Note expensive involvement despite minimal abnormalities on plain radiograph. **(E)** MRI showing invasive aspergillosis in the maxillary

sinus extending through bone to involve the roof of the mouth.

In the absence of bone marrow recovery, virtually all granulocytopenic patients with invasive aspergillosis will die despite receiving maximal antifungal therapy. The objectives of therapy are to delay progression and allow time for bone marrow recovery. Adjunctive therapy with granulocyte-stimulating factors such as G-CSF and GM-CSF should be considered to hasten bone marrow recovery. Many studies using standard dosages of amphotericin B (in the range of 0.5 mg/kg/day) still reported mortality rates of 75100%. Although encouraging findings indicate improved survival with higher dosages of amphotericin B (1.01.5 mg/kg/day), [463] the overall prognosis remains dismal, as reflected in the recent report by Pannuti et al., [464] in which *Aspergillus* was the cause of 36% of nosocomial pneumonias after bone marrow transplantation and resulted in the death of 19 of 20 infected patients.

Three lipid formulations of amphotericin B are indicated for immunocompromised patients with invasive aspergillosis who are refractory to or intolerant of conventional amphotericin B: ABLC (amphotericin B lipid complex, Abelcet), ABCD (amphotericin B colloidal dispersion, Amphotec), and liposomal amphotericin B (AmBisome). [465] [466] [467] While controversy exists concerning equivalent dosages, we recommend administration of 5 mg/kg/day as a starting dosage for any of the formulations used.

In general, surgical resection of lesions has little role in treating severely immunocompromised patients with invasive aspergillosis when the disease is often multifocal, and other medical conditions frequently preclude even less invasive procedures. However, resection may be considered in selected patients who are considered good surgical candidates, who are not responding to antifungal therapy, and whose noninvasive evaluation indicates disease confined to a single accessible area. Surgery may also have a role in the treatment for bone and soft tissue extension of infection that develops during antifungal therapy. [468]

A question that often arises is how to approach patients with a previous history of invasive aspergillosis who subsequently need myelosuppressive chemotherapy. That issue was addressed in a study by Karp et al. [469] conducted in 1988, in which 10 patients with AML and a prior history of invasive aspergillosis underwent 14 subsequent courses of chemotherapy. In nine of these patients, prophylaxis with amphotericin B (1 mg/kg/day) plus 5-FC was begun before institution of chemotherapy. All these patients survived the ensuing granulocytopenic episode without evidence of reactivation of invasive aspergillosis. By contrast, the one patient who did not receive prophylactic therapy suffered reactivation of aspergillosis and died. On the basis of these data, prophylaxis with amphotericin B with or without 5-FC seems reasonable in certain high-risk patients. However, more data are needed before firm recommendations can be established.

Infections Due to *Cryptococcus neoformans*

Cryptococcal infection can cause disease ranging from mild or asymptomatic to life-threatening and affects both immunocompetent and immunosuppressed individuals. Of patients with cryptococcosis in the pre-AIDS era, >50% had no predisposing factors, and white males predominated. [470] [471] The recent increase in cases of cryptococcal infection is largely due to the increasing numbers of patients with HIV infection, among whom it is one of the most common life-threatening infections. Other immunosuppressed populations at risk include patients receiving therapeutic doses of corticosteroids, those with lymphoid malignancies (particularly Hodgkin disease), patients with sarcoidosis (even if not receiving corticosteroids), patients with organ transplants, and patients with diabetes mellitus. [470] [471] The most common site of serious *Cryptococcus* infection is the CNS, followed by the lungs. Other sites, such as skin, bone, kidneys, and other viscera, have been reported less frequently. Interestingly, when CNS cryptococcosis occurs, there is no apparent pulmonary involvement in most cases. Conversely, respiratory involvement frequently occurs in isolation, although it often coexists with extrapulmonary disease, particularly in the immunosuppressed population. [472] The onset of CNS cryptococcal infection is frequently insidious, although heavily immunosuppressed populations may have an abrupt or even fulminant onset. Typically, symptoms are subtle, evolve over weeks to months, and most frequently include waxing and waning fevers, headaches, dizziness, somnolence, and signs of cognitive impairment. In addition, cranial nerve abnormalities are seen in 20% and papilledema in 30% of cases. Classic meningeal signs, such as nuchal rigidity, are rare. Symptoms and signs associated with pulmonary cryptococcosis are often mild or may be entirely absent. Typically, symptoms, if they occur, may include mild aching pain, scant hemoptysis, and, rarely, pleuritic pain, rales, or friction rubs. [472] Chest radiographs may show an isolated pulmonary nodule, an interstitial infiltrate, or a consolidative process.

In patients with significant deficiencies in cell-mediated immunity, any unexplained CNS or pulmonary signs or symptoms should raise the suspicion of infection with *Cryptococcus*. Subtle or intermittent symptoms should not be disregarded. Fever may be absent but may also be the only clue to infection, even with significant CNS disease; unexplained fever in patients with AIDS or other causes of impaired cell-mediated immunity should prompt a workup for cryptococcal infection. Immunosuppressed patients are at increased risk of disseminated disease, and this should be investigated even if initial symptoms or signs indicate an isolated site. The appropriate workup includes, at a minimum, cultures of suspected sites, tests for cryptococcal antigen in CSF and serum, and CSF examination. If tissue specimens are obtained, the diagnosis may also be established histopathologically.

CSF examination is helpful in establishing the diagnosis of CNS disease. In non-AIDS patients, abnormalities may include elevated opening pressure, low glucose concentration (50%), elevated protein concentration, and a mononuclear cell pleocytosis (usually with <500 cells/mm ^{3}).[472] [473] Importantly, AIDS patients or patients receiving high doses of corticosteroids may have little or no inflammatory response and consequently have little or no pleocytosis in the face of significant CNS disease. This is considered a poor prognostic sign. Overall, mass lesions due to *Cryptococcus* are relatively rare but may occur in 1025% of patients. If suspected, mass lesions should be ruled out before lumbar puncture.

The latex agglutination test for detection of cryptococcal polysaccharide antigen is >90% sensitive and specific for the diagnosis of cryptococcal disease and should be performed on both serum and CSF of patients in whom the diagnosis is suspected. [473] False-positive results may occur in the presence of rheumatoid factor (which may be eliminated by digestion with pronase or addition of reducing agents), in some malignancies, or by cross-reactivity with the rarer fungus *Trichosporon beigelii*.[474] [475] [476] Approximately 25% of HIV-infected patients will have a false-negative antigen in the CSF; the yield is often improved with repeated sampling. Specimens for India ink staining and for culture should always be obtained when possible. When the meninges are involved, *Cryptococcus* will usually grow from CSF specimens. Results of sputum cultures in

pulmonary cryptococcosis are more variable, however. Sputum cultures are frequently negative, particularly if disease is limited to a solitary nodule. A retrospective review from Duke University has shown excellent results from the culture of bronchoalveolar lavage fluid; however, only five patients were sampled. [477] In addition, positive sputum cultures for *Cryptococcus* are occasionally encountered in the absence of any evidence of parenchymal disease. [478]

The only appropriate therapy for CNS cryptococcosis is amphotericin B, with or without 5-FC. The combination of amphotericin B and 5-FC for 6 weeks is generally considered the treatment of choice for cryptococcal meningitis in non-AIDS patients. In a 1979 study comparing 0.4 mg/kg/day of amphotericin B alone for 10 weeks with a combination of 0.3 mg/kg/day of amphotericin B plus 5-FC for 6 weeks, no difference in mortality was found between the two regimens, but the combination regimen resulted in higher cure rates, fewer relapses, more rapid sterilization of the CSF, and decreased nephrotoxicity. [479] More recent data (in a 1987 report) indicate that in selected patients with mild meningitis in the absence of risk factors, 4 weeks of combination therapy might suffice. [480] If 5-FC is used, care must be taken to monitor serum 5-FC levels closely, to avoid toxicity (diarrhea, hepatitis, and bone marrow suppression), maintaining the peak serum concentration at 4080 gml. We and others have found that in patients with normal renal function, initial dosages of 5-FC of 25 mg/kg q.i.d. are adequate (as opposed to 37.5 mg/kg per dose, which is often recommended).

In patients in whom 5-FC is contraindicated or cannot be tolerated, successful therapy with amphotericin alone at dosages of 0.50.75 mg/kg/day can be effective and should be continued for at least 6 and perhaps 10 weeks (for immunosuppressed patients, a minimum of 10 weeks is recommended). Patients with lymphoreticular malignancies or those requiring continuation of corticosteroid therapy may need more protracted antifungal regimens; in these cases, the duration of therapy is adjusted according to the results of clinical and laboratory response.

The most appropriate therapy for CNS cryptococcosis in AIDS patients has not yet been defined, but it is clear that eradication of the organism is rarely achieved and that long-term suppressive therapy is usually indicated. A retrospective review of treatment of cryptococcosis in AIDS patients, published by Chuck and Sande [481] in 1989, indicated that the addition of 5-FC to amphotericin B neither enhanced survival nor prevented relapse in this population. In addition, AIDS patients appear to be particularly susceptible to the toxicities of 5-FC, with >50% requiring its discontinuation because of secondary cytopenias, according to this study. [481] Because this study was uncontrolled and flucytosine levels were not measured, and because other groups have reported success with the combination of amphotericin B and

flucytosine, the role of flucytosine remains controversial. [477] Additional studies prospectively comparing fluconazole and amphotericin B with and without flucytosine have shown varying results; the optimal therapy for cryptococcal infection in HIV-infected patients is unknown. [482] [483] The 4060% rate of relapse after cessation of treatment mandates lifelong maintenance therapy for HIV-infected patients. Initially, most patients received weekly amphotericin B, but maintenance with fluconazole has proved more effective with the advantages of fewer side effects and available oral preparations. [484]

After therapy, patients should have repeat lumbar punctures performed at least every few months for the first year, as most relapses occur within the first 6 months; a reasonable schedule is at 1, 3, 6, and 12 months after the conclusion of therapy. The CSF should be followed even if the original disease did not involve the CNS, as relapses have been found to occur there. Moreover, CNS disease can relapse at extraneural sites.

Other Fungal Infections in Immunosuppressed Patients

Zygomycosis (Mucormycosis)

Infections due to members of the Mucoraceae family are the fourth to fifth most commonly encountered mycoses in compromised patients. The Mucoraceae include the genera *Rhizopus*, *Rhizomucor*, *Mucor*, and *Absidia*. Patients at risk for zygomycosis include those with granulocytopenia, diabetic ketoacidosis, kwashiorkor, and those receiving deferoxamine. The clinical and radiologic manifestations of zygmycosis may resemble those of aspergillosis. The two most common clinical presentations are rhinocerebral and pulmonary zygomycosis, most commonly seen in patients with uncontrolled ketoacidosis or with granulocytopenia. Early and aggressive surgical debridement, intravenous amphotericin B, and correction of underlying metabolic abnormalities or immunologic deficits are essential for the successful treatment of rhinocerebral zygomycosis. Treatment of pulmonary and disseminated disease requires early initiation of intravenous amphotericin B therapy and reversal of immunologic impairment.[485] Lipid formulations of amphotericin B have been especially useful in the management of zygmomycosis, where patients such as those with diabetes mellitus may already have some preexisting renal insufficiency.

Pseudallescheria boydii

Pseudallescheria boydii is a soil saprophyte and a common cause of mycetoma. However, various medical centers have increasingly reported *P. boydii* as a cause of lethal disseminated infection in immunocompromised patients. [486] The populations at risk and the clinical and histopathologic manifestations of disseminated pseudallescheriosis are similar to those of disseminated *Aspergillus* infection. However, *P. boydii* is usually resistant to amphotericin B but is susceptible to antifungal azoles, including itraconazole and miconazole. [487] Given the dismal prognosis of infection due to this pathogen, combination therapy with amphotericin B and an antifungal triazole in profoundly compromised patients may enhance therapeutic efficacy. Although intravenous miconazole has been invoked as the preferred azole, this compound may cause fatal ventricular arrhythmias, hepatitis, and phlebitis. Other antifungal azoles, including ketoconazole, itraconazole, and saperconazole, have been used with varying degrees of success. [488] [489] Thus, itraconazole, 812 mg/kg/day administered orally, may provide a better therapeutic index if adequate plasma levels can be achieved. Whether the new third-generation antifungal triazoles will be effective against *P. boydii* infections awaits further investigation.

Fusarium Species

Disseminated infections with *Fusarium* spp. usually occur in granulocytopenic patients. They are often associated with prominent erythematous maculopapular to nodular skin lesions. Biopsy will reveal branching septate hyphae invading blood vessels, and the organism can be cultured from the lesions. Amphotericin B is the drug of choice for therapy, although resistance has been reported and mortality is as high as 75%.

Trichosporon beigelii

Disseminated disease due to the yeast *T. beigelii* has been increasingly documented in severely immunosuppressed patients and may resemble disseminated candidal disease. [46] Important risk factors for infection include granulocytopenia, corticosteroid use, and the presence of an intravascular catheter. [490] The

lungs, kidneys, skin, and eyes are the main sites affected. In untreated patients, serum and CSF may be falsely positive for cryptococcal antigen. [476] [490] Bone marrow recovery is the most important factor for a favorable outcome. Most isolates of *T. beigelii* are resistant to the fungicidal effects of amphotericin B. Laboratory and clinical studies demonstrate that fluconazole is safe, effective, and superior to amphotericin B in the successful treatment of invasive trichosporonosis. [490] [491]

CLINICAL APPROACH TO VIRAL INFECTIONS IN IMMUNOCOMPROMISED PATIENTS

Viral infections cause a wide range of disorders in patients with impaired immunity, ranging from subclinical infection to overwhelming disease and death. Of the viruses causing disease in this population, those belonging to the herpes group are encountered most commonly. The human herpesviruses that are most frequently encountered clinically include HSV, VZV, CMV, EBV, and HHV-6. Almost all these viruses are encountered with greater frequency in patients with immune dysfunction than in normal hosts. Patients with defects in cell-mediated immunity are the major population at risk. Impairment of cell-mediated immunity that may lead to serious viral infection is seen in patients with hematologic malignancies (particularly Hodgkin disease and the non-Hodgkin lymphomas), those with HIV-1 infection, patients undergoing organ transplantation (bone marrow, kidney, liver, heart), patients receiving corticosteroids or other aggressive immunosuppressive agents (including many cytotoxic antineoplastic regimens), severely malnourished individuals, and those with primary congenital or acquired defects in cell-mediated immunity.

A characteristic shared by each of these viruses is that they can cause disease either at initial exposure (i.e., primary infection) or after reactivation of latent disease. Indeed, latency is the hallmark of herpesvirus infections and, by application of current molecular biologic techniques, the mechanisms by which these viruses establish and maintain latency as well as undergo reactivation from the latent state are being elucidated. [492]

Infections Due to Herpes Simplex Virus

Infection with HSV may cause significant morbidity but is only rarely fatal in the compromised host. HSV infection usually represents reactivation of latently established disease.

When HSV infection occurs even in the most severely immunocompromised patients, it tends to remain localized and only rarely disseminates to distant sites. Although disseminated HSV infection can lead to death, the morbidity associated with localized HSV infection in compromised patients is a far more clinically relevant issue. The most common sites at which HSV occurs in non-AIDS patients are the mouth and perioral area, the nares, and the esophagus. In addition, a patient with a previous history of genital or perianal HSV may experience reactivation at these sites. However, the absence of a history for recurrent herpes does not preclude the presence of latent virus, since >50% of latent HSV infections in normal hosts are asymptomatic. Pain is the hallmark of lesions attributable to HSV. As compared with its effects in healthy individuals, the infection in compromised patients causes more symptoms (predominantly pain), is associated with larger and more numerous lesions, and persists for a longer period (Fig. 79-9). Chronic ulcerated lesions in the oral or anogenital region may persist for weeks to months in certain subgroups, such as those with hematologic malignancies or AIDS. [493] [494] [495] Esophagitis due to HSV typically manifests with burning pain on swallowing with or without associated dysphagia, and may or may not be associated with visibly apparent oral lesions. HSV esophagitis may be clinically indistinguishable from other causes of similar symptoms in this

Box 79-3. APPROACH TO VIRAL INFECTIONS HERPES SIMPLEX VIRUS

HERPES SIMPLEX VIRUS

In compromised hosts, HSV is rarely fatal but is a significant cause of morbidity. For treatment of symptomatic infection, either oral acyclovir (200 mg five times per day) or intravenous acyclovir (750 mg/m^2 /day in three divided doses) is effective. Patients with persistently compromised immune status (e.g., those with AIDS) may need chronic suppressive treatment. Acyclovir resistance may develop.

VARICELLA-ZOSTER VIRUS

Those at risk of primary infection (chickenpox) who are exposed to an infectious source should receive zoster immune globulin (ZIG) and be isolated from other susceptible patients. ZIG can decrease both the morbidity and the mortality associated with subsequent infection. In seriously compromised cancer patients who develop primary chickenpox (and who do not receive ZIG or early antiviral therapy), visceral dissemination will occur in about one-third, and 20% may die. Prompt institution of intravenous acyclovir (1,500 mg/m^3 /day in three divided doses) can decrease the morbidity and mortality. Acyclovir should be continued for 7 days and until complete crusting of the lesions.

Secondary VZV infection (zoster) can also cause significant morbidity in compromised patients, although dissemination and death are less frequent than with primary disease. Among seriously compromised cancer patients who do not receive antiviral therapy, cutaneous dissemination occurs in 2550% and visceral dissemination in 819%. The lungs and liver are the most common visceral sites of dissemination. Intravenous acyclovir (1,500 mg/m^2 /day in three divided doses) can decrease dissemination and hasten healing of lesions and should be administered as soon after the appearance of lesions as possible (preferably within 72 hours). We begin all high-risk patients on intravenous acyclovir. (High-risk patients we define as those undergoing neutropenia-producing cytoreductive therapy, those who have received total body irradiation or bone marrow transplantation within the previous year, those with Hodgkin disease or non-Hodgkin lymphoma, those with AIDS, and other patients with significant depression of cell-mediated immunity, such as those receiving high doses of corticosteroids.) Therapy should continue for 7 days or until the lesions have crusted. We discourage the use of oral acyclovir for prophylaxis or treatment because of the low serum levels attained and the development of resistance. Patients with acyclovir-resistant HSV or VZV infection may be treated with foscarnet.

CYTOMEGALOVIRUS (CMV)

Ganciclovir is the drug of choice for patients with evidence of CMV infection. Foscarnet serves as second-line therapy and, on occasion, can be used in combination with ganciclovir when there is evidence of disease progression on monotherapy.

Figure 79-9 Extensive oral herpes simplex in a granulocytopenic patient with chemotherapy-induced mucositis and oral candidiasis.

population, including chemotherapy-induced mucositis, *Candida* esophagitis, and CMV esophagitis.

Mucocutaneous HSV infection may also cause secondary complications such as bleeding or infection. Mucosal disruption may lead to localized secondary bacterial infection and may also provide a portal of entry for bacteria into the bloodstream.

Dissemination beyond the oral, anogenital, nasal, or esophageal mucosa occurs rarely. The incidence of dissemination is not well established but is probably <1%. The most common sites of dissemination are the skin, lungs, liver, CNS, and adrenals. The diagnosis of disseminated HSV should be considered in any patient with cell-mediated immunity defects and unexplained findings referable to these sites.

The diagnosis of localized oral, nasal, or anogenital HSV infection is rarely problematic. Early lesions usually have a characteristic vesicular appearance, and cultures are usually positive within 48 hours. When obtaining material for culture for HSV, it is important to remember the following steps. False-negative results may be obtained from lesions that appear either very early (i.e., before vesicle formation) or late in the course of evolution (after crusting). Ideally, culture material should consist of serous fluid from vesicles that is obtained after gentle unroofing. Also, specimens should be promptly inoculated into tissue cultures and should not be kept at room temperature for prolonged periods. It is helpful to store frozen culture medium on the hospital floors so that it is readily available to the clinician. Techniques such as direct immunofluorescence assay, ELISA, and monoclonal antibody staining allow for rapid diagnosis.

The definitive diagnosis of HSV esophagitis or disseminated disease may be more elusive. Accordingly, for patients with defects in cell-mediated immunity in whom the diagnosis is suspected on clinical grounds, empirical therapy is often instituted. In patients with esophagitis, the simultaneous presence of characteristic oral lesions may point toward the diagnosis but neither confirms nor rules out other contributing factors. In the absence of oral lesions, positive oral cultures may indicate esophageal infection, but they may also reflect asymptomatic excretion or infection at another site. In these settings, empirical therapy with acyclovir or amphotericin B, or both, may be indicated, and in selected patients esophagoscopy and biopsy may be performed (see also discussion of *Candida* esophagitis).

The diagnosis of HSV pneumonitis presents similar problems. Positive cultures of respiratory secretions usually reflect asymptomatic excretion or excretion from another infected site (e.g., oral cavity), but occasionally they may indicate lung or tracheobronchial involvement. Lavage fluid showing multinucleated giant cells may be helpful but is not specific. The diagnosis of HSV meningoencephalitis is made by use of PCR technology for HSV DNA in CSF. The PCR test is extremely sensitive, specific, and rapid, becoming positive as early as 1 day after disease onset. [496] Even in PCR- or biopsy-confirmed cases, HSV is seldom cultured from the CSF.

Acyclovir is the drug of choice for the treatment of HSV infections in immunosuppressed patients. For mucocutaneous disease, either oral or intravenous acyclovir is effective in shortening the length of symptoms, the time of virus shedding, and the time to healing. Because many patients with oral or esophageal HSV infection have difficulty swallowing, intravenous administration is often more useful. The appropriate intravenous dosage is 250 mg/m ^{2} (or 5 mg/kg) t.i.d. Therapy should be continued for 1 week or until lesions have crusted. Patients with diagnosed or suspected visceral or CNS dissemination should receive intravenous acyclovir at a dosage of 500 mg/m^2 (or 10 mg/kg) t.i.d., and therapy should be continued for 10 days. During the past several years, treatment of HSV infections has been increasingly complicated by the emergence of acyclovir-resistant virus. Resistant HSV has primarily been isolated in the most immunosuppressed patients, such as those with AIDS or who have undergone bone marrow transplantation. [497] [498] In a review by Englund et al., [497] seven patient isolates of 207 were found to be resistant to acyclovir; all seven of these patients were immunocompromised from marrow transplantation (four cases), solid organ transplantation (two cases), or AIDS (one case). Although resistance to acyclovir has been associated with chronic low-dose acyclovir in both animal models and case reports, no specific regimen or dose has been implicated. [499] [500] Spontaneous mutations in the viral thymidine kinase lead to a mixed population of HSV, and chronic acyclovir therapy may permit the emergence of the acyclovir-resistant viral population. Resistant HSV is usually susceptible to foscarnet, which is used for successful treatment of these patients. [498]

Antivirals

Recently, two new orally available antiherpes drugs have become available, famciclovir and valaciclovir. The former is a

prodrug of penciclovir, an agent with potent activity against both VZV and HSV types 1 and 2. Famciclovir is effective for the treatment and suppression of genital herpes in normal hosts and is a promising agent for use in immunocompromised patients with mild HSV recurrences because of its oral bioavailability and its twice daily schedule of administration, which make it much simpler to take than acyclovir, which requires dosing five times daily. [501] Valaciclovir, a prodrug of acyclovir, is also highly active against herpes simplex and zoster viruses but is currently contraindicated in immunocompromised patients because of reports of thrombotic thrombocytopenic pupura/hemolytic uremic syndrome (TTP/HUS) in patients with advanced HIV and bone marrow and renal transplant recipients. TTP/HUS has not been reported in association with famciclovir, but clinical trials in immunocompromised patients are ongoing. [502]

Infections Due to Varicella-Zoster Virus

In contrast to HSV infection, VZV infection in compromised patients may be associated with significant morbidity and mortality. Both primary disease (chickenpox) and reactivation of latent disease (zoster or shingles) are clinically important in this population.

Primary Varicella Infection (Chickenpox)

In noncompromised patients, chickenpox is a highly contagious but relatively benign, self-limited disease that requires no therapy. Primary infection usually occurs during childhood (usually by the age of 3 years) and may result in either subclinical or clinically apparent disease. Approximately 90% of individuals have acquired antibodies to VZV (implying primary infection) by the age of 15 years. [503] In healthy children, chickenpox is usually limited to the skin. When it occurs in adults, 15% also have radiographic evidence of pulmonary involvement, although fewer have pulmonary symptoms, which are usually mild in nature. [503] [504] In immunocompetent patients, dissemination is rare, with a self-limited cerebellar ataxia occurring in 1 in 4,000 children and encephalitis in 0.10.2%. [503] By contrast, primary varicella frequently disseminates and can cause serious morbidity and mortality in patients with impaired cell-mediated immunity. Children with immune impairment represent the highest-risk group for primary varicella, which parallels its age distribution in the normal host, with only 10% of adults at risk of primary disease. However, for patients of any age with a newly diagnosed disease associated with defective cell-mediated immunity (e.g., Hodgkin disease) or for those about to receive therapy that can result in impaired cell-mediated immunity (e.g., intensive chemotherapy or corticosteroids), it is prudent to check for a clinical history of chickenpox or to check serum titers in the absence of clinical information. The absence of VZV antibody titers indicates a significant risk of the acquisition of primary disease, if exposed, and has important implications for management after potential exposure.

Of those seriously immunocompromised children who contract primary varicella and who do not receive either ZIG or early therapy with acyclovir, about one-third will experience visceral dissemination; among these children mortality is in the range of 720% (usually due to progressive pulmonary insufficiency). [66] The lung is the major site of dissemination, which occurs 37 days after the onset of skin lesions, with chest radiographs classically showing diffuse nodular infiltrates. The CNS and liver are two other frequent sites of dissemination. VZV hepatitis in the absence of CNS or pulmonary involvement rarely causes death.

Among children, those at highest risk for serious disseminated VZV are those with malignancy who are undergoing intensive cytoreductive therapy, those receiving organ transplants, and those with primary disorders of cell-mediated immunity. Among children being treated for malignancy who develop VZV, those with leukemia and lymphoma represent the largest group, probably because hematologic malignancies are the most common in this age group. Dissemination is more likely in children with 500 lymphocytes/mm^3 at the onset of disease and in those in whom chemotherapy was continued after the onset of skin lesions. [66] Disseminated VZV occurs more often in patients with advanced disease, although this may be related to the use of more aggressive therapy. [67]

The diagnosis of primary cutaneous chickenpox is usually made relatively easily on clinical grounds from the appearance of the lesions. However, immunosuppressed patients, particularly those with AIDS, occasionally develop atypical lesions such as papules or hyperkeratosis. A high index of suspicion must be maintained in susceptible hosts. Knowledge of antecedent VZV antibody titers or of a clinical history of prior infection can be helpful in this setting. A specimen should be obtained for viral culture from any suspicious vesicular lesion by unroofing the vesicle and scraping cells from the base of the lesion (not vesicular fluid) in order to capture this highly cell-associated virus. Cultures of skin lesions often yield positive results, with shell-vial cultures for VZV taking only a few days to become positive. Immunofluorescent stains on scrapings from skin lesions (the direct fluorescence antibody test) are very helpful in early diagnosis and are often more sensitive than

culture. Acute and convalescent serum antibody measurements are rarely helpful in confirming the diagnosis retrospectively.

All immunosuppressed patients with suspected primary VZV infection should undergo chest radiography and measurement of liver transaminases in order to establish a baseline and to detect clinically silent disseminated disease. Examination of the sputum in VZV pneumonia may show multinucleated giant cells, and culture may yield positive results. CNS involvement may be very difficult to diagnose with certainty ante mortem; PCR may be a useful technique in the diagnosis of CNS disease due to VZV.[505]

Patients with confirmed or suspected primary varicella should be placed in immediate isolation to avoid exposure of other susceptible patients. Other immunocompromised patients at risk of acquisition of primary varicella who had contact with the patient during the infectious stage (beginning 48 hours before the appearance of the lesions and lasting until crusting of the lesions) should be contacted and promptly given varicella-zoster immunoglobulin. The incubation period is 1021 days after exposure; exposed patients should consequently avoid contact with other patients for that period.

Early institution of intravenous acyclovir will dramatically reduce the incidence of visceral dissemination of primary varicella. In a randomized double-blind placebo-controlled trial of acyclovir in immunosuppressed children with primary varicella, pneumonitis developed in five of 11 placebo recipients but in none of 11 patients who received acyclovir.[506] Vidarabine therapy can also be effective, although it is rarely used, as acyclovir is widely available. [507] Intravenous acyclovir should be instituted at a dose of 500 mg/m^2 (or 10 mg/kg) t.i.d.; therapy should be continued for at least 7 days, or until all lesions have crusted. Patients receiving this dose of acyclovir should be well hydrated in order to maintain urine flow and avoid renal precipitation and toxicity. Therapy for disseminated disease is identical, although more protracted courses may be required.

Herpes Zoster

Herpes zoster, or shingles, is believed to represent reactivation of latent disease. Although some reports have suggested that zoster can be acquired exogenously, this has not been firmly substantiated, and the vast majority of cases are not temporally associated with antecedent exposure. [69] [71] [508] Although zoster can

occur in healthy individuals, it is clearly more common in certain immunosuppressed populations. Patients with malignancy, especially those with Hodgkin disease, are at highest risk (15%), followed by patients with non-Hodgkin lymphoma (8%), and patients with solid tumors (2%). [67] [69] [505] [509] [510] [511] [512] [513] [514] Zoster is more common in patients with advanced disease, as opposed to those with limited disease or in remission. However, in certain subgroups (e.g., patients with Hodgkin disease or lymphomas), an increased risk continues even after cure of the malignancy. [515] Zoster is more likely to develop at skin sites that have been previously damaged by tumor or radiation therapy. More intensive immunosuppression is associated with a higher risk of zoster (e.g., patients who receive combinations of chemotherapy and radiation therapy are at greater risk than those who receive either modality alone). Following significant immunosuppressive therapy such as for bone marrow transplantation, the increased risk for zoster may last 1 year.[515] Zoster usually appears unilaterally and follows a dermatomal distribution even in immunosuppressed patients. Early lesions may be very subtle (Fig. 79-10). Rarely, it may present with cutaneous dissemination without a prior history of dermatomal involvement (so-called atypical disseminated zoster or varicelliform zoster, which resembles primary varicella). [69] [513] [516] Visceral dissemination of zoster occurs less frequently than does dissemination of primary varicella infection. Prior to the prompt, routine use of acyclovir in all immunosuppressed patients with zoster, the incidence of dissemination was 2450%, while visceral dissemination (to the lungs, CNS, liver, and uvea) occurred in 819%. [517] [518]

Figure 79-10 Early lesions of zoster in an immunosuppressed patient.

In the current era, the liberal use of acyclovir has dramatically reduced the incidence of disseminated zoster.

Guidelines for the diagnosis of zoster are similar to those for the diagnosis of primary varicella. When an immunosuppressed patient with suspected or diagnosed zoster is encountered, several important questions arise. First, has the patient had significant contact with other patients who may be at risk for the development of primary varicella? Although patients with zoster are less infectious than those with primary varicella, direct contact may spread infection to susceptible individuals, who should receive ZIG. Second, is the disease localized, or is there any evidence of cutaneous or visceral dissemination? All patients at risk of dissemination should undergo a baseline physical examination, chest radiography, and measurement of liver transaminases. Third, is the patient a candidate for intravenous therapy? Clearly, any patient with disseminated disease is a candidate for therapy with intravenous acyclovir.

In addition, patients with localized disease who are at significant risk for dissemination should be treated with acyclovir. This includes (1) patients with an underlying diagnosis of either Hodgkin disease or non-Hodgkin lymphoma, whether or not undergoing therapy (those receiving therapy will be at higher risk of dissemination); (2) patients with any malignancy who are undergoing aggressive cytotoxic therapy (defined as therapy that produces significant leukopenia); (3) patients who have received total body irradiation or bone marrow transplantation, for 1 year after the procedure; (4) patients with AIDS; and (5) other patients with severe congenital or acquired defects in cell-mediated immunity (including those receiving systemic corticosteroids or other immunosuppressive drugs). Intravenous acyclovir is recommended for immunosuppressed patients with dermatomal zoster.

Attempts should be made to treat patients as soon after the appearance of the lesions as possible (preferably within 72 hours), even if the lesions are confined to a single dermatome, since earlier therapy may result in improved outcome. However, the results of studies summarized following indicate that patients with older lesions that have not healed should also receive therapy.

Although both vidarabine and acyclovir have been shown in controlled trials to be effective for the treatment of zoster in immunocompromised patients, acyclovir has been more effective.[517] [518] [519] [520] A 1986 study by Shepp and colleagues [520] compared intravenous acyclovir with vidarabine in compromised patients. Acyclovir was found to be significantly better in preventing disease progression or dissemination, shortening culture positivity, decreasing new lesion formation, and decreasing time to pain resolution and crusting of lesions. In addition, acyclovir is extremely well tolerated and lacks the neurologic side effects seen occasionally with vidarabine therapy.

The first randomized, double-blind, placebo-controlled trial of acyclovir for zoster in immunosuppressed patients was reported in 1983 by Balfour and co-workers. [517] A 1-week course of acyclovir, 1,500 mg/m^2 /day given intravenously, halted significant progression of disease in patients presenting with either localized or cutaneous disseminated disease. For patients who presented with lesions confined to a single dermatome, acyclovir did not prevent local skin progression (i.e., either increase in the rash within the initial dermatome or extension to a new contiguous dermatome). However, it did decrease wider cutaneous spread, as well as visceral dissemination in patients who presented with either localized or disseminated cutaneous disease. Of the four patients randomized to placebo in whom visceral disease developed, three died. Two patients who presented with initial visceral dissemination and received acyclovir both survived. Acyclovir was effective at halting progression of disease even if begun in patients whose rash was >72 hours old at entry.

On the basis of these data, intravenous acyclovir at 1,500 mg/m^2 /day, given on an every-8-hours basis, is the treatment of choice for zoster in immunosuppressed patients. It should be continued for a minimum of 7 days, or until crusting of the lesions is noted. Oral acyclovir, even at high doses, is not appropriate therapy for zoster infections. The bioavailability of oral acyclovir is only 15%, and systemic concentrations achieved following oral dosing are not sufficient to inhibit VZV replication (VZV is 1020 times more resistant to acyclovir than is HSV). [521] Famciclovir, which has excellent oral bioavailability and activity against VZV, has been shown to be effective in treating zoster in the normal host, in whom it decreased postherpetic neuralgia. Famciclovir may also be useful in immunocompromised hosts.[501]

Clinically significant acyclovir-resistant VZV has become an increasing problem in the AIDS era. Chronic infection, often with atypical lesions and pain, is not uncommon in AIDS patients. As in acyclovir-resistant HSV, resistant VZV is often associated with chronic low-dose acyclovir use. [522] [523] In order to decrease the risk of developing resistance, it is best to aggressively treat the original VZV infection with high-dose intravenous acyclovir. Since viral susceptibility patterns are not

readily available, treatment decisions must often be based on the clinical response to therapy. Foscarnet is an alternative in most patients with resistant VZV infection.[523]

Infections Due to Cytomegalovirus

CMV causes a variety of syndromes in both immunocompetent and compromised hosts. The virus is ubiquitous, and most of the population is eventually infected, although clinical disease is relatively rare in healthy individuals. In noncompromised hosts, in addition to subclinical infection it may cause heterophil-negative mononucleosis and, rarely, has been associated with more serious complications, including interstitial pneumonitis, hepatitis, Guillain-Barré syndrome, meningoencephalitis, myocarditis, and hemolytic anemia.

In immunosuppressed patients CMV may cause significant morbidity and mortality. Of patients with hematologic disorders, those who present the highest risk of acquiring serious infection are bone marrow transplant recipients, particularly those undergoing allogeneic bone marrow transplantation, those who receive total body irradiation as part of the ablative regimen, and those who develop acute GvHD after transplantation.[524] [525] Other patients with hematologic malignancies (e.g., leukemia, lymphoma) are also at risk, although the incidence is lower. Other groups at risk include AIDS patients and recipients of solid organ transplants. In immunocompromised populations, disease may represent either acquisition of primary infection or, more commonly, reactivation of latent infection. Transfusion of seronegative blood products into seronegative recipients can dramatically decrease the acquisition of primary disease in selected populations.

CMV may infect many organ systems in compromised patients. In the bone marrow transplant population, interstitial pneumonia is the most common and most serious complication, associated with a high mortality rate. However, clinically important infection of other organ sites has been recognized with increasing frequency, most notably in AIDS patients but in other populations as well. The GI tract may be infected at any site from the esophagus to the colon. Submucosal ulcerations are common, and symptoms may range from isolated fever to severe hemorrhage or explosive diarrhea. CMV has also been implicated in the development of pancreatitis and cholecystitis.[526] [527] CMV retinitis may progress to blindness if untreated and occurs in 1020% of adult AIDS patients, although it has also been described in other immunosuppressed populations.[528] CNS involvement in non-AIDS patients is probably rare and has been reported only anecdotally. Neurologic complications in HIV-infected patients include subacute encephalitis, dementia, and polyradiculopathy.[529] This discussion focuses on CMV pneumonitis, the most commonly encountered serious CMV infection in non-AIDS patients and the most thoroughly studied.

Cytomegalovirus Pneumonitis

Depending on the presence or absence of specific risk factors, up to 50% of allograft bone marrow recipients develop interstitial pneumonia, and 70% of these cases will be associated with CMV. Typically, this infection occurs within the first 3 months after allogeneic marrow transplantation, with a median onset of about 60 days. Cases developing later than 100 days have also been well documented, primarily in patients with chronic GvHD.[530] Diffuse infiltrates are most common, but localized or nodular infiltrates have been described. Pleural effusions are rare.

CMV pneumonia is clinically indistinguishable from other causes of diffuse infiltrates in the compromised host, especially *P. carinii* infection and respiratory viruses such as influenza and RSV. While positive cultures from blood, urine, or respiratory secretions may raise suspicion of infection, they do not necessarily correlate with pulmonary infection. Serology for CMV may not be helpful because of false-negative results seen with immunosuppression. To establish the diagnosis, direct examination of pulmonary specimens is required. Although only open lung biopsy can be considered definitively diagnostic, bronchopulmonary lavage may be of value, particularly in bone marrow transplant patients. In examining specimens, use of the shell-vial culture system with immunofluorescent antibody staining frequently yields culture results positive for CMV within a few days.[531] [532] Classic histologic examination of tissue is the reference standard for the diagnosis of interstitial pneumonitis due to CMV. It will reveal typical intranuclear inclusions of CMV (Fig. 79-11). It should be stressed that even if diagnosis of CMV pneumonia is made or strongly suspected, other potential pathogens should still be sought, as CMV has been identified in association with other organisms.

Therapeutic options for treating serious CMV infection are limited and complicated by serious toxic effects. Both foscarnet and ganciclovir appear to be effective in treating CMV infections in patients with AIDS; however, the use of both therapies is limited by toxic effects, the need for intravenous dosing, and the emergence of resistant strains of CMV.[533] [534] Foscarnet not only has activity against CMV, it also shows in vitro inhibition of HIV reverse transcriptase; some studies have suggested improved survival of AIDS patients with CMV retinitis treated with foscarnet.[535] [536] [537] CMV isolates from both AIDS patients and marrow transplant recipients have been found to be ganciclovir resistant. The clinical significance is unclear. Resistance has been associated with progressive clinical disease. However, patients may be infected with multiple strains, and the virus isolated may not have the same antiviral susceptibilities as the actual infecting strain. It is impossible to make a clinical distinction of progressive CMV disease due to a virulent strain from disease due to a resistant one. Although foscarnet has been used to successfully treat patients with ganciclovir-resistant CMV, therapy with both foscarnet and ganciclovir has been beneficial with particularly aggressive disease.[538] [539] The neutropenia and thrombocytopenia that often accompany ganciclovir therapy are problematic in patients with bone marrow suppression from chemotherapeutic agents, zidovudine, or their underlying disease.[533]

Ganciclovir alone has not been effective in altering the outcome of CMV pneumonia in patients who have received bone marrow transplants.[540] [541] Studies have documented improved outcome in marrow transplant recipients with CMV pneumonia

Figure 79-11 Pulmonary biopsy specimen with cell showing typical intranuclear inclusion of cytomegalovirus (arrow).

who were treated with combinations of ganciclovir (2.5 mg/kg t.i.d. or 5 mg/kg b.i.d.) and high intravenous doses of immunoglobulin; overall survival improved to 5070%, as compared to <15% survival for historic controls.[542] It should be noted that although AIDS patients frequently appear to respond to ganciclovir or foscarnet therapy, relapse is almost certain when therapy is discontinued. Accordingly, continuous prophylaxis with ganciclovir or foscarnet is required. Immunocompromised patients with CMV disease should also receive maintenance therapy until immune system recovery. Potential therapies now being investigated include immunotherapy with CMV-specific CD8-positive lymphocyte subsets and treatment with CMV-specific monoclonal antibody.[543] [544] [545]

Infections Due to Respiratory Viruses

The respiratory virusesRSV, influenza, parainfluenza, and adenoviruscommonly cause upper and lower respiratory tract infections in immunocompetent children and adults. These viruses are becoming increasingly recognized as important community-acquired and nosocomially acquired pathogens in immunocompromised patients, particularly those undergoing intensive therapy for leukemia or recipients of bone marrow or solid organ transplants. RSV is a frequent cause of lower respiratory tract infection in young children and it is associated with mild upper respiratory infections in older children and adults, but is not considered a significant pathogen in the older age group. However, a number of studies have recognized that life-threatening respiratory disease due to RSV occurs in moderately to severely immunocompromised adults.[84] [546] [547] Englund et al.[84] described 11 immunocompromised adult patients with RSV infection, most of whom presented with cough, fever, and rhinorrhea. Lobar or interstitial infiltrates were observed in eight patients, and four died of progressive interstitial pneumonia despite treatment with ribavirin. Among bone marrow transplant patients, those who develop RSV pneumonia prior to engraftment appear to have a worse prognosis than those in whom engraftment has already occurred.[546] In a study of adult patients with acute leukemia who were hospitalized for acute respiratory illness, RSV was isolated from 10%. Among the nine patients with RSV infection, five died of interstitial pneumonitis.[547] In addition, the same group at the M.D. Anderson Cancer Center reported that one-third of adult leukemia patients who were hospitalized with acute respiratory illness had influenza A isolated from respiratory secretions, and 80% of those had an associated viral pneumonia.[548] The high rate of pneumonia in this selected group of patients hospitalized for respiratory symptoms is probably an overrepresentation of those with more severe infections. In a study of immunocompromised outpatients, including renal and bone marrow transplant patients and those with leukemia, 25 patients with influenza A were identified, of whom 22 had a clinical course indistinguishable from that of an immunocompetent host with influenza.[549] Unlike other respiratory viruses, adenovirus may disseminate, resulting in pneumonitis, hepatitis, colitis, or hemorrhage cystitis. In one study of adenoviral infections in immunocompromised patients, 12 of 15 had pneumonia and eight had hepatitis.[550] Shields et al.[551] reported a 5% incidence of adenoviral infection after bone marrow transplantation. In both studies, the adenoviral infection, often a pneumonia, was shown to increase mortality.

A limited number of antiviral agents are available for treatment of respiratory viral infections in immunocompromised patients, and none has been formally evaluated in clinical trials in this population. Ribavirin, a synthetic nucleoside analog with activity against RSV, influenza, and parainfluenza viruses, has been used anecdotally

for treatment of RSV in immunocompromised patients. In a study of 19 bone marrow transplant recipients with acute respiratory illness due to RSV, 16 patients developed pneumonia. Mortality was 100% in those who were either untreated or treated late, i.e., after the onset of respiratory failure, whereas it was 22% in those who received therapy with ribavirin plus IVIG prior to the onset of profound respiratory compromise. [552] Although early diagnosis and treatment appear to be beneficial in severely immunosuppressed bone marrow transplant recipients, it is not clear that those who have RSV infection in the setting of less immune dysfunction still require drug therapy. Amantadine is effective therapy for influenza A (not B) in immunocompetent adults, in whom it shortens the duration of fever and systemic symptoms if given within 48

hours of the onset of symptoms. It has not been formally evaluated in immunocompromised patients but it is strongly recommended for those who do develop influenza A infection.

CLINICAL APPROACH TO PARASITIC INFECTIONS IN IMMUNOCOMPROMISED PATIENTS

Pneumocystis carinii Pneumonia

P. carinii pneumonia is the most common parasitic disease affecting immunocompromised patients. The populations most commonly affected are those with hematologic malignancies (particularly ALL, Hodgkin disease, and non-Hodgkin lymphomas) or AIDS. In addition, however, *P. carinii* pneumonia can occur in patients with solid tumors, transplant recipients, and other immunosuppressed populations, particularly in those receiving therapy associated with impaired cell-mediated immunity (e.g., corticosteroids). Of all the subgroups at risk for *P. carinii* pneumonia, adult AIDS patients have by far the greatest relative risk.

In non-AIDS patients the most common clinical manifestations of *P. carinii* pneumonia include fever, cough, and tachypnea, generally with intercostal retractions and the absence of detectable rales. A chest radiograph typically shows a hazy bilateral alveolar infiltrate, which often begins at the hilus and spreads to the periphery. Arterial blood gas measurements reveal a low Pa_{O_2} , normal Pa_{CO_2} , and alkaline pH. The clinical presentation can be indolent (12 months) but is more often rapidly progressive (45 days). Chest radiographic findings are occasionally atypical (e.g., lobar consolidation, effusion, or nodular or unilateral pneumatocoeles); in rare cases, the radiograph may appear normal despite the presence of pneumatocoeles on biopsy. *P. carinii* pneumonia in cancer patients differs from that in AIDS patients; the median duration of symptoms is 28 days in AIDS patients but 5 days in non-AIDS patients. [553] In AIDS patients, disseminated *P. carinii* infections have recently been reported: although the lungs are still the most common site of infection, the lymph nodes, spleen, liver, bone marrow, adrenal glands, kidneys, and GI tract are also commonly involved. [554]

The diagnosis of *P. carinii* pneumonia requires demonstration of cysts or trophozoites in pulmonary material from patients with a clinically compatible course; cysts have been found in asymptomatic, previously healthy individuals autopsied after traumatic death. Classically, material obtained from bronchoalveolar lavage or open lung biopsy and stained with Gomori methenamine-silver nitrate or toluidine blue has been the most reliable for diagnosis. At the NCI, immunofluorescent monoclonal antibody stains on induced sputum specimens have given rapid and reliable results (Fig. 79-12).[555]

In clinical situations in which the likelihood of *P. carinii* pneumonia is great, the choice is between proceeding with a diagnostic procedure and administering an empirical course of therapy with trimethoprim-sulfamethoxazole. If techniques for examining induced sputum or bronchoalveolar lavage fluid are readily available, these are initially the procedures of choice for establishing the diagnosis. However, if they are not available, or if the patients clinical or hematologic status does not permit bronchoalveolar lavage, an empirical trial of trimethoprim-sulfamethoxazole (20 mg/kg/day of trimethoprim) plus erythromycin (for *Legionella*) is recommended, rather than proceeding directly to open lung biopsy. This approach is based on the results of a randomized NCI trial demonstrating that in

Figure 79-12 (A) Cluster of *P. carinii* obtained from bronchoalveolar lavage (stained with toluidine blue). **(B & C)** *P. carinii* from induced sputum specimen stained with immunoflurescent monoclonal antibody.*(Courtesy of Drs. V. Gill and J. Kovacs, Clinical Center, National Institutes of Health.)*

non-neutropenic patients with diffuse infiltrates, empirical therapy is as safe and effective as open-lung biopsy. [556] The clinician should realize that a response to therapy may not be apparent for 45 days. Indeed, progression over the first few days does not necessarily imply inappropriate or ineffective therapy. It is theorized that this delay in improvement is due to the hosts inflammatory response; for this reason, steroids are recommended during the first 72 hours for patients with an arterial oxygen pressure of <70 mm Hg or an arterial-alveolar gradient of <35 mm Hg. [557] If the patient fails to improve (e.g., continued fever, depressed Pa_{O_2} , or progressive infiltrates) after 4 days of therapy, modification is then appropriate. In this setting we prefer to add pentamidine (4 mg/kg/day) rather than discontinue the trimethoprim-sulfamethoxazole, since progression may represent slow response rather than true failure.

If a histologic diagnosis is necessary and not achievable by bronchoalveolar lavage, not all procedures, such as transtracheal aspiration, transbronchial biopsy or aspiration, or open lung biopsy, are of comparable diagnostic accuracy. Burt and colleagues [558] examined each of 17 patients who had undergone open lung biopsy to evaluate whether the diagnosis of a diffuse interstitial infiltrate could be established with a transthoracic needle aspirate and a transbronchial brush and biopsy. The patients in this unique study served as their own controls. The diagnosis was established from only 30% of the aspirates and from 59% of the transbronchial biopsy samples, suggesting that open lung biopsy is the procedure of choice. Open lung biopsy provides the soundest guidance for patient management, especially if the patient is neutropenic and requires multiple antimicrobial agents.

Because patients who are candidates for open lung biopsy are often thrombocytopenic, appropriate hematologic support for surgery is vital. Elevation of the platelet count to a surgically safe level of >60,000/mm^3 can usually be accomplished by infusion of 812 units of platelet concentrates 1 hour before surgery. Maintenance of the platelet count at this level for 24 hours after surgery with additional platelet concentrates minimizes any postoperative bleeding complications.

Because of the importance that *P. carinii* has assumed in patients with AIDS, the search for new therapeutic agents has intensified. Alternative regimens studied have included dapsone alone, trimethoprim with dapsone, clindamycin with primaquine, atovaquone, eflornithine, trimetrexate, and piritrexim. [311] The efficacy of trimethoprim-sulfamethoxazole as primary prophylaxis against both *P. carinii* pneumonia and toxoplasmosis in AIDS patients is unknown. A French study found that the combination of dapsone and pyrimethamine was as effective as aerosolized pentamidine in preventing *P. carinii* pneumonia and was also effective in preventing toxoplasmosis in *Toxoplasma*-antibody-positive patients. [559]

Another clinical dilemma is the treatment of patients who develop *P. carinii* pneumonia while on a preventive regimen. Although it is logical to assume drug failure and change regimens for treatment, there are no data to support this, and simply switching to a parenteral route of administration may suffice for treatment. Chapter 80 - Nutritional Support of Patients with Hematologic Malignancies

Saundra N. Aker
Polly Lenssen

INTRODUCTION

Patients with hematologic malignancies are highly heterogeneous in terms of their nutritional needs and requirement for nutritional intervention. Patients with aggressive leukemias and lymphomas receive among the most intensive of oncologic therapies and frequently experience significant toxicities involving the gastrointestinal tract as well as other organ systems, decreased dietary intake, and weight loss. Patients with good-risk acute lymphocytic and chronic leukemias less commonly encounter significant nutritional problems.

The advent and widespread use of central venous access devices has helped obviate iatrogenic malnutrition in cancer patients. The use of total parenteral nutrition (TPN), however, has come under increased scrutiny, and among patients with solid tumors has not prolonged survival and may actually increase morbidity. [1] [2] This chapter addresses the appropriate use of TPN and other dietary intervention strategies, such as tube feedings and low microbial diets, in patients with hematologic malignancies.

NUTRITIONAL PROBLEMS

Protein-Calorie Malnutrition

Significant weight loss at diagnosis is not a prevalent finding. DeWys and colleagues [3] reported that only 4% of patients with acute myeloid leukemia (AML), 10% with favorable-prognosis non-Hodgkin lymphoma (NHL), and 15% with unfavorable-prognosis NHL presented with more than 10% weight loss during the 6 months before initiation of chemotherapy. Among pediatric patients with newly diagnosed acute leukemia, very few present with significant weight loss. [4] [5] [6] [7] [8] The risk of the development of malnutrition subsequent to diagnosis depends on the toxicity of the therapy administered and the progression of the disease. Rickard and coworkers [9] identified several types of pediatric patients at high risk for nutritional depletion, including patients with NHL involving the gastrointestinal tract, AML, poor-prognosis acute lymphocytic leukemia (ALL), and patients who have experienced multiple relapses of their leukemia. [9] By the time patients with hematologic malignancies become candidates for marrow transplantation, malnutrition is more prevalent. Deeg and coworkers categorized a large cohort of adult and pediatric marrow graft recipients by weight status and found that except for chronic myelogenous leukemia (CML) in chronic phase and low-risk pediatric ALL, 828% of patients have mild to moderate malnutrition pretransplant (Table 80-1).[10]

Some limited data are available about the effect of protein-calorie malnutrition on outcome in hematologic malignancies. DeWys and investigators [3] found that weight loss before diagnosis had no influence on survival in patients with AML but was associated with a significant decrease in survival in patients with favorable- and unfavorable-prognosis NHL. During marrow transplantation, underweight patients are at an increased risk of early death. Among adults, survival to day 150 post-transplant is significantly worse for patients at 8595% ideal body weight (p = 0.004) or <85% ideal body weight (p = 0.0001) than for patients at 95140% ideal body weight status. Underweight children had a less marked but similar decrease in survival when compared to well-nourished children (p = 0.22 for <85% vs. 95140% ideal body weight and p = 0.01 for 8595% vs. 95140% ideal body weight). [10]

Weight loss of 1015% correlates with a 20% loss of protein mass and clinically significant impairment of physiologic function. [11] The adverse consequences of malnutrition on immunity, especially T-cell function, phagocytosis, and complement-mediated defenses, are well described. [12] [13] The effects of malnutrition on gastrointestinal function and immunity may be particularly relevant in hematologic malignancies. The thinning of mucous membranes, decrease in secretory IgA, and altered gut flora observed in malnutrition have been linked to an increase in the incidence of gastrointestinal infection. [14] [15] Because the gastrointestinal barrier can be breached during intense oncologic therapy, enteric infections are common and have been implicated as a source of bacteremias and sepsis. [14] [16] [17] Inadequate protein intake during an insult such as endotoxin as well as lack of luminal nutrition (e.g., during TPN) are associated with bacterial transfer across the intestinal mucosa and impairment of gut-associated lymphoid function and morphology in experimental models. [18] [19] [20] [21] [22] [23] [24] The role of dietary variables in bacterial translocation and gut immunity has not been established in humans. [25] [26] Nonetheless, the adequate nourishment of major organs, especially the gastrointestinal tract, seems prudent in immunocompromised patients.

Altered Metabolism

The metabolism of malignant bone marrow is markedly accelerated. Energy expenditure averages 3550% higher than predicted in both pediatric and adult patients with leukemia. [27] [28] [29] [30] Rates of whole-body protein synthesis and breakdown are almost twice normal. [28] [30] Similar derangements in energy and protein metabolism have not been found in patients with

TABLE 80-1 -- Patients with Malnutrition Prior to Marrow Grafting

Diagnosis	Adults		Children	
	Total N	N <95% IBW (%)	Total N	N <95% IBW (%)
AML, low risk	114	15 (13.2)	43	7 (16.2)
AML, high risk	307	40 (13.0)	105	24 (22.8)
ALL, low risk	35	4 (11.4)	21	0
ALL, high risk	158	28 (25.9)	217	25 (11.5)

Lymphoma, relapse	159	23 (14.5)	25	7 (28.0)

Abbreviations: ALL, acute lymphocytic leukemia; AML, acute myelogenous leukemia; CML, chronic myelogenous leukemia; IBW, ideal body weight.

Data from Deeg HJ et al. [10]

lymphoma.[30] Energy expenditure decreases in patients with acute leukemia within days of starting chemotherapy [29] [31] further evidence that the leukemia itself induces the high metabolic rate. Analogously, maintenance chemotherapy in children with ALL in remission appears to exert no significant adverse effects on energy metabolism.[7] [32] During induction chemotherapy[29] or marrow transplantation, [33] energy expenditure and protein losses increase presumably due to the complications that arise during neutropenia.

Toxicities of Oncologic Treatment

The nutritionally relevant toxicities of oncologic treatment are summarized in Table 80-2 . Aggressive multimodal treatment often produces multiple toxicities; when prolonged, it can lead to significant nutritional deficits, particularly for children. The nutritional consequences of biologic response modifiers are associated with anorexia and mild to moderate gastrointestinal disturbances. [34] [35]

ASSESSMENT OF ALTERED NUTRITION STATUS

Basic Evaluation

Initial and serial nutritional evaluation and screening are indicated in all patients (see Algorithm for Nutrition Assessment and Intervention). Early identification of depleted weight status (either rapid weight loss or inadequate reserves when compared to an ideal body weight estimate) and poor oral intake may avert the morbidity associated with moderate to severe malnutrition. In a survey of 173 pediatric oncology patients of whom 45% had leukemia or lymphoma, Tyc and colleagues found that poor oral intake, even as a subjective report, was the single best predictor of need for intervention with TPN or enteral tube feeding. [36] The mean length of time after diagnosis for nutrition support intervention was 33 weeks in this cohort, suggesting that as soon as poor oral intake is identified there may often be sufficient time to implement earlier intervention programs to increase caloric intake, including nutritional counseling and behavioral therapies. Earlier intervention may potentially avert the need for more invasive and costly nutrition therapies. [36]

Weight assessment as an index of body composition is of less value in states of fluid imbalance (edema, dehydration, iatrogenic fluid overload). Weight must be interpreted with caution in metabolically stressed patients, such as those experiencing infectious complications or organ dysfunction with induction therapy or marrow grafting.[37] Actual nutrient intake as documented by the dietitian often provides the best guide for judging nutritional adequacy during periods of stress. In many institutions, bedside metabolic monitors are available that measure energy expenditure and help establish the energy goals of nutrition therapy.

Other measures of nutrition assessment, including immune function tests and serum protein data, have not added to clinical judgment in predicting nutrition-associated complications or survival in surgical patients. [38] [39] Similar studies have not been reported in oncology patients. However, measurements of serum albumin, prealbumin, and transferrin seem to reflect metabolic stress, not the adequacy of recent nutrient intake, in patients with leukemia undergoing induction chemotherapy[29] [40] or marrow transplantation.[41] [42]

Pediatric Assessment

Accurate serial weight and height measurements are essential in the assessment of growth and development in children and adolescents. Lack of weight gain in growing children is indicative of nutritional deterioration; weight loss flags the need for

TABLE 80-2 -- Nutritional Problems Associated with Treatment of Hematologic Malignancies

Treatment	Complications
Chemotherapy	
Alkylating agents[a]	Nausea, vomiting

ALGORITHM FOR NUTRITION ASSESSMENT AND INTERVENTION SCREEN FOR NUTRITIONAL RISK

Step 1Obtain height, weight, and weight history. Compare current weight with usual and ideal weight.

Step 2Ask about changes in dietary intake compared to normal and any oral or gastrointestinal symptoms (diarrhea, constipation, nausea, vomitting, xerostomia, oral or esophageal pain, dysgeusia)

Step 3Does patient have:

10% weight loss in last 6 months (5% in children)?
90% ideal weight (<10th percentile weight/height in children)?
or
Poor appetite or physiologic or metabolic problem interfering with intake/assimilation of an adequate diet?

immediate dietary evaluation and intervention. Weight-for-height assessment is the appropriate tool to assess adequacy of body reserves, using standardized charts in prepubertal children [43] and tables in postpubertal adolescents. [44] Van Eys [45] identifies children who are <90% of the standard weight/height ratio (50th percentile) as at risk and those who are <80% as in need of vigorous intervention, whereas Kibirige and coworkers [46] suggest that patients below 95% of standard height/weight ratio may require supplemental nutritional support. Rickard and colleagues [9] define pediatric oncology patients as malnourished if weight-for-height falls below the fifth percentile when height is above the fifth percentile for age, while patients who are below the fifth percentile in both weight and height for age are chronically malnourished.

Serial heights should also be plotted on velocity charts. [47] Decreased height velocity has been observed in children receiving 18 or 24 Gy whole-brain irradiation within 6 months of therapy, [48] [49] [50] as well as in those undergoing marrow transplantation prepared with total-body irradiation [51] or chemotherapy only. [52] The potential role of chronic nutrient deficits has not been evaluated in poor growth velocity. However, nutrition evaluation is always indicated in children with growth rates below the fifth percentile.

NUTRITIONAL INTERVENTION

Dietary Recommendations and Modifications

Dietary recommendations during periods of treatment toxicities and prolonged anorexia have been extensively reviewed. [35] [53] [54] Modifications in consistency, texture, and taste of food are required when patients experience mucositis, esophagitis, xerostomia, or dysgeusia. [55] [56] Reduction of fat and lactose content may decrease nausea or diarrhea. A dietitian can recommend appropriate nutritional supplements in patients who exhibit malabsorption or show an inability to gain weight. During hospitalization,

a food service that is individualized and that includes frequent follow-up by trained nutrition staff best meets the needs of patients undergoing intense oncologic therapy. [9] [57] [58] [59]

Diet Guidelines for Immunosuppressed Patients

Hospitals treating oncology and peripheral stem or marrow transplant patients routinely provide some form of low microbial food service, particularly for those undergoing gastrointestinal decontamination and treated in ultraisolation laminar air flow (LAF) or HEPA-filtered environments. [60] [61] [62] [63] Diets historically used in these types of protective environments can vary in the level of microbial restriction ranging from sterile to cooked food only diets. [60] [61] [64] Sterile diets consist of commercially canned, steam autoclaved, or oven-baked food and require aseptic food and tray preparation and distribution from separate kitchen facilities. A sterile diet is used in few institutions because of high production costs. [62]

Low microbial or cooked food diets vary widely in terms of food choices (e.g., the exclusion or inclusion of fresh fruits and vegetables) and bacterial content and are generally empirically formulated, although some institutions culture foods and assess acceptability when developing such diets. [61] [65] [66] Moe[61] cultured 198 foods prepared by conventional methods. Although 80% of beverages, starches, cooked fresh meats and entrees, and frozen vegetables were acceptable, only 36% of pasteurized dairy products and 42% of dessert and snack items met minimal microbiologic criteria. Up to 17 different species of gram-negative rods in concentrations as high as 10^6 /cfu/ml in milk, pudding, and ice cream were identified. Ayers et al. [67] found that serving foods containing only *Bacillus* resulted in transient colonization with *Bacillus* spp. in 41% of patients studied, but no infections occurred.

The protective benefit of low microbial diets against infection has not been firmly established, owing to lack of controlled trials. [60] [61] Nonetheless, the possibility that food may serve as a source of contamination in immunosuppressed patient populations including marrow transplant recipients has been shown by reports of pathogenic organisms implicating food and other sources. [67] [68] [69] [70] [71] [72] [73] [74] Case reports of *Lysteria monocytogenes* and *Clostridium botulinum* infections in marrow transplant recipients have proven difficult to attribute to contaminated foodstuffs. [72] [73] [74] The incubation period (e.g., up to 30 days for *L. monocytogenes*) for these as well as other specific organisms may be such that suspect foodstuffs have been discarded and an accurate food intake history is difficult. Furthermore, the majority of the cases of *Listeria* infection in marrow transplant patients have been detected in the ambulatory care setting, making it more difficult to trace to specific food intake. [72] Fungal infections are also common in the immunosuppressed host, but difficult to link with food-originated infection. Numerous foods, such as aged cheeses and others (e.g., miso and tempeh, which are fermented products), as well as naturopathic substances, [75] may serve as sources of fungal infections.

Fresh fruits and vegetables have historically been excluded from low microbial diets. Organisms routinely found on washed raw fruits and vegetables do not appear to be common sources of infection in immunosuppressed patients. At the Fred Hutchinson Cancer Research Center, 29 cultures of assorted raw, washed fruits showed gram-positive cocci and gram-negative rods (<10^1 /cfu/ml) of common origin in foods (S.N. Aker unpublished data, 1997). One of three strawberry cultures showed <2002,000/cfu/ml of three mold types. Thirty-six samples of raw, washed vegetables resulted in a broader variety of organisms at levels of <10^1 /cfu/ml of gram-positive and gram-negative organisms with few yeasts or molds. The organisms cultured from these fruits and vegetables are not representative of common infections routinely seen in the immunosuppressed cancer and marrow transplant patient populations.

TABLE 80-3 -- Diet Guidelines for Immunosuppressed Patients

These diet guidelines restrict high-risk foods as *potential* sources of organisms known to cause infection in immunosuppressed persons. It is recommended that patients follow the diet guidelines during treatment with immunosuppressive therapy (e.g., steroids, cyclosporine, chemotherapy, radiation, etc.) and/or for a minimum of 3 months following marrow or peripheral stem cell transplantation.

Food Restrictions
Raw and undercooked meat (including game), fish, shellfish, poultry, eggs, hot dogs, tofu, sausage, bacon
Cold smoked fish and lox; pickled fish
Unpasteurized and raw milk products including cheese and yogurt
Aged cheese (e.g., brie, camembert, bleu, roquefort, sharp cheddar, Stilton)
Refrigerated cheese-based salad dressings, (e.g., bleu cheese), not shelf-stable
Mexican hot pepper (e.g., hot chili pepper), farmers and feta cheeses
Unwashed raw vegetables and fruits and those with visible mold; all raw vegetable sprouts (e.g., alfalfa, mung bean)
Commercial unpasteurized fruit and vegetable juices
Raw and unpasteurized honey
All miso products (e.g., miso soup); tempeh; Maté tea
Raw, uncooked brewers yeast
All moldy and out-dated food products
Well water, unless tested yearly and found safe

Courtesy of the Clinical Nutrition Department, Fred Hutchinson Cancer Research Center, Seattle, WA.

Except for infrequent reports such as cyclosporiasis associated with imported fresh raspberries [76] and *Escherichia coli* 0157:H7 contamination of unpasteurized apple cider and other fruit juices [77] and raw vegetable sprouts, food outbreaks associated with raw, washed domestic fruits and vegetables are rare.

The use of strict isolation environments has been largely replaced with single hospital rooms with strict handwashing only for severely neutropenic patients. Furthermore, the trend of using the ambulatory care setting whenever possible to manage neutropenic patients has made obsolete past approaches to dietary precautions with immunocompromised patients. Immunosuppressed patients with hematologic malignancies, wherever their care environment, may best be counseled to follow a low-risk diet as summarized in Table 80-3 . The goals of a low-risk diet are both to minimize the introduction of high-risk foods and potential pathogenic organisms via food and to promote healthy food options in patients who historically exhibit poor oral intake. Such diet guidelines should ideally be accompanied with education on safe food handling.

Tube Feedings

Published literature on tube feedings in patients with hematologic malignancies is sparse, although there is renewed interest in the use of enteral nutrition because of the gut atrophy, greater expense, and infection risk associated with TPN. The risks of tube feeding are intuitively recognized as those associated with neutropenia, thrombocytopenia, mucosal and esophageal ulceration, vomiting, diarrhea, and decreased intestinal motility, which may predispose to hemorrhagic problems and sinusitis from the irritation of a feeding tube, aspiration pneumonia, and nutrient malabsorption.

Diarrhea was the primary complication observed in adults with acute leukemia receiving nasogastric tube feedings because of nausea and vomiting during administration of cytosine arabinoside, 6-thioguanine, and daunorubicin. [78] Diarrhea and poor gastric emptying also limited the ability to deliver adequate volumes of tube feeding to patients receiving high-dose chemotherapy and autologous marrow rescue for treatment of

solid tumors, necessitating supplementation with parenteral nutrition. [79] Tube feedings were otherwise tolerated in both reports. Tube feedings were less successful in patients with leukemia undergoing allogeneic marrow transplantation with more intensive conditioning, including total-body irradiation. [57] Most patients randomized to an enteral feeding program were crossed over to TPN or required supplemental intravenous amino acids, and very few patients had successful tube placements because of nausea, vomiting, and diarrhea.

These studies raise concerns about the microbiologic safety of enteral nutrition. There was a trend toward more bacteremias in the autologous patients on tube feedings.[79] *Pseudomonas* sepsis was associated with a hospital-made pasteurized formula in one patient undergoing induction therapy despite selective gastrointestinal decontamination to eliminate gram-negative rods and yeast. [78] Significant contamination can also occur with commercially sterile formulas in the clinical setting, owing to open feeding systems, low osmolar formulas, inadequate handwashing, and prolonged hang times at room temperature. [80] [81] [82] [83] [84] Patients receiving antacids, gastric acid inhibitors, H_2-antagonists, antibiotics, steroids, or immunosuppressive therapy may be at increased risk of bacterial colonization during tube feedings. [85]

Several studies of gastrostomies in pediatric cancer patients, which included patients with hematologic malignancies, have reported high success rates in achieving body weight goals and overall low rates of significant complications, [86] [87] although wound infections are higher in patients with cancer compared to patients with a non-cancer diagnosis.[88] Acquino and coworkers[86] reviewed the use of permanently placed gastrostomy tubes in 25 children with cancer; infections at the tube site occurred during periods of severe neutropenia at a rate of only 1.58 episodes per 1,000 days of use compared with rates of 5.0/1,000 days reported with TPN. [89] In another review of surgical or percutaneous endoscopic gastrostomies in 33 pediatric cancer patients, 14 developed infection or colonization with bacteria or fungi at the insertion site, but only 1 patient developed a bacteremia. [87] The authors also reported bleeding complications at the tube site in eight patients, one of whom required surgical exploration to control bleeding after the tube was accidentally dislodged. [87]

For the patient who has a functional gastrointestinal tract and requires nutritional intervention, tube feedings should be considered, as noted in the algorithm. If the anticipated duration of enteral feeding is less than several weeks, then nasoenteric placement is recommended. If a longer period of feeding is expected, a gastrostomy or jejunostomy placement should be considered. Only commercially sterile products should be administered, preferably in a closed feeding system, for a hang time not to exceed 8 hours. In patients with unexplained fever or diarrhea, the enteral feeding should be cultured. Proper tube insertion, formula selection and administration, and monitoring of complications are extensively reviewed by Rombeau and Caldwell. [90]

TOTAL PARENTERAL NUTRITION

Infectious Complications

Most patients with hematologic malignancies have central catheters placed for central venous access. In patients provided with TPN, an increase in infection rates has been observed compared to patients with central catheters not on TPN. [41] [89] [91] In 310 children with cancer and central venous lines (including 244 patients with acute leukemia), administration of TPN was associated with a 2.4-fold increase in the risk of infection ($p < 0.001$), defined as documented catheter-related septicemia, catheter exit site, port, or tunnel infection, or sepsis of unknown origin. [89] Among 104 adult and pediatric recipients of allogeneic marrow grafts, Weisdorf and coworkers documented bactermias in 72% of patients randomized to TPN versus 48% randomized to hydration therapy during the first post-transplant month ($p < 0.001$).[41] Lough and associates demonstrated similar findings in a smaller study of 29 allogeneic and autologous transplant patients in which 57% of the patients randomized to TPN developed positive blood culture compared to <7% randomized to maintenance hydration for 14 days ($p < 0.05$). [91] No deaths were attributed to the infectious complications described in these reports.

The etiology of the association of TPN and infectious complications remains to be established. Suggested hypotheses for this phenomenon are overfeeding of dextrose or lipid, deficiency of glutamine in TPN formulas, and lack of enteral stimulation of gut immunity. Elevated serum glucose impairs neutrophil and complement function and in particular predisposes patients to *Candida* infections.[92] [93] Maintenance of serum glucose below 200 mg/dl during TPN by targeting energy provision to metabolic needs, administration of insulin as necessary, and substitution of a greater proportion of dextrose energy with lipid may help reduce infection. Analogous to the potential dangers of overfeeding dextrose, it appears that lipids in only large doses (up to 4 g/kg) or at very fast infusion rates (100200 ml/hr of 20% emulsions) demonstrate any adverse effect on neutrophil, phagocyte, and reticuloendothelial system function. [94] There is no evidence that lipids affect humoral immunity or the complement system, although their impact on T-cell lymphocyte activities is not clearly established. [95] In general, an infusion of moderate amounts of lipids (2530% of total calories) over a minimum of 12 hours is considered prudent and safe practice. Indeed, a large randomized trial failed to show an association between such a moderate dose of lipid (2530% of total energy) versus a low dose (68% of total energy to prevent essential fatty acid deficiency) and bacterial and fungal infections during the first hospitalization for marrow grafting in patients with hematologic malignancies. [96]

The addition to TPN of glutamine, a non-essential amino acid oxidized by stimulated lymphocytes and macrophages and intestinal mucosal cells, has been reported to reduce infectious complications[97] and hospitalization time[97] [98] following marrow grafting. It is postulated that pharmacologic doses of intravenous glutamine may maintain the gut mucosal barrier during periods of gut rest, as has been described in animal models of methotrexate or radiation-induced intestinal injury. [99] [100] [101] The adverse effects of non-glutamine-enriched TPN on human intestinal immunity have yet to be confirmed. [102] Data are also lacking on the effect of glutamine supplementation on long-term survival in patients with hematologic malignancies; because glutamine enhances the synthesis of the intracellular antioxidant glutathione, it is possible that pharmacologic doses given at the same time as antitumor therapy could be protective of the tumor.

Finally, the role of enteral stimulation on infection outcome deserves consideration. Numerous trials in surgical patients have demonstrated reduced infectious morbidity and improved survival in patients randomized to tube feeding compared to TPN. [103] [104] Similar trials have not been reported in cancer patients. In the absence of any major gastrointestinal dysfunction, transition to tube feeding or encouragement of oral feeding, even in minimal amounts, are appropriate low-risk interventions in patients requiring TPN until more data are available to guide nutrition therapy in this area.

Efficacy

Do the benefits of weight maintenance and provision of macronutrient and micronutrient substrates outweigh the infectious risks of TPN? Limited studies are available to guide the decision to intervene with TPN. Popp and coworkers [105] found no difference

in long-term survival among patients with advanced diffuse lymphoma undergoing multidrug chemotherapy randomized to adjunctive TPN or to oral nutrition. A few studies suggest TPN may promote hematopoietic recovery during intensive induction therapy for AML [106] or following marrow grafting.[107] In marrow graft recipients, implementation of TPN during the conditioning regimen in well-nourished patients results in improved long-term survival. [41] Weisdorf and colleagues [41] randomized allogeneic and autologous marrow graft recipients to either TPN or hydration through the first month post-transplant. Among control patients, 60% were crossed over to TPN (median day 21 post-transplant) because of nutritional depletion. Overall survival (Fig. 80-1) and time to relapse were significantly improved in the patients receiving prophylactic TPN. When the autograft patients were analyzed separately, significant differences in survival and relapse rates were not found, but the small numbers of autograft patients limited the power of the study to detect true differences. Other studies have not confirmed improved survival with TPN during marrow transplantation but, again, small study populations may have limited the ability to detect differences. [57] [91]

Other patient populations may benefit from TPN. Rickard and coworkers [108] found that children with advanced malignant disease, including relapsed leukemia and advanced NHL, required TPN to reverse malnutrition. Additionally, these clinical investigators identified those children with AML and poor-prognosis ALL as appropriate candidates for TPN.[109] Although improved survival with adjunctive TPN during therapy has not been adequately investigated, maintenance of major organ system function and, in children, growth maintenance and restoration of play are important considerations when oral or enteral feedings fail.

Implementation and Formulations

Safe and appropriate TPN may be initiated and monitored in consultation with a hospital nutrition support service or with a nutrition support-certified or oncology dietitian. Adequate delivery of TPN has been enhanced by the use of multilumen central venous access devices. [110] Iatrogenic fluid overload poses a greater risk to patients receiving multiple intravenous therapies than does inadequate nutrition. Table 80-4 outlines an approach to implementation of TPN.

Research on the pharmacologic applications of nutritional support have intensified as evidence accumulates about the modulation of physiologic, immune, and endocrine functions by nutrients. TPN solutions enriched with branched-chain amino acids have been investigated as a fuel source designed to blunt the muscle catabolism and obligatory nitrogen losses associated with marrow transplantation with mixed success. [42] [111] Taurine, another non-essential amino acid not contained in adult TPN solutions, may also be deficient following marrow grafting. [112] Taurine conjugates hepatotoxic bile acids and improves bile acid secretory rates. [113] Clinical trials may be warranted to determine the benefits of taurine in marrow graft patients who experience a high incidence of liver dysfunction and biliary sludge. [114] Glutamine-supplemented TPN is discussed earlier under infectious complications.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

NUTRITIONAL SUPPORT IN MARROW AND PERIPHERAL STEM CELL TRANSPLANTATION

Standard supportive care during the first month post-transplant has included TPN, [41] [42] [97] [110] and many patients with slow gastrointestinal healing or graft-versus-host disease (GVHD) have relied on TPN to some degree for extended periods in the ambulatory setting. [115] As other supportive measures diminish the toxicity associated with transplantation, the role of TPN as well as its substitution with enteral feedings will require re-examination.

Early initiation of TPN should be considered in patients with impaired pretransplant nutritional status, oral intake less than basal needs for 3 to 4 days, or gastrointestinal toxicities that are anticipated to interfere with recovery of oral intake within 1 week. Among patients who are at an increased risk of GVHD, early TPN intervention helps prevent significant weight loss before the onset of acute or chronic GVHD when metabolic needs appear higher and may be more difficult to achieve.[116] The decision to terminate TPN may depend on a constellation of clinical factors, including nutritional status, severity of gastrointestinal toxicities, ability to sustain or progress with oral intake, and the physiologic and psychological impact of TPN. In a large, double-blind trial that included adult and pediatric allogeneic and autologous transplant patients, Charuhas and colleagues compared the effect of continuing TPN or changing to hydration fluids on the time to resume adequate oral intake in patients who were not able to eat 70% of estimated maintenance energy needs at time of hospital discharge. [117] Patients randomized to hydration fluids met oral calorie goals a median of 6 days sooner than patients on TPN (p = 0.049) without evidence of adverse consequences, such as increased hospital readmissions or clinically significant weight loss, when TPN was withheld for up to 1 month. It appears safe to discontinue TPN when patients are eating 30% of estimated energy needs at hospital

Figure 80-1 Influence of TPN on overall survival in marrow graft recipients. Life-table curves (Kaplan-Meier plot) show overall survival in TPN prophylaxis versus control groups, p = 0.011. Tick marks indicate length of survival at analysis. *(From Weisdorf et al.,[41] with permission.)*

TABLE 80-4 -- Approach to TPN Management

1. Determine macronutrient requirements (protein, dextrose, lipid, and fluid) .

			+50 ml/kg for each kg 1120 kg
			+20 ml/kg for each kg 2140 kg

2. Provide electrolytes, vitamins, and trace elements daily, altering requirements based on organ function .

Electrolyte or Micronutrient	Adult	Adolescent	Children
Potassium[b] *Available as phosphate, chloride, and acetate salts. Increased needs with amphotericin, thiazide diuretics, steroids, anabolism, GI losses. Decreased needs with spironolactone, renal dysfunction, tumor lysis syndrome.*	60120 mEq		23 mEq/kg
Sodium[b] *Available as chloride, acetate or phosphate salts. Increased needs with GI losses. Decreased needs with pulmonary edema, congestive heart failure, VOD*	50100 mEq		24 mEq/kg
Calcium *Available as gluconate salt. Increased needs with foscarnet. Decreased need with renal dysfunction, tumor lysis syndrome*	1025 mEq	0.250.5 mEq/kg	1030 mEq

Phosphorus *Available as potassium or sodium salts. Increased needs with diuretics, cyclophosphamide, cisplatinum, foscarnet, anabolism. Decreased needs with renal dysfunction*		1020 mM	0.51.0 mM/kg	12 mM/kg
Magnesium *Available as sulfate salt. Increased needs with amphotericin, cyclosporine, cisplatinum, foscarnet, GI losses, anabolism. Decreased needs with renal dysfunction, tumor lysis syndrome*		1632 mEq		0.250.5 mEq/kg
Zinc *Available as chloride or sulfate salt in both single entity or combination preparation. Increased needs with GI losses, wound healing*		2.54.0 mg		100 g/kg[c]
Copper *Available as sulfate salt in both single entity or combination preparation. Increased needs with GI losses. Decreased needs with cholestasis.*		0.51.5 mg		20 g/kg[c]
Manganese *Available as chloride salt in both single entity or combination preparation. Decreased needs with cholestasis.*		150800 mcg		210 g/kg[c]
Chromium *Available as chloride salt in both single entity or combination preparation*		1015 mcg		0.2 g/kg[c]
Selenium *Available as selenious acid in both single entity or combination preparation*		4080 mcg		3 g/kg
Electrolyte or Micronutrient		**Adult**	**Adolescent**	**Children**
Molybdenum *Available as ammonium molybdate as single entity.*		20120 g		0.25 g/kg
Vitamins *Available as adult and pediatric multivitamin combinations of water- and fat-soluble vitamins or single infusions of cobalamin, folate, thiamine, pantothenic acid, pyridoxine, ascorbic acid, and vitamin K.*	A	3,300 IU (990 RE)		2,300 IU (690 RE)
	D	200 IU (5 RE)		400 IU (10 RE)
	E	10 IU (6,7 RE)		10.4 IU (7 RE)
	B_1 (thiamine)	3.0 mg		1.2 mg
	B_2 (riboflavin)	3.6 mg		1.4 mg
	Niacin	40 mg		17 mg
	Folic acid	400 g		140 g
	B_6 (pyridoxine)	4 mg		1.1 mg
	Panthothenic acid	15 mg		5.0 mg
	Biotin[d]	60 g		20 g
	B_{12} (cobalamin)	5 g		1.0 g
	C	100 mg		80 mg
Vitamin K *Available as a component of pediatric but not adult multivitamin combinations*		12 mg (or 10 mg once weekly)		200 g (as part of multivitamin combination)
Iron *Available as iron-dextran*		Contraindicated in patients with hematologic malignancies		

***3. Monitor for special managements issues*.**	
Refractory hyperglycemia	Limit dextrose to <3 mg/kg/min in adults, <710 mg/kg/min in children; increase lipids to 5060% total energy
Hypertriglyceridemia	>500 mg/dl: limit lipids to 48% total energy to provide essential fatty acids
	>2000 mg/dl: discontinue lipids to decrease risk of pancreatitis
Fluid overload	Provide concentrated dextrose, lipid, amino acid solutions to maximize nutrient support
4. Monitor ability to eat or transition to tube feeding, or both, as soon as feasible.	

Abbreviations: GI, gastrointestinal; TPN, total parenteral nutrition, VOD, veno-occlusive disease.

Recommended daily trace element supplementation for adults from American Medical Association: Guidelines for essential trace element preparations for parenteral use. JAMA, 241:2051, 1979.

Recommended daily vitamin supplementation for adults and adolescents from Multivitamin preparations for parenteral use: A statement by the nutron advisory group. JPEN J Parenter Enteral Nutr 3:258, 1979.

Recommended daily vitamin, mineral and trace element supplementation for children from Greene HL, Hambridge KN, Schanler R et al: Guidelines for the use of vitamins, trace elements, calcium, magnesium, and phosphorus in infants and children receiving total parenteral nutrition: Report of the Subcommittee on Pediatric Parenteral Nutrient Requirements from the Committee on Clinical Practice Issues of the American Society for Clinical Nutrition. Am J Clin Nutr 48:1324, 1988.

[a]To calculate carbohydrate dose, divide total mg dextrose per day by 1,440 min/day/wt in kg. For example, 1,700 ml 25% dextrose in a 70 kg patient = 425 g dextrose × 1,000 mg/g 1,440 min/day/70 kg = 4.2 mg/kg/min dextrose.
[b] After determining phosphate needs, remainder provided primarily as chloride salt (except in presence of metabolic acidosis) to meet chloride needs.
[c]Up to 5 years; older than 5 years, use guidelines for adolescent and adult.
[d]Currently available multivitamin combinations do not contain biotin.

discharge unless a clinical condition, such as malnutrition, malabsorption, or significant gastrointestinal toxicities, warrant otherwise.

Total energy and protein (oral plus TPN) support is recommended at stress levels during the neutropenic period based on the well-described losses of nitrogen and body cell mass.[37] [42] [118] Patients who still require TPN after engraftment and are otherwise without infectious problems or GVHD may be supported at maintenance needs. Few studies have been reported to characterize micronutrient status following marrow grafting. Serum levels of the antioxidants vitamin E and -carotene in patients on TPN are markedly depressed, but the clinical significance is unknown. [119] Preliminary reports suggest that depleted antioxidant status is associated with increased free radical activity post-transplant. [120] [121] No correlations have been established between these findings and the degree of toxicities observed with cytoreductive therapy nor the effect on tumor cell killing. In experimental models, vitamin C at therapeutic doses protects bone marrow cells, [122] suggesting cautious use of antioxidants with our current state of knowledge. Manganese toxicity that manifested as a Parkinson-like syndrome with brain magnetic resonance imaging suggestive of manganese accumulation has been described in a patient with cholestatic liver disease who was supplemented with 0.3 mg/day of manganese during 2 months of TPN.[123] These investigators found elevated serum manganese levels in eight other transplant patients with liver disease, suggesting the need to restrict manganese in the presence of cholestasis. [123]

Gastrointestinal Complications

Histologic and functional abnormalities of the intestinal tract result from cytoreduction therapy, infectious complications, and GVHD and have been reviewed by Beschorner[124] and McDonald and colleagues.[125] Chemoradiotherapy results in moderate to extensive necrosis of intestinal crypts and diffuse mucosal abnormalities, which resolve histologically by day 20 post-transplant. [125] Normal digestion and absorption may not recover as quickly. Both proximal and terminal small intestinal absorption is impaired for prolonged periods, even in the absence of GVHD, as evidenced by abnormal D-xylose and Schilling tests at 4 months post-transplant. [126] [127] [128] Permeability studies suggest that mucosal damage is equivalent for conditioning with chemotherapy only and chemoradiotherapy and is greater in patients over 30 years of age.[129]

Mucosal competence is also impaired. Salivary IgA concentrations

are one-half normal levels as late as day 90 post-transplant. [130] Whether IgA secretions at other intestinal sites show similar prolonged immunodeficiency is unknown. The number of immunoglobulin-containing plasma cells in the small intestine decreases after chemoradiotherapy but appears to recover within weeks, provided intestinal GVHD does not develop. [131]

Nausea, vomiting, diarrhea, and oropharyngeal mucositis inhibit oral intake for 1 month (Fig. 80-2). The severity of mucositis is increased in patients treated with total-body irradiation[132] or methotrexate as prophylaxis against GVHD.[133] Limited data are available on the way in which growth factors might influence recovery from mucositis. Nemunaitis and coworkers[134] described no difference in the severity of mucositis in a randomized, double-blind trial of granulocyte-macrophage colony-stimulating factor (GM-CSF) in autologous marrow graft recipients, most of whom received total-body irradiation as part of cytoreduction therapy. When TPN was used as a surrogate for gut toxicity, Sheridan and colleagues found decreased use in patients who received GM-CSF after busulfan and cyclophosphamide and autologous marrow grafting when compared with historical controls, [135] whereas Bruemmer and coworkers observed no difference in length of TPN support in patients undergoing unrelated allogeneic marrow grafting with or without GM-CSF. [136] The effect of peripheral versus marrow as the source of stem cells on recovery of oral intake has not been reported.

The use of pharmacologic doses of oral glutamine to reduce the severity of oral mucositis following BCNU, etoposide, and melphalan and autologous grafting for hematologic malignancies has been explored by Jebb and coworkers.[137] No differences in patient or observer mucositis score, diarrhea, or days of TPN required were observed in a double-blind trial that randomized patients to 16 g glutamine or placebo daily from day 1 post-transplant until mucositis resolved.

Organ Complications

Veno-occlusive Disease

Hepatic veno-occlusive disease (VOD) is characterized by occlusion of small hepatic veins, damaged hepatocytes, fluid retention, ascites, hepatomegaly, and jaundice. The pathophysiology, diagnosis, and treatment of this disease have been reviewed by Shulman and Hinterberger. [138] Insidious weight gain is the first sign of the disorder, and if it progresses, more severe symptoms of liver failure occur, including encephalopathy, coagulopathy, and renal failure. [139] [140] [141] Fluid and TPN management are controversial because limitation of fluids to minimize edema and ascites is frequently complicated by intravascular volume depletion and deterioration of renal function. Conversely, repleting the intravascular space often results in pulmonary edema and massive ascites.

Daily weights and thrice weekly serum bilirubins in the immediate post-transplant period facilitate early detection of disease in patients at increased risk. Nomograms for six time intervals between day 1 pretransplant and day +16 post-transplant that estimate the probability of developing severe VOD using total serum bilirubin and percent weight gain above baseline have been published. [142] In patients with weight gain and decreased urinary sodium excretion, restriction of total fluid and sodium may decelerate fluid accumulation. Concentrated TPN solutions are indicated if renal perfusion is adequate. The capacity to eliminate intravenous lipids from the bloodstream should be monitored in patients with severe VOD. If encephalopathy develops, the benefits of Hepatamine (an amino acid solution with lower aromatic amino acids, tryptophan, and methionine content) have not been established. [143] If hyperbilirubinemia persist longer than 1 week, the biliary-excreted trace elements, copper and manganese, should be removed from TPN. Measurement of energy needs with indirect calorimetry if available may avert additive hepatotoxicity associated with overfeeding, as well as the risks of debilitation with prolonged underfeeding.

Renal Disease

Renal insufficiency is typically multifactorial and associated with total-body irradiation, chemotherapy, drug toxicities, sepsis, and especially liver toxicity. [144] Renal damage is suspected when serum creatinine level is twice baseline. An elevated blood urea nitrogen, however, may be partially due to nonrenal factors, including increased protein intake, gastrointestinal bleeding, or hypercatabolism. Prolonged protein restriction to minimize a rise of blood urea nitrogen should be avoided to ensure that adequate calorie and protein support are provided.

Figure 80-2 Average daily oral calorie intake in adult marrow transplant recipients (n = 295).

Renal complications are managed by maintaining intravascular volume and correcting electrolyte imbalances. The large fluid load necessitated by TPN is problematic in the oliguric patient and requires daily manipulation, depending on urine output and clinical signs of fluid overload. Hypervolemic hyponatremia is treated with water restriction to prevent congestive heart failure. General indications for hemodialysis are extracellular fluid volume expansion, acidemia, hyperkalemia, and azotemia.

The primary goal of nutritional therapy in acute renal failure is to minimize uremia toxicity and other metabolic derangements and yet prevent malnutrition. Protein levels are typically restricted before dialysis by the TPN volume tolerated. During dialysis, protein intake should meet stress needs as defined in Table 80-4 . Serum triglycerides need to be monitored weekly because the clearance of intravenous lipids may be reduced. [145] Water-soluble vitamins are lost in the dialysate and should be provided instead of standard intravenous multivitamins, in an effort to prevent excessive serum vitamin A levels. [146]

Pulmonary Disease

Pulmonary edema due to increased capillary permeability following cytoreduction therapy may be compounded by iatrogenic fluid overload. Management includes reducing total sodium from oral intake, TPN, and medications, and using concentrated TPN solutions. During ventilator dependency, adequate TPN or tube feeding should be provided to preserve muscle reserves.

Graft-versus-Host Disease

Acute GVHD

Minimal to life-threatening skin, liver, and intestinal GVHD can occur as early as the first week post-transplant, but more typically after evidence of donor engraftment. Approximately 30% of patients with human leukocyte antigen-identical sibling donors develop clinically significant GVHD. Both the incidence and severity are higher in patients who are older, undergo transplants from an unrelated or human leukocyte antigen-incompatible family donor, or fail to tolerate sufficient prophylactic drug therapy.[147]

In the most severe form of acute intestinal GVHD, voluminous diarrhea is a prominent manifestation, with the volume corresponding to the extent of mucosal damage.[148] The diarrheal fluid is green and watery, with ropy strands of mucus, protein, and cellular debris, and often contains occult blood. Protein content is high, as evidenced by falling plasma protein levels or by measurements of fecal -antitrypsin in fecal water. [149] Associated symptoms include anorexia, nausea, vomiting, and crampy abdominal pain, which may be related to food ingestion or may occur spontaneously owing to the secretory nature of the diarrhea. Other causes of diarrhea should always be ruled out because enteric pathogens and late-onset conditioning toxicities may occur with similar signs and symptoms of acute intestinal GVHD. [150] Biopsy findings range from necrosis of individual intestinal crypt cells to total mucosal denudation. [151] [152] Intestinal function has received limited study, and the characteristics of malabsorption have yet to be determined. No evidence suggests that early post-transplant restriction of food protein as potentially antigenic stimulants decreases the risk of acute GVHD.[153] Fluid and electrolyte management may be problematic in patients with large volume diarrhea (>2.53.0 L/day). Antidiarrheal agents are generally contraindicated because of the risk of ileus and abdominal distention. The use of octreotide acetate has been reported to control

diarrhea with variable success, but may lower serum cyclosporine levels. [154] [155] [156]

Weisdorf and colleagues [157] described a syndrome of upper intestinal GVHD presenting clinically as anorexia, dyspepsia, food intolerance, nausea, and vomiting. The clinical picture frequently progressed to symptomatic lower gastrointestinal involvement after failure of immunosuppressive therapy, suggesting that this syndrome may be an early manifestation of a unique intestinal immunopathology. Prolonged nausea and vomiting constitute indication for endoscopic evaluation to establish a diagnosis of stomach or upper intestinal GVHD. [158]

The oral mucosa may also be involved in acute GVHD. Oral examination reveals erythema and lichenoid changes that cannot be differentiated from conditioning-induced mucositis until approximately 3 weeks post-transplant. [159] [160] It may evolve into a chronic form, and patients may develop taste fatigue with prolonged use of oral supplements and bland foods, experiencing significant weight loss unless supported with TPN or tube feeding.

Acute liver GVHD is characterized by abnormal liver function tests, jaundice, and mild hepatomegaly. [125] Hepatic synthesis and enterohepatic circulation of bile salts may be diminished or inhibited, resulting in steatorrhea.

Adequate nutrition is a vital adjunct to immunosuppressive drugs in the treatment of acute GVHD. Energy needs during acute GVHD have been predicted at 4550 kcal/kg in adults and 65 kcal/kg in children. [116] In intestinal GVHD, the patient is initially dependent on TPN because complete bowel rest is the only means of decreasing diarrhea. [148] Additional daily zinc is recommended at 10 mg/L of stool volume in excess of 1 liter. When diarrheal volumes diminish and abdominal pain subsides, isotonic oral liquid supplements are introduced to stimulate intestinal regeneration and assess absorption. Guidelines for the introduction of oral intake have been empirically derived using a five-phase regimen, which emphasizes foods low in lactose, fat, fiber, and total acidity. [161] Severe ileal involvement or liver GVHD may necessitate prolonged fat restriction.

Drug therapy for GVHD often has a profound effect on nutritional status and may require nutritional intervention as summarized in Table 80-5 .

Chronic GVHD

Chronic GVHD is a multisystem disorder that affects 3540% of allogeneic marrow graft recipients, presenting 70400 days post-transplant. [162] Clinical manifestations that may adversely affect nutritional status include anorexia, mucositis, xerostomia, dysphagia, esophageal stricture, cholestatic liver disease, diarrhea or steatorrhea, dyspnea and limited exercise tolerance, restricted joint mobility, and generalized wasting (Table 806). Even skin disease can affect nutritional therapy in that adequate sources of vitamin D must be achieved through diet or multivitamin supplementation because the use of sun-blocking agents diminish photosynthesis of vitamin D in the epidermis. Because immunosuppressive therapy invariably includes steroids, vitamin D and calcium status must be optimized to prevent clinically significant osteoporosis. Loss of vertebral bone mass at 1 year post-transplant has been described by Stern and investigators in a small series of patients treated with cyclosporine and corticosteroids. [163] In prescribing a multivitamin/mineral supplement, iron-free formulas are recommended because iron overload is a frequent finding in long-term survivors. [164] When skin disease is treated with psolaren plus ultraviolet A radiation, supplemental -carotene, which protects against ultraviolet radiation, [165] should be discouraged.

Oral disease is common, with frank stomatitis occurring in a significant portion of patients. Pain, burning, and loss of taste have been described as prodromes of chronic GVHD. [166] In severe cases, only bland liquids and soft foods may be tolerated. Complete nutritional supplements and nutrient-dense carbohydrate polymers are important dietary adjuncts in patients experiencing

TABLE 80-5 -- Nutritional Consequences of GVHD Immunosuppression

Immunosuppressive Agent	Nutritional Effects	Recommended Interventions
Corticosteroids	Muscle wasting	Early intervention with physical therapy if exercise level low; high protein intake (twice normal requirements)
	Sodium and fluid retention	Low sodium diet if edema limits mobility
	Hyperphagia and weight gain	Regular exercise, dietary counseling
	Hyperglycemia	Insulin therapy, blood glucose monitoring, dietary counseling to limit overfeeding and excessive total carbohydrate intake. Oral agents have not been shown to be safe or efficacious
	Hyperlipidemia	No intervention (lipid-lowering agent if patient with history of pancreatitis); reassess plasma lipids several months after discontinuation of drug to assure return to baseline level
	Bone loss, fracture risk	Vitamin D: 400800 IU/day
		Calcium: 8001,200 mg/day children, 151,600 mg/day adolescents and adults
		Bone density studies, endocrinology consult in patient with suspected osteoporosis
Cyclosporine, FK-506	Renal insufficiency	Maintenance fluid or more via oral ± intravenous; routine monitoring serum creatinine
	Magnesium wasting	Magnesium replacement via oral ± intravenous route; oral dosing often limited by diarrhea (protein complex forms may be better tolerated); routine monitoring serum magnesium
	Hyperglycemia	May exacerbate hyperglycemia observed with corticosteroids (see corticosteroids)
	Hyperlipidemia	Usually not to same degree as with corticosteroids (see corticosteroids)
	Hyponatremia	Limit free water; encourage fluid with solute
Mycophenolate mofetil	Diarrhea, vomiting	Rule out other causes of diarrhea; otherwise antiemetic therapy and adequate hydration status

weight loss. If significant weight loss occurs, gastrostomy feeding may be indicated.

Esophageal webbing or stricture can result in severe swallowing difficulties. [125] Typical symptoms include pain and difficulty in swallowing food and pills, as well as retrosternal pain caused by esophageal thinning. Webs and strictures are managed with periodic dilation. Diet tolerance varies widely and may be limited to liquids in patients with extensive webbing. Gastrostomy tubes may be indicated when the passage of food is obstructed.

TABLE 80-6 -- Nutrition-Related Problems 1 Year After Bone Marrow Grafting

Sign/Symptom	Chronic GVHD Status[a]		
	None (%)	Limited (%)	Extensive (%)
Weight loss	27	19	33
Weight gain	14	28	34
Oral sensitivity	7	14	41
Xerostomia	10	11	27
Stomatitis	3	3	14

Anorexia	3	6	13
Reflux symptoms	1	6	12
Diarrhea	3	3	12
Steatorrhea	1	0	9
Dysgeusia	0	0	6
Esophageal stricture	0	0	2
Dyspnea	0	0	7
Contractures	0	0	2

[a]Among 192 allogeneic transplant recipients. Percentage of total number of patients is shown.

Diffuse intestinal involvement is a rare manifestation of chronic GVHD. [125] Bacterial overgrowth, medications, chronic liver GVHD, and pancreatic insufficiency may contribute to diarrhea or steatorrhea. When weight loss occurs in chronic liver GVHD, the relative contributions of deficient energy intake and malabsorption need to be determined. Patients are often anorectic, yet others have good dietary intake but significant stool nutrient losses. A malabsorption work-up may include quantitative stool fat collection, Sudan stain for stool fat, serum carotene, serum D-xylose or Schilling test, or serum vitamin D. Vitamin D status is of special concern because inadequate hepatic and renal hydroxylation to the active metabolite may occur. In patients with malabsorption, a moderate fat restriction, calorie supplementation with medium-chain triglycerides, and mineral and fat-soluble vitamin supplementation may be necessary interim measures. Some patients respond to pancreatic enzymes. In patients who fail to gain weight, a gastrostomy feeding should be considered given the known slow resolution of the disease.

Children with extensive chronic GVHD represent a special risk group. Decreased height velocity has been related to pretransplant cranial irradiation, both chemotherapy-only and total-body irradiation conditioning regimens, and chronic GVHD. [51] [52] Although prednisone therapy has been incriminated in growth stunting, catch-up growth has not been observed following cessation of treatment. [51] The contribution of poor nutrient intake as a factor in growth failure after transplantation has not been investigated. Children displaying weight loss, inappropriate weight gain, or growth failure deserve thorough nutritional evaluation to rule out treatable dietary deficiencies. Height should be monitored every 3 months post-transplant for the purpose of early detection of growth failure. When growth velocity falls below the third percentile, treatment with growth hormone is recommended to optimize growth potential. [167]

ACKNOWLEDGMENT

Preparation of this work was supported in part by grant #DK35816 from the Clinical Nutrition Research Units, US Department of Health and Human Services.

Chapter 81 - Psychosocial Aspects of Hematologic Disorders

Jeannie V. Pasacreta
Ruth McCorkle

Major changes in the understanding and treatment of cancer have led to a wider range of treatment options and increasing length of survival from time of diagnosis. Although such advances are quite positive, their impact on the emotional lives of patients and families faced with complex treatment decisions as well as the emotional consequences of chronic illness cannot be overlooked.

Hematologic malignancies often carry a large burden of emotional consequences attributable to the chronic nature of the diseases. Involvement with a complicated and fragmented health care delivery system; the need for episodic and aggressive treatment; remissions and exacerbations of acute and uncomfortable symptoms; family separation; financial burden; functional limitations and role disruptions are but a few of the

issues that characterize the life of patients with hematologic malignancies, not to mention the threat to life that these diagnoses impose.

Because hematologic malignancies are known to be fatal when untreated, their diagnosis often leads to fear and intense psychological concerns. Psychosocial issues associated with all cancers may be intensified in patients with hematologic malignancies because of their association with a poor prognosis, a prolonged treatment course often involving numerous hospitalizations, and the systemic nature of the diseases. [1] Death, discomfort from painful medical procedures, body image disturbances secondary to hair loss, central line catheters, sexual dysfunction related to fatigue and fertility, and role and relationship disruptions resulting from lengthy hospitalizations are just a sampling of the issues that confront the patient with hematologic malignancies, highlighting the necessity for monitoring of and attention to the psychosocial needs that accompany all aspects of the illnesses.

The goal of this chapter is to provide information on factors that affect psychosocial adjustment among patients with chronic illness, the wide range of psychological responses that are possible throughout the illness trajectory, and the efficacy of various modes of psychosocial intervention in minimizing distress and promoting adaptation. Some practical guidelines regarding patient management and identification of patients who may require formal psychiatric consultation are offered.

CHANGES IN TREATMENT AND SOCIETAL ATTITUDES: ACCOMPANYING TRENDS IN PSYCHOSOCIAL ISSUES

The secrecy that prevailed in the 1960s and prohibited disclosure of a cancer diagnosis by most physicians [2] [3] has given way to the practice of imparting the particulars of diagnosis, treatment options, and prognosis on a routine basis. Despite this change, it has been suggested that ongoing fears and concerns among health care providers about cancer have led to a discrepancy between attitude and action, resulting in communication of emotionally laden information in a fashion ranging from overprotective and paternalistic to blunt and matter-of-fact. [4] [5]

Discrepancies between attitude and practice have also been demonstrated by clinicians who avoid clear, open discussions of topics such as prognosis and death despite consistently expressed beliefs regarding the importance of openness and honesty with all mentally competent patients. Therefore, although the prevailing attitude in health care supports the disclosure of medical information and active involvement of patients in decisions that affect them, the actual behavior of health care providers likely reflects a more limited improvement in patient care. [5]

Clinicians should be mindful of how their personal views and concerns about cancer affect communication with patients, especially at key decision-making and transition points along the continuum of care. The use of peers and alternate providers to assist patients with issues and concerns that are particularly upsetting for primary clinicians are useful strategies for ensuring maximum support for patients faced with the complex decisions inherent in the treatment of hematologic malignancies.[6]

CLINICAL COURSE OF HEMATOLOGIC MALIGNANCIES

In contrast to many solid tumor cancers, treatment of hematologic malignancies often involves numerous and lengthy hospitalizations and ongoing outpatient monitoring of the patients condition. The clinical course of cancer typically follows one of several possible trajectories (Fig. 81-1). A number of patients respond to the curative attempt with long-term remission, remain well, and are, after a period, considered cured. Some patients

Figure 81-1 Clinical course of a patient with a hematologic malignancy. *(Adapted from Levenson JA, Lesko LM: Psychiatric aspects of adult leukemia. Semin Oncol Nurs 6:76, 1990, with permission.)*

have a positive response to a curative attempt but then relapse. Other patients begin treatment with a hope for cure, but do not respond and progressively decline. In some patients, the disease is too far advanced when diagnosed, and they experience a progression of their disease.

The acute stress response[7] has been described as a usual response to the diagnosis of cancer, occurring at each transitional point of illness (beginning treatment, relapse, treatment failure, disease progression). The response is characterized by shock, disbelief, anxiety, depression, sleep and appetite disturbance, and difficulty performing activities of daily living. The acute stress response usually subsides when the medical condition stabilizes and the patient knows what to expect in terms of a treatment plan. Because of the protracted hospitalization associated with the hematologic malignancies and often life-threatening complications such as neutropenia and sepsis, the acute stress response may occur periodically, especially during times of medical crisis or periods associated with excessive physical symptomatology, or both. Emotional support, giving clear information, controlling physical symptoms such as pain and nausea, and enhancing patient control over the environment can enhance resolution and inhibit more severe and long-standing emotional sequelae.

Diagnostic Phase

The prediagnostic and diagnostic phases are the time of initial symptom discovery. Systemic symptoms such as weakness and fatigue are often ignored initially; [1] medical advice is usually sought when symptoms persist and worsen. The period of suspect symptoms associated with a definitive diagnosis is often characterized by fear, shock, and disbelief.

The period from time of diagnosis through initiation of treatment is characterized by medical evaluation, the development of new relationships with unfamiliar medical personnel, and the need to integrate a barrage of information that is at best frightening and confusing. Within the context of this anxiety-provoking situation, a decision must be made regarding treatmentas one man aptly stated, a decision upon which my very life or death might be based. This statement illustrates the tremendous responsibility, concern, and isolation that many people experience during this period. [8]

Because of the particularly poor prognosis often associated with hematologic malignancies by the general public, patients and their families are often anxious when receiving initial information regarding diagnosis and treatment. Consequently, care should be taken to repeat information at several sessions and to inquire about the patients and familys understanding of facts and options.

TABLE 81-1 -- Factors That May Predict Poor Coping in Patients with Cancer

Past psychiatric history
Limited social support
Alcohol or drug abuse
Recent losses
Advanced disease
Uncontrolled symptoms
Pessimistic outlook on life
Multiple obligations

Adapted from Rowland,[45] with permission.

Weissman and Worden[9] described the first 100 days after diagnosis as the period of existential plight in cancer. Patient concerns focused on existential issues of life and death more than on concerns related to health, work, finances, religion, self, or relationships with family and friends. Although it is unusual to observe extreme and sustained emotional reactions as the first response to a cancer diagnosis, it remains important to assess the nature of the patients reaction carefully. Initial reactions are often predictive of later adaptation. [10] [11] Early assessment by clinicians can help to identify people at risk for later adjustment problems and in greatest need of ongoing psychosocial support [12] [13] (Table 81-1).

Initial response to diagnosis may be profoundly influenced by a persons prior association with cancer. [1] Those with memories of close relatives with cancer often demonstrate heightened distress, particularly if the relative died or had negative treatment experiences. During the diagnostic and early treatment period, patients may search for explanations or causes for their cancer and may struggle to give personal meaning to their experience. [14] Because many clinicians are guarded about disclosing information until a firm diagnosis is established, patients may develop highly personal explanations that can be inaccurate and provoke intensely negative emotions. Ongoing involvement and accurate information minimize uncertainty and the development of maladaptive coping strategies based on erroneous beliefs.

Although the literature substantiates the devastating emotional impact of a cancer diagnosis, it is also well documented that many patients cope effectively. Positive coping strategies such as taking action and finding favorable characteristics in the situation have been reported as effective. Maintaining optimism [15] and having an active determination to recover have been associated with positive adjustment. Contrary to the beliefs of many clinicians, denial has also been found to assist patients

in coping effectively with a diagnosis of cancer, unless used to an excessive degree.

With the firm establishment of the cancer diagnosis, planning for treatment begins. If patients have been given a clear explanation of their condition while encouraged to maintain hope, the initial reaction of shock, fear, and desperation can give way to a sense of optimism. [7] Health care providers have an important role in monitoring and possibly mediating psychosocial adjustment. Keeping patients informed and actively involved in their care and being aware of the unique meaning that people may associate with a diagnosis of cancer are vital. Those with pervasive and unyielding negative affect that persists long after that crisis of diagnosis may require ongoing psychosocial intervention throughout treatment and the disease course. [16]

The Treatment Decision

Psychosocial factors are critical parameters in considering which treatment is best for a particular patient. [17] The development of a treatment plan should include information about all aspects of the medical/surgical treatments as well as what is known about the psychosocial sequelae.

Often, patients react to a diagnosis of cancer with feelings of fear and helplessness. The patient looks to the primary physician for a curative treatment that will preserve quality of life. The patient may feel threatened and think nothing can be done but rely on the doctors. Combating feelings of helplessness during this period can help to alleviate painful anxiety. This is best done by a member of the health care team who has established a treatment alliance with the patient. The health care provider should make the patient feel like a partner in everything that takes place. This is especially true regarding decisions about treatment choice.

Active treatment for cancer usually initiates another acute phase of the cancer experience. It can occur while a patient is receiving treatment, or as a complication of treatment. An important standard of clinical practice, based on extensive research, is to provide patients with information to prepare them for treatment. These studies provide convincing evidence that patients who receive specific information about the nature, pattern, and timing of treatment side effects report less disruption in activity than those who are not given this detailed information. [18] Some providers wait until patients complain about potentially expected side effects. When this happens, patients may become skeptical about the completeness or accuracy of any future information given by the person. This potential distrust has important implications for decision making, for patient choice of care-setting in the future, and for recommendations made by patients to others who are seeking a source of cancer care.

The Decision for Bone Marrow Transplantation

Bone marrow transplantation (BMT) is used increasingly for the treatment of malignant and hematologic disorders. [19] The decision to undergo a BMT is a major life crisis for the patient and family. In addition to the very real threat of death, patients experience social isolation, bodily discomfort, major body image changes, and a sense of loss of control. These issues lead to a myriad of emotions, including hope, anger, depression, anxiety, anticipation, guilt, and joy. [20]

Every aspect of the patients personal and professional life is disrupted with BMT. [21] The financial burden is tremendous, including medical expenses for the patient and marrow donor in the case of an allogeneic BMT, in addition to potential travel expenses and loss of income for other family members. [22] Patients and their immediate families are often far from usual support systems because of the distance to the BMT center. In some cases, family members who have not been close in the past may be forced by the situation to interact with each other, leading to additional stress.

Grant and colleagues[23] recently reported that BMT patients seem to experience more fatigue than other patients in studies done on quality of life. The effects of treatment for cancers of all stages can include transient or permanent physical changes, distressing physical symptoms, and functional impairments. Increasingly, intensive cancer therapies, given in the hospital, produce severe and at times life-threatening side effects. The somatic symptoms often experienced by hospitalized patients with cancer include chills, fever, stomatitis, pain, nausea, vomiting, alterations in mobility, inability to tend to self-care needs, and, at times, total dependence on caregivers. There are a number of studies that have been done on BMT recipients, and a range of physical, psychological, and social problems have been identified.

Some preliminary studies have linked negative emotions such as depression with long-term survival among BMT patients. [24] [25] Although such studies have been small and inconclusive and recognize the multiple factors contributing to outcome,

further research in this area is needed. Several BMT centers use routine psychosocial screening [26] and follow-up of BMT patients because of the length of the hospitalization, the aggressiveness of the treatment protocols, and the high incidence of complications and physical discomfort. Interventions that maximize patient control have proven useful.[16] Fear of the unknown can be decreased through patient education about procedures and potential complications. Participation in support groups during hospitalization has proven to be helpful to both patients and family members. [27] In addition to routine psychosocial assessment and follow-up evaluation, routine social work referrals are recommended to assist patients in dealing with the commonplace financial and insurance issues. [28] [29]

Cancer is well recognized as a chronic disease, requiring patients to undergo treatment and long-term surveillance months and years after diagnosis. Strauss [30] has identified critical problems needing attention if patients and families are to be helped to normalize life with chronic illness. These include management of regimens and symptoms, redesigning lifestyles, minimizing financial stress, and confronting psychological, marital, and family problems.

Survivorship

The successful treatment of the hematologic malignancies has resulted in cure for many patients and progressively longer lives for others. Longer survival, however, is not without significant emotional sequelae. [11] [31] [32] [33] [34] [35] Innovative and new treatments may produce long-term physiologic consequences, such as infertility and organ system failure, that can magnify and exacerbate the psychological issues initially associated with diagnosis and treatment. [36] [37] Many patients lack information about what to expect once they are discharged from the hospital. Clinicians need to establish ongoing mechanisms to monitor patients symptoms, psychosocial status, and the problems they are having in terms of resuming activities and responsibilities. The clinician is then in a position to help the survivors to find the best solution for their situation.

The overwhelming evidence from the literature involving survivors with different cancer diagnoses is that, on the average, most do very well after the initial adjustment in the first 12 years post-treatment. Psychological aspects of survivorship may include concern over the termination of treatment, fear of relapse, preoccupation with somatic symptoms, re-entry into previous roles, lingering affinity with death, and financial, job, and insurance difficulties. These issues may manifest in a variety of ways, including denial of past illness, leading to medical compliance issues; ongoing problems with anxiety, panic, and depression; and inability to re-enter previous roles. There is considerable evidence that the wide range of surgical, chemotherapeutic, and radiation therapies can leave permanent damage to organs and physiologic functioning, and disfigurement across the different hematologic diagnoses (Table 81-2). Health care providers should be mindful of psychological sequelae among patients, even within the context of remission and a hopeful prognosis, and refer to a mental health specialist, if necessary.

Progressive Disease

The psychosocial issues experienced by the person with cancer depend in part on the clinical course of the disease process. As the disease progresses, the person often reports an upsetting scenario that includes frequent pain, disability, increased dependence, and diminished functional ability. [7]

The development of a relapse after a disease-free interval can be especially devastating for patients and those close to them. The medical work-up is often difficult and anxiety provoking,

TABLE 81-2 -- Long-term Consequences of Therapies for Hematologic Cancers

Anxiety
Depression
Fear of recurrence

Disfigurement
Conditioned nausea and vomiting
Unemployment
Denial of life insurance
Denial of health benefits
Increase in life insurance rates
Difficulty changing health care coverage
Breakdown of marriage/relationship
Decline in participation in leisure activities
Diminution of support from others
Disruption in sexual functioning
Infertility

and psychosocial problems experienced at the time of diagnosis frequently resurface, often with greater intensity. [7] Shock and depression often accompany relapse and require the patient and family to re-evaluate the future. In spite of the overwhelming nature of the psychosocial responses, however, most patients do indeed cope effectively with progressive illness, and it is important to recognize that intense emotions do not necessarily equate with maladaptive coping.

Investigators studying quality of life in patients with cancer have demonstrated a clear relationship between a persons perception of quality of life and the presence of discomfort.[37] [38] As uncomfortable symptoms increase, perceived quality of life diminishes. Thus, an important goal in the psychosocial treatment of patients with advanced cancer centers around symptom control.

An issue that repeatedly surfaces among patients, family members, and professional care providers deals with the use of aggressive treatment protocols [39] in the presence of progressive disease. Often, patients and families request participation in experimental protocols, even when there is little likelihood of extending survival. Controversy continues about the efficacy of such therapies and the role health professionals can play in facilitating patients choices about participating.

The need for health care professionals to establish structured dialogue between patients, family members, and health care providers regarding treatment goals and expectations is essential. That certain patients respond to investigational treatment with increased hope, despite progressive disease, should be a consideration in treatment planning. The need to separate and clarify the values, thoughts, and emotional reactions of care providers, patients, and families to these delicate issues is important if individualized care with attention to the particular patients psychosocial needs is to be provided.

It is beyond the scope of this chapter to present a comprehensive overview of the psychosocial reactions of patients to the process of dying. Once the terminal period has begun, it is not usually the fact of dying, but the quality of dying, that seems to present the overwhelming concern. [40]

FACTORS THAT INFLUENCE PSYCHOSOCIAL ADJUSTMENT

Psychosocial responses to cancer vary widely and are influenced by several factors that clinicians should bear in mind when considering the responses of individual patients. A review of the literature points to key factors that may have an impact on psychosocial adjustment. These include (1) previous coping strategies and emotional stability, and (2) the existence of social support.

Previous Coping Strategies and Emotional Stability

One of the key predictors of psychosocial adjustment to cancer is the coping strategy and emotional stability of the person before diagnosis. People with a history of poor psychosocial adjustment before development of cancer are at highest risk of emotional decompensation and should be monitored closely throughout all phases of treatment.[40] This is particularly true of people with a history of a major psychiatric syndrome or psychiatric hospitalization, or both.

Because a persons coping style is determined relatively early in life and remains stable over time and across situations, it serves as a useful predictor of adjustment to cancer. Several investigators have identified specific personality characteristics, coping strategies, or life experiences that either enhance or inhibit positive adjustment to cancer. Those coping strategies found to be most effective have included a fighting spirit and having a feeling of control over events, resulting in active participation in treatment. By contrast, poor adjustment has been associated with avoidant coping strategies, prior negative sexual experiences, body image problems, and inhibition in discussing personal and sexual problems. [41]

The Existence of Social Support

Social support has consistently been found to influence a persons psychosocial adjustment to cancer. The ability and availability of significant others in dealing with diagnosis and treatment can significantly affect the patients view of himself or herself. Those diagnosed with all types of life-threatening chronic disorders experience a heightened need for interpersonal support. Those who are able to maintain close connections with family and friends during the course of illness are more likely to cope effectively with the disease than those who are not able to maintain such relationships.

Living with a chronic illness often requires continuing care and management by a team of specialists. Care is usually provided through follow-up visits to ambulatory or outpatient clinics and consulting rooms, rather than through hospitalization. Historically, patients often are not referred to home nursing care once they are discharged from the hospital. An initial home nursing visit can be invaluable in assisting the patient and family with the transition, in addition to identifying areas in which ongoing assistance is needed. Home care referral can assist families, who are increasingly relied on within the current health care system, to be the major providers of care outside the hospital. The phenomenon of caregiver burden acknowledges that cancer affects not only the patient, but the members of the family. [42] The burden that caregiving places on the family highlights the familys needs and the importance of targeting support information that can help reduce family caregiver burden. Helping to arrange respite care for the patient also aids in relieving caregiver burden.

DIFFERENTIATING PSYCHIATRIC COMPLICATIONS FROM EXPECTED PSYCHOLOGICAL RESPONSES

Most patients manifest transient psychological symptoms that are responsive to support, reassurance, and information about what to expect regarding the cancer course and its treatment. Some require more aggressive psychotherapeutic intervention, such as pharmacotherapy and ongoing psychotherapy. The following guidelines can assist the clinician in identifying those patients who exhibit behavior suggesting the presence of a psychiatric syndrome.

Most patients do not react to a diagnosis and treatment for cancer by development of a clinically diagnosable psychiatric condition. In some cases, however, a psychiatric syndrome does occur. If the patients problems become severethat is, if the provider believes that supportive measures are insufficient and ineffective in controlling emotional distressreferral to a psychiatric clinician is indicated. Factors that can prevent adjustment to cancer and its treatment include a history of significant depression, manic-depressive illness, schizophrenia, neuroses, organic mental conditions, personality disorders, lack of social support, or inadequate control of physical discomfort.

Because transient symptoms of anxiety and depression are common in patients with cancer, the ability of health care providers to distinguish expected reactions from more severe psychiatric complications is crucial. Anxiety and depression are common symptoms that are particularly evident at transition points during the clinical course of cancer. These symptoms usually subside within 24 weeks and are responsive to supportive reassurance and information regarding what to expect during the course of treatment. For a proportion of patients, psychological distress does not subside with usual interventions. Unfortunately, clinically relevant and severe psychiatric syndromes are often missed by nonpsychiatric care providers. It can be difficult to detect serious psychiatric reactions in patients because several of the diagnostic criteria used to evaluate the presence of severe depression (i.e., lack of appetite, insomnia, decreased sexual interest, diminished energy) may overlap with usual disease and treatment effects. In addition, it is not unusual for health care providers to confuse their own fears about cancer with the emotional reactions of their patients (i.e., I too would be extremely depressed if I were in a similar situation).

General guidelines designed assist in distinguishing patients who should be referred for evaluation by a trained psychiatric clinician include the following:

1. Past history of psychiatric hospitalization or significant psychiatric/personality disorder
2. Persistent refusal, indecisiveness, or noncompliance with regard to needed treatment
3. Persistent symptoms of anxiety and depression that are unresponsive to usual support from health care providers or family members; symptoms may present in the form of constant fear associated with treatment and procedures or excessive crying and hopelessness that worsen rather than improve with time
4. An abrupt, unexplained change in mood or behavior
5. Insomnia, anorexia, diminished energy out of proportion to expected treatment effects
6. Persistent suicidal ideation
7. Unusual or eccentric behavior or confusion (may be indicative of an organic mental disorder)
8. Excessive guilt and self-blame for illness
9. Evidence of dysfunctional family coping or complex family issues

After referral to a psychiatric specialist, one or a combination of several therapeutic modalities may be used. Cancer and its treatment may precipitate an exacerbation of an underlying mental illness to which the patient was already predisposed and that may require extensive treatment (e.g., hospitalization for a psychosis, ongoing pharmacotherapy or psychotherapy). A discussion of these specialized forms of treatment is not warranted here, but the interested reader can consult appropriate standard texts.[41]

MANAGEMENT OF PSYCHOSOCIAL PROBLEMS

Increased length of survival from time of diagnosis has highlighted the need for psychopharmacologic, psychotherapeutic, and behaviorally oriented interventions to reduce distress, promote adjustment, and improve quality of life for patients with cancer. Numerous studies have documented the efficacy of a

variety of modalities in managing psychosocial problems for such patients. Problems that can be managed effectively include emotional distress such as anxiety and depression; sexual dysfunction; body image disturbances; marital and family difficulties; noncompliance, pain, and neurologic complications such as delirium and dementia induced by brain metastasis or treatment, anticipatory and post-treatment nausea and vomiting; and anorexia and feeding problems.

Pharmacologic Interventions

Pharmacotherapy, as an adjunct to one or more of the psychotherapies, can be an important aid in bringing psychological symptoms under control. Psychopharmacologic agents for the treatment of psychiatric complications associated with cancer are reviewed only briefly here. For a thorough review, as well as expanded treatment guidelines, the reader is referred to a comprehensive chapter by Massie and Lesko. [43]

For patients with excessive anxiety, factors other than a psychological state must first be evaluated. Metabolic abnormalities, pain, hypoxia, and drug withdrawal states can all present as anxiety. Medications such as steroids and antipsychotics, often used to control nausea, can also cause anxiety characterized by agitation and motor restlessness. After medical or drug-induced causes for anxiety are ruled out, an anxiolytic agent is the treatment of choice, with the exception of patients who present with panic episodes, in which case tricyclic antidepressants are most efficacious. Anxiolytic agents are often fast acting and effective (Table 81-3). These drugs are most effective when used at adequate dosages and as standing orders. Use of these medications may also assist the patient to participate in psychotherapy, which can provide more permanent control over psychological symptoms. When anxiety develops in the context of the terminal stages of cancer, it is often secondary to hypoxia or an untreated pain syndrome. Intravenous morphine sulfate is usually an effective palliative treatment. [40]

There are a number of anxiolytics available to treat patients with cancer. These drugs are similar in their overall clinical effects. Because of their shorter half-lives, alprazolam and lorazepam have advantages for elderly patients because toxicity from sedating medications is more common and withdrawal reactions may occur on abrupt discontinuance unless the drug is tapered gradually.

It is common for patients with cancer to demonstrate transient depressive symptoms at various points in the illness trajectory, particularly when a hope for cure is no longer realistic. In patients who exhibit prolonged or severe depressive symptomatology, a major depressive illness must be considered. Depression can be related to recurrence of a past depressive disorder; stress associated with cancer treatment; or disease or treatment effects. Certain medications and cancer treatment agents can produce severe depressive states. A diagnosis of major depression in patients with cancer relies heavily on the presence of affective symptoms such as hopelessness, crying spells, guilt, preoccupation with death or suicide, diminished self-worth, and loss of pleasure in most activities, such as being with friends and loved ones. The neurovegetative symptoms that usually characterize depression in physically healthy people are not good predictors of depression in the medically ill because the cancer and its treatment can also produce these symptoms. A combination of psychotherapy and antidepressant medication often proves useful in treating major depression in patients with cancer (Table 81-4).

The primary medical contraindication to the use of tricyclic antidepressants is significant cardiac conduction delay, which should be ruled out before initiating treatment. These medications are started in low doses (2550 mg) and are increased slowly, over days to weeks, until symptoms improve. Peak dosages are usually substantially lower than those tolerated by physically healthy people. Antidepressant medications may take 26 weeks to produce their desired effects. Patients may need ongoing support, reassurance, and monitoring before experiencing the antidepressant effects of medication. Patients require close monitoring during the initiation and modification of psychopharmacologic regimens by a consistent provider.

Selective serotonin reuptake inhibitors (SSRIs) are a more recently discovered class of antidepressants than the tricyclics and are widely precribed in the general population (Table 81-4). These antidepressants are often desirable because fewer anticholinergic, cardiac, or cognitive adverse effects occur, compared with tricyclic antidepressants. [44] Undesirable side effects for a cancer population may include agitation and anorexia. [44]

Psychostimulants such as dextroamphetamine and methylphenidate (Table 81-4) have been useful in the treatment of depression in medically ill patients. Advantages include rapid onset of action and rapid clearance if side effects occur. They can also counteract opioid-induced sedation and improve pain control through a positive action on mood. Common side effects of psychostimulants include insomnia, anorexia, tachycardia, and hypertension, although incremental increases in dosage allow adequate monitoring of therapeutic versus side effects. In patients with cardiac conduction problems, stimulants may be the treatment of choice. In patients with cancer, a 1- to 2-month trial can provide remission from depression even after discontinuation of the drug.

Psychotherapeutic Modalities

Depending on the nature of the problem, the treatment modality may take the form of individual psychotherapy, group therapy, family therapy, marital therapy, behaviorally oriented therapy, or some combination. [16] Table 81-5 outlines the major psychotherapeutic modalities and the advantages, goals, and indications for each.

TABLE 81-3 -- Commonly Prescribed Anxiolytics in Patients with Cancer

Drug	Starting Dosages	Absorption	Half-Life	Comments
Alprazolam (Xanax)	0.250.5 mg po tid	Intermediate	Intermediate	Generalized anxiety; panic attacks; mixed anxiety; depression; detoxification of patient may be difficult.
Lorazepam (Ativan)	0.51.5 mg po tid	Intermediate	Intermediate	Similar to alprazolam; can produce transient amnesia; given before procedures and chemotherapy. Agent of choice with hepatic impairment.
Diazepam (Valium)	2.55 mg po tid	First	Long	Because of long half-life, not ideal for patients with organic neurologic syndromes.

CONCLUSIONS

The psychosocial issues faced by people diagnosed and treated for cancer are influenced by sociocultural, medical, family, and individual factors. Although involvement in decision making is clearly a positive aspect of current cancer therapies, great care should be taken to ensure the communication of timely, repeated, and relevant information consistent with the patients needs, tolerance, and comprehension. A multidisciplinary approach is essential to guarantee the communication of comprehensive information to all patients. Patients should be given the opportunity to speak with multiple members of the treatment team and other patients who have experienced similar management and treatment protocols. Care should be taken to provide needed information from a variety of expert perspectives while respecting the unique characteristics, psychosocial profiles, needs, and desires of each individual. In treatment settings with limited resources, every effort should be made to enlist the help and support of providers and services that can assist patients

TABLE 81-5 -- Psychotherapeutic Modalities in the Oncology Setting

Modality	Selected Indications	Goals and Advantages	Comments
Individual psychotherapy	Prolonged adverse reactions to diagnosis, treatment, and other aspects of chronic illness (i.e., anxiety, depression)	Support patient and enhance ability to cope with distressing feelings. Short-term therapy; focused and goal directed.	Pharmacotherapy and family involvement are useful adjuncts in some cases.
Support groups	Patients desire exposure to others who are experiencing chronic illness	Support patient and enhance coping ability. Usually does not involve a fee. Patients benefit by observing the coping strategies of others.	Expands social network of patients with limited support systems.
Family and marital therapy	Relationship problems secondary to illness (i.e., family tension, role changes, conflict, sexual problems)	Assists couples to clarify problems and solve them together. Addresses role changes in family system.	Problems, issues, and concerns about children can be addressed.
Progressive muscle relaxation and guided imagery	Patients desire assistance with control of pain; anxiety; anticipatory and post-treatment nausea and vomiting; fears associated with medical procedures	Increase sense of control and participation in treatment. Individualized to meet patients preferences and circumstances. Time limited and goal directed. Evaluated in terms of observable changes in symptoms.	Realistic goals should be stated explicitly (some patients view relaxation and guided imagery as a cancer cure).

with their complex treatment decisions. Referral to community resources and support services after discharge from the hospital is often helpful, even for patients who cope well with initial treatment. [45]

Most patients undergoing cancer treatment, as well as their families, experience expected periods of emotional turmoil that occur at transition points along the clinical course of cancer. For a small proportion of patients, more severe psychiatric complications may occur, warranting referral to a psychiatric specialist. A variety of psychotherapeutic modalities are useful in helping patients work through the expected emotional responses to cancer, as well as more severe responses. Supportive psychotherapeutic measures should be used routinely because they minimize distress and enhance feelings of control and mastery over self and environment. For these reasons alone, their value in the care of patients with cancer is paramount. Again, for patients who are not responsive to routine support and information, referral to a psychiatric specialist may be indicated.

Throughout the clinical course of cancer, the patients relationship with health care providers as well as the presence of a supportive social network are important factors in ensuring successful negotiation of the many physical and psychosocial demands imposed by a cancer diagnosis and treatment. Further investigation regarding the utility of systematically tested interventions aimed at promoting psychosocial adjustment to cancer are needed. Investigation aimed at enhancing our understanding of the behaviors of people experiencing the crisis of cancer and identification of those in need of intensive psychosocial support is also needed.

As scientific inquiry continues to produce vast, although sometimes conflicting information regarding etiology and treatment for cancer, concurrent investigation regarding the psychosocial aspects of the disease is crucial. This line of inquiry will, at the very least, assist in promoting emotional well-being in patients faced with an extreme and unexpected life crisis. At best, expanding the knowledge base relative to the psychosocial aspects of cancer may provide some missing links regarding psychosocial adaptation and quality of life, and their impact on survival.

Chapter 82 - Pain Management and Antiemetic Therapy in Hematologic Disorders

Janet L. Abrahm

INTRODUCTION

Relieving the pain of patients who have hematologic disorders requires a multifaceted approach. [1] [2] An understanding of the transmission of the pain signal and a thorough evaluation of the pain complaint provide a rational basis for treatment decisions. Once the source of the pain has been identified, both nonpharmacologic and pharmacologic therapies can be employed. The neurosurgical methods of pain control are not discussed in this chapter; those interested in these techniques are referred to several excellent reviews. [1] [2] [3]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

TRANSMISSION OF THE PAIN SIGNAL

For a patient to feel pain,[1] a signal arising from a noxious stimulus in the periphery must be transmitted to the centers in the brain that create the experience of pain. Following activation of peripheral receptors by chemical, thermal, or mechanical stimuli, the signal passes along myelinated A- or unmyelinated A- or C fibers and enters the spinal cord via the dorsal root ganglion. Chemicals released at the site of tissue injury initiate or increase the transmission of the signal. Histamine, serotonin, and bradykinin activate local fibers directly, and prostaglandins, which do not themselves activate these fibers, sensitize them to lower levels of mechanical and chemical stimulants.[4]

The dorsal horn of the spinal cord is where the peripheral signals are received and modulated. The excitatory amino acids (glutamate and aspartate) and neuropeptides (substance P and calcitonin gene-related peptide) enhance transmission of the peripheral signal. [1] [5] But a complex interaction of other neurotransmitters (-aminobutyric acid [GABA], glycine, adenosine, bombesin, cholecystokinin, dynorphin, enkephalin, neuropeptide-Y, neurotensin, substance P, somatostatin, and vasoactive intestinal peptide) determines whether the signal will proceed up the spinothalamic tract. [1] Those signals that are transmitted ascend in one of the two contralateral spinothalamic tracts: the paleospinothalamic tract, which mediates the suffering and autonomic reactions to pain, or the neospinothalamic tract, which localizes the pain and records its intensity. [1]

Transmission of the pain signal can be inhibited at several sites along this course. Inhibitory signals arise from the somatosensory cortex, the paraventricular hypothalamic nucleus, the pontine lateral tegmental field, and the nucleus raphe magnus. They travel down the spinal cord via the dorsal longitudinal fasciculus to the dorsal horn to inhibit transmission of the pain signal. [6] The neurotransmitters involved in this inhibition include serotonin, norepinephrine, and the endogenous opiates -endorphin, enkephalin, and dynorphin. [6] Opiate receptors for both endogenous and exogenous opioids are present in the dorsal horn of the spinal cord, in those ventromedial thalamic nuclei that transmit signals from the paleospinothalamic tract, in the periaqueductal gray, the periventricular diencephalon, and the amygdyla, but not in the neospinothalamic tract. [6] Thus, exogenous opioids can provide relief from suffering without affecting the localization of the source of pain, and, when they are applied directly to the spinal cord (e.g., after surgery), low-dose opioids provide effective pain relief without systemic side effects. [7]

EVALUATION OF THE PAIN COMPLAINT

Initial Evaluation

In evaluating the complaint in patients with hematologic disorders, efforts are initially directed toward determining the cause(s) of the pain: (1) the disease itself, (2) the specific therapy for the disease, and (3) unrelated disorders. Splenomegaly, bone injury (infarction, infection, hemarthroses, infiltration), leptomeningeal infiltration, and spinal cord compression frequently accompany hematologic diseases. Chemotherapy and radiation therapy can cause mucositis, typhlitis, hemorrhagic cystitis, and peripheral neuropathy, and myalgia can follow steroid withdrawal. [8] Immunosuppression, caused by the diseases themselves or by the therapies used to treat them, leads to painful infections such as perirectal abscesses, herpetic or candidal esophagitis, and herpes zoster.

Distress, however, may arise from nonanatomic sources. The pain complaint may represent the patients only means of expressing nonspecific feelings of distress to the physician. Chapman[9] recognized three categories of this distress: (1) anxiety, arising from fear of disfigurement or of uncontrollable pain, fear of loss of social position or of self-control, or fear of death; (2) anger at the failure of the physicians to provide a cure; and (3) depression from loss of physical ability, a sense of helplessness, and the impact of financial problems. In addition to these psychological, social, and financial contributions, spiritual concerns may exacerbate any concomitant painful sensations. [10] Alleviating them can significantly reduce distress and decrease the need for pain medications or other interventions.

Furthermore, for the patient whose complaint of pain does not seem to have a straightforward explanation or who has not responded well to the therapeutic maneuvers outlined below, additional questions must be asked to uncover the source of the distress. Patients may deny their disease and use the complaint of pain to justify their incapacity. Their denial is demonstrated by answers to the following types of questions. *How would life be different without the pain?* Such patients will give unrealistic assessments of the extent of their abilities if only the pain were gone. Hidden fears, resentments, and distrust of the physician may be revealed by answering the question, *What do you think is causing the pain?* Unrealistic expectations of pain treatment may be revealed by answers to the question, *To what extent do you expect your pain to be relieved?* The patient may expect that taking one pill a day will provide total relief, while the physician expects that even a multimodality regimen will relieve only 75% of the pain. A contract detailing the expectations of both patient and physician may be formulated once these unspoken assumptions are understood. Finally, other sources of confusion in the way the patient communicates the type of pain experienced can be clarified by the answer to the question, *Do you seem to show your feelings about the pain to the same extent that your family and friends do?* Patients may come from cultural backgrounds different from the person reporting the pain, and people with cultural differences often report pain very differently. [11] [12] [13] For example, patients of stoic stock may not communicate their distress to their spouse, who may then question the patients need for opioid pain medication (i.e., if they

themselves were in that much pain, they would be sure to tell their spouse). Unless the cultural differences are explored, adequate pain control might not be achieved.

Continued Assessment

Effective pain management requires repeated comprehensive assessment of the patients pain. Pain reports by patients should be believed. The clinician may not be aware that the clinical presentation of a patient suffering from chronic pain is very different from that of a patient in acute pain. If a patient does not manifest the common autonomic manifestations of acute pain (e.g., tachycardia, sweating, elevated blood pressure) or facial grimacing, the clinician might doubt that the patient is suffering from severe pain. It must be understood that a patient with severe but chronic pain will not manifest these autonomic findings but will often be withdrawn, quiet, depressed, or irritable, and will move very little spontaneously but complain of discomfort when moved. When the pain is relieved, these patients often exhibit completely different behaviors, becoming mobile, engaged, and involved with other people. Therefore, the first component in the assessment is to believe the patients complaint.

Patient reports of pain are valid, reliable, and reproducible. [1] These reports should be used, much as a blood sugar measurement is used in diabetic patients, to monitor the efficacy of the therapy. A variety of assessment tools that can be completed within 510 minutes are available. [1] [14] [15] They should be used to determine a number of aspects about the pain, including the pain location, intensity, quality, onset, and duration; what relieves or exacerbates it; and its functional consequences, including how the pain affects the patients ability to sleep or eat and how it affects physical activity, relationships with others, emotions, and concentration. The goal is to lower the pain *to a level acceptable to the patient.* Communication between nurse and physician is greatly improved by using these tools rather than mere qualitative descriptors, such as the pain is better. Using, for example, a scale of 0 (no pain) to 10 (the worst pain one can imagine), a decrease in pain intensity from 10 to 8 indicates that the patient needs a stronger pain medication, while a decrease from 10 to 3 suggests that the current medication regimen is effective.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

THERAPY

A major component of pain therapy is an attempt to ameliorate the underlying cause of the pain. Surgery, chemotherapy, radiation therapy, and antibiotics may all be employed. However, the pain can still be treated effectively during diagnostic testing to define the cause, during specific therapy, or after all disease-related therapies are exhausted.

The goal of pain management is to relieve pain while preserving the patients ability to perform normal activities. This requires expertise on the part of health care personnel, who seek to maximize the relief obtained while minimizing side effects and alterations in daily routines. A multifaceted approach is required that includes nonpharmacologic approaches, anesthetic techniques, correct use of a variety of medications so that pain will be relieved with a minimum of side effects, and patient and family education at each step to foster communication and cooperation with the therapeutic plan.

Nonpharmacologic Methods of Pain Management

Cognitive-Behavioral Interventions

Education and Reassurance

Patients with serious hematologic disorders are often required to undergo extensive diagnostic testing, which can include painful procedures. A rehearsal of the planned test or procedure, including a discussion (or view) of the appearance of the room and the length of time to be spent in the test apparatus, can minimize the patients anxiety. Such explanations, offered preoperatively, lessen the need for postoperative medication and shorten the patients hospital stay. [16] To divert attention from certain procedures (e.g., bone marrow aspiration or biopsy) that take place in the physicians office or in the patients room, a pleasant distraction can be helpful.[17] For example, the physician might encourage the patient to bring in a portable tape player with earphones so that the patient can listen to a favorite piece of music or a book on tape while the procedure is taking place. Alternatively, the physician might turn on the television or radio in the patients room and encourage the patient to pay attention to that, rather than to the procedure. Patients with a good imagination can pretend to be in a place they have previously enjoyed (e.g., at the beach or in the mountains). They can dissociate themselves [18] from the procedure by concentrating on those pleasant memories and thereby diminish the painfulness of the procedure.

Hypnosis

Practitioners with formal training in hypnosis can use more elaborate hypnotic techniques to help their patients deal with painful procedures or conditions. [17] [18] Hypnosis takes advantage of the natural ability to enter a trancelike state. An athlete playing through the pain is an example of the spontaneous induction of such a state. Patients who are trained to enter a trance at will can modify their perception of pain and diminish sleeplessness, anxiety, and the anticipation of discomfort. [19] Hypnotic training of patients with sickle cell anemia or hemophilia decreases the frequency and pain intensity of painful crises [20] or bleeding episodes, [21] [22] respectively.

Even in the absence of a formal hypnotic induction, the words used by the practitioner to describe procedures are very important. For example, the suggestion that hand or arm coolness and numbness will persist after application of an alcohol swab may markedly diminish the discomfort of starting an intravenous line. Using the phrase You will feel something; Im not sure what you will feel, as everyone feels this a little differently in place of This is going to hurt a lot! gives the patient permission to alter the sensation and may also diminish the experience of pain.

Counseling

Psychological counseling provides education, support, and skill development for patients with pain. [23] It can improve patients ability to communicate their pain to care personnel and may be effective in overcoming anxiety and depression. Spiritual counseling aids patients who have lost hope, can find no meaning in their lives, or feel they are being punished or have been forsaken by God. [24] They may interpret their pain in the light of these feelings. Through counseling, they can regain a sense of worth and belonging. As they recast the pain in its true light, it is often diminished.

Cutaneous Techniques

Acupuncture, massage, vibration, and applying cold or heat to the skin over injured areas are often very effective. Cold wraps, ice packs, or cold massage using a cup filled with water that has frozen into a solid piece of ice relieve the pain of muscles that are in spasm from nerve injury. Heat from heating pads, hot wraps, or paraffin treatments can soothe injured joints but should not be used over areas of vascular insufficiency. [25]

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) devices are indicated for patients with dermatomal pain, such as postherpetic

neuralgia (see discussion under Postherpetic Neuralgia) or radiculopathy from spinal cord compression. [26] For optimal effect, a physiatrist or physical therapist familiar with the device should train the patient in its use.

Anesthetic Techniques

EMLA, a cream containing two topical anesthetics (lidocaine 2.5% and prilocaine 2.5%) is used, especially in children, to decrease the pain of superficial cutaneous procedures (e.g., venous cannulation or skin anesthesia prior to lumbar puncture, bone marrow aspiration, or biopsy). [27] [28] [29] To achieve anesthesia, the EMLA cream must be applied 11 1/2 hours before the planned procedure in a mound under a semipermeable dressing such as Opsite or Tegaderm. [30] [31] When EMLA is used as directed, methemoglobinemia has not been a problem even in infants as young as 3 months old; [32] [33] skin blanching occurs, sometimes exceeding, but in other studies equaling, the frequency of that found with placebo moisturizing cream placed under the occlusive dressing. [31] [34]

Trigger-point injections, nerve blocks, and neurolytic procedures are useful for both acute and chronic localized pain. After excisional biopsy of an axillary lymph

node, for example, a burning, constricting pain in the posterior arm and chest wall may develop; this pain is often promptly relieved by trigger-point injection. [35] [36] Lymphoma or myeloma may involve the spine and lead to vertebral collapse or pain from progressive disease that is refractory to antineoplastic therapy. Such pain is often particularly difficult to manage. Insertion of temporary or permanent indwelling epidural or intrathecal catheters to deliver either opioids or local anesthetic agents, or both, can be very effective, especially in relieving lower thoracic or lumbar spine pain, as well as pelvic and lower extremity pain. [37] [38] Those interested in the indications for and techniques of the anesthetic and neurolytic procedures are referred to several reviews. [39] [40]

Drug Therapy

Drugs useful for pain relief include nonopioid analgesics, opioids, and adjuvant drugs that either potentiate the actions of opioid analgesics or treat their side effects. Most patients require a combination of medications for optimal pain relief (Fig. 821).

Nonopioid Analgesics

Nonopioid analgesics should be given to patients with mild to moderate pain. Aspirin, acetaminophen, and nonsteroidal anti-inflammatory drugs (NSAIDs) are especially useful in treating bone pain as they decrease local prostaglandin release and may thereby reduce the sensitization of pain receptors. [41] It is important to prescribe an adequate dose of each drug at regular intervals, switching to another nonopioid analgesic only when maximal doses of the first have become ineffective.

Tramadol, which binds opioid receptors and shares opioid-induced side effects but is not an opioid, also relieves mild to moderate pain. A dose of 100 mg is more effective than 60 mg of codeine.[42] Ketorolac tromethamine (Toradol) is an NSAID of particular value in relieving moderate to severe acute pain. A dose of 30 mg of ketorolac given intramuscularly equals the pain-relieving potency of 15 mg of morphine intramuscularly, and acute toxicity is minimal if the total daily dose is under 100 mg.[43] However, ketorolac has all the side effects of the NSAIDs and is not recommended for long-term use. If that degree of pain relief is needed chronically, an opioid agent should be substituted.

Since the NSAIDs can cause renal insufficiency in a significant number of patients, renal function should be assessed 1 or 2 weeks after initiation of any of these agents. NSAIDs should

Figure 82-1 Strategy for pharmacologic management of pain. Multiagent therapy is usually required for optimal pain management. Patients with mild to moderate pain should be started on a nonopioid analgesic or on a combination of nonopioid analgesic and a short-acting opioid. If this combination does not produce adequate relief, or if patients present with severe pain, stronger opioids, in either short-acting or sustained-release form, should be begun immediately. These patients should also receive nonopioid analgesics, if indicated. Laxatives are given to all patients receiving opioids (even for mild pain), and adjuvant tricyclic medications for sleep are offered. Other adjuvant agents should be included as indicated (see text). The drug names given are meant to be illustrative; they are drugs commonly used.

, adjuvant drug;

, an opioid;

, a short-acting opioid;

, a long-acting opioid;

, a nonopioid analgesic (ASA, aspirin; ACET, acetaminophen; NSAID, nonsteroidal anti-inflammatory drug);

, a tricyclic antidepressant;

, combination drugs Percodan, Percocet, and Tylox all include both an opioid and a nonopioid analgesic.

be used with caution in patients with a history of aspirin allergy or asthma because they will precipitate bronchospasm in as many as 20%. [44] Significant edema can occur in patients with cirrhosis or congestive heart failure. [44] If NSAIDs are required in patients with a history of significant gastritis or ulcer disease, or who are over 70, concomitant omeprazole should be considered. [45]

The nonopioid analgesics should be continued in appropriate cases when opioid analgesics are added, as they will potentiate the pain-relieving effect of the opioid (Fig. 821).[46] However, when aspirin is included in a fixed drug combination (e.g., Percodan), salicylate toxicity may develop if the patient takes the pills more often than the prescription indicates. The metabolism of salicylates is limited by the capacity of the hepatic microsomal system. Once that is saturated, salicylate levels are dependent on renal clearance. Thus, small increases in maintenance doses can lead to serious salicylism. [47] Patients with low albumin levels or acid urine are particularly susceptible to the development of salicylate toxicity. [48]

Adjuvants for Neuropathic and Bone Pain

Tricyclic antidepressants (e.g., amitriptyline, nortriptyline), anticonvulsants (phenytoin, carbamazepine, gabapentin, and clonazepam), and steroids are nonopioid analgesics that demonstrate particular efficacy in relieving pain from nerve injuries. The tricyclic antidepressants are the drugs of choice for painful

MANAGEMENT OF SEVERE PAIN

Narcotic therapy is the cornerstone of management of the patient presenting with severe pain. Our practice is to begin with reassurance of patients and their families. We tell them that to relieve the pain as quickly as possible, we will initiate the use of intravenous opioid medications immediately, but that we will begin oral pain medication as soon as the pain is well controlled. Without this explanation, patients have misinterpreted the morphine drip as an indication that they were considered terminal. The starting dose is calculated from the patients baseline opioid requirement or weight (e.g., 0.05 mg/kg/hour of morphine). With continuous patient monitoring, a morphine bolus is given, the drip is begun, and every 2030 minutes the degree of pain relief is reassessed. If the relief is inadequate, another bolus is given; in patients without severe underlying chronic obstructive pulmonary disease, the drip is adjusted upward every 812 hours based on the number of boluses required. There is no maximal morphine dose; we give whatever is required to relieve the pain. If the patient falls asleep, this is usually an indication that pain relief has been achieved, not that the dose should be lowered. We lower the dose if the respiratory rate falls to below 1012 breaths per minute.

Agents to prevent side effects are begun along with the opioid (Fig. 821). All patients are given Senokot or Senokot S, one or two tablets orally daily, up to a maximum of 8 pills per day. If more laxative effect is needed, lactulose is added. The starting dose is 1530 ml PO at bedtime, repeated if necessary in the morning. Lactulose is effective and, unlike other agents, does not produce either cramping or a feeling of fullness. Amitriptyline (10 or 25 mg PO) is usually ordered as a patient may refuse sleep medication. In opioid-naive patients, Compazine (10 mg PO tid or bid) is given for the first 4872 hours to prevent the otherwise common development of nausea. In patients with bone or nerve pain, appropriate adjuvants are added (see text).

When pain relief is adequate, the patient is converted to an equivalent dose of oral morphine. Three times the parenteral dose is required (Table 821). For example, a patient who requires 10 mg of morphine per hour (i.e., 240 mg/24 hours IV) will need 720 mg/day of the oral long-acting agent (240 mg × 3). This can be given as 360 mg PO every 12 hours. Two hours after the oral opioid is begun, the drip is discontinued. Short-acting immediate-release morphine should be available for rescue dosing (see text for dosing recommendations). If the amount of opioid taken as a rescue dose is significant (>25% of the daily dose), the total dose of long-acting agent is adjusted upward accordingly.

peripheral neuropathies and for postherpetic neuralgia. They have anticholinergic side effects of varying intensity and must be used with caution in those who are elderly or who have cardiac conduction abnormalities or bladder outlet obstruction. Phenytoin and carbamazepine, drugs used to treat trigeminal neuralgia, can also be effective for postherpetic neuralgia.[49] [50] Corticosteroids given epidurally, intravenously, or orally are useful for tumor cell lysis (e.g., in leukemia, lymphoma, and myeloma) and can also provide nonspecific relief for patients with spinal cord compression and plexus infiltrations. Doses of 16100 mg of dexamethasone are needed to reduce vasogenic edema in spinal cord compression,[51] but lesser doses (620 mg/day) can be helpful in patients with plexus injuries.[8] Patients must be monitored for the development of oral or esophageal candidiasis and steroid-induced delirium. Steroids are also effective for bone pain, as are pamidronate (90120 mg),[52] calcitonin (100200 IU bid),[53] and strontium chloride (^{89} Sr).[54]

Opioid Analgesics

Patient Education

Opioid analgesics are the mainstay of therapy for moderate to severe pain of malignant or nonmalignant origin. To ensure patient compliance with an opioid prescription, however, education of other members of the health care team, the patient, and the family is often required to dispel the many misconceptions associated with opioid therapy. Even physicians who are cancer specialists hesitate to prescribe opioids as needed for patients with severe pain.[55]

Fear of addiction is a common cause of inadequate dispensing of opioids[56] and a barrier to their acceptance by patients.[55] The physician can increase compliance by providing a full explanation of the differences between addiction and physical dependence, along with reassurance that research has repeatedly indicated that patients with malignancies who take opioids do not become addicts.[57] [58] Patients may also fear that if they take opioid medications for moderate pain, these medications will no longer be effective if more severe pain occurs. Since this fear, if unexpressed, can lead to undertreatment, the topic should be addressed even if the patient does not raise the question. A functional goal of therapy, such as returning to a favorite hobby or reinstituting normal activities of everyday life, may enable the patient and the family to accept the opioid. Finally, misconceptions about religious teachings may prevent health care personnel, patients, and their families from giving or accepting adequate pain medication. Catholics, for example, may not be aware of the Churchs position, as stated in the current catechism, that opioids may be used at the approach of death, even if their use ultimately shortens the patients life.[59] [60] The Church does not consider this use of pain medication to be a means of suicide or euthanasia.[61]

Choice of Medication

Since a wide variety of medications are available, pharmacokinetic considerations and side-effect profiles should be considered when choosing opioid agents. Intermittent moderate to severe pain lasting hours to several days is amenable to oral analgesics with short half-lives (34 hours) with appropriate potency (e.g., immediate-release oxycodone or morphine, hydromorphone [Dilaudid]). Severe pain of relatively constant intensity should be treated with oral sustained-release morphine or oxycodone (taken every 8 or 12 hours[62] [63]) or transdermal fentanyl (renewed every 4872 hours). In addition, a 1224-hour formulation of oral morphine (Kadian, Kapanol) is available; for patients unable to take pills, the capsule can be opened and the pellets sprinkled on food or suspended in water and given through a feeding tube.[64]

Drugs with short half-lives should also be used for rescue doses, given for pain with movement (incident pain) and for between-doses pain exacerbations. The dose of the rescue medication should be 10% of the total 24-hour dose.[65] For example, if a patient is receiving 180 mg of oral sustained-release morphine twice a day, the rescue dose should be 10% of 360 mg, which is 36 mg of short-acting morphine. Agents with short half-lives should also be used in the elderly and in patients with impaired renal or hepatic function.[65] In patients with a previous drug abuse history, agents with longer half-lives, such as methadone or levorphanol, are preferred.

The side-effect profiles of the opioid agents differ widely. It is often useful, therefore, to switch to another agent if a patient

TABLE 82-1 -- Relative Potencies of Commonly Used Narcotics

Drug	Epidural	IM (mg)	PO (mg)

Morphine	1	10	30 (repeated dose)
			60 (single dose)
Codeine		130	200
Oxycodone (in Percodan, Tylox)		N/A	20
Meperidine (Demerol)		75	300
Levorphanol (Levo-dromeran)		2	4
Hydromorphone (Dilaudid)		1.5	7.5
Methadone		10	20
Fentanyl		0.1	

Adapted from Foley,[1] with permission.

is experiencing dose-limiting side effects with the initial opioid chosen. [66] For example, if the patient receiving morphine experiences disabling nausea, the substitution of hydromorphone at an equianalgesic dose should be considered (Table 821). Because of incomplete cross-tolerance, the initial dose for patients on higher doses of opioids should be only one-half to two-thirds the calculated equianalgesic dose. [65] For example, in the same patient taking morphine (360 mg/day PO), hydromorphone should be begun at 45 or 60 mg/day (one-half or two-thirds the 90-mg dose that would be equianalgesic). For patients receiving even higher doses of opioid, as little as 20% of the replacement opioid may be appropriate. [67] The short-acting rescue medication (5 or 6 mg hydromorphone) will provide relief if this initial dose does not prove adequate.

Meperidine is not indicated for chronic use in patients with long-lasting moderate to severe pain. [1] It provides pain relief for only about 12 hours [8] and gives rise to an active metabolite, normeperidine, which induces dysphoria, is excitatory to the central nervous system, and can cause seizures. [68] Normeperidine has a half-life of 1324 hours, which can lengthen with renal failure. [69] Thus, the frequent administration of meperidine required for pain control causes normeperidine levels to rise and increases the likelihood of seizures even in patients with normal renal function. [1] The seizure incidence is further increased if the opioid antagonist naloxone (Narcan) must be given.[70] Other opioids are therefore better choices for patients with moderate or severe pain who will require days of sustained analgesia. In sickle cell disease, for example, intravenous or oral sustained-release morphine has been shown to be very effective in both inpatient and outpatient pain management. [71] Should hyperirritability or a seizure occur in a patient receiving meperidine, intravenous diazepam (Valium) rather than phenytoin should be used to control the seizure,[72] and morphine should replace the meperidine for pain control.

Routes of Delivery

Opioids can be delivered noninvasively (orally, rectally, or transdermally) or invasively (subcutaneously/intravenously or by spinal infusion). For patients switched from oral or rectal to parenteral or spinal medication, or vice versa, the dose must be altered accordingly to avoid overdose or undertreatment (Table 821). No matter which route is chosen, patients experiencing continuous pain should receive the analgesics regularly and be awakened, if necessary, to administer medications that will prevent recurrence of the pain. [1]

Oral.

Most patients will be able to achieve excellent pain relief with either short-acting or sustained-release oral opioid preparations. Oral transmucosal fentanyl citrate induces rapid analgesia, relieves anxiety, and produces sedation. [73] It is especially useful in children and can relieve breakthrough pain in adults.

Rectal.

Rectal opioids (morphine, oxymorphone, and hydromorphone) replace IM injections for patients who are suddenly unable to take oral medications. They have about the same potency and half-life as orally administered agents [74] [75] [76] [77] and must therefore be administered frequently. In single-dose bioavailability studies of sustained-release morphine preparations, despite delayed absorption from the rectal route, total morphine absorption over 24 hours was equivalent, whether the drug was given orally or rectally. [74] [75] [76] [77]

Transdermal.

The transdermal fentanyl patch (Duragesic) delivers the lipophilic fentanyl into the fat-containing areas of the skin. The drug diffuses continuously from the patchs reservoir through a rate-controlling membrane and is absorbed from the skin depot into the bloodstream, where it is rapidly metabolized (Figure 822). [78] The onset of pain relief is delayed about 12 hours and a relatively constant plasma concentration of fentanyl is not reached until about 1420 hours after the initial patch is placed.[78] Rescue medication must therefore be provided during the first 48 hours of use of the patch. [79] Similarly, if a patient develops signs of fentanyl overdose, naloxone (Narcan) must be given until the skin reservoir has become depleted. [80] About 50% of the drug is still present 24 hours after patch removal. [81] Converting patients from oral or parenteral medication to the patch is easily accomplished using the table provided in the package insert. [82] Most patients will require dose escalations, as the conversion is a conservative one. A new patch is applied every 72 hours, although a few patients require a new patch every 48 hours.

The transdermal system is an effective method of delivering pain relief for patients with (1) moderate to severe pain, (2) no oral route available or no desire to take pills, and (3) a stable level of chronic pain. Side effects include those due to the contact adhesive, along with those commonly associated with other opioids, but may be better tolerated than those caused by morphine. [81] [82] [83]

The transdermal system should not be used in septic patients, those experiencing acute pain, or those with markedly fluctuating opioid requirements. When the patients temperature rises to 40°C, drug absorption from the skin can increase by as much as 35%. [78] If hepatic function is impaired or sepsis or shock develops and blood flow to the liver decreases, plasma concentrations may rise sharply. [81] Lower doses may also be required

Figure 82-2 Duragesic is a rectangular transparent unit comprising a protective liner and four functional layers. Proceeding from the outer surface toward the surface adhering to the skin, these layers are (1) a backing layer of polyester film, (2) a drug reservoir of fentanyl and alcohol USP gelled with hydroxyethyl cellulose, (3) an ethylenevinyl acetate copolymer membrane that controls the rate of fentanyl delivery to the skin surface, and (4) a fentanyl-containing silicone adhesive. Before use, a protective liner covering the adhesive layer is removed and discarded.

TABLE 82-2 -- Adverse Effects from Spinal Infusions

Narcotic	Anesthetic	Catheter-Related	
		Epidural	Subarachnoid
Respiratory depression	Hypotension	Insertion related (e.g., hematoma)	Insertion related (e.g., hematoma)
Sedation		Fibrosis	CSF leak
		Skin abscess	Meningitis

Data from Paice and Williams.[38]

in elderly patients or in those with respiratory insufficiency. [84]

Subcutaneous and Intravenous.

Continuous subcutaneous or intravenous administration of opioids can provide pain relief in the shortest amount of time, with a minimum of oversedation. The drugs can be delivered by portable infusion pump and initiated or continued in the home. [85] [86] [87] Guidelines for their use are available. [88] Patient-controlled analgesia (PCA) systems for subcutaneous or intravenous drug delivery have the advantage of responding to the individual patients threshold for pain while eliminating delays when nurses must administer supplemental medication.[89] The pumps administer a continuous fixed infusion of the opioid chosen and allow the patient to self-administer boluses of additional medication at frequencies chosen by the physician. By recording the additional amounts of self-administered medication, the devices also facilitate the adjustment of the continuous dose required for pain relief.

Spinal.

Epidural or intrathecal opioid infusions, which include the option of patient-controlled epidural analgesia, can be helpful for selected patients with pain below the midthoracic area.[37] [90] The infused opioids block pain transmission by binding to receptors in the dorsal horn of the spinal cord. [6] [7] Since the drug is being infused in close proximity to the receptors, only a small amount of opioid is needed and the systemic side effects are reduced. Problems with this delivery system in patients who are not opioid naive[38] are listed in Table 822 . If tolerance to the opioid develops and higher doses are required for relief, the incidence of side effects will approach that of systemically administered opioids. Addition of local anesthetic or alpha-adrenergic agent (e.g., clonidine) [91] to the epidural opioid infusion allows for fairly rapid lowering of the opiate concentration and reestablishment of opioid sensitivity. [38] [39]

Adjuvant Medications

Adjuvant medications are used both to add to the analgesic effect of the opioids and to treat the complications they induce.

Adjuvant Analgesics

Adjuvant analgesics enhance the pain-relieving properties of opioids. Tricyclic antidepressants are among the most effective psychotropic analgesics. [50] It has been suggested that they produce these effects by raising the concentration of the endogenous pain inhibitors serotonin and norepinephrine [92] [93] and increase the bioavailability of morphine. [94] These tricyclics act more promptly and at lower levels as opioid adjuvants than they do as antidepressants (e.g., amitriptyline is effective within 23 days at 50100 mg/day).[93]

The addition of dextroamphetamine or methylphenidate (2.57.5 mg PO or 10 mg IM bid[95] [96]) permits lowering of the opioid dose by one-third to one-half while maintaining equivalent analgesia and less sedation. [95] Pemoline is a chewable psychostimulant that is chemically unrelated to amphetamines but that may be as useful in reversing opioid-induced sedation. [97] Patients are started on one tablet (18.75 mg) in the morning and at noon, and the dose is gradually increased to a total of 75 mg/day. These combinations are very useful, for example, in treating neutropenic patients with perirectal abscesses whose severe pain generally occurs as the neutrophil count rises. Tolerance to the amphetamine effect does not develop before 23 weeks of therapy, by which time the abscess pain has usually resolved.

Hydroxyzine (25100 mg PO or IM)[98] [99] also has opioid-potentiating abilities, diminishes opioid-induced nausea and vomiting, [99] and is especially useful in patients who might benefit from an anxiolytic agent.

Laxatives

Constipation is the most common opioid-induced side effect (Fig. 821);[53] laxatives should therefore be given routinely, not on a PRN basis, [1] [53] [100] to patients treated with any of the drugs listed in Table 821 . Detailed bowel preparation recommendations can be found,[8] [100] [101] but none has been studied in a controlled fashion. If bowel obstruction occurs, pain relief can be maintained with methylphenidate or dextroamphetamine. Alternatively, methotrimeprazine, a phenothiazine, can be substituted for a short time.[102] Single-dose studies of 15 mg IM of methotrimeprazine have shown this drug to be equivalent to 15 mg IM of morphine. The recommended parenteral starting dose is 510 mg. Both clonidine[103] and continuous subcutaneous infusion of metoclopramide (to 60 mg/day) [104] reverse the opioid bowel syndrome,[103] enabling patients to return to oral opioids.

Nausea

Prochlorperazine (10 mg bid or tid) will prevent the nausea that occurs in most patients during the first days of opioid therapy. Relieving constipation, or changing the opioid (e.g., from morphine to oxycodone) will often eliminate the later development of nausea. Rarely, patients will need oral or intravenous ondansetron (8 mg bid to tid).[105]

Sleep Medications

Sleep medications that produce sedation (benzodiazepines, barbiturates, chloral hydrate) are not good choices for patients receiving opioids, as these drugs will produce excessive daytime sedation. Tricyclic antidepressants (e.g., 1050 mg of amitriptyline) are preferred as they produce only nighttime sedation and act as opioid adjuvants (Fig. 821).[50] [93]

Naloxone

Naloxone (Narcan) reverses opioid-induced respiratory depression, although repeated doses are often required. [8] Respiratory depression can occur in patients with mild to moderate pain during the initial use of opioids, although it is rare in patients with severe pain or in those chronically receiving opioids. Caution should be exercised before administering naloxone to the patient who is chronically receiving opioids, to avoid precipitation of severe withdrawal. In such cases, it is inadvisable to administer the usual 0.4 mg/ml dose; rather, 0.4 mg of naloxone should be diluted with 10 ml of saline and only enough given to reverse respiratory depression. [1] In a comatose patient, endotracheal tube placement is recommended to prevent aspiration from the salivation and bronchial spasm that will be induced. [1]

SPECIFIC CLINICAL PROBLEMS

Oral Complications

Oral complications of chemotherapeutic and marrow transplant regimens can be a frequent cause of pain. A thorough dental evaluation and prompt treatment of infections can minimize the discomfort arising from underlying periodontal disease and caries, secondary bacterial, viral, and fungal infections, and mucositis. [106] Preventive regimens include saline, sodium bicarbonate,

---

or chlorhexidine gluconate rinses, acyclovir, amphotericin, and ice. [107] Sucralfate,[108] capsaicin,[109] and granulocyte-colony-stimulating factor [110] diminish the incidence, duration, and intensity of chemotherapy-induced mucositis. Viscous lidocaine (Xylocaine) or a slurry of sucralfate, diclonine, or Kaopectate in diphenhydramine provides symptomatic treatment of mucositis pain.[111] For individual lesions, benzocaine in Orabase can be helpful. Milk of magnesia, which dries the mucosa, is not recommended.[106] The more severe cases, occurring in marrow transplant recipients, usually require infusional morphine therapy, delivered by standard drip or PCA.[111] Pilocarpine (57.5 mg tid or qid 1 hour before meals) reverses xerostomia from neck irradiation [112] and opioids. Sugar-free hard candy is also useful for opioid-induced xerostomia.

Coagulation Disorders

Patients with inherited or acquired disorders of coagulation may have excessive risk of bleeding if aspirin-containing pain relievers are used. [113] [114] If acetaminophen is not effective, these patients may obtain significant relief from ibuprofen or from the nonacetylated salicylates, such as salsalate (Disalcid) or choline magnesium trisalicylate (Trilisate), which do not prolong the bleeding time. [114] [115] [116] Since these agents share aspirins ability to compete with warfarin for albumin binding, [48] careful monitoring of patients coagulation parameters is recommended when these drugs are started or stopped.

Postherpetic Neuralgia

Postherpetic neuralgia can be a difficult problem for patients with hematologic disorders and has been the subject of several reviews. [49] [117] Phenytoin (300 mg/day) or carbamazepine (started at 100 mg/day and slowly titrated to 400800 mg/day) has some efficacy, but amitriptyline is the agent of choice, having been effective in 6070% of patients in a randomized double-blind controlled trial. [118] [119] Elderly patients, however, do not tolerate the anticholinergic side effects well. Nortriptyline (Pamelor) may be useful in these patients. Topical lidocaine gel or ointment (510%) [120] and EMLA[121] can also be effective. Topical capsaicin (0.075%), which depletes substance P, has shown efficacy in a multicenter, double-blind, randomized placebo-controlled trial. [122] Capsaicin (0.075%) is also used for musculoskeletal discomfort. TENS devices provided relief for 1 year in 50% of postherpetic neuralgia patients, and 30% were pain free at 2 years. [26] Acute herpes zoster pain may be diminished by a combination of acyclovin and prednisone. [123]

Sickle Cell Anemia

Patients with sickle cell anemia suffer from both chronic and episodic pain. Chronic arthritic pain can be treated with physical therapy and full doses of antiarthritic medication, but some patients require low doses of chronic opioid therapy to maintain independent functioning. Several studies have confirmed the safety and efficacy of long-term opioids in the treatment of pain of nonmalignant origin. [71] [124] [125] [126] In some cases, joint replacement may be required.

When a patient with sickle cell anemia experiences a severe episode of pain, it is always important to attempt to define the precise cause of the pain before attributing it to a vaso-occlusive crisis. To manage crisis pain, except in patients with renal failure, nonopioid analgesics that treat bone pain, a tricyclic adjuvant such as amitriptyline, and laxatives should be added to opioid therapies (Fig. 821). Oxygen is not required in the absence of documented hypoxia. [127]

Because intravenous access is often difficult in these patients, opioids such as morphine can be given orally [128] on a fixed schedule, with a patient may refuse provision. Meperidine should be avoided in this population for the reasons mentioned above, and has been associated with seizures in between 1% and 12% of sickle cell patients.[129] Furthermore, patients with sickle cell anemia absorb intramuscular meperidine poorly. [130] In that minority of patients who need large doses of medication, intravenous morphine delivered by standard drip or PCA is usually effective. [71] [131] Unfortunately, morphine has been noted to cause rash, pruritis, nausea, and vomiting in a significant number of patients.[132] To dispel any atmosphere of distrust between patient and health care provider, [128] a contract agreed to by both provider and patient can be established. [133] The contract describes the dose, duration, and type of analgesics to be used and is updated yearly. When the crisis is resolved, the dose is tapered daily, without lengthening the interval between doses; if necessary, the patient is begun on equivalent doses of an oral opioid medication.

Problems of the Elderly

Pain management in the elderly is complicated by difficulties in pain assessment as well as by the altered pharmacokinetics of opioids and of psychotropic adjuvant medications.[134] Elderly patients may under-report pain. [135] Physicians may ascribe observed limitations in social contact and physical activity to age-related changes when in fact they are pain-induced limitations. [136] Family members can be crucial to success in managing an elderly patients pain.

Elderly patients are particularly susceptible to the side effects of NSAIDs, and patients taking them should be monitored closely. [134] In elderly patients (ages 7089), the volume of distribution for opioids is generally smaller, the drugs have a longer plasma half-life, and renal and hepatic clearance is decreased, all of which lead to a prolonged duration of effect.[136] Therefore, the effective doses for these patients are one-half to one-quarter of those needed in younger patients. [134] [136] Drugs with short half-lives should be used (e.g., oxycodone or hydromorphone), and initial doses should be low. [136] Patients should be monitored carefully for the development of sedation or confusion, especially if they are receiving antihistaminic agents (cimetidine, diphenhydramine) or drugs with anticholinergic activity.

The acute urinary retention due to opioids (especially in patients with prostatic hypertrophy) and the hypotension and tachycardia caused by tricyclic compounds can be more frequent and of more clinical severity in this population. The starting dose should be low (usually 10 mg at bedtime), and the dose should be slowly increased as tolerated. Doxepin, which does not share these side effects, may be a better tolerated opioid adjuvant. [92]

Patients with Opioid Addiction

A team approach, including the patients family and drug counselor, maximizes the coordination of care for these patients. Opioid requirements may be significantly higher, and dosing intervals are shorter in the addict. [137] [138] In patients on methadone maintenance, therapeutic dosing must be provided over and above their baseline dose.[137] In all cases, the goal should be to deliver adequate medication to relieve the patients pain. It has been recommended that (1) the physician always work from a written treatment plan, (2) one physician prescribe all psychotropic medication, (3) information about the patients drug use be obtained from sources in addition to the patient, and (4) when the question of addiction first arises, consultation be obtained from an addiction medicine specialist. [138] If opioids are needed, patients should be given limited quantities of long-acting medications on a scheduled basis.

Both former opioid abusers themselves and the physicians caring for them hesitate to use opioids for pain relief, as they fear inducing a relapse of the addiction. [139] This concern is based

on the observation that once a receptor has been habituated to the opioid, it retains its avidity for opioids, even after a long period of abstinence. [137] In addition to those noted above, suggested techniques to minimize these risks include discussion of the individuals concerns and increased involvement by the patients in their recovery programs.[137]

ANTIEMETIC THERAPY

A number of effective antiemetic therapies are used to prevent the nausea and vomiting induced in patients by treatment of their hematologic disorders with chemotherapy or radiation therapy. These antiemetic therapies markedly improve patients quality of life. Most patients can expect complete control of nausea and vomiting.[140]

Pathophysiology of Vomiting

The means by which chemotherapy agents induce vomiting are still incompletely understood but are thought to include stimulation of the chemoreceptor trigger zone, which is probably the most common mechanism; gastrointestinal injury; stimulation of the cerebral cortex; inner ear processes; and changes in taste and smell. [140]

Although the sites of emetic action of the chemotherapeutic agents have not been identified, blocking agents directed against type 3 serotonin receptors (5-HT_3 receptors) have been effective in inhibiting chemotherapy-induced nausea and vomiting. Higher centers in the brain, such as the cortex, are also thought to be involved in producing anticipatory nausea and vomiting. Thus, cognitive therapy, as well as antianxiety and amnesic agents, may provide effective antiemesis.

Therapy

Anticipatory Nausea and Vomiting

Anticipatory nausea and vomiting (ANV) is thought to be a classic conditioned response. [141] Chemotherapy administration (the unconditioned stimulus) results in nausea and vomitingthe unconditioned response. Clinic sights, smells, and sounds are the conditioned stimulus. After frequent pairings of chemotherapy administration and the clinic sights, smells, and sounds, the response (nausea and vomiting) can be triggered in the absence of any chemotherapy by clinic sights, smells, or sounds or simply by seeing clinic personnel, even at a location distant from the site of treatment.

Patients in whom post-treatment nausea or vomiting never develops do not develop ANV either. In those who do experience post-treatment nausea and vomiting, the risk of developing ANV increases with the increasing frequency, severity, and duration of the symptoms. [138] Other possible predisposing factors include susceptibility to motion sickness,[142] [143] awareness of tastes or odors during infusions, younger age, lengthier infusions, greater autonomic sensitivity, and general anxiety or emotional distress.[140] [141]

The best way to prevent ANV is to give aggressive antiemetic therapy and to treat anxiety with the agents described below. However, in patients for whom this approach has not been successful and in whom ANV develops, a variety of behavioral techniques have been helpful. These include hypnosis, [144] progressive muscle relaxation with guided imagery,[145] systemic desensitization, [146] and distraction.[147] Results may be optimized if a therapist trained in these techniques works with the patient, but a recent study of progressive muscle relaxation with guided imagery suggests that patients can apply this technique on their own. [141] [145]

Two different drug regimens have been shown to reduce ANV. Clonidine can be given for 5 days before chemotherapy. [148] Alternatively, alprazolam can be given the night before, the morning of, and just before chemotherapy, and then qid for 2 days after therapy. [149] Alprazolam significantly reduced ANV compared with placebo, even though it had no effect on anxiety levels.

Antiemetic Agents

Most studies of the potent antiemetic agents have been conducted in patients receiving therapy with cisplatin, a drug of high emetic potential. Although cisplatin is not generally used to treat patients with hematologic malignancies, the data are included in the following discussion, as the findings can probably be extrapolated to other drugs of equivalent or less emetogenic potential. When available, data regarding efficacy in patients receiving radiation therapy or emetogenic drugs commonly used to treat hematologic disorders are reviewed.

Choice of Agent

The choice of antiemetic agent(s) depends on (1) the emetogenic potential of the chemotherapy or radiation therapy regimen, (2) the side-effect profile of the antiemetic agent(s), and (3) patient preferences and characteristics.

The emetogenic potential of the drugs is shown in Table 823 . Although most drugs produce emesis 12 hours after they are given (in patients who have never before received

TABLE 82-3 -- Emetogenic Potential of Drugs Commonly Used to Treat Hematologic Malignancies

Emetogenic Potential	Drug
High (>90%)	Carmustine (>250 mg/m^2) Cyclophosphamide (>1,500 mg/m^2) DTIC Mechlorethamine
Moderately high (6090%)	Cyclophosphamide (>750 mg/m^2 1,500 mg/m^2) Cytarabine (>1,000 mg/m^2) Doxorubicin (>60 mg/m^2) Methotrexate (>1,000 mg/m^2) Procarbazineoral

Moderate (3060%)	Azacytidine Cyclophosphamide (<750 mg/m^2) Cyclophosphamideoral Cytarabine (1,000 mg/m^2) Doxorubicin (2069 mg/m^2) Epirubicin (90 mg/m^2) Idarubicin Methotrexate (2501,000 mg/m^2) Mitoxantrone (<15 mg/m^2)
Moderately low (1030%)	Asparaginase Etoposide Melphalan Mercaptopurine Methotrexate (>50 mg/m^2 <250 mg/m^2) Pentostatin Thiotepa
Low (<10%)	Bleomycin Busulfan (regular dose) Chlorambuciloral 2-Chlorodeoxyadenosine Fludarabine Hydroxyurea -Interferon Methotrexate (50 mg/m^2) Thioguanineoral Vinblastine Vincristine

COMBINATION ANTIEMETIC REGIMENS*

High to Moderately High Emetogenic Potential

Ondansetron, 24 mg PO × 1 or 8 mg IV bid
OR

Granisetron, 1 mg IV or 2 mg PO
OR

Dolasetron, 1.8 mg/kg IV or 200 mg IV or 100 mg PO qd, plus

Dexamethasone, 1020 mg IV × 1 over 15 minutes, ± lorazepam, 1 mg qd and pm

May replace dexamethasone with metopimazine, 35 mg/m^2 24 continuous infusion, then 30 mg PO qid × 4 days[162]

For treatment failures

Dexamethasone, 1020 mg IV/PO q1224h, plus

Metoclopramide, 2 mg/kg/dose IV/PO q6h, plus

Diphenhydramine, 2550 mg IV/PO q6h, plus

Lorazepam, 1 mg qd IV/PO

Moderately High to Moderate Emetogenic Potential

Ondansetron, 8 mg IV (<60- to 75-kg patient) or 8 mg PO bid
OR

Granisetron, 2 mg PO qd or bid, plus

Dexamethasone, 1020 mg IV

Moderately Low or Low Emetogenic Potential

Dexamethasone, 1020 mg PO or IV over 15 minutes
OR

Prochlorperazine, 10 mg PO or 25 mg parenterally q6h prn
OR

Thiethylperazine, 10 mp PO q46h
OR

(If control is not achieved, or there is past history of inadequate control)

Ondansetron, 812 mg IV (<60- to 75-kg patient) or 8 mg PO bid or tid, or

Thiethylperazine, 10 mp PO q46h
OR

(If control is not achieved, or there is past history of inadequate control)

Ondansetron, 812 mg IV (<60- to 75-kg patient) or 8 mg PO bid or tid, or granisetron, 2 mg PO qd, plus

Dexamethasone, 1020 mg IV
OR

Dexamethasone, 10 mg IV/PO q12h, plus

Metoclopramide, 2 mg/kg/dose IV/PO q6h, plus

Diphenhydramine, 25 mg IV/PO q6h

For Prevention of Delayed Nausea and Vomiting

Ondansetron, 8 mg PO bid × 3 days, ±

Dexamethasone, 8 mg PO bid × 3 days
OR

Dexamethasone, 46 mg PO bid × 2 days, then 24 mg PO bid × 2 days, ± lorazepam
OR

Metoclopramide, 0.5 mg/kg PO qid × 4 days, plus

Dexamethasone, 8 mg bid PO × 2 days, then 24 mg bid × 2 days, plus

Diphenhydramine, 50 mg PO q68h, plus

Lorazepam, 1 mg PO q68h

Breakthrough Nausea and Vomiting

Prochlorperazine, 10 mg q46h IV or PO, or 25 mg PR
OR

Thiethylperazine, 10 mg q46h PO or PR
OR

Metoclopramide, 2040 mg PO q46h, or 12 mg/kg q34h IV, plus

Diphenhydramine, 2550 mg PO/IV q46h

* Data from Johnson et al., [155] Bradbury[203] , and NCCN.[205]

chemotherapy), the onset of emesis from high-dose intravenous cyclophosphamide is delayed until 918 hours after treatment, [150] and from high total doses of cisplatin until 2472 hours later.[151]

The side-effect profiles for the antiemetic agents are discussed below. Past history of alcohol intake and patient age modify certain aspects of the profiles. Patients who have a history of alcohol intake of more than five alcoholic drinks per day (>100 g of alcohol) tend to have less nausea and vomiting. This has been studied carefully in patients receiving high-dose cisplatin therapy [152] [153] but has been anecdotally observed in patients receiving other agents.

Younger patients have a higher incidence of chemotherapy-induced nausea and vomiting and of acute dystonic reactions after receiving metoclopramide therapy: trismus or torticollis was seen in only 2% of patients over 30 years of age but in 27% of younger patients. [154] Even if they are receiving only moderately emetogenic therapy, they should be given an antiemetic regimen for high-emetogenic drugs. [155] Younger patients find cannabinoids more effective than do older patients because they can better tolerate the side effects associated with the therapeutic doses of these agents. [156] Elderly patients also have a high risk of extrapyramidal side effects and are more susceptible to anticholinergic and sedating side effects. [155] 5-HT_3 receptor antagonists are therefore preferred to regimens containing metoclopramide and diphenhydramine.

Patient preferences regarding degree of alertness can help the health care provider choose an antiemetic regimen, as can the level of anxiety the provider observes in the patient. Some patients do very well with regimens that include no antianxiety agents; others may benefit from the inclusion of those agents, despite the somnolence that accompanies their use.

5-HT_3-*Receptor Antagonists (Ondansetron, Granisetron, Dolasetron)*

Ondansetron and granisetron are the best studied of the 5-HT_3 -receptor antagonists; this class also includes the drugs dolasetron, tropisetron, and RG 12915. Several studies of patients receiving regimens that include cyclophosphamide, methotrexate, or doxorubicin showed significant efficacy and superiority of ondansetron over placebo.[157] [158] [159] Ondansetron also demonstrates efficacy in patients with emesis (induced by non-cisplatin-containing chemotherapy) that has been refractory to standard antiemetics, with complete control achieved in 50% of these patients. [160] [161] When dexamethasone is added, control rises to as high as 91%.[162]

Ondansetron effectively prevents nausea and vomiting in patients treated with highly emetogenic agents for acute leukemia, [163] [164] for multiple myeloma (i.e., high-dose melphalan), [165] or who are being prepared for bone marrow transplant with cyclophosphamide and total-body irradiation. [166] [167] In the transplant patients, 83% of patient-days were without any vomiting or retching, and in a further 10% there were no more than two emetic episodes. Ondansetron is also effective in preventing emesis induced by single- or multiple-fraction radiation therapy. [168] [169] Ondansetron is as effective as metoclopramide in preventing nausea induced by cisplatin[170] [171] [172] or by cyclophosphamide, alone or with doxorubicin chemotherapy. [173] [174] [175]

Oral granisetron has shown equivalence to ondansetron in studies of patients receiving cisplatin- or carboplatin-based regimens. [140] [176] [177] In patients receiving moderately emetogenic therapy, oral granisetron with dexamethasone was as effective as intravenous ondansetron and dexamethasone. [178] [179] Oral or intravenous granisetron, and dexamethasone were effective in a bone marrow transplant program in which patients were treated with Cytoxan and total-body irradiation [180] and, along with oral prochlorperazine, were also effective in patients undergoing peripheral blood stem cell transplants for which patients received Cytoxan, VP-16 or thiotepa, and cisplatin. [181]

Ondansetron and the other 5-HT_3 -receptor antagonists have

far fewer side effects than metoclopramide. Reports of extrapyramidal reactions are very rare, [182] and sedation, dystonic reactions, akathisia (severe restlessness, ants-in-pants feeling), and tardive dyskinesias do not occur; patients develop only constipation, mild headache, and elevations in transaminases. [140]

The therapy of choice for moderately or highly emetogenic chemotherapy is therefore a 5-HT $_3$ -receptor antagonist plus a corticosteroid (usually dexamethasone). [140]

Metoclopramide

Metoclopramide is a substituted benzamide capable of blocking the emetic activity of chemotherapy agents by blocking 5-HT $_3$ receptors in the chemoreceptor trigger zone. Delivery of the drug on a schedule that maintains adequate levels during expected emesis appears to be important. [140]

Metoclopramide is also effective in radiation therapy-induced emesis, possibly because this type of emesis may be induced by serotonin release from the small bowel or by vagal nerve stimulation. Metoclopramide is effective in preventing nausea induced by chemotherapeutic agents, even of high emetogenic potential. [183] [184] [185] [186] [187]

However, the side effects, which may be caused by the interaction of metoclopramide with dopamine receptors, can be quite troublesome. They include akathisia, dystonic reactions (age related), sedation, and diarrhea. Benzodiazepines such as lorazepam can prevent or reverse the akathisia, and diphenhydramine or Cogentin can prevent or reverse the dystonias. [188] However, these agents induce additional side effects, including dry mouth and sedation. Furthermore, short-term high-dose metoclopramide or long-term use of the drug has been associated with persistent and disabling movement disorders, especially tardive dyskinesias. [189] [190]

Corticosteroids

The mechanism of the antiemetic action of corticosteroids remains undefined. Corticosteroids are effective used alone to prevent emesis induced by agents of moderate or low emetogenic potential. [191] [192] [193] They are also a useful component of antiemetic therapy regimens that include either ondansetron, granisetron, or metoclopramide, and add efficacy in randomized controlled trials. [140] [176] [178] [180] [181] [194] Dexamethasone and methylprednisolone are the best-studied agents, but no trials have demonstrated the superiority of one agent over another.

Benzodiazepines

The benzodiazepine lorazepam has only mild antiemetic activity on its own. [188] It markedly decreases the akathisia and anxiety associated with metoclopramide therapy, however, and induces a dose-related memory loss and marked sedation. [188] [195] [196] Alprazolam is useful in preventing ANV.

Other

Other agents that are more active than placebo include the butyrophenones haloperidol and droperidol, [197] the phenothiazine prochlorperazine, [198] and the cannabinoids dronabinol (THC) and nabilone. [140] [156] [199] [200] These agents are less effective drugs than the agents mentioned above, and all but prochlorperazine are associated with significant side effects. All cause sedation. In addition, the butyrophenones produce dystonic reactions, akathisia, and occasionally hypotension. The cannabinoids cause ataxia, dry mouth, orthostatic hypotension and dizziness, euphoria or dysphoria, and a feeling of being high. [201>]

Combination Antiemetic Therapy

For drugs of low or moderately low emetogenic potential, no antiemetic drug or dexamethasone alone may be sufficient. For drugs of higher emetogenic potential, however, standard antiemetic treatment usually includes combinations of several antiemetic agents along with agents designed to treat anxiety, provide amnesia, or prevent known side effects. For drugs with high emetogenic potential, it is very important to give antiemetic therapy for an adequate period before administering chemotherapy agents, and to continue to prevent emesis for about 2472 hours after the drugs have been given. Other agents useful in combination include transdermal scopolamine and metopimazine, a new dopamine D_2 antagonist, which is a phenothiazine derivative. Transdermal scopolamine adds efficacy when added to a standard regimen of metoclopramide and dexamethasone. [202] Metopimazine significantly enhances the efficacy of ondansetron when used twice a day in patients receiving moderately emetogenic drugs. [162]

Chapter 83 - Indwelling Access Devices

Janet L. Abrahm
Jane Bradley Alavi

INTRODUCTION

Indwelling devices that permit chronic access to the venous and central nervous systems have permitted novel and more comfortable forms of treatment for both children and adults. Indwelling central venous access devices are useful for patients who require frequent administration of blood or blood products, peripheral stem cell apheresis, or infusional therapy with medications such as chemotherapeutic agents, desferoxamine, amphotericin, or pain medications. Similarly, through the use of indwelling epidural or intrathecal catheters and Ommaya reservoirs, prolonged access to the cerebrospinal fluid (CSF) may be obtained for the delivery of chemotherapy, antibiotics, antifungal agents, or pain medications. The choice of the appropriate device and application of careful maintenance procedures can minimize the associated complications and maximize the patients quality of life.

INDWELLING CENTRAL VENOUS ACCESS DEVICES

Chronic venous access devices can minimize the discomfort of repeated venipuncture; prevent venous thrombosis, phlebitis, and vesicant infiltration; maintain patient mobility; and minimize hospital stays. Certain patients with hematologic diseases are at increased risk for the development of thrombophlebitis from standard (peripheral) intravenous lines and may therefore be best served by an indwelling access device. Factors associated with this increased risk include (1) age of the patient (>60 years); (2) certain characteristics of the solutions being infused (e.g., hypertonicity of the solution, irritating diluents such as alcohol, highly acidic or alkaline pH, particulate matter in the solution); (3) type of drugs infused (vesicant chemotherapy, certain antibiotics, dexamethasone, furosemide, phenytoin); (4) factors associated with the catheter itself and its insertion (size and composition, traumatic insertion, microbial contamination); and (5) duration of infusion (85% of cases of phlebitis occur 2448 hours after placement of the intravenous line). [1] [2] [3] [4] [5] Since patients with these risk factors or with visibly poor peripheral venous access can usually be identified before therapy begins, early placement of an indwelling device is reasonable. To minimize the occurrence of septic episodes, the devices should be placed before the administration of agents that induce neutropenia. [6] [7] [8] With intraoperative platelet transfusions, catheters can be safely placed in patients whose thrombocytopenia is not due to disseminated intravascular coagulation. [8]

Device Types

Catheters

In all indwelling catheters used for prolonged central venous access, the proximal capped portion of the catheter exits from a subcutaneous tunnel on the chest or abdominal wall while the distal tip is indwelling in a central vein (Fig. 83-1).[9] All catheters are composed of either radiopaque elastomeric hydrogel, polyurethane, or silicone elastomer but differ in type of opening and internal diameter. [10]

Catheters with a simple opening at the distal tip include those placed at the bedside (midline catheters and peripherally inserted central catheters [PICCs]) and the tunneled Hickman, Broviac, and apheresis catheters, which are surgically inserted. Midline catheters, which do not extend into the veins beyond the arm itself, come in 24 to 16 gauge and are 38 inches long. [5] [10] The PICCs, which terminate in the superior vena cava, vary in size from 1.9 to 4.8 F (23 to 16 gauge) and are 1527 inches long. [10] [11] The tunneled catheters range from 2.7 to 12.5 F and are 29.542.7 inches long. [10] For apheresis (e.g., for peripheral stem cell harvest, or for preoperative exchange transfusions or vaso-occlusive crisis in patients with sickle cell disease [12]), 8.4 to 11.5-F catheters are available and are 5.418 inches long. [10]

The Groshong catheter, available in a variety of internal diameters, has a three-position valve adjacent to a closed distal tip. The valve remains closed at rest but opens outward for infusion when positive pressure is applied and opens inward for aspiration when negative pressure is applied. [13] Catheters with a Groshong-type opening are available as peripherally or surgically inserted devices.

For patients requiring nutritional support or infusional therapy along with blood sampling and blood product administration, all the above-mentioned catheters are available with double lumens, and there is a triple-lumen tunneled catheter available. [10] [14] Double-lumen devices have either 1.3-mm internal diameters each or 1.0- and 1.6-mm internal diameters; those with triple lumens have 1.0-, 1.0-, and 1.25-mm internal diameters (Fig. 83-2).

Figure 83-1 Schematic diagram of an indwelling central venous catheter in place. Insertion site refers to the insertion of the proximal end of the catheter into the central vein; the exit site denotes the exit of the distal end of the catheter at the chest wall. Clamp attached to the catheter is shown next to the Luer-Lok cap at the distal end. *(From Hickman Subcutaneous Port, Use and Maintenance, and How to Care for Your Hickman or Broviac Catheter. Davol Inc., Cranston, RI, with permission.)*

Implantable Central Venous Devices (Ports)

Totally implantable central venous access devices consist of single- or dual-lumen ports that may be round, square, oval, or hexagonal [10] and are connected to a radiopaque silicone elastomer or polyurethane catheter (Fig. 83-3).[9] [10] The port includes a self-sealing silicone septum with a body of plastic or metal, both of which will cause an artifact on magnetic resonance imaging (MRI). [10] The artifact effect is greater with stainless steel than with plastic. No portion exits onto the chest wall. This port is surgically placed in a subcutaneous pocket, and the catheter is inserted into a central vein. The single or double port is connected to a catheter with either a standard opening or a Groshong-type valve. Attached catheters range from 4 to 12 F and from 19.7 to 34.5 inches long. [10] For continuous infusions, these devices require an external infusion pump.

Ports that can be placed in the antecubital fossa are also available (the Port-A-Cath P.A.S. Port and the CathLink). [7] [10] [15] [16] [17] The P.A.S. Port reservoir is much smaller than the standard port, and the septum has only a 6.6-mm internal diameter. The attached 5.8-F polyurethane catheter has a 1.0-mm internal diameter, the same size as the Broviac. The CathLink catheter is made of a new polyurethane material (Chronoflex), and a series of panels with centrally located openings replaces its silicone septum. CathLink is accessed by standard peripheral intravenous catheters, such as angiocatheters. [8]

Other implantable devices have self-contained pumps. These devices and guidelines for their use are discussed elsewhere. [18] [19] [20] [21]

Device Choice

Patient characteristics and preference as well as the duration of use, purposes for which the device is required, and relative complication rates all aid in deciding among the types of

Figure 83-2 Central venous catheters with built-in clamps. **(A)** Hickman and Broviac single-lumen catheters. **(B)** Hickman and Leonard round dual-lumen catheters. **(C)** Hickman triple-lumen catheters. *(From Hickman Subcutaneous Port, Use and Maintenance, and How to Care for Your Hickman or Broviac Catheter. Davol Inc., Cranston, RI, with permission.)*

catheters and in choosing between catheters and ports (Table 83-1).[5] [7] [9] [14] [22] [23] [24] [25] [26] [27] [28]

Patient Characteristics and Preference

For female patients, or for any patient being treated in the outpatient setting, peripherally accessed devices may be the devices of choice, as the patient need not disrobe. The peripheral devices are also helpful in patients with chest wall abnormalities that would preclude the use of centrally placed catheters or ports (e.g., subcutaneous carcinoma of the chest wall, open wounds, tracheostomies, or fibrosis induced by radiation therapy). [8] [14]

Catheters with Groshong-type valves, which require less care, are preferred for patients unable to care for a Hickman or Broviac catheter at home. [13] [25] [30]

Children and adolescents have a lower risk of complications with ports than they do with catheters. [24] Four prospective nonrandomized studies indicated a significantly lower complication rate for the ports than for the catheters, especially in the

Figure 83-3 Totally implanted Hickman subcutaneous (central venous access) port with a noncoring needle in place. *(From Hickman Subcutaneous Port, Use and Maintenance, and How to Care for Your Hickman or Broviac Catheter. Davol Inc., Cranston, RI, with permission.)*

youngest children. [22] [24] [31] Ports are also useful for adult patients who are unable to care for a catheter or who do not wish to do so, and for those who prefer a less visible access device.

In obese patients and in patients with thrombocytopenia, the subcutaneous location of the ports poses a problem. In the obese patient, it may be difficult to find a port placed on the chest wall. For the patient with chronic thrombocytopenia (platelet count < 20,000/mm ^{3}), neither type of port may be satisfactory because of the risk of hematoma associated with the recurrent needle punctures required for access. Ports have been successfully used, however, to give prophylactic factor VIII therapy to children with severe hemophilia. [32] [33] [34]

Duration of Use

Because a surgical procedure is not needed, midline catheters and PICCs are useful for patients needing only short-term access, usually several weeks to months. The average PICC is in place for 210 weeks, but they have functioned for more than 300 days. [5] [11] [35] [36]

In patients needing a longer-duration of infusion and more extensive supportive care, surgically placed catheters and ports are generally preferred. Both catheters and ports have remained in place safely for months to years. [37] [38] Although the initial installation cost is greater for the ports than for the tunneled or nontunneled catheters, the replacement and maintenance costs of the catheter make it more expensive after 6 months of use. [24] [25] [26] The P.A.S. Port is even more cost-effective than a standard port because it does not require fluoroscopy, an operating room, or a physician for placement; physician assistants can place them safely. [10] [39] [40] [41]

Purpose for Which the Device Is Required

PICCs are used for antifungal therapy, hyperalimentation, or infusion of chemotherapy regimens that may include vesicant

TABLE 83-1 -- Choice of Indwelling Venous Access Device

[a] Peripherally inserted central catheter.

agents. [11] [30] [42] [43] Their smaller bore makes them less useful for blood drawing or transfusion. The P.A.S. Port is not recommended when fluids or blood products must be given rapidly, because the flow rate is only 610 ml/minute, which is less than that of standard central lines or ports placed in the chest. [41]

In general, surgically implanted catheters are more useful than ports or PICCs in patients in whom frequent access to the device or frequent blood drawing or blood product administration is needed. [7] The larger-bore catheters are more useful for blood drawing and blood product administration because the incidence of clotting after such use is lower with them than with smaller-bore devices. [37] Groshong-type catheters, however, may be less useful in patients from whom blood must be drawn frequently because the valve may make blood aspiration more difficult. If a port or a PICC is chosen, the catheter with the largest bore is recommended. In the larger-gauge PICCs, which collapse easily, blood drawing is usually more successful if a syringe is used instead of a vacuum tube collection system. [42]

Continuous vesicant infusion may be more safely accomplished with catheters, as they avoid the danger of needle dislodgment and disconnection of the catheter from the septum associated with the implanted ports. [44] However, the use of a needle-containing device called a Gripper, which holds the needle in the port, may decrease the incidence of needle dislodgment.

For support during autologous or allogeneic bone marrow transplantation, double- or triple-lumen catheters are used. [45] [46] In those transplant patients undergoing peripheral stem cell apheresis, percutaneously placed translumbar silicone apheresis catheters are preferred, because the internal diameter of the Hickman catheter

is often too small.[47]

Relative Complication Rates

Midline catheters are associated with lower rates of phlebitis than short peripheral catheters and with lower infection rates and lower cost than PICCs or tunneled catheters.[5] PICCs cause more phlebitis than tunneled catheters, and earlier reports indicated that the infection rates associated with their use were also higher than those for tunneled catheters. Recent studies, however, suggest that the infection rates may be the same for PICCs and tunneled catheters. [5] [8] Conflicting data have been reported regarding the relative complication rates seen with tunneled catheters and ports, although the overall complication rate is probably less for the ports than for the catheters. Five of six prospective randomized trials and all retrospective studies, including one cohort study and one matched study, found a significantly higher rate of complications with tunneled catheters than with ports. [5] [7] [48] [49] Only catheter occlusion is no more likely with catheters than with ports. [7] Patients with ports also reported fewer restrictions in activity and hygiene. [48]

In human immunodeficiency virus (HIV)-infected patients, retrospective studies demonstrate that catheters [50] [51] [52] appear to cause more infectious complications than ports (0.47 to 0.97 per 100 days, versus 0.17 to 0.39 per 100 days). [52] [53] Patients receiving infusional ganciclovir through catheters for cytomegalovirus retinitis who had neutrophil counts less than 1,000/mm^3 were at particular risk for early septicemia. [52]

Device Insertion

Catheters

Catheters can be inserted nonsurgically or surgically. Midline catheters and PICCs are placed nonsurgically in the hospital or in the home by appropriately trained physicians or nurses. [10] [30] [42] Insertion failure can occur in 822% of attempts, although the failure rate decreases with experience. [11] After careful skin preparation using sterile technique and, for large-gauge introducers, local anesthesia, the catheter is inserted in the antecubital fossa into the basilic vein. PICC catheters are advanced into the superior vena cava (or, less frequently, the axillary, innominate, or subclavian vein) and secured by sutures or sterile tape. If chemotherapy, total parenteral nutrition solutions, or certain hyperosmolar solutions are to be infused, radiologic verification of the catheter tip position in the superior vena cava is recommended.[10]

Tunneled Hickman, Broviac, and Groshong catheters (and ports; see below) are inserted surgically in an operating suite or minor procedure room, physicians office, radiology suite,[54] or at the bedside. [8] All catheter insertion techniques include (1) creating a subcutaneous tunnel on the anterior chest wall, (2) pulling the catheter up through the tunnel, and (3) positioning the catheters Dacron cuff(s) in it, leaving its remaining proximal portion, with the Luer-Lok tip, exiting from the tunnel on the chest wall (Fig. 83-1). [7] [13] [22] [55] The distal catheter tip is then usually placed percutaneously into the central circulation through the axillary, subclavian, or cephalic vein[20] [56] and threaded into the superior vena cava under fluoroscopic guidance. [10] Its position in the superior vena cava at the right atrial junction [8] should be confirmed by chest radiography. In patients expected to need crutches for a prolonged period of time, catheters should be inserted via the internal or external jugular vein or in the subclavian vein lateral to the midclavicular line to prevent pinching the catheter in the costoclavicular space, which leads to catheter pinch-off and fracture.[28]

No significant difference has been found in time to failure or in infection or obstruction rate of catheters inserted percutaneously rather than under direct visualization.[20] [57] [58] Catheters should be inserted by experienced personnel, however, as complication rates fall with increasing experience in catheter insertion. [37] [59] [60] If the chest wall or the superior vena cava and subclavian veins are not usable, the best alternative site is the inferior vena cava. [20] [47] [61] [62] Apheresis catheters for peripheral stem cell harvest are preferentially inserted into the inferior vena cava. Techniques for their insertion are reviewed elsewhere. [47]

Ports

Ports are surgically inserted into the antecubital fossa or chest or abdominal wall with the patient under local anesthesia. [63] If possible, they should be placed in the nondominant arm or in the side of the chest near it to minimize the probability of needle dislodgment or coring of the port septum during continuous access. [19]

The P.A.S. Port can be inserted at the bedside by physicians or physician assistants. [8] [39] [40] [41] It consists of an implantable port with an attached polyurethane radiopaque catheter, the distal tip of which contains an electromagnet. The port is placed percutaneously in a pocket in the antecubital fossa. The venous catheter is introduced using the same techniques as described above for PICCs without attached ports. [39] [40] [41] [42] Fluoroscopy is unnecessary, as the progress of the catheter toward the right atrium can be externally tracked with a hand-held sensor wand (Cath-Finder) that detects the electromagnet in the distal tip. [10] A chest radiograph to verify catheter position is still recommended prior to infusion of certain solutions. [39]

The chest wall ports are placed into a subcutaneous pocket in the infraclavicular space, and the attached catheter is placed under fluoroscopic guidance into the subclavian, jugular, or cephalic vein and threaded through the superior vena cava to the junction with the right atrium (Fig. 83-3). No portion of the device remains visible.

Device Management

Catheters

Care of nontunneled and tunneled catheters is begun by the nurses and later taught to patients and their families. To minimize

infectious complications, it is preferable to assign this responsibility (as well as infusions and blood sampling through the catheter) to nurses expert in catheter care and use.[5] [22] [64] [65] [66] Standard procedures are available and should be adopted by each institution, to be followed by all who care for the patient. [14] [30] [42] [67]

Patient and family education in catheter care is required to maintain patency, to prevent damage to the external portion of the catheter, to prevent air embolization, and to reduce the risk of infection. [13] [23] [30] [42] Instructions should cover permissible activities, techniques of dressing change, heparin instillation, and changing the Luer-Lok plug, as well as emergency care in the event of damage to the external portion of the catheter. This educational program should be started well in advance of patient discharge, to ensure patient and family competence, and may be reinforced by an educational booklet, [68] by attendance at a hands-on class, or by nurses sent into the home, at least initially, to verify compliance with procedures. Patients with catheters or ports in place should be given written information about the device[19] as well as a medical alert card, necklace, or bracelet indicating its location and type of access and a person to be contacted if problems arise. [30]

Dressing changes for surgically inserted catheters require sterile technique for 2 weeks after insertion, until fibrous growth into the Dacron cuffs is complete. [9] [23] [64] The catheter exit site is cleaned with a povidone-iodine solution. Hydrogen peroxide is also sometimes used, as it prevents scab formation at the site. Sterile dressing changes are done every other day or every third day for 23 weeks after insertion, depending on the dressing materials used. [9] [14] [23] The type of dressing, if any, needed to cover the site is controversial. [14] [23] [30] One prospective randomized study indicated that when a rigorous cleaning protocol was followed, the incidence of site infection was not different whether standard gauze and povidone-iodine, a transparent polyurethane dressing (e.g., Opsite and Tegaderm) that is permeable to water vapor, or no dressing was applied. [69] Another study, however, found an increased risk of infection when transparent dressings were used. [70] The advantages and disadvantages of transparent dressings, gauze, or no dressing have been reviewed. [30] Moisture vapor-occlusive dressings are strongly recommended for patients with tracheostomies or open wounds near the catheter site. After 23 weeks, clean technique is used in some institutions for non-neutropenic patients, and a Band-Aid or small gauze dressing may be used to cover the exit site. [9] [71] More complete guidelines for access and maintenance of surgically inserted catheters are available. [5] [14] [67]

The catheter is not usually considered to be securely anchored in place until 1021 days after catheter placement, although insertion site stitches are usually removed after 10 days. Even then, catheters should not be allowed to hang freely; instead, they should be taped to the chest wall or inserted into a brassiere cup. [30] A clamp should be immediately available in the event of any breaks in the line. Some manufacturers include a clamp placed on the catheter (Fig. 83-2). Patients should be

advised to keep the catheter out of the reach of pets or small children, who could inadvertently dislodge it by pulling on it.

Since a thrombus on the catheter tip can be the nidus for a bacterial or fungal infection, [72] [73] every effort should be made to prevent one from forming. In a prospective randomized trial, low-dose coumadin (1 mg/day) begun 3 days before catheter insertion and continued for 90 days significantly decreased the rate of venogram-proved thromboses from 38% in control patients to 9.5% in those treated with warfarin. [74] In addition, heparin should be instilled in PICC and Hickman- and Broviac-type catheters after each episode of blood drawing or blood product administration and when the catheters are not being used for intravenous therapy. A minimum of 5 ml of heparin in saline (100 U/ml) should be instilled in each lumen [14] because such flushes reduce bacterial growth on catheter tips. [75] In the outpatient setting, PICCs require 12 ml daily, [14] while for tunneled catheters, twice weekly flushes may be adequate if the catheter is not being used. [30] A further decrease in intraluminal infection rate in immunocompromised, non-neutropenic patients with tunneled catheters may be provided by adding vancomycin (25 g/ml) to the heparin flush. [76] [77] The PICC or tunneled line is then plugged with a Luer-Lok injection plug, which is taped in place and changed once a week. [9] [14]

It should be remembered, however, that the use of the heparin flush will alter coagulation tests if blood is drawn through the catheter. [78] The first 10-ml sample will show spurious elevations in levels of fibrin degradation products, prothrombin times, and partial thromboplastin times, and spuriously low fibrinogen levels. Elevations in the prothrombin time and partial thromboplastin time will persist in the second 10-ml sample.

Catheters with Groshong-type valves require less maintenance than do Hickman or Broviac-type catheters. However, they do require a 5-ml normal saline flush weekly or after use [9] [13] [14] [29] because the special valve can be kept in the open position by small clots or solid residues from medications, and blood will flow back into the catheter, forming a clot.

For apheresis catheters used for peripheral stem cell harvest, a regimen of aspirin, 325 mg/day, begun the day after catheter placement led to a greater number of thrombosis-free apheresis procedures than was noted with historical control subjects. [79] More detailed guidelines for nursing education and practice regarding maintenance of catheters are available. [67]

Ports

Ports can be used immediately after insertion. However, because postoperative edema and discomfort often delay any attempts at access for several days, patients should be sent from the operating room with the Huber needle in place and ready for use. [19] [30] [80]

To access a port that has no needle in place, the skin is prepared with povidone-iodine solution [81] and a freezing agent (ethylene dichloride) or topical anesthetic cream (EMLA) [82] is applied, followed by insertion of a 19- to 22-gauge Huber needle (depending on the product to be infused) (Fig. 83-3). [19] This steel needle has a deflected point and side opening, designed to prevent coring of the septum. [18] The needle is primed with saline, attached to a saline-containing syringe and connecting tubing, and then inserted perpendicular to the septum. [83] Correct placement in the port can be confirmed by aspiration for blood return. However, aspiration for blood is often unsuccessful, usually because the needle is misaligned or a fibrin sheath has formed, creating a ball-valve effect. In the absence of swelling after a 10- to 20-ml saline infusion, the needle can be assumed to be correctly placed and the port safely used. [9] Detailed accessing procedures for drawing blood and for administering drugs and blood products are available. [19] [83]

During use, the port is covered with a transparent occlusive sterile dressing, further reinforced by a window frame of paper tape. [18] [30] [83] The dressing is changed when the needle is changed, as well as when the dressing becomes nonocclusive or wet or evidence of infection or skin irritation develops. After each use or every 4 weeks, implanted access devices also require heparin instillation (35 ml of 100 U/ml heparinized saline solution) or a 20-ml saline flush. [9] [18] [30] Use and maintenance of the peripheral port are essentially the same as for ports implanted in the chest wall. [15] More detailed guidelines for nursing education and practice regarding the maintenance of implanted ports and reservoirs are available. [80] [84]

Device Removal

Nontunneled catheters are removed nonsurgically by applying steady tension. If the catheter appears to be stuck, measures

should be taken to reverse vasospasm (e.g., application of warm compresses, flushing with normal saline). [10] If the catheter remains fixed, a cutdown on the venous insertion site to remove thrombotic material is usually effective. [8] Tunneled catheters should be removed by surgical cutdown around the cuff, which should be entirely removed. [8] For cases in which bacterial studies of the internal catheter tip are desired, blunt dissection of the cuff, with transection of the catheter above it and sterile removal of its inner portion, can be performed under local anesthesia. [44] [85] Ports, including the reservoir, catheter, and all suture materials, are removed surgically with the patient under local anesthesia. [8]

Complications

Complications of indwelling vascular access devices include those occurring during initial placement, cutaneous reactions to standard care materials, mechanical problems, phlebitis and infiltration, infection, hemorrhage, catheter occlusion of nonthrombotic or thrombotic origin, and vesicant drug extravasation.

Initial Placement

Rarely, patients who have had a midline catheter composed of a hydrogel elastomer inserted and flushed experience an anaphylactoid reaction (5% of which are complicated by cardiac arrest). [5] [86] This reaction was not seen when silicone midline catheters were used. [87] Some 14% of patients in whom a central catheter is inserted percutaneously develop a pneumothorax. [8] Other surgical complications include hemorrhage into the thoracic space, venous or cardiac perforation, and pericardial tamponade. [8]

Cutaneous Reactions

Approximately 5% of patients develop skin reactions to the products used in caring for the devices. [88] These reactions include erythema, urticaria, exanthematous or purpuric eruptions, and skin peeling or abrasion. These skin abnormalities must be distinguished from exit-site infections by appropriate culturing of the site for bacteria. In uninfected patients, change of the dressing material, tape, and local skin care regimen is effective in reversing the skin abnormalities. [88]

Skin erosion over the implanted ports, either from malnutrition, separated wound edges, local infection, or carcinoma metastatic to the skin, occurs in 310% of patients, and removal of the port is always required. [30] [89] P.A.S. Ports may cause this complication more frequently than ports placed on the chest or abdominal wall. [8]

Mechanical Problems

Catheters

Damage to the external segment of the tunneled catheter includes (1) separation between the Luer-Lok connection and the tubing; (2) cracks caused by repeated cross-clamping, if rubber-tipped forceps are not used; and (3) cuts made by scissors mistaken for clamps. [9] Catheter repair kits should therefore be available. Patients should also be instructed to contact their physicians or the oncology nursing staff immediately if the catheter is damaged at home.

Catheter fractures and emboli occur in about 0.2% of subclavian catheter insertions. [8] The internal portion of the catheter usually fractures at the junction of the clavicle and first rib, [90] and angiographic studies reveal the pathognomonic catheter pinch-off sign. [91] Catheter pinch-off occurs when catheters inserted medially to the midclavicular line become compressed by shoulder movements. [91] The resulting fragments migrate to the right heart or pulmonary artery and cause thromboses, cardiac arrythmias, and fatal emboli; extravasation of fluids, lymph, or vesicant agents may also ensue. [8] [90] Patients complain of pain or swelling at the port or vein

insertion site, chest pain, cough, or palpitations. [90] Catheter fragments are usually removed percutaneously. [90]

PICC lines can also embolize if they are sheared by needles, sutures, or surgical instruments while they are being inserted. If the fragment cannot be prevented from migrating more proximally by applying local pressure at the break site or by placing a tourniquet proximal to the site, it can be removed by venous cutdown. [90] [92] If it has migrated, percutaneous techniques or a thoracotomy will be required, [90] [92] but some fragments are never retrieved.

Apheresis catheters placed in the inferior vena cava can also develop fractures of the external segment, with visible leakage, [47] and they can be repaired using the kits mentioned above. Fractures of the internal portion of the catheter, however, require catheter removal. Most of these fractures can be detected by injecting radiologic contrast material through them and observing the flow of the dye fluoroscopically. [47]

Ports

The port may flip within its pocket because of defective suturing or excessive arm movement, or because of manipulation by the patient. [30] [93] This malposition can be surgically corrected.

Phlebitis and Infiltration

Phlebitis and infiltration are uncommon complications associated with properly positioned centrally placed access devices but are noted with the P.A.S. Port [8] and in 2.223% of patients with PICCs. [5] [16] [42] [94] [95] A randomized controlled trial compared the complications associated with steel needles, small-bore short Teflon catheters, and PICCs. [96] PICCs were associated with the highest incidence of phlebitis (27%) and the lowest incidence of infiltration (8.1%), steel needles were associated with the lowest incidence of phlebitis (8%) and the highest incidence of infiltration (45%), and Teflon catheters fell in between, with a 1920% incidence of both phlebitis and infiltration. The aseptic phlebitis usually occurs within the first week after PICC insertion. It can be prevented by administration of nonsteroidal anti-inflammatory agents [39] or treated with warm compresses applied for 4872 hours. [42] Catheter removal is usually not required.

Infection

Definitions

The Centers for Disease Control have established the following definitions for catheter- and port-associated infections: [5]

Colonized catheter: growth of 15 colony-forming units (semiquantitative culture) or >10^3 (quantitative culture) from a proximal or distal catheter segment in the absence of accompanying clinical symptoms.

Exit-site infections: erythema, tenderness, induration, or purulence within 2 cm of the skin at the exit site of the catheter.

Pocket infection: erythema and necrosis of the skin over the reservoir of a totally implantable device, or purulent exudate in the subcutaneous pocket containing the reservoir.

Tunnel infections: erythema, tenderness, and induration in the tissues overlying the catheter and >2 cm from the exit site.

Catheter-related bloodstream infection: isolation of the same organism (i.e., identical species, antibiogram) from a semiquantitative or quantitative culture of a catheter segment and from the blood (preferably drawn from a peripheral vein) of a patient with accompanying clinical symptoms of bloodstream infection and no other apparent source of infection. In the absence of laboratory confirmation, defervescence after removal of an implicated catheter from a patient with bloodstream infection may be considered indirect evidence of catheter-related bloodstream infection.

Infusate-related bloodstream infection: isolation of the same organism from infusate and from separate percutaneous blood cultures, with no other identifiable source of infection.

Incidence

Both retrospective and prospective studies showed exit-site infections to be responsible for 3945.5% and tunnel infections for 20.322% of all catheter-related infections. [37] [97] Skin contaminants are the likely source of infections for catheters in place for less than 10 days, while the catheter hub is the more likely source if the catheter has been in place for more than 30 days. [98] Prophylactic antibiotics have not consistently proved beneficial in preventing these infections, and their use is not recommended. [5] [23] [37] Similarly, silver-impregnated cuffs do not decrease infection rates. [99] Infections are generally prevented by meticulous insertion and maintenance techniques. [64] [65] With maximal barrier precautions, catheter insertion at the bedside is associated with no higher an infection incidence than placement in the operating room. [5]

The incidence of device-associated infection varies depending on the type of device inserted and the medical disorder of the patient. Overall, the incidence of midline catheter-associated infections is 0.8 per 1,000 days of patient use [86] and that of tunneled catheters is about 13 per 1,000 days of patient use. [23] The use of multiple-lumen catheters probably increases the infection rate significantly. [5] The infection rate with implanted ports is lower, 0.3 per 1,000 patient-days for ports inserted on the chest wall and 0.8 per 1,000 patient-days for P.A.S. Ports. [23] [100] [101] Patients with HIV infection [50] [51] [52] [53] or those receiving a bone marrow transplant [45] [46] [102] have significantly higher rates of both catheter- and port-related infections. Patients with hemophilia [33] and sickle cell anemia [103] do not (0.60.86 per 1,000 days of patient use).

Organisms

Staphylococcus, Streptococcus, and *Candida* species are the most common infecting organisms. [23] [104] Both staphylococcal and candidal organisms adhere to the fibrin or fibronectin sheaths surrounding indwelling catheters, and the staphylococcal slime further promotes bacterial proliferation on the catheter surface. [73] [104] In patients not infected with HIV, an average of 28% of infections are due to coagulase-negative staphylococci, 16% to *Staphylococcus aureus,* and 8% to enterococci. [5] Other gram-negative organisms, including *Pseudomonas,* also cause infection. [8] [105] *Pseudomonas* is particularly problematic when showering or swimming has been allowed. *Xanthomonas* infections can be particularly troublesome.

A reported 5.49.9% of infecting organisms are fungal, three-quarters of which are *Candida* species, [4] [23] [37] [106] [107] although nosocomially acquired cutaneous infections with *Aspergillus flavus* have been noted at the sites of insertion and along the subcutaneous tract of Hickman catheters. [108] [109] [110] Liposomal amphotericin B was successful in eradicating a port-associated fungemia from *Fusarium oxysporum* in an HIV-infected patient. [111] Septicemia due to catheter infection by either typical or atypical *Mycobacterium* species has also been noted. [22] [112] [113] [114] [115]

In HIV-positive patients, staphylococci are the most common infecting organisms, [50] [51] [52] but *Pseudomonas* species causing fatal septicemias, [50] [52] [116] [117] [118] [119] other gram-negative organisms, [120] and lactobacilli [121] are increasingly reported. *S. aureus* is the most common organism infecting ports of patients with hemophilia, especially those with inhibitors. [33]

Indications for Removal

Exit-Site and Tunnel Infections

Exit-site infections caused by bacteria rarely require catheter removal for resolution, as most (69100%) will respond to antibiotics

TABLE 83-2 -- Indications for Catheter Removal

Venous access devices
Exit-site infection caused by atypical mycobacteria
Tunnel infections
Bacteremia caused by *Staphylococcus aureus, Xanthomonas, Pseudomonas* spp.
Fungemia
Central nervous system access devices
Deep catheter track or epidural space infection

alone.[37] [59] [60] [97] [103] These infections are most often caused by *S. epidermidis.*[20] [23] Similarly, with implanted ports, infections of the skin pocket have been found to resolve in about 70% of cases without removal of the device.[22] [23] [38] [63] [103]

Tunnel infections, by contrast, usually do not respond to antibiotics; they have been reported to resolve without catheter removal in only 2550% of cases. [37] [59] [60] [97] Catheters were removed from all patients with cutaneous *Aspergillus* infection, six of whom recovered after antifungal therapy and local wound care (Table 83-2).[108] Resolution of leukopenia was required for infection resolution. Similarly, *Mycobacterium* [22] and atypical mycobacterial infection of the tunnel or exit site requires catheter removal as well as excision of infected tissue.[115]

Septicemia

In a patient with septicemia and a catheter or port in place, it is often difficult to determine whether the catheter itself is truly infected or whether the bacteremia is from another source. Quantitative culture is the most sensitive technique,[5] but the semiquantitative roll-plate method is most often used to diagnose catheter-related infections.[122] [123] Both, however, require that the catheter be removed. Quantitative blood culture techniques can be used with a catheter in place. If the colony count in cultures of blood drawn from the catheter is 5 to 10 times greater than the count in cultures of peripherally drawn blood, the infection is very likely to be catheter related.[5] For presumed *Candida* infection, it has been suggested that molecular analysis of material from various anatomic sites may help determine the true source of the infection (e.g., sputum versus blood) and prevent needless device removal.[124]

In assessing the cause of infection in a patient with a port, care must be taken not to draw blood for culture through a possibly infected port pocket unless the Huber needle is already in place. Accessing a port through an infected port pocket could introduce organisms into the reservoir, and from there into the systemic circulation.[30] [103] [125] To determine whether a port is truly infected, after it is removed, material within the port should also be cultured.[126]

When another source is definitely identified, however, the catheters can usually be left in place, because the incidence of hematogenous colonization is low (1%). [37] [55] When there is no thrombophlebitis, even when the catheter is believed to be the source of the infection, or when no source is clearly identified, resolution of bacterial septicemia occurs in 75% of episodes without removal of the catheter.[23] [127]

The possibility of clearing the infection without catheter removal, however, is much lower in patients with septic thrombophlebitis, occluded catheters, exit-site infections, or bacteremia due to *S. aureus, Xanthomonas,* or *Pseudomonas* or fungal septicemia.[8] [23] [52] [128] [129] In one retrospective review, adult cancer patients with candidemia did just as well with catheters left in place as those whose catheters were removed,[130] and in one pediatric study, *Candida* fungemia was treated successfully with the line left in place.[6] In other studies, however, children with catheter-related candidemia had higher rates of treatment failure, secondary complications, and mortality if the catheters were left in place during antifungal treatment.[131] [132] In general, catheter

removal is recommended in patients with bacteremia due to *S. aureus, Xanthomonas,* or *Pseudomonas* and in those with fungemia due to either *Aspergillus* or *Candida* (Table 83-2). Successful surgical removal of right atrial thrombi superinfected with *C. tropicalis* and *S. epidermidis* has been reported in several patients, including those with sickle cell anemia.[133] [134] Replacement of catheters on the contralateral side within 13 days after removal is usually not associated with recurrent catheter infection.[55] [63]

Hemorrhage

Despite the frequent occurrence of thrombocytopenia in patients with indwelling access devices, few bleeding complications are associated with their placement or with the placement of the larger apheresis catheters.[55] [55] Capillary fragility from prolonged steroid therapy, however, may contribute to perioperative hemorrhage.[59] Pressure dressings and platelet transfusions given pre- and postoperatively usually control local oozing.[55] However, in patients with uncontrolled disseminated intravascular coagulation, excessive bleeding has occurred with catheter insertion; many groups consider disseminated intravascular coagulation an absolute contraindication to catheter placement.[23] [55] [59] In contrast, catheters and ports have been placed without excessive bleeding in patients with hemophilia when factor levels were maintained at 100% preoperatively and for 5 days postoperatively.[33] [34]

Catheter Occlusion

Nonthrombotic Causes

Although clot is the most common cause of occlusion,[104] inability to aspirate blood from the port or catheter does not necessarily mean that it has clotted. Other causes include a malpositioned Huber needle, catheter abutment against the wall of the vein, catheter kinking, catheter pinch-off, precipitation of drug solutions in the catheter lumen, development of fibrin sheaths, and catheter migration with resultant malposition of the tip.[30] [104] [135] Algorithms for the evaluation and treatment of catheter occlusion are available.[104]

Catheter abutment may resolve by changing the patients position or by performing a Valsalva maneuver.[14] [19] [30] Repositioning patients with catheter pinch-off will often relieve the compression and re-establish catheter function.[90]

Precipitation of incompatible solutions occurs with etoposide, calcium, diazepam, phenytoin, heparin, and TPN infusions.[104] Catheter blockage due to precipitation of calcium carbonate was reported at from 8 to 24 weeks in 50% of patients with metastatic colon carcinoma receiving once weekly 24-hour infusions of high dose 5-fluorouracil (2,600 mg/m2) and leucovorin (500 mg/m^2).[136] Although precipitates may occasionally resolve with warm soaks over the tunnel site, dilute solutions of hydrochloric acid have successfully cleared precipitates from TPN solutions alone, or with lipids, etoposide, calcium salts plus sodium bicarbonate, and heparin with incompatible antibiotics.[8] [104] The 0.20.5 ml solution of 0.1M HCl is instilled and allowed to stand for 20 minutes.[104] Febrile reactions may occur. Sodium bicarbonate has, in one study, resolved a phenytoin precipitate.[137]

Occlusion by a fibrin sheath, leading to a ball-valve effect,[9] [20] occurs in 1020% of cases.[135] [138] The fibrin sleeve itself may embolize as well.[139] [140] Techniques using nonlytic and lytic agents to remove the sheaths have been described.[19] [30] Lytic therapy is discussed below.

Maintaining correct position of the catheter tip can help prevent numerous complications. Catheter migration occurs in 5.529% of insertions when the subclavian approach is used.[141] Review of the patients chest radiograph will most commonly show the malpositioned catheter tips to be in the ipsilateral jugular vein or in the contralateral brachiocephalic vein. Venous thrombosis can occur as a result of damage to the endothelium, turbulence created by the tip at venous branching points, or insufficient dilution of infusates that cause thrombophlebitis. Catheter erosion through the vessel or cardiac wall can produce extravasation, fistula formation, and pericardial tamponade.[90] Catheters inserted into the left internal jugular or subclavian veins have also eroded into the bronchi; the ensuing venobronchial fistulas

were associated with cough, pneumonia, and respiratory failure. [142] Repositioning the catheter can usually be done without catheter removal, using angiographic techniques. [135] [141]

PICC malposition ranges from 2155%. [90] The catheters can usually be repositioned by trained nurses employing simple bedside techniques. [90] Migration of the apheresis catheter in the subcutaneous space also manifests as access failure, since the catheter tip is pulled back to the wall of the inferior vena cava or out of the intravascular space. [47] Intravascular malposition can be corrected by tip deflectors or J-wires. [143]

Thrombosis

Thrombosis can occur in the catheter itself or in the superior vena cava or veins of the upper extremity. The thrombus usually results from failure to follow standard flush procedures. Thromboses were seen in 16% of implanted ports. [38] An incidence of 18% is reported with PICCs, [144] but the incidence of thrombosis in patients with properly cared for centrally inserted catheters is only 010%. [27] [38] [145] [146] Retrospective studies of sickle cell patients indicated no increased incidence of thrombosis necessitating catheter removal as compared with patients with cancer or AIDS. [103] The incidence is equally low in syngeneic and allogeneic marrow transplant patients, despite the use of multiple-lumen catheters. [45] [46] [47] In patients undergoing autologous marrow transplantation, however, the incidence of thrombosis is 1320%. [146] This higher incidence may be due to the increased number of patients in this group who have platelet counts greater than 150,000/mm ^{3} and to the frequent placement of two catheters at bone marrow harvest. [146]

Noninvasive methods used for diagnosis, including duplex ultrasound, [145] [147] MRI, [148] Doppler imaging, [145] [149] and plethysmography, [145] have low sensitivity or have not been reliable, and nuclear scans have been falsely normal because of the development of collateral circulation. [145] Venography is recommended to support the clinical diagnosis. [38] [47] [145] In patients with prior subclavian catheterization, however, duplex scans may be useful to predict the success of repeat catheter placement. [150]

Therapy

The course of action in patients undergoing high-intensity antineoplastic therapy and in whom asymptomatic subclavian or innominate vein thromboses develop is unclear. Asymptomatic occlusion is seen in 25% of patients undergoing autologous marrow transplantation; partial occlusion develops in an additional 34%. [151] Because the incidence of complications caused by these thrombi is unknown, no therapeutic recommendations can be made.

Patients with symptomatic upper extremity deep venous thrombosis (DVT), however, probably do require therapy. They may develop septic thrombophlebitis, [23] [37] superior vena cava syndrome, major long-term upper extremity disability, venous gangrene, and pulmonary emboli. In one retrospective study and review, 12% of patients with catheter-induced upper extremity DVT developed pulmonary emboli, 40% of which occurred in patients receiving anticoagulant therapy. [145] A 16% incidence of pulmonary emboli was found in a prospective study of patients with upper extremity DVT in whom lung scans were performed within 24 hours of venographic diagnosis of the thrombosis. [152] Patients with polyurethane and siliconized catheters had a significantly lower incidence of emboli than those with polyvinyl chloride or polyethylene catheters (7% vs. 26%). [152]

There is no consensus about the best therapy for patients with upper extremity DVT. Some reports suggest that conservative therapy (heat and elevation) is efficacious, producing resolution of edema and pain and minimal chronic venous insufficiency. [146] Other investigators have recommended anticoagulation with heparin, thrombolysis, or surgical clot removal. [38] [47] [145] [153]

Anticoagulation with heparin, however, has not been consistently successful in preventing pulmonary emboli from subclavian vein thrombi. [141] [152] [154] Therefore, bolus or infusional thrombolytic therapy with streptokinase, urokinase, or tissue plasminogen activator (t-PA) is usually considered. Bolus thrombolytic therapy has reopened occluded catheters in 8590% of episodes, and removal of the catheter is not usually required. [64] [153] [155] [156] [157] [158] One commonly used procedure is to instill 13 ml of a solution of streptokinase (75010,000 IU/ml) or urokinase (5,000 IU/ml) into the catheter or port, leave it in place for 20 minutes to 1 hour, and then aspirate at 5-minute intervals until the catheter reopens. [67] If the first instillation is ineffective, the procedure can be repeated or the other solution used. [47] [104] [155] [157] [159] No excessive bleeding has been noted, even in patients with hemophilia. [33] A randomized trial comparing bolus urokinase (10,000 U) with t-PA (2 mg) suggested marked superiority for t-PA. Twenty-five of 28 t-PA-treated versus 13 of 22 urokinase-treated catheters returned to normal function, 17 versus 7 were normal radiographically, and 13 versus 4 needed only one drug instillation. [158] Similarly, fibrin sheaths have been dissolved in 87% of patients in whom streptokinase was infused (3,000 IU/h) into each catheter lumen for 1224 hours. [135] No fevers, coagulation abnormalities, or other adverse reactions have been noted with urokinase, but streptokinase can cause mild to moderate systemic reactions (fever and chills) in patients with recent streptococcal infections or in those who have previously received the drug for thrombolysis. Once patency is restored, heparin is usually given for 57 days.

For thrombi refractory to the bolus administration of streptokinase or urokinase, options to dissolve the thrombus include infusions of urokinase or streptokinase through a catheter placed at or within the clot. [153] [160] High-dose streptokinase therapy is effective [160] but expensive and is associated with a high incidence of bleeding. It is not recommended for patients with such bleeding risks as thrombocytopenia or mucositis. Infusion of urokinase for 2472 hours restored catheter patency in 74% of patients (81% of those with clots present for less than 7 days and 56% of those with clots present for more than 7 days). [153] Infusion into the superficial venous circulation of the involved extremity was not effective. Even though a low infusion concentration was used (5,000 IU/h of streptokinase or 5002,000 IU/kg/h of urokinase), a systemic lytic state was documented. Therefore, urokinase infusion should not be undertaken in patients with contraindications to systemic fibrinolytic therapy. [161] Another regimen for refractory clots involves an infusion of urokinase (40,000 U/h) for 6 hours. This regimen led to dissolution of thrombi in 90% of patients; a repeat 6-hour infusion raised the dissolution rate to 95%. [162] [163] Infusions as short as 13 hours were successful in half the cases studied. [164] Addition of heparin to the 1- to 12-hour infusion did not improve the results. [164] No bleeding complications were seen. In patients with catheter tips placed below the carina and not adherent to the venous wall, there is a low risk of reocclusion; these catheters need not be removed. [164] The same urokinase instillation technique is recommended for patients with occluded ports. [80] Successful clot resolution with urokinase was reported in 5087% of patients. [22] [63]

Vesicant Drug Extravasation

It is very unusual for a spontaneous leak to form in a large-bore catheter, but an attempt to irrigate an occluded catheter with a small syringe can cause a rupture through which the drug can extravasate. [9] [55] Occlusion of the catheter tip by a fibrin sheath may force drug back up the sheath and through the exit site of the catheter. [38] [165] This so-called back-tracking appears to be more common with percutaneously placed access devices. [90]

Leaks may develop if the catheter is disconnected from the reservoir or if the catheter is punctured by mistake by the Huber needle. [30] In addition, outpatients using a port for continuous infusion of chemotherapy can experience drug extravasation if the Huber needle is dislodged from the septum. [44] [166] [167] [168] Even usually nonvesicant drugs can produce skin necrosis severe enough to warrant removal of the port. [44] Use of the Port-a-Cath port, which has a thicker septum than the MediPort or Infus-a-Port devices, has been associated with only a 34% incidence of extravasation. [63] [166] [167] [168] The thickness of the septum has been postulated to be responsible for the low incidence of needle displacement noted with the Port-a-Cath, [168] but no randomized trials have compared complications associated with the three devices. Securing the needle to the chest wall with tape has been recommended, [166] [167] but use of a Gripper needle provides a much more secure needle placement and may lower the incidence of this complication. If infusion pumps are used, attention must be paid to minimizing tension between the needle and the infusion tubing.

Treatment protocols for vesicant drug extravasation, as recommended by the Oncology Nursing Society, [169] [170] [171] [172] [173] [174] [175] [176] are outlined in Table 83-3 . In studies of their use (excluding the recommended therapy with dimethyl sulfoxide [DMSO]), 89% of vesicant extravasations were reported to resolve without additional

TABLE 83-3 -- Management of Vesicant Drug Extravasation

Drug Therapy	Antidote Preparation	Method of Administration

Antibiotics[170] [171] [176] Dactinomycin Mitomycin Plicamycin Daunorubicin Doxorubicin	None	Apply 12 ml of 1 mmol DMSO (50100%) to an area twice that of the affected area once. Air dry without a dressing. Apply *cold* packs for 20 minutes qid for 2448 hours, then use normally
Vinca alkaloids[171] [172] [173] Vincristine Vinblastine Vindesine Etoposide	Add 1 ml preservative-free normal saline to 1 vial containing 150 U hyaluronidase	Inject 5 1-ml doses subcutaneously into site with multiple injections. Apply *warm* compresses for 20 minutes, qid for 72 hours
Alkylators[170] [174] [175] Mechlorethamine	Mix 1.6 ml of 25% sodium thiosulfate with 8.4 ml sterile water for injection	Inject 5 ml IV through existing line. Apply *cold* packs to the site for 20 minutes, qid for 72 hours

therapy. [170] However, 30% of anthracycline extravasations progressed to ulceration. A prospective uncontrolled study of anthracycline extravasation showed that the application of DMSO four times a day for 4 days prevented progression to ulceration in all patients. [176]

At many centers, it is recommended that an extravasation kit be kept in units in which vesicant drugs are given. The kit includes the appropriate medications, as well as order sheets preprinted for immediate use. In general, if an antidote is to be administered through the device, as much of the residual drug as possible should be aspirated from the needle, tubing, and tissues before the antidote is given. If swelling or pain persists for 7296 hours after drug administration, a plastic surgeon should be consulted.

CENTRAL NERVOUS SYSTEM ACCESS DEVICES

In patients with hematologic disorders, devices that permit chronic access to the CNS are useful for a variety of purposes. The available devices include temporary or permanent epidural catheters, ports with attached silicone elastomer catheters, implanted pumps with attached silicone elastomer catheters, and Ommaya reservoirs. The choice of device is determined by a number of factors, including available routes, duration of therapy, cost, efficacy for the therapy planned (e.g., antineoplastics versus pain medication), and the ability of the patient and family to care for the device. [177]

Catheters

Local anesthetics alone or combined with fentanyl, given through temporary epidural catheters (in place for less than 5 days), have successfully managed the pain and improved oxygenation in children with sickle cell crisis. [178] Chronic epidural access has become widely available since the development of a permanent epidural catheter that can be placed percutaneously. [179] The catheters are most commonly used for pain control. The catheter consists of three pieces: two radiopaque silicone rubber cathetersan epidural segment (1.3-mm outer diameter, and an exteriorized line (3.1-mm outer diameter, 0.68-mm inner diameter) with an external Luer connector and a subcutaneous Dacron cuffand a splice segment that joins the two catheter segments. [179]

Insertion

Catheter insertion is done under local anesthesia. [179] A paravertebral incision is made at the level of the L-2 dorsal spine and the epidural portion of the catheter is inserted through a 14-gauge Hustead or Touhy needle to the desired spinal cord level. Epidural placement is verified by fluoroscopy and sensory blockade. The exteriorized line is then tunneled from a subcostal location on the mid-nipple line around to the lower end of the paravertebral incision, and the splice segment is secured to the two catheters and then to the supraspinous tissue to avoid kinking. A Millex-OR 0.22-micron filter is attached to the Luer connector, and a locking Luer injection cap is connected to the filter.

Access and Management

The catheter can be used immediately. Bolus doses can be given from a syringe, or the catheter can be connected to external pumps that deliver continuous infusion opioid with bolus rescue doses or combinations of opioids and local anesthetics (see Chap. 82). Only preservative-free solutions can be used. Wound and catheter exit-site cleaning and dressing changes are recommended until the last sutures are removed, usually 3 weeks. After that, the exit site is cleaned every other day with hydrogen peroxide and povidone-iodine wash, and the filter and injection port are changed every 4 days using sterile technique. [179] More detailed nursing protocols for accessing and managing these catheters and for monitoring patients receiving epidural opioids are available. [67] Patient and family education in catheter care can be effectively supplemented by referral to a home health or hospice agency. [177]

Complications

The catheters can remain safely in place for months, [180] but even temporary catheters can cause serious infections if left in place for days to weeks. [181] Complications include those attributable to the opioids being infused, pain during injection, [182] myoclonus, [183] epidural fibrosis, [184] obstruction and dislocation, [182] [185] and infection. [180] [182] [186] [187] Patients whose catheters take longer to insert have higher infection rates. [187] Exit-site and superficial catheter track infections occur infrequently (in about 10% of patients). [180] [186] The epidural space infection rate has been reported as 1 in 1,702 days of catheter use, similar to the infection rate of 1 in 1,045 per days of use associated with the Hickman catheter. [181] *S. aureus* and *S. epidermidis* account for two-thirds of all the infections. [180] [181] Exit-site and superficial catheter track infections may be cleared without catheter removal, [180] [186] but catheter removal is required for patients with deep catheter track or epidural infections (Table 83-2). [180]

Epidural Ports/Implanted Pumps

Epidural ports (e.g., Port-a-Cath) and implanted pumps (e.g., Infusaid) have also been used to deliver bolus or continuous infusions of opioids into the epidural or intrathecal space to relieve pain of malignant or nonmalignant origin. [183] [188] Subarachnoid infusions using the implanted pumps are recommended as efficacious and cost-effective for patients with a relatively long life expectancy (>3 months). [183] The use of implanted pumps has been reviewed elsewhere. [189]

Complications include both those noted above for implanted ports, and pain on injection of morphine, pump pocket seromas, CSF leaks, CSF hygromas, and postspinal headache. [183] [190] But the use of injection ports appears to reduce the rate of complications associated with percutaneously inserted epidural catheters. A retrospective comparison of catheters with or without associated injection ports indicated that those attached to ports became dislodged much less frequently and were associated with half the infection rate per 1,000 patient-days. [191] Port removal rates for infection were similar to removal rates of ports used for vascular access (10%). [190] Because the seromas act as growth media for bacterial contamination, they should be monitored carefully. The management of hygromas and postspinal headache is reviewed elsewhere. [183] Detailed access and management procedures for epidural ports and implanted pumps and for monitoring patients receiving opioids through them are available. [21] [80]

Ommaya Reservoir

The Ommaya reservoir device was first described in 1963 by Ommaya, [192] and with minimal changes it is still used for access to the spinal fluid within the cerebral ventricle. The reservoir is used to remove CSF for culture, cytology, or measurement of drug levels; to drain cysts in craniopharyngiomas and astrocytomas; to administer antibiotics or antifungal agents; to administer intraventricular chemotherapy to treat leukemic or carcinomatous meningitis; to administer interferon or lymphokineactivated killer cells directly into a tumor; and to administer opioid pain medications. [177] [193]

The device consists of a dome- or mushroom-shaped capsule with a top made of a self-sealing silicone elastomer that can be punctured numerous times without leaking. The flat base of the

capsule, by contrast, is composed of firm polypropylene and is not easily punctured. An outlet arm connected to a ventricular catheter is attached at the base, either laterally or in the center, extending downward. Capsules range in size from 12 mm in diameter (for babies) to 30 mm. Those commonly used for adults have an internal volume capacity of 1.452.4 ml.

Insertion

The Ommaya reservoir is placed subcutaneously by a neurosurgeon. [194] Prior to insertion, computed tomography (CT) is generally required to evaluate ventricular size and placement. Presoaking the device in Bacitracin to prevent subsequent infection has been advocated. [195] For placement, the ventricular catheter is passed through a bur hole into the frontal horn of the right lateral ventricle or, if necessary, into that of the left lateral ventricle or the ventricle body. The catheter end is connected to the base or side arm of the capsule, which then is fitted into the bur hole or a subgaleal pocket. The Silastic skirt of the reservoir may be sutured to the periosteum. A postoperative CT scan is suggested to verify the catheter tip position.

Accessing the Device

The Ommaya reservoir can be used immediately postoperatively for sampling CSF or for injection of drugs. Usually, however, it is not accessed until the third postoperative day. [193] The thoroughly cleaned, gently shaved scalp is prepared with three iodine scrubs and, with use of sterile technique, the reservoir is accessed obliquely with a 23- or 25-gauge butterfly needle inserted with the bevel downward. [193] The CSF can be directly aspirated, or antibiotics or chemotherapeutic agents can be administered through a second syringe attached to the butterfly needle. After removal of the needle, the injected medication can be gently pumped into the spinal fluid by emptying the capsule using repeated pressure, but, to allow CSF to refill the reservoir, one should avoid steadily compressing the device. [196] Once the incision has healed and the stitches have been removed, no special local care or flushing is required. The device can remain in place for months or years. More detailed accessing and management guidelines are available. [80]

Complications

Infection

In general, the Ommaya reservoir has proved very safe, with a complication rate of approximately 1020%, [194] [195] [197] [198] although higher rates were reported in the past. [199] The most common complication is infection, which occurs in about 1015% of patients, [198] especially those who have undergone radiation therapy or who required a second surgical procedure for revision of the catheter. [194] Most infections have been due to *S. epidermidis,* but infections due to numerous other gram-positive and gram-negative bacteria as well as fungal organisms have been documented. [198] [200] In general, the device is not removed, and patients are treated as though they had meningitis. For infections with *S. epidermidis,* vancomycin is given intravenously [201] or, in refractory cases, instilled into the reservoir. [202] Removal of the reservoir is sometimes required.

Miscellaneous

Neurologic complications are rare when the catheter is placed into the nondominant ventricle, but a variety of other complications, which occur infrequently, have been reported. These include (1) intraventricular hemorrhage or subdural hematoma shortly after catheter placement; (2) leakage of CSF around the catheter, primarily in patients with increased intracranial pressure, which caused backflow of fluid along the catheter and produced a subgaleal collection; [199] [203] (3) reservoir leaks after repeated use; [197] (4) occlusion by cellular debris or, when a catheter is placed directly into a tumor, by very proteinaceous tumor fluid; [197] (5) obstruction by lodging of the catheter in brain tissue or abutment against a ventricle wall; [197] (6) seizures immediately after injection of medications; [197] (7) white matter disease (leukoencephalopathy or brain necrosis), most often due to methotrexate injection via the Ommaya device, although found with systemic administration of methotrexate as well; [197] [204] and (8) tumor growth around the cannula. In one case, the catheter may have permitted the spread of Burkitt lymphoma cells from the meninges into the cerebral tissue, where the tumor was found. [205]

Part VII - Transplantation

Chapter 84 - Overview of Stem Cell Transplantation

Philip McGlave

INTRODUCTION

Hematopoietic stem cell transplantation has come of age. Over the last four decades this therapy has been used to correct a variety of marrow failure states, inborn errors of metabolism, immune deficiencies, hematologic malignancies, and even solid tumors. [1] [2] [3] [4] [5] [6] [7] [8] [9] [10] [11] [12] [13] [14] [15] This chapter provides a brief overview of principles underlying clinical human stem cell transplantation. Various aspects of human hematopoietic stem cell transplantation are discussed in Chapters 85 , 86 , 87 , 88 , 89 , 90 , 91 , 92 , 93 , 94 , 95 , 96 , 97 .

The first successful transplants were performed with stem cells derived from the marrow of identical twins (syngeneic transplantation); however, application of transplantation therapy broadened with the use of stem cells obtained from either related or unrelated donors (allogeneic transplantation) suitably matched at the human leukocyte antigens (HLA), or even with a patients own stem cells (autologous transplantation). [16] [17] The term bone marrow transplantation (BMT) is historically applied to the field; however, stem cell transplantation may be a more appropriate term since peripheral blood, umbilical cord blood, and even fetal liver are also used as sources of hematopoietic stem cells for human transplantation therapy. [18]

ALLOGENEIC STEM CELL TRANSPLANTATION

Donor-Recipient HLA Matching

In distinction to transplantation of either syngeneic or autologous stem cells, transplantation of allogeneic stem cells requires careful matching of donor and recipient. Failure to do so is associated with both graft rejection and graft-versus-host disease (GVHD). Either rejection or GVHD can occur when immunocompetent cells of host or donor respectively respond to alloantigens encoded by the major histocompatibility complex (MHC) and peptides presented in association with these MHC antigens (reviewed in Martin[19]).

The MHC is located on chromosome 6 in humans and encodes two distinct human HLA families implicated in alloreactivity. HLA class I antigens are encoded by three loci termed HLA-A, HLA-B, and HLA-C. HLA class II antigens are encoded by three loci termed HLA-DR, HLA-DP, and HLA-DQ (reviewed by Dupont and Yang [20]).

In both the related and unrelated donor transplant setting, optimal clinical results are achieved when donor and recipient are matched at both HLA class I and HLA class II. Successful allogeneic transplantation can occur, however, even with some degree of HLA mismatch. Both rejection and GVHD can occur even in cases where apparent MHC matching is achieved, suggesting that in some cases mismatch of antigens not recognizable with current serologic or molecular testing methods, or perhaps not encoded by the MHC, may have clinically relevant consequences.

Transplant Principles

Successful allogeneic stem cell transplantation depends on three principles demonstrated first in animals then in the human clinical setting. First, hematopoietic stem cells obtained from donor marrow or other sources can be infused into the venous blood system and engraft in the recipients hematopoietic microenvironment. [21] Second, the recipients immune system will tolerate engraftment of donor stem cells so that rejection does not occur. [22] Third, immune effector cells from the donor will tolerate host tissue so that fatal GVHD does not occur. [23]

Preparative Regimen

To ensure engraftment, recipients are treated with a preparative regimen usually consisting of a combination of cyclophosphamide and total body irradiation or busulfan and cyclophosphamide (discussed in Chap. 91). The use of these agents in human clinical transplantation is predicated on early animal experiments demonstrating their immunosuppressive effects in the stem cell transplant setting. [24] [25] [26] [27] In some cases, such as the hemoglobinopathies, the preparative regimen arguably creates space for donor stem cell engraftment, while in other cases, such as the leukemias, it provides an antitumor effect. In all cases, however, the preparative regimen immunosuppresses the recipient so that donor stem cells (the graft) will be tolerated.

Graft-versus-Host Disease

GVHD occurs when immune effector cells from the donor engraft and attack host tissue (discussed in Chap. 93).[28] Acute GVHD occurs in the first several months after engraftment, while a somewhat different clinical syndrome termed chronic GVHD occurs later. Chronic GVHD often appears as a sequela of acute GVHD and can be a source of chronic illness. GVHD may be exacerbated by mismatch of major or minor donor-recipient histocompatibility antigens, infection, prior host tissue damage inflicted by the underlying disease, previous therapy, or the preparative regimen. [29] [30] [31] Cyclosporine has become the backbone of in vivo GVHD prophylaxis and treatment. This compound has a specific suppressive effect on T-lymphocyte function and is often used in combination with other immunosuppressive agents such as steroids, methotrexate, and antithymocyte globulin as well as with a variety of novel immunosuppressive agents. [32] [33] [34]

Acute GVHD can also be prevented or ameliorated by ex vivo depletion of T lymphocytes (T-cell depletion) from the stem cell inoculum. Ex vivo T-cell depletion can be accomplished by negative selection of T cells with monoclonal antibodies, antibodies conjugated to toxins (immunotoxins), or other innovative approaches. Alternatively, positive selection of hematopoietic stem cells based on their physical characteristics provides an inoculum relatively depleted of T cells. [35]

Graft-versus-Tumor Effect

Early investigators postulated that effective antitumor therapy with stem cell transplantation might require not only an ablative effect of the preparatory regimen, but also an ongoing, allogeneic graft-versus-tumor or graft-versus-leukemia effect. [16] [36] The graft-versus-tumor effect plays a role in the long-term suppression of malignant clones of host origin, which

sometimes survive even the most rigorous preparative regimens (discussed in Chap. 96).

In certain conditions such as transplant therapy for chronic myelogenous leukemia (CML), the graft-versus-tumor effect is very important. Efficient prevention of GVHD with ex vivo T-cell depletion may result in eventual relapse in the majority of CML transplant recipients, presumably because donor cells necessary for the graft-versus-tumor effect are also damaged or removed by a process designed to remove GVHD effector cells. In other hematologic malignancies and solid tumors, a graft-versus-tumor effect may have varying clinical relevance. [37]

Clinical Application

The first successful use of human hematopoietic stem cell transplantation was reported in the late 1950s by E. Donnall Thomas and colleagues, who demonstrated that marrow cells from identical twin donors could reconstitute hematopoiesis after supralethal irradiation therapy for acute lymphocytic leukemia. [16] Subsequently, investigators used marrow transplants to restore immune function in children with immune deficiencies and to attempt correction of inborn errors of metabolism.

By the late 1970s Thomas and his group had ushered in the era of successful antitumor therapy with stem cell transplantation when they reported that HLA-matched sibling transplantation could be used to correct refractory cases of acute leukemia. [17] A similar story unfolded in the treatment of CML[38] and other hematologic malignancies, as well as severe aplastic anemia and other marrow failure states. [39] [40] Dramatic improvement in transplant outcome occurred when investigators realized that stem cell transplant therapy was most effective when used early in the disease course rather than as a last resort in patients with advanced or

therapy-refractory disease (discussed in Chaps. 85 and 86).[4] [6] [8]

Alternative Donors

Application of donor stem cell transplantation was broadened when investigators demonstrated that alternative donors could be used as a source of stem cells. Alternative donors include related donors mismatched at one or more HLA antigens, and HLA-matched (or one-antigen-mismatched) volunteer unrelated donors located through registries such as the National Marrow Donor Program (discussed in Chap. 89).[41] [42] [43] [44] [45] [46] Perhaps the most exciting recent development has been the successful use of placental umbilical cord blood derived either from related or unrelated donors for successful stem cell transplantation (discussed in Chap. 90).[47] [48]

AUTOLOGOUS STEM CELL TRANSPLANTATION

Transplant Principles

Autologous transplantation is most commonly used to re-establish hematopoiesis after high-dose cancer chemotherapy or radiation therapy. This approach permits the use of antitumor agents in doses much higher than can be provided in a conventional therapy setting. Autologous stem cell transplantation is most useful in circumstances where a correlation exists between increased therapy dose and tumor response, and where the dose-limiting feature of therapy is hematopoietic suppression (discussed in Chaps. 87 and 88). [49] [50]

In selected cases autologous stem cell transplantation may have advantages over allogeneic transplantation. There is no need to identify HLA-matched related or unrelated donors. Immunologic complications of allogeneic transplantation such as rejection and GVHD are avoided. The use of immunosuppressive agents for transplant preparation, GVHD prophylaxis, and GVHD treatment is unnecessary. Not surprisingly, peritransplant mortality is lower. Hospital stay and convalescence periods are shorter. Older patients tolerate the autologous stem cell transplant procedure relatively well.

Unfortunately, autologous stem cell transplantation has important drawbacks. The benign stem cell population may be reduced or damaged by previous therapy, resulting in delayed or partial engraftment. The stem cell inoculum, whether derived from marrow or blood, may be contaminated with clonogenic malignant cells capable of re-establishing tumor in the transplanted recipient. [51] [52] [53] Finally, autologous stem cell transplantation does not provide an ongoing graft-versus-tumor effect analogous to that observed after allogeneic transplantation. [37]

Clinical Application

Autologous stem cell transplantation has proven useful in a variety of circumstances. Autologous transplant therapy for selected subsets of patients with acute nonlymphoblastic leukemia in first remission as well as for patients with poor-prognosis intermediate- or high-grade lymphoma can result in long-term disease-free survival in the majority of cases.[5] [54] [55] [56] Best results are achieved when transplantation is performed early in the disease course. In distinction to allogeneic transplantation, older recipient age is not necessarily correlated with poorer outcome.

The use of autologous stem cell transplantation in the treatment of a variety of other hematologic malignancies, including CML, multiple myeloma, myelodysplastic syndromes, and low-grade lymphomas, is being assessed.[57] [58] [59] [60] Similarly, the efficacy of autologous stem cell transplantation following high-dose combination chemotherapy is being tested in solid tumors, including breast cancer, ovarian cancer, lung cancer, brain tumors, and other neoplasms. [61] [62] [63] [64] [65] [66] [67] [68] [69] [70] [71] [72] [73]

Priming and Stem Cell Mobilization

The use of priming with growth factors and, in some cases, chemotherapy prior to stem cell harvest has been a major advance in autologous transplantation (discussed in Chaps. 92 and 94). The priming process facilitates the collection by pheresis of a mobilized peripheral blood mononuclear cell population enriched for hematopoietic progenitors.[74] Chemotherapy priming may add an antitumor effect in some cases.[75] The use of progenitors mobilized by priming as well as the peritransplantation use of hematopoietic growth factors can provide engraftment of white blood cells and platelets in less than 2 weeks. The shortened time to engraftment associated with stem cell mobilization and judicious peritransplant use of hematopoietic growth factors, the aggressive prophylactic and empirical use of antimicrobial agents and transfusion products, and other advances in the field have resulted in a growing shift to outpatient-based autologous transplantation (discussed in Chap. 97).[76]

FUTURE DIRECTIONS

The future of stem cell transplantation seems assured. The development of internationally linked unrelated adult donor and umbilical cord blood registries continues to increase the likelihood that a suitable unrelated donor can be found for patients lacking a related donor. New molecular methods for testing of donor and recipient antigens clinically relevant to allogeneic transplantation will allow refinement of the donor selection process (reviewed by Petersdorf et al. [77]). Heightened understanding of the cellular and molecular events underlying GVHD will probably result in improved prophylaxis and treatment of this stubborn clinical problem.

Advances in autologous stem cell transplantation may depend on the use of this procedure as a platform for further innovation. An enriched population of benign stem cells can be

obtained by ex vivo methods such as purging of malignant cells, or by positive selection based on the physical characteristics of the benign progenitor. [12] [61] The benign progenitor population can be expanded ex vivo and perhaps transduced with a variety of genes designed to provide an antitumor effect (discussed in Chap. 95).[78] Endogenous effector cell populations can be stimulated by administration of IL-2 or other cytokines to provide post-transplant antitumor immunotherapy. [79] Finally, autologous antigen-presenting cells such as dendritic cells, or effector cells themselves such as cytotoxic T lymphocytes or natural killer cells, can be isolated, stimulated, and expanded ex vivo, then reinfused to provide additional antitumor therapy. [80] [81]

Even as the stem cell transplant field advances, a variety of innovative, non-transplant-based approaches to human marrow failure states, hematopoietic malignancies, and solid tumors are emerging. It is likely that optimal patient care will be predicated on an open-minded approach to disciplined, clinical testing and the comparison of transplant-based and non-transplant-based therapy.

Chapter 85 - Hematopoietic Stem Cell Transplantation for Nonmalignant Diseases

H. Joachim Deeg

Administration of bone marrow cells for the treatment of anemia associated with leukemia or infections was used first approximately a century ago (reviewed in Santos[1]). However, only after the development of the atomic bomb and the observations of the medical effects of radiation exposure at Hiroshima and Nagasaki did systematic research into the possibility of marrow transplantation begin. [2] Studies on total body irradiation (TBI) in animal models revealed three levels of TBI-related injury: a marrow syndrome (hematopoietic failure) at approximately 500700 cGy, an intestinal syndrome (severe enteritis) at 1,20010,000 cGy, and a cerebral syndrome (coma) at even higher doses.[1] [3] Shielding of the spleen during TBI, implantation of autologous (patients own) or syngeneic (identical twin) spleen cells, or infusion of syngeneic marrow cells after TBI rescued animals from the marrow syndrome.[1] [3]

Initially, humoral factors released by the spleen or by other hematopoietic cells were thought to be responsible for marrow recovery, a concept certainly of interest in view of the current use of hematopoietic growth factors. Subsequent studies showed, however, that hematopoietic reconstitution derived from the infused or implanted cells,[4] the most effective way being intravenous (IV) injection. By a mechanism now termed homing and mediated by a series of receptors and counter-receptors on cells and vascular endothelium, injected hematopoietic cells reached the marrow cavity and other hematopoietic organs. Studies in a rat model showed that hematopoiesis in lethally irradiated animals was restored by parabiosis with a normal animal, [5] proving in principle the presence of circulating stem cells in peripheral blood, subsequently confirmed in dogs, nonhuman primates, and other species. These observations,

TABLE 85-1 -- Nonmalignant Diseases Treated by Stem Cell Transplantation

Acquired	Congenital	
Aplastic anemia	Hematologic defects	Mucopolysaccharidoses
	Fanconis anemia	Hurlers disease

	Osteopetrosis	

particularly with parabiotic animals, are of central importance to the current clinical work on the use of mobilized peripheral blood progenitor cells (PBPC): quite likely, the irradiation treatment of the recipient animal triggered a rise in various growth factors that, by way of cross-circulation, were able to release early hematopoietic precursors from the marrow into the peripheral circulation.

Although the infusion of autologous or syngeneic cells rescued marrow-ablated animals without complication, animals given cells from a nonidentical twin (allogeneic) donor acquired secondary disease, now known as graft-versus-host disease (GVHD). [3] These observations showed convincingly that transplantation of spleen or

marrow cells comprised not merely a transfer of hematopoietic stem cells, but that such infusions also mediated immune effects. [6] [7] The development of GVHD was detrimental because it resulted in significant morbidity and mortality. Although moderate GVHD was associated with improved survival in transplanted mice with leukemia because of what has been termed a graft-versus-leukemia effect, [8] no such benefit could be expected in recipients transplanted for a nonmalignant disorder.

The first modern clinical transplantation attempts, beginning in 1957, mostly in patients with end-stage leukemia, [1] [9] [10] were discouraging: patients transplanted from a syngeneic donor did well immediately post-transplantation, but died from progressive leukemia. Patients transplanted from an allogeneic donor usually died with severe GVHD. Work by Dausset and others beginning in the late 1950s showed that, similar to earlier observations in mice, human patients differed from each other and from their donors in regard to major histocompatibility complex (MHC) antigens. [11] With the use of appropriate typing sera and cellular assays, matched individuals suitable as marrow donors could be distinguished from mismatched individuals. [12] With these insights, and driven by the pioneering work of Thomas, Good, Santos and others, hematopoietic stem cell transplantation has evolved as the treatment of choice for diseases such as severe aplastic anemia, severe combined immunodeficiency (SCID), other congenital diseases, and numerous malignant disorders.

Table 85-1 lists nonmalignant disorders that are accepted as indications for transplantation therapy. These indications are continuously under revision as nontransplantation modalities, including hematopoietic growth factors, cytokines, immunotoxins continue to evolve. Although the number of separate disease entities amenable to transplantation is considerable, most transplantations are performed to cure malignancy, and a smaller proportion are carried out for nonmalignant disorders.

RATIONALE FOR TRANSPLANTATION

Hematopoietic stem cells for transplantation can be obtained from various donors and different sources (Table 85-2). Depending on the patients underlying disease and the objectives

TABLE 85-2 -- Potential Stem Cell Donors

Stem Cell Source		Histocompatibility Barrier	
		Minor	**Major**
Autologous	Patients are their own donors		
Syngeneic	Monozygotic (identical) twin		
Allogeneic	HLA genotypically identical donor	+	
	HLA phenotypically identical donor		
	Related	+	/+
	Unrelated	+++	/+
	HLA-nonidentical donor		
	Related	+	++
	Unrelated	+++	++
Xenogeneic	Different species donor	+++	+++

HLA, human leukocyte antigen.

of therapy, however, only some of these possibilities may be useful and available for a given patient. [13] Myelosuppression is often the dose-limiting toxicity of chemoradiation therapy used for treatment of malignancies. In those patients, infusion of hematopoietic stem cells capable of hematopoietic reconstitution serves as a rescue procedure. A second use for transplanted hematopoietic stem cells is as replacement therapy in patients with congenital or acquired marrow failure or immunodeficiencies. Along these lines, hematopoietic stem cells or more mature precursors may also be important as vehicles for gene therapy [14] to replace defective or missing enzymes (e.g., adenosine deaminase; glucocerebrosidase). Finally, it was noted that patients with aplastic anemia or other disorders who also had an autoimmune disease (e.g., rheumatoid arthritis), when transplanted with normal allogeneic marrow, were not only cured of their hematologic disease but had sustained improvement or resolution of their autoimmune disorder (reviewed in Marmont [15] [16]). Results obtained in animal models of spontaneously occurring autoimmune disorders are compelling.[17] [18] These findings suggest, therefore, that marrow transplantation can also be used to correct autoimmune diseases.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

DONOR SELECTION

The choice of a source of hematopoietic stem cells depends on several factors, the most important of which is the patients disease. Although autologous stem cells obtained from marrow or peripheral blood should be available for every patient except, possibly, patients with severe aplastic anemia, the use of autologous cells would not be useful for genetically determined disorders. A haploidentical donor (matched at one half of the HLA loci, such as a parent, sibling, or child) would be available for most patients, but significant human leukocyte antigen (HLA) differences still present major problems for transplantation because of GVHD and the risk of rejection. Thus, the preferred donor is a genotypically HLA-identical sibling.

Approximately 2530% of patients who have siblings can be expected to have an HLA genotypically identical donor. In addition, approximately 1% of phenotypically matched donors among closely related family members can be identified, and a rare patient will have an identical twin donor. These statisticsthat is, the lack of a matched related donor in 7075% of patients who could benefit from transplantationhave stimulated the development of transplantation in two directions: (1) the establishment of large data banks of volunteer unrelated allogeneic donors, and (2) the development of techniques to purge autologous marrow or PBSCs.

Thanks to the efforts of the National Marrow Donor Program (NMDP) in the United States as well as other donor registries in the United States and worldwide, more than 2 million volunteer donors have been typed for HLA-A and -B antigens, and more than 500,000 are also typed for HLA-DR (MHC class II) antigens. [19] Similar registries have been established in the United Kingdom, France, Germany, Japan, and other countries. If an unrelated donor search is initiated, computer inquiries quickly generate the probability of identifying such a donor. In North America, the probability of finding an HLA-A, -B, -DR match during the initial search is approximately 5055%; an additional 1215% of patients find a match when available HLA-A and -B matched donors are typed for DR, and 20% of patients have a one-HLA-locus-incompatible unrelated donor available. [20]

As discussed previously, autologous or syngeneic hematopoietic stem cells would not be an option for the treatment of genetically determined diseases because the same defects as those to be corrected would also be present in the transplanted cells. An autologous stem cell approach may be possible, however, with acquired disorders. Granulocyte colony-stimulating factor (G-CSF) mobilized PBSCs have been harvested and transplanted even in patients with severe aplastic anemia. A benefit is expected only if residual normal stem cells are present in the patient and no stromal defect exists in the marrow. The possibility also has to be considered that the treatment given in preparation for transplantation might have an effect similar to that of immunosuppressive therapy in patients with aplastic anemia, as discussed elsewhere. In patients with paroxysmal nocturnal hemoglobinuria (PNH), phenotypically normal (CD50+, CD59+) hematopoietic precursors have been demonstrated, and the possibility of using those for transplantation has been suggested. [21] The experience in patients with autoimmune disorders is too limited to permit comment. However, experiments in rodents (e.g., with experimental allergic encephalomyelitis) suggest that transplantation of autologous stem cells depleted of T lymphocytes can restore neurologic function by eliminating V-8positive autoreactive T cells. [22] This is a rapidly developing area of research, and new insights are likely to be gained in the near future.

PREPARATIVE REGIMENS FOR TRANSPLANTATION

Rationale for Conditioning

In preparation for hematopoietic stem cell transplantation, it is necessary for several reasons to condition the patient:

1. To eradicate the patients disease or at least reduce the number of abnormal or defective cells below detectable levels; this applies to allogeneic, syngeneic and autologous donors.
2. To suppress the patients immunity, natural or acquired through allosensitization, to prevent rejection of donor cells; this applies to allogeneic but not to autologous cells or to syngeneic cells, which should not encounter a histocompatibility barrier. However, immunosuppression is needed in preparation for some syngeneic transplants in patients with aplastic anemia, apparently to eliminate autoimmune reactivity that may interfere with sustained hematopoietic reconstitution.
3. To create space so that donor cells can establish themselves in the recipient marrow, an issue that has been discussed predominantly for diseases where the patients marrow may be very cellular, as seen for example in patients with thalassemia.[23] This concept of space creation, however, is somewhat controversial, and recent research in animal models has shown that engraftment is possible without recipient conditioning, albeit with extremely high cell doses. [24]

Exceptions to the requirement of conditioning exist in children with SCID in whom HLA-identical and occasionally even HLA-haploidentical marrow engrafts without conditioning. This is apparently related to the nature of the underlying disease, namely, a T-cell defect that does not allow for rejection of transplanted donor cells, and in which partial donor engraftment may completely correct the genetic defect. [25] [26]

Modalities of Conditioning

Therapeutic modalities used to prepare patients for transplantation have been reviewed extensively elsewhere. [13] [27] In principle, they comprise the following.

Irradiation

Irradiation is given either in the form of TBI, total lymphoid irradiation, or modifications thereof. Exposure rate, fractionation schedule, and total dose are important parameters. The optimum regimen has probably not been defined yet and may

differ for different diseases. Many investigators attempt to avoid the use of irradiation in patients who are transplanted for nonmalignant disorders, at least in patients transplanted from an HLA-identical related donor. Others have used 300 cGy TBI or 400600 cGy of thoracoabdominal irradiation, usually delivered at exposure rates of 725 cGy/min and combined with cyclophosphamide. Low-dose TBI is also frequently given to patients with lysosomal storage diseases. In patients transplanted from an HLA-nonidentical or unrelated donor, TBI is often used at higher total doses, such as 11 × 120 or 6 × 200 cGy given over 34 days. For some indications, usually malignant disorders, bone-seeking (e.g., holmium) or other isotopes (e.g., ^{131} I) conjugated to monoclonal antibodies directed at lymphoid or myeloid antigens (e.g., CD20, CD45) are used.

Chemotherapy

Chemotherapy, particularly cyclophosphamide (120200 mg/kg over 24 days), although quite toxic, is included in most regimens. In patients with aplastic anemia and Fanconis anemia (FA), cyclophosphamide has been used successfully as a single agent for transplant conditioning. For other indications, such as for thalassemia, sickle cell anemia, and some storage disorders, cyclophosphamide is frequently combined with busulfan (±antithymocyte globulin [ATG]).

Biologics

Biologic reagents such as ATG (a polyclonal antibody preparation) or monoclonal antibodies directed at T-cell antigens or adhesion molecules are used to suppress recipient immunity. These reagents are in general noncytotoxic and associated with little acute clinical toxicity.

Cellular Therapy

Viable donor buffy coat cells have been used to facilitate engraftment in patients with severe aplastic anemia. The observation that broad T-lymphocyte depletion of donor marrow (see later) increased the probability of graft failure has led to protocols of selective T-cell addback to ensure engraftment. It has recently been suggested that a combination of low-dose (well tolerated) TBI and repeated donor cell infusion may be effective in achieving sustained engraftment.

Other procedures include plasmapheresis of the patient to remove isoagglutinins directed at the donors ABO blood group or, conversely, removal of plasma from the donor marrow to remove isoagglutinins directed at recipient cells. Alternatively, the donor red blood cells with which recipient antibodies may react can be removed, thus minimizing the risk of transfusion reactions. [13]

TRANSPLANTATION PROCEDURE

Sources of Hematopoietic Stem Cells

Hematopoiesis evolves through three embryologic stages: mesodermal (yolk sac), hepatosplenic, and medullary. At the time of birth, the bone marrow has usually become the only site of hematopoiesis. In contrast to other species such as mice, in which splenic hematopoiesis persists throughout life, in adult human beings extramedullary hematopoiesis occurs only under pathologic conditions (e.g., chronic myelogenous leukemia, myelofibrosis). Accordingly, hematopoietic stem cells can be obtained from fetal (but not adult) livers, whereas an adult donor usually can donate stem cells only in the form of bone marrow or from peripheral blood wherein some stem cells circulate (Table 85-3). As discussed previously, the presence of circulating stem cells in blood was previously proven in animal models by

TABLE 85-3 -- Sources of Stem Cells

Bone marrow
Peripheral blood
Cord blood
Fetal liver

the fact that transplantations with cells exclusively obtained from peripheral blood resulted in complete lymphohematopoietic reconstitution. This finding was not necessarily surprising (but reassuring nevertheless) because bone marrow cells are usually transplanted through transfusion into a vein, from which they cross the pulmonary vascular bed and into bone arteries to home to the marrow cavity.

Bone Marrow

For the marrow harvest, the donor receives anesthesia and, under sterile conditions, multiple small-volume aspirates of marrow are obtained from both posterior iliac crests.[28] Additional potential aspiration sites are the anterior iliac crests, the sternum, and, in children, the tibia head. Every aspirate consists of a mixture of marrow cells and peripheral blood (owing to perfusion of the marrow space and damage inflicted by needle placement and aspiration). It appears that the larger the volume aspirated, the greater the relative contribution of blood, including T lymphocytes. Therefore, with a single aspirate, no more than 35 ml should be removed. Approximately 1015 ml/kg donor weight are collected. The marrow is then passed through filters, either manually or in closed systems, to break up cell aggregates and remove bone particles. If no ABO incompatibility exists and if the marrow is not to be subjected to any in vitro purging procedure, the resulting cell suspension is infused intravenously, usually through an indwelling IV catheter (e.g., Hickman line). If the plan is to process the aspirated marrow before infusion, peripheral blood contamination need not be a concern. Treatment of marrow with monoclonal antibodies and complement, magnetic beads, or other techniquesthat is, those aimed at removing marrow T lymphocytesalso removes T lymphocytes contributed by blood. The marrow cell yield declines somewhat with donor age (Table 85-4).

Peripheral Blood Stem Cells

Hematopoietic stem cells are present at low concentrations outside the bone marrow.[29] One such alternative source, peripheral blood, contains dramatically increased frequencies of early hematopoietic precursors during the recovery phase after cytotoxic therapy.[30] The administration of recombinant hematopoietic

TABLE 85-4 -- Marrow Cell Yield by Donor Age[a]

[c]Nucleated marrow cells × 10^8 /kg donor weight (median).
[d]Nucleated marrow cells × 10^7 /mL marrow (median).

growth factors, such as G-CSF or c-kit ligand (Steel factor), has a similar effect, and the peak of stem cell yield at 56 days after initiation of treatment with growth factor is more predictable than with chemotherapy. It would also be difficult to justify administration of chemotherapy to normal donors, whereas growth factors appear to be tolerated with very few side effects. A single leukapheresis on a normal donor may be sufficient to harvest the numbers of cells required for a transplant; the goal is usually at least 5 × 10^6 CD34+ cells/kg of recipient weight.[31] As discussed elsewhere, the transplantation of mobilized PBPCs rather than normal marrow cells is associated with a very rapid hematopoietic recovery in the recipient.

Umbilical Cord Blood

Umbilical cord blood, representing a segment of the peripheral circulation of the fetus, is another rich and easily accessible source of hematopoietic stem cells. [32] [33] [34] Because there is also evidence that cord blood cells are less immunocompetent than adult cells, cord blood cells might carry a lower risk of inducing GVHD than adult marrow cells. Although the concentration of stem cells is high (frequency of long-term culture-initiating cells approximately 1:100, compared with 1:500 in

peripheral blood), the small volume usually available (100150 mL) may limit the use of these cells for transplantation.

Fetal Liver

For several months during human fetal development, the liver is physiologically part of the hematopoietic tissues. It is during this time, from the second to the seventh monthand ideally before the onset of lymphopoiesisthat fetal liver cells, a mixture of hepatocytes and hematopoietic stem cells, can be used for transplantation. Fetal liver cells have been studied extensively in experimental models and have been shown to reconstitute both hematopoietic and immunologic systems in children with congenital immunodeficiencies.[35]

Fetal liver cells can be obtained only from aborted fetuses, and are not routinely available. Because of ethical concerns and the development of alternative approaches (HLA-nonidentical donor, T-cell depletion), fetal liver cells have recently been used only by a few investigators and for very selected indications.

PERITRANSPLANTATION AND POST-TRANSPLANTATION CARE

Hematopoietic stem cell transplantation is intensive therapy. Complications are related to the underlying disease, therapy given before transplantation, the preparative regimen (regimen-related toxicity), the interactions of donor cells with recipient tissue, and prophylactic and therapeutic measures administered after transplantation.

Many of the patients coming to transplantation have received nontransplantation therapy for extended periods of time. For example, although patients with aplastic anemia who have an HLA-identical related donor and are no older than 45 years of age usually receive a transplant as first-line therapy, all others are initially treated with immunosuppressive therapy, transfusions, and hematopoietic growth factors. Only when these attempts fail and an alternative donor is identified will a transplant be considered. As a result, almost all these patients become allosensitized and transfusion refractory. Because of prolonged neutropenia and immunosuppression, many are infected, often with fungal organisms, including *Candida*, *Aspergillus*, and *Mucor* species. Only hematopoietic reconstitution can eradicate these organisms. However, it is necessary to give aggressive antibiotic therapy before conditioning is initiated. Similarly, patients with FA or thalassemia may have received multiple transfusions. In addition to allosensitization, iron overload develops. In patients with thalassemia, the presence of hepatic fibrosis is a significant risk factor for transplantation outcome. Pretransplantation infections are also common in patients with severe combined immunodeficiency, dyskeratosis congenita, and other immunodeficiencies.

With currently used conditioning regimens, all patients experience severe pancytopenia before hematopoietic reconstitution from the transplanted (donor-derived) stem cells occurs. Pancytopenia may last 24 weeks with marrow cells, but possibly only 1012 days with the use of mobilized PBPCs. With cord blood cells, recovery may take 56 weeks. The administration of growth factors such as G-CSF, granulocyte/macrophage colony-stimulating factor (GM-CSF), or c-kit ligand early after transplantation accelerates granulocyte recovery after marrow infusion. It is not clear whether post-transplantation growth factors further accelerate recovery after transplantation with mobilized PBPCs; there is a minimum time interval required for cell replication and differentiation. [31] [36] Virtually all marrow recipients need transfusion support with platelets and red blood cells. Erythropoietin administration post-transplantation has been shown to speed reticulocyte recovery and moderately reduce the red blood cell transfusion requirements in some patients. [37] Conceivably, the recently cloned thrombopoietin [38] will be able to enhance platelet recovery.

Infection prophylaxis consists mostly of systemic broad-spectrum antibiotics. [39] Granulocyte transfusions are warranted only in granulocytopenic patients in whom bacterial or fungal septicemia is not controlled by antibiotics. Treatment of patients in laminar air flow rooms and with gastrointestinal decontamination may reduce the frequency of infections and the duration of febrile episodes. [40] Because of an 8090% risk of reactivation of herpes simplex virus, prophylaxis with acyclovir is given for the first month post-transplantation. Some protocols also include the infusion of IV immunoglobulins on a weekly basis. Trimethoprim-sulfamethoxazole is given primarily for *Pneumocystis carinii* prophylaxis, but also reduces the incidence of other infections, in particular in patients with chronic GVHD. Fluconazole may be administered as antifungal, and ganciclovir as anticytomegalovirus prophylaxis.

Because of mucositis and gastroenteritis, most patients are unable to eat in the early post-transplantation period and require parenteral nutrition and hydration.

After allogeneic transplantation, all patients receive some form of GVHD prophylaxis. [41] [42] Modalities involve in vivo administration of immunosuppressive agents such as methotrexate (MTX), cyclosporine (CSP), glucocorticoids, or FK506, either alone or in combination. [43] The most widely used regimen is a combination of MTX, 10 mg/m^2 IV on day 1, 3, and 6 (or 15 mg/m^2 on day 1, and 10 mg/m^2 on days 3, 6 and 11), and CSP, given daily starting on day 1, usually at doses of 35 mg/kg/day IV in the early postgrafting period and subsequently at 12 mg/kg/day orally, at gradually tapering doses for 6 months. [44] [45] Alternatively, T lymphocytes, responsible for triggering GVHD, are depleted from the donor marrow in vitro before infusion (see later).

CLINICAL RESULTS

Acquired Disorders

Aplastic Anemia

The original description of aplastic anemia as *myelophthisis* very aptly indicates the fact that not only is erythropoiesis defective, but that the marrow fails in all lineages. Nevertheless, the differential diagnosis may at times be difficult, and the distinction from a myelodysplastic syndrome (MDS; refractory anemia) may be impossible.[46] However, patients in whom a cytogenetic abnormality is identified should be treated as MDS because transplantation regimens used for aplastic anemia, when

applied to these patients, are unsuccessful and are followed by early relapse and evolution into leukemia. [47]

TREATMENT DECISIONS FOR PATIENTS WITH SEVERE APLASTIC ANEMIA

Severe aplastic anemia has served as an important model for marrow transplantation. [48] Mechanisms involved in severe marrow failure include stem cell damage, immune-mediated inhibition of hematopoiesis, functional inadequacy of the marrow microenvironment, and others. [49] Some patients respond to immunosuppressive therapy with ATG, CSP, glucocorticoids, or combinations thereof. [50] However, even in patients who respond to this treatment, hematopoiesis usually is *not* normal, and both responding and nonresponding patients are at risk for development of a clonal hematopoietic disorder (i.e., PNH, MDS, or myeloid leukemia). In various series, an incidence of 1545% has been observed. [51] [52] [53]

Transplantation from a Matched Related Donor

The only definitive treatment of aplastic anemia is allogeneic stem cell transplantation. In patients with an HLA-identical, healthy sibling donor, marrow transplantation is the treatment of choice. Opinions about the upper age limit of patients differ, although 45 years is accepted by most transplantation centers.

In early trials, 3060% of previously transfused (allosensitized) patients conditioned with cyclophosphamide failed to achieve sustained engraftment, and only 4050% became long-term survivors. Conversely, among untransfused patients, only 5% failed to engraft, and 75% survived with normal hematopoiesis (Fig. 85-1 (Figure Not Available)). With the addition of viable donor leukocyte (buffy coat) infusions to the marrow or the use of TBI (e.g., 300 cGy) or total lymphoid irradiation (400750 cGy) given in combination with cyclophosphamide, the probability of graft failure was reduced to 515% even in transfused patients, and 7080% of patients survived with sustained engraftment.[48] [54] One disadvantage of the addition of donor buffy coat cells (which contain immunocompetent peripheral blood T lymphocytes) was an increase in the incidence of chronic GVHD to as high as 50% even in children. [48] The use of irradiation, in particular limited-field irradiation, has been associated with an increased risk of post-transplantation (i.e., apparently treatment-related) malignancies. [55] Furthermore, radiation exposure is associated with impaired growth and development in children and infertility in adults. [56] [57] Therefore, alternative immunosuppressive approaches of comparable efficacy but fewer side effects were sought.

Studies in patients who had rejected a first marrow graft

Figure 85-1 (Figure Not Available) Effect of transfusion status on survival in patients with aplastic anemia. Patients were transplanted between 1978 and 1991 using cyclophosphamide-based conditioning. The transfused group of patients (n = 115) had an increased incidence of graft rejection relative to untransfused patients (n = 53), presumably due to sensitization to the donors non-HLA antigens resulting from prior blood transfusions. *(Modified from Doney et al.,[52] with permission.)*

after preparation with cyclophosphamide had shown that a combination of ATG and cyclophosphamide was successful in most in achieving sustained engraftment of a second marrow inoculum.[58] Based on these results, this regimen (cyclophosphamide 4 × 50 mg/kg plus ATG 3 × 30 mg/kg) was introduced as conditioning for the initial transplant. Recent results show that this approach allows for engraftment in 95% of patients and survival in excess of 90% [59] (Fig. 85-2). Furthermore, for reasons that are not completely understood, the probability of chronic GVHD, still a major problem after transplantation (Fig. 85-3), was reduced.[59] Results of these and other representative trials are summarized in Table 85-5 .

Transplants from Alternative Donors

Only 2530% of patients have an HLA-matched donor in the family. As discussed, first-line treatment for the remaining 70% of patients is usually immunosuppressive therapy, and transplantation is considered if that approach fails. The reason to delay transplantation is that results with HLA-nonidentical

Figure 85-2 Survival of 39 patients with aplastic anemia given an HLA-identical marrow transplant and postgrafting graft-versus-host disease prophylaxis with methotrexate/cyclosporine after conditioning with cyclophosphamide plus antithymocyte globulin. Figure 85-3 Prevalence of chronic graft-versus-host disease (GVHD) in 78 patients with aplastic anemia transplanted at the Fred Hutchinson Cancer Research Center and given HLA-identical marrow transplants after conditioning with cyclophosphamide only (Cy) or Cy combined with antithymocyte globulin (Cy + ATG), followed by GVHD prophylaxis with methotrexate/cyclosporine. *(Courtesy of R. Storb, Fred Hutchinson Cancer Research Center, Seattle, WA.)*

marrow donors are inferior.[60] [61] [62] An analysis of results at the Fred Hutchinson Cancer Research Center shows that 3045% of patients who receive a transplant from an HLA-nonidentical donor and are conditioned without the use of TBI fail to achieve engraftment, and only 1535% become long-term survivors. Acute GVHD occurs in 7080% of patients and chronic GVHD develops in 50%. With the use of TBI (e.g., 6 × 200 cGy) in addition to cyclophosphamide for conditioning, engraftment is usually achieved, and 50% of patients have long-term survival (Table 85-6).

The establishment of registries of volunteer, normal, unrelated donors (e.g., NMDP; Anthony Nolan Foundation; Stefan Morsch Foundation) typed for HLA has provided the option of stem cell transplantation to additional patients. Some data are summarized in Table 85-6 . Overall results of unrelated donor transplants are inferior to those obtainable with HLA-identical sibling donors but comparable with early results achieved with sibling donors. Retrospective analyses show a probability of survival of 3035%. Data from a recent study using low-dose TBI, ATG, and cyclophosphamide suggest that survival in the range of 5055% can be achieved with transplantation from an unrelated donor matched for HLA-A, -B, and -DRB1. [63]

Syngeneic Transplants

Of interest with regard to disease mechanisms are the results in patients with aplastic anemia transplanted from a syngeneic (monozygotic twin) donor. In this donorrecipient combination, no histocompatibility barriers exist and the infusion of normal stem cells should lead to prompt hematopoietic reconstitution. However, this approach is not uniformly successful, and approximately 50% of patients require an immunosuppressive conditioning regimen. These observations support the notion that in some patients aplastic anemia is immunologically mediated, as was suggested by in vitro studies. [64]

If aplastic anemia is a stem cell disorder, autologous stem cell transplantation is in principle not an option. However, if residual normal stem cells are present, it is possible that treatment with G-CSF to mobilize stem cells, with conditioning treatment given before the reinfusion, modifies the patients immune status and the marrow microenvironment such that the

reinfused cells encounter growth conditions that allow for hematopoietic repopulation. [65]

Other Acquired Disorders

Pure Red Cell Aplasia

Some patients who present with red cell aplasia of undetermined etiology and who do not respond to treatment with glucocorticoids or other nontransplantation regimens aimed at the underlying disorder are referred for marrow transplantation. These patients are transplanted with conditioning regimens as used for aplastic anemia. No large series has been reported. Available data suggest that problems with sustained engraftment may be encountered. [66]

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria is an acquired clonal disorder of hematopoiesis due to somatic mutations in the X-linked *PIG-A* gene. This gene is responsible for a protein that affects the synthesis of glycosylphosphatidyl-inositol, an anchor for numerous cell surface antigens. Cells arising from the mutated clone gain a survival advantage. Patients present either with marrow aplasia or with hemolytic or thrombotic complications while maintaining a cellular marrow. As discussed previously, PNH develops in 2030% of patients with aplastic anemia treated with immunosuppressive therapy. [51] Some patients show evolution into acute leukemia.

Allogeneic stem cell transplantation is effective therapy for patients with either aplastic or cellular marrows. Approximately 80% of patients survive in the long term after conditioning with cyclophosphamide, given alone or combined with busulfan, TBI, procarbazine, or ATG. Transplantation corrects hematopoiesis and resolves thrombotic complications.[67] Observations in patients infused with marrow cells from a syngeneic donor without receiving conditioning confirm the assumption that the PNH clone has a survival advantage and requires cytotoxic therapy for elimination. [68]

Investigators of the International Bone Marrow Transplant Registry recently summarized information on 41 patients with PNH transplanted in 19781992 (unpublished report). Two transplants were from monozygotic twin donors, 35 from an HLA genotypically or phenotypically identical family member, and 4 from an HLA-matched unrelated donor. The time interval from diagnosis to transplantation was 2240 (median, 34) months, and patients were 1047 (median, 27) years of age at the time of transplantation. Conditioning regimens included cyclophosphamide alone or combined with TBI, limited-field irradiation, or busulfan. One identical twin recipient received no conditioning. Two-year survival among HLA-identical sibling transplants was 47%. Among five recipients of marrow from alternative donors (one parent; four unrelated), one is surviving. Both twin recipients are surviving, one after failing the initial marrow infusion and receiving conditioning followed by a second marrow infusion. The most common causes for treatment failure were lack of sustained engraftment and infections.

One group of investigators reported that normal CD34+, CD38 hematopoietic precursors can be obtained from the marrow of patients with PNH and separated from CD34+ cells that do not express CD59 or decay accelerating factor. [21] This would suggest the possibility of performing transplantations with normal autologous cells in patients with PNH.

Acquired Immunodeficiency Syndrome

Because of the decline in CD4+ lymphocytes and the severe immune defects associated with acquired immunodeficiency syndrome (AIDS), it was thought that transplantation of normal hematopoietic cells, particularly when combined with antiviral therapy, might allow for immunologic reconstitution and control human immunodeficiency virus (HIV). Holland and colleagues reported the case of an HIV-1infected patient in whom an undifferentiated lymphoma had developed. [69] The patient was conditioned with TBI and cyclophosphamide followed by allogeneic marrow and high-dose zidovidine. The patient engrafted, and marrow (and other) cultures became HIV-1 negative, and antibodies to HIV disappeared. The patient died of lymphoma relapse on day 47. At autopsy, all tissues were negative for HIV-1 by polymerase chain reaction, suggesting that HIV-1 had been suppressed to nondetectable levels. Additional reports on transplantation for AIDS appeared subsequently, but no long-term success was reported. [70] [71] Vilmer and colleagues reported on three patients in whom AIDS had developed at 856 months after marrow transplantation for aplastic anemia or leukemia. [72] These patients were given six sequential lymphocyte infusions from the original marrow donor combined with interferon (IFN)- and later IFN-. All three patients showed hematologic and immunologic improvement, although CD4 levels did not normalize.

More recently, Ho et al. proposed to transplant stem cells transfected with retroviral vectors containing the gene for a hairpin ribozyme capable of cleaving HIV-1 RNA. In vitro studies showed, indeed, that transfected cells were resistant to infection by HIV. [73] Ongoing studies are exploring the possibility of combining a hematopoietic stem cell transplant with cytotoxic T cells specific for HIV-1. [74]

Autoimmune Disorders

Anecdotal observations in patients who received a stem cell transplant for various indications, but who also had an autoimmune disorder (e.g., rheumatoid arthritis), show that with a successful transplantation, the autoimmune disorder usually also improved. [75] Marmont recently summarized results on nine patients with rheumatoid arthritis, of whom four survive in unmaintained remission from arthritis after allogeneic transplants; one patient relapsed after two years. One patient with CREST (calcinosis, Raynauds phenomenon, esophageal motility disorder, scleroderma, and telangiectasis) had a transient response after autologous transplantation, whereas one patient with myasthenia gravis achieved a complete remission. [16] Other groups have carried out stem cell transplantations for multiple sclerosis [5] [76] and scleroderma (P. McSweeney et al., Fred Hutchinson Cancer Research Center, Seattle, unpublished data), and early results suggest improvement of symptoms. Data on more than 40 patients with various disorders transplanted under the auspices of the European Bone Marrow Transplant Group were presented at a recent meeting

(A. Gratwohl, Kantos Spital, Basel, Switzerland, personal communication). Early results are encouraging. In addition, several animal models (e.g., of immune-mediated diabetes or experimental allergic encephalomyelitis) show that allogeneic transplants, and in some instances even T-cell depleted autologous transplants, result in complete remission of the immune disorder.

Based on these data, additional clinical protocols have been activated to test the toxicity and efficacy of stem cell transplantation in patients with systemic lupus erythematosus, systemic sclerosis, multiple sclerosis, and other indications.

Langerhans Cell Histiocytosis

Langerhans cell histiocytosis, formerly called histiocytosis X, is an uncommon disorder of childhood. Children whose disease progresses to the disseminated form have a poor prognosis. Because the originator cell of the disease is thought to be marrow derived, marrow-ablative therapy and transplantation should provide effective therapy. Both autologous and allogeneic approaches have been taken. [77] [78] [79] [80] [81] The numbers of patients reported are small. However, after conditioning with chemotherapy (e.g., etoposide and cyclophosphamide) and TBI, engraftment is

achieved, with approximately half of the patients surviving free of disease. [78] [82]

Congenital Disorders

Several congenital disorders such as Wiskott-Aldrich syndrome or dyskeratosis congenita are characterized by both hematologic and immunologic defects. They are discussed under sections on either hematologic or immunologic disorders, although this assignment may appear arbitrary.

Hematologic Defects

Fanconis Anemia

Fanconis anemia is a syndrome of chromosome fragility that is associated with various malformations, hematopoietic failure, and the development of MDS, leukemia, and nonhematopoietic malignancies. The disease is heterogeneous; at least five complementation groups have been recognized, and one of the genes (*FAC*) has been cloned. [83] The only definitive treatment available to correct the hematopoietic abnormalities is hematopoietic stem cell transplantation. Results are summarized in Table 85-7 . Because of toxicity associated with commonly used conditioning regimens [84] and the documented susceptibility of FA cells to alkylating agents, [85] many conditioning regimens have used limited-field irradiation and rather low doses of cyclophosphamide (approximately 10% of the dose used to condition patients with aplastic anemia). With this approach, survival in patients transplanted from an HLA-identical sibling has increased to 8090%. [86] [87] [88] The success rate with HLA-nonidentical and unrelated transplantation is approximately 30%. [89] Although failure of engraftment with sibling transplants has been rare, nonengraftment is observed in 2030% of patients transplanted from an alternative donor. [88] [89]

Patients with FA who are transplanted when they contract MDS or leukemia have a probability of survival in remission of approximately 25%.

Nonhematologic complications are not prevented by transplantation. In fact, a recent analysis of transplantation results in patients with marrow failure identified FA as the major risk factor for the development of solid tumors after transplantation. [90]

Thalassemia

Anecdotal reports in the early 1980s showed that, in principle, thalassemia was curable by marrow transplantation. [91] However, not all patients were treated successfully; outcome appeared to depend on disease duration and prior therapy. Based on those findings, Lucarelli and colleagues subsequently analyzed their results and developed a classification system for patients with thalassemia. [23] Considering hepatomegaly, portal fibrosis, and inadequacy of iron chelation therapy as criteria, these investigators categorized patients as class 1 if none of these factors was present, class 2 if one or two, and class 3 if three factors were present. [23] [92] In 1993, they reported results in 89 class 1 patients transplanted in Pesaro from 1982 to 1992. [93] The most frequently used conditioning regimen employed busulfan plus cyclophosphamide and CSP as GVHD prophylaxis. The probabilities of survival, rejection-free survival, nonrejection causes of death, and rejection were 92%, 85%, 6%, and 8%, respectively. Outcome in class 2 and class 3 patients, many of whom were older, was inferior. These results have been confirmed in several hundred patients transplanted in Pesaro and reported subsequently: [94] overall survival and disease-free survival rates were 82% and 75%, respectively. Results from a recent review are summarized in Figure 85-4 . An analysis of results in 215 patients in class 3 transplanted from an HLA-identical sibling donor showed age and conditioning regimen to be critical factors for outcome. [95] Cyclophosphamide doses of <200 mg/kg were associated with 5-year survival probabilities of 0.74 and 0.63 for patients younger than 17 years of age and older patients, respectively. Outcome was inferior at 200 mg/kg. In addition, and similar to earlier observations in patients with aplastic anemia, pretransplantation transfusion with more than 100 units of red blood cells decreased the 5-year survival probability from 0.53 to 0.24. Clearly, therefore, transplantation early in the disease course (i.e., in young and not heavily transfused patients) yields optimum results.

The U.S. experience with transplants for thalassemia was summarized by Walters and colleagues. [96] Thirty patients were identified who had been transplanted in 19811992. Patients were 0.514 years of age; 27 received marrow from an HLA-identical sibling, and 3 from an alternative donor. Most patients were conditioned with busulfan, 1224 mg/kg in combination with cyclophosphamide, 120240 mg/kg; some received TBI, 720 cGy plus cyclophosphamide, 120 mg/kg. Among HLA-identical transplant recipients followed from 0.2 to >10 years, the event-free survival rate was 54%; the actuarial rate of recurrence of thalassemia was 24%. It is not entirely clear why survival was lower than seen in Pesaro; however, it is important to note that American patients were not classified according to the Pesaro classification. Similar results have been reported from Thailand. [97]

Sickle Cell Disease

In 1994, Johnson and colleagues summarized results in five patients with sickle cell disease who had been transplanted in the United States. [98] Three of the patients had experienced cerebrovascular accidents or severe vaso-occlusive crises. Two patients were transplanted for other indications (acute leukemia and Morquios disease, respectively). Conditioning consisted of cyclophosphamide plus busulfan or TBI. All patients acquired the donors hemoglobin pattern. With a median follow-up of approximately 1.5 years, all patients were surviving and apparently had benefited from the transplantation.

Results of a multicenter study involving 22 patients <16 years of age were presented by Walters et al. [99] The indications for transplantation included a history of stroke (n = 12), recurrent acute chest syndrome (n = 5), or recurrent pain crisis (n = 5). Patients were conditioned with busulfan plus cyclophosphamide plus ATG. Twenty patients survived with a follow-up of 1051 (median, 24) months, and 16 of these have donor engraftment, with mixed donorhost chimerism being present in 1. Four patients rejected their graft and had recurrence of sickle cell disease (n = 3) or acquired marrow aplasia (n = 1). The two deaths were related to intracranial hemorrhage and GVHD, respectively. Probability of survival (event-free survival) at 4 years was 91% (73%). Lung function and central nervous system vasculopathy stabilized.

Vermylen and Cornu reported on 42 patients transplanted in Belgium. [100] [101] Engraftment was sustained in 36 patients, and all became symptom free. Five patients rejected their graft. Of these, two were retransplanted successfully, and three had autologous recovery. One patient died with GVHD, and 41 are alive 175 months after transplantation, 6 with chronic GVHD. Similar results have been reported from France. [102]

At least one study indicates that even patients who fail to engraft and experience autologous recovery show improvement of their disease because of increased levels of fetal hemoglobin. [103]

Walters and colleagues also carried out an analysis to determine why many patients are not referred to transplantation. Among 4,848 patients <16 years of age, 315 (6.5%) were found to meet protocol entry criteria. Among these, 128 (41%) had HLA typing performed, and 44 (i.e., 14% of those meeting entry criteria) had an HLA-identical sibling. Reasons for not proceeding with transplantation included a lack of a suitable donor

TABLE 85-7 -- Fanconis Anemia: Results of Marrow Transplantation from Related and Unrelated Donors

[a]Four patients received cord blood from an HLA-identical newborn sibling.
[b]The Cy dose was increased in patients who showed evidence of transforming into myelodysplastic syndrome.

Figure 85-4 Results in patients with thalassemia. The Kaplan-Meier estimates of survival to December 1997 for 649 patients with thalassemia younger than 17 years who received HLA-identical transplants using regimens containing busulfan 14 mg/kg and cyclophosphamide 200 mg/kg through 1996. The categorization into risk classes is described in Lucarelli et al. [214] *(Courtesy of G. Lucarelli Hospital of Pesaro, Pesaro, Italy, and R.A. Clift, Fred Hutchinson Cancer Research Center, Seattle, WA.)*

(24%), lack of financial or psychological support (10.5%), and parental or physician refusal (14%); history of medical noncompliance and others accounted for the remainder.

Blackfan-Diamond Anemia

Blackfan-Diamond or congenital hypoplastic anemia is a rare disorder of erythropoiesis presenting with normochromic, macrocytic anemia. Malformations such as triphalangeal thumb or cleft palate may be associated. The disease occurs sporadically or in an autosomally inherited form. Standard treatment is glucocorticoids. Other agents used for immunosuppressive treatment of aplastic anemia such as ATG and CSP have little effect. [104] If a suitable donor is identified, those patients usually receive a marrow transplant.[105] Although no large series have been presented, case reports show that transplantation is successful in correcting the hematopoietic defect.[106] [107] [108]

Dyskeratosis Congenita

Patients with dyskeratosis congenita are referred for transplantation because of pancytopenia and marrow failure. Results on small groups of patients have been reported from several centers. Langston and colleagues described eight patients, six of whom were transplanted from an HLA-identical sibling after conditioning with cyclophosphamide, and two from an unrelated donor after conditioning with TBI (6 × 200 cGy) plus cyclophosphamide. [109] Two patients died early and could not be evaluated for engraftment, and six patients achieved sustained engraftment. Three patients died from infections, one patient from GVHD, and three patients from pulmonary fibrosis at 70 days, 8 years, and 20 years, respectively. One surviving patient was recently diagnosed with colon carcinoma. Observations by other teams are similar.[110] [111] [112] [113] [114] Thus, as observed in patients with FA, marrow transplantation effectively corrects hematopoietic defects but does not affect other disease manifestations. Of particular note is the late development of pulmonary fibrosis. [109] [114]

Familial Erythrophagocytic Lymphohistiocytosis

Familial erythrophagocytic lymphohistiocytosis is a rare, nonmalignant disorder associated with pancytopenia and hemophagocytosis. Some patients are treated successfully with immunosuppression.[115] [116] Some patients without response have been treated successfully by allogeneic marrow transplantation. [117]

Chediak-Higashi Syndrome

Chediak-Higashi syndrome in its accelerated phase has some similarity to Langerhans cell histiocytosis and familial erythrophagocytic lymphohistiocytosis (see earlier). Although the disease responds to treatment with etoposide, remissions are usually short. Preliminary results suggest that at least half of these patients are cured by marrow transplantation if applied early in the course. [118]

For all other diagnoses listed in Table 85-1 , very few or single cases treated with marrow transplantation have been reported, [119] and no general recommendations

can be made at present.

Immune Defects

The treatment of immune defects with transplantation and nontransplantation modalities is described in detail in textbooks of clinical immunology and pediatric hematology/oncology. Only some diagnoses and principles are discussed in the following sections.

SCID

Marrow transplantation is the treatment of choice for SCID. [25] With HLA genotypically identical transplants, approximately 90% of children survive, usually with donor T-cell engraftment. B cells, monocytes, as well as red blood cells usually remain of host origin. Even HLA-haploidentical marrow grafts (from a parent), depleted of T cells to prevent GVHD, have been successful in 5060% of patients. Although engraftment is achieved in many patients without prior conditioning, an immunosuppressive regimen is required in patients with SCID and associated adenosine deaminase deficiency. [25] [35]

Filipovich recently summarized results of an international review of transplants from unrelated donors that included 100 children treated in the United States and 7 in Europe for 12 different immunodeficiencies. [120] Among these, 27 had SCID or one of its variants (22% X-linked SCID; 3% SCID with adenosine deaminase deficiency; 22% with Omenns syndrome; 53% with other variants, including ZAP-70 deficiency), the distribution being rather different from that in children transplanted from an HLA-identical sibling (35% X-linked; 32% lymphogenic). Patients were 6 weeks to 3.7 years (median, 9 months) of age at the time of transplantation. The survival rate at 3 years was 61%. Very encouraging was the observation that the incidence of acute GVHD was not different from that with HLA-identical sibling transplants. As illustrated in Figure 85-5 , outcome was inferior to that observed with HLA-identical sibling transplants

Figure 85-5 Probability of survival after marrow transplantation for severe combined immunodeficiency dependent on marrow stem cell source and marrow manipulation. Data on unrelated donor transplants were provided by the National Marrow Donor Program; all other data were collected by the International Bone Marrow Transplant Registry. BMT, bone marrow transplantation. *(Reproduced with permission from Filipovich.[120])*

but superior to that achieved with unmodified or T-cell-depleted haploidentical marrow from related donors. A major complication after T-cell-depleted haploidentical transplantation was the development of a post-transplantation lymphoproliferative disorder, which occurred in 32% of these patients. [121] The diagnoses of Omenns syndrome and pulmonary infection were associated with poor outcome. [122] [123]

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome is a rare disease, and transplantation experience at any given institution is limited. A recent report presented data on 26 patients transplanted at a single center. [124] Among 10 patients given unmodified marrow from an HLA-genotypically identical donor, 8 are surviving at 1.516.5 years with normal hematologic and immunologic parameters. Sixteen patients were given an HLA partially incompatible transplant (T-cell depleted in 15) from a related donor after conditioning with busulfan and cyclophosphamide; 12 patients engrafted, and 6 patients became long-term survivors. The addition of monoclonal antibody (MAB) against LFA-1 and CD2 appeared to enhance engraftment. Complications included delayed immunoreconstitution, infections, and the development of Epstein-Barr virus-associated lymphoproliferative disorders. These authors suggested that the transplantation indication should be liberal in patients with an HLA-identical donor, but should be restricted to patients with severe disease if an HLA-identical donor is not available.

In the international survey cited previously, 30 patients with Wiskott-Aldrich syndrome were identified who had received a transplant from an unrelated donor. Patients were 0.519.7 (median, 2.1) years of age at transplantation. Conditioning usually included busulfan, cyclophosphamide, and ATG. The actuarial survival rate at 3 years was 67%. As shown in Figure 85-6 , this was inferior to results with matched siblings (92%) but better than outcome with haploidentical related transplants (45%). The incidence of acute GVHD grades IIIV was 50%. A major prognostic factor was age, with 20 of 23 boys transplanted at younger than 5 years of age surviving, compared with 1 of 8 older than 5 years. The age effect appeared to correlate with disease progression.

With various other defects, T-cell deficiencies, and phagocytic disorders, post-transplantation survival rates range from 20 to 80%, and, as expected, the outcomes tend to be better with HLA-identical than with nonidentical donors. Chief causes of morbidity and mortality are GVHD, severe infections in the early post-transplantation period, and Epstein-Barr virus-associated lymphoproliferative disorders.

Figure 85-6 Probability of survival after transplantation for Wiskott-Aldrich syndrome dependent on stem cell donor. Sources of data as in Figure 85-5 . *(Reproduced with permission from Filipovich.[120])*

Osteopetrosis

Osteopetrosis is a disease of abnormal bone formation and hematopoietic failure. The genetic defect involves osteoclast function and may occur in a dominant (usually milder) and a recessive form (usually more severe). In 1980, Coccia et al. reported a successful allogeneic marrow transplant in a patient with osteopetrosis. [125] The patient showed improved hematopoiesis, bone restructuring, hearing, vision, and development. Gerritsen et al. summarized results of transplantation for autosomal recessive osteopetrosis in 69 patients treated in 19761994. [126] Four patients infused with marrow without prior conditioning experienced no lasting benefit. Sixty-five patients were prepared with myeloablative therapy. Among those transplanted from an HLA-identical sibling donor, the 5-year survival rate was 79%; among patients transplanted from an alternative (related or unrelated) donor, the 5-year survival rate was 38%. Osteoclast function developed in all patients with engraftment. Particularly in children 2 years of age or older, recovery tended to be associated with hypercalcemia. Among 15 patients with visual impairment at the time of successful transplantation, two showed subsequent improvement. Similar results have been obtained at other centers. [127]

In patients transplanted from HLA-haploidentical donors, graft failure has been a problem. [126] [128] The use of MAB against CD18 as part of the conditioning regimen has improved results. [128] [129]

Thus, even though success is not achieved uniformly, marrow transplantation after marrow-ablative conditioning remains the treatment of choice for patients with osteopetrosis.

Storage Diseases

Although transplantation success has in general been excellent with immunologic and hematopoietic disorders, results in patients with mucopolysaccharidoses, mucolipidoses, and other lysosomal storage diseases have been less consistent. [130] Dramatic improvements have been observed with adrenoleukodystrophy, globoid cell leukodystrophy, and Hurlers disease. Results with Hunters disease, however, have not been encouraging, and Sanfilippos disease may be a contraindication. [131] For all diagnoses in these disease categories, transplantation should be carried out only at specialized centers.

Hurlers Disease

Hurlers disease is a disease caused by -L-iduronidase deficiency and associated with progressive cerebral atrophy and declining intellectual function. Because the defective enzyme is expressed in hematopoietic cells, transfer of cells from a normal donor may provide the enzyme level required to maintain intellectual function. In 1993, Whitley et al. reported results in 11 consecutive patients who had been followed for 3.88.9 years after transplantation. [132] Nine patients (82%) were surviving, seven with complete donor engraftment, and two as mixed chimeras. Iduronidase levels reflected the donor genotype and the level of engraftment. Urinary glycosaminoglycan excretion had declined to normal levels. All surviving children achieved normal or near-normal intracranial pressure within 1.5 years of

engraftment, and there was no progression of cerebral atrophy. Among nine survivors, four children with a developmental quotient >80 pretransplantation maintained scores above that level post-transplantation. In the five survivors with lower pretransplantation scores, significant cognitive defects have developed post-transplantation.

In 1996, Peters et al. summarized results in 40 children transplanted from volunteer unrelated donors. [133] Patients were 0.93.2 (median, 1.7) years of age at transplantation and were conditioned with high-dose chemotherapy alone or combined with irradiation. Twenty-five patients achieved engraftment, and

50% were alive at 2 years, two-thirds with sustained allografts, and one-third with autologous hematopoiesis. The marrow cell dose was correlated with engraftment and survival. T-cell depletion and the type of conditioning did not appear to affect engraftment. Baseline and post-transplantation neuropsychological data were available in 11 surviving patients with engraftment. Among six children with pretransplantation mental developmental indices >70 who have been followed long enough for evaluation, none has shown a decline in age-equivalent scores. Among children with a baseline score <70, post-transplantation scores have continued to decline in five, whereas they have remained stable or improved in three.

These data suggest that in children with Hurlers disease, early marrow transplantations may stabilize or improve mental development, although this conclusion has been challenged.[134] Despite these concerns and despite considerable transplant-related problems, transplantation remains the only effective treatment option for these patients. Gene transfer experiments show encouraging in vitro results, but additional work is required before clinical application can be considered. [135]

Hunters Syndrome

Hunters syndrome results from a defect in the iduronate-2-sulfatase gene on the X chromosome. The disease typically progresses to severe mental retardation and death in adolescence. In an attempt to correct the enzyme deficiency, allogeneic marrow transplantation has been carried out in some of these patients. At least one patient, transplanted at the age of 2.7 years, has been reported who showed a regression of hepatosplenomegaly and a stabilization of his neuropsychological profile at 2 years after transplantation.[136] Other reports, however, show disease progression after transplantation, [137] and the current assessment is that patients with Hunters syndrome in general do not benefit from transplantation. [131]

Gauchers Disease

Gauchers disease is another lysosomal storage disease related to a defect of glucocerebrosidase (cerebroside--glucosidase). Gauchers disease may present in various forms at various stages in life.[138] Bone marrow transplantation can completely correct the defect.[139] [140] Because this disease can be traced to a single enzyme (gene) defect, it has become an attractive target for gene therapy. Attempts to date have not been successful, however, basically because of the very low transfection efficiency in transplanted cells. [141]

The recognition that the success rate with transplantation is in general better the younger the patient, has led to attempts at intrauterine transplantation. If a firm diagnosis can be established by amniocentesis, this approach may indeed yield superior outcomes. Very promising results have been reported in patients with SCID or Wiskott-Aldrich syndrome.[142] [143]

Others

Patients with adrenoleukodystrophy, metachromatic leukodystrophy, and globoid cell leukodystrophy and others may also benefit from allogeneic stem cell transplantation.[144] [145] [146] [147]

An interesting by-product of transplantation for storage disorders has been the documentation of donor-derived microglial cells in the recipients central nervous system, and, based on these findings, the speculation that a GVH reaction may occur in the brain. [148]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

POST-TRANSPLANTATION COMPLICATIONS AND THERAPEUTIC INTERVENTIONS

Complications associated with current regimens used for hematopoietic stem cell transplantation are frequent and depend on diagnosis, pretransplantation therapy, conditioning regimen, type of transplant, patient age, patient immune status, and other factors. By definition, these problems are iatrogenic and, as such, they should be amenable to treatment modifications that will result in therapeutic gains.

GVHD

Graft-versus-host disease is a major complication of allogeneic marrow transplantation, [41] [42] and occurs in a proportion of patients despite the use of GVHD prophylactic regimens. With a combination of CSP (given daily) and MTX (given on days 1, 3, and 6 or 1, 3, 6, and 11), acute GVHD is observed in 1050% of patients given an HLA-identical transplant and in 5090% of patients transplanted from an alternative donor. The corresponding figures for chronic GVHD are 2050% and 3060%, respectively. Preceding acute GVHD is the single most important risk factor for the development of chronic GVHD. [149] [150] Acute GVHD may occur within 56 days of transplantation, particularly among HLA-nonidentical transplant recipients, or as late as 5060 days post-transplantation, but usually develops within a month of transplantation. The main target organs of GVHD are the immune system, skin, liver, and intestinal tract, although other organs may be involved. [151] Only skin, liver, and intestinal tract are currently considered in GVHD grading systems. [152] The basic requirements for the development of GVHD as summarized by Billingham are (1) transfer of immunocompetent cells; (2) histoincompatibility of donor and recipient (for major or minor antigens), and (3) inability of the recipient to destroy the donor cells.[6] These conditions are met after allogeneic marrow or PBPC transplantation, unless donor T lymphocytes are removed from the transplanted cells (T-cell depletion) before infusion. This approach, however, carries the risk of engraftment failure (see later).

The result of interactions between donor and host cells is an activation and clonal expansion of donor T cells (afferent phase of the graft-versus-host reaction/GVHD). Activation leads to a complex pattern of cytokine release, recruitment of secondary effector cells, and destruction of recipient target cells and tissues (efferent phase).[42] These interactions occur not only in recipients who differ from the donor for MHC class I or II antigens but even between HLA (MHC)-matched people, because of differences in non-HLA or minor antigens encoded by genes outside of but presented by the MHC. GVHD-like reactions have also been observed after syngeneic or autologous transplantation, triggered apparently by inappropriate reactions to self-antigens. [153] [154]

The immunopathophysiology underlying GVHD is complex. Detailed discussions have been presented elsewhere. [41] [42] [155] As described previously, transplant recipients are usually prepared for transplantation with cytotoxic therapy. [156] This results in tissue damage and release of cytokines, including IFN-, tumor necrosis factor (TNF)-, and interleukin (IL)-1, [157] which, among other effects, lead to enhanced expression of MHC antigens and critical adhesion molecules, such as LFA-1 and CD44.[42] The observation that the incidence of GVHD is in general somewhat lower in patients with aplastic anemia (and other nonmalignant disorders) is consistent with such a notion, insofar as conditioning regimens for these diseases are less intense than those for malignant disorders. [158]

In allogeneic transplantation, mature donor T cells recognize alloantigens in the host and become activated. This recognition is facilitated by the milieu generated by the initial tissue damage and cytokine-induced increases in host cell surface receptors. Both CD4+ cells, which recognize MHC class II antigens, and CD8+ cells, which react primarily with MHC class I antigens and their associated peptides (in the case of GVHD, minor antigen peptides) can be involved. Activated donor T cells then proliferate and secrete IL-2. Activated T cells also express CD40 ligand, which provides a signal for CD40 on dendritic cells, thereby enhancing their maturation and function as

antigen-presenting cells. Furthermore, activated T cells express Fas-ligand, and are involved in Fas-mediated apoptotic cell death, a hallmark of GVHD. If the principal T-cell response is a T-helper $_1$ or inflammatory response (IL-2 and IFN- release), these cytokines activate additional donor (and residual host) mononuclear cells and macrophages to secrete IL-1 or TNF-. The result is further release of cytokines that amplify local tissue injury, at least in part through active nitrogen intermediates. If the principal T-cell response is a T-helper $_2$ response in which IL-4 and IL-10 predominate, the overall result, at least in murine models, is a chronic or stimulatory form of GVHD with increased IgE synthesis and exaggerated lymphoproliferation. [159] [160] [161] [162]

The chronic GVHD syndrome has prominent features of autoreactivity, [41] [155] and T lymphocytes with abnormal cytokine profiles (secreting, e.g., IL-4 and IFN-) may be present.[163] Experimental evidence suggests that thymic damage, inflicted by the conditioning regimen and acute GVHD, results in a failure of intrathymic selection and an escape of autoreactive cells to the periphery. [164] Such a mechanism also readily explains the occurrence of syngeneic or autologous GVHD.

Methods of GVHD prophylaxis are summarized in Table 85-8 . Combination regimens of MTX and CSP with or without the addition of IV immunoglobulins offer the most effective currently available prophylaxis. [45] [165] The value of added prednisone is controversial. [165] [166] Ongoing trials with FK506 are encouraging and are expected to yield results similar to those obtained with CSP. [167] In vivo administration of MAB (murine or the humanized form) against the IL-2 receptor or MAB neutralizing TNF- have been of only transient benefit. [168] [169] [170] [171] Soluble IL-1 receptor or IL-1 receptor antagonist has yielded encouraging preliminary results in prevention and treatment of GVHD.[159] [172] Although these agents are antigen nonspecific and may not interfere with the initial steps of allogeneic activation, they may be able to prevent the manifestation of the graft-versus-host reaction (i.e., GVHD), and possibly interfere with other disease processes, such as septicemia or capillary leak syndrome, associated with diffuse tissue damage.

T-cell depletion of donor marrow by 24 log, clearly effective in reducing the incidence of GVHD, has been complicated by an increased probability of graft failure (1030% with HLA-identical, 3060% with HLA-nonidentical transplants). [173] [174] [175] Because failure of sustained engraftment is a potential problem in patients with aplastic anemia even with unmanipulated marrow, T-cell depletion has been applied only very cautiously to this patient group. However, promising results have been reported in patients transplanted with marrow from alternative donors, T-cell depleted with MAB T10B9 and complement (Table 85-6).[61] Of note is the observation in several studies that the incidence of GVHD was lowest in patients who showed mixed

chimerism the coexistence, at least transiently, of donor and host lymphohematopoietic cells postgrafting. [176] The mechanism is not clear. However, recent data from studies aimed at inducing mixed chimerism by design have confirmed the clinical observations. [177]

Graft-versus-host disease is the most important risk factor for long-term survival, and in patients with nonmalignant disorders is not associated with any beneficial effect. Therefore, if GVHD develops, it requires aggressive therapy, not only for the acute but for the chronic form. Current therapy for acute GVHD includes glucocorticoids, CSP, monoclonal antibodies, humanized monoclonal antibodies (e.g., anti-Tac), immunotoxins, and cytokine blockade. [43]

Graft Failure

The problem of graft failure has been introduced previously. The depletion of T cells from the donor marrow removes an important element of GVHD that also counteracts residual host cells, thus rendering T-cell-depleted marrow more susceptible to rejection. The probability of rejection is further exacerbated by recipient sensitization to HLA antigens, predominantly through blood transfusions given pretransplantation. [178] [179] These problems have usually been countered by intensification of the conditioning regimen, which in turn has resulted in increased transplant-related toxicity. There is evidence that certain rat anti-human MABs (e.g., Campath I G) or an antibody directed at LFA-1 given as part of the conditioning regimen, or ATG or MAB/immunotoxin conjugates administered postgrafting, may reduce the graft failure rate without increasing toxicity. [180] [181]

In some patients, graft failure is not due to frank immunologic rejection but to a failure to thrive of transplanted cells. This may be the case in approximately 5% of patients with aplastic anemia. Recombinant growth factors (e.g., G-CSF, GM-CSF, IL-3) given prophylactically or therapeutically may be beneficial in some patients,[182] including those with marrow microenvironmental defects or with cytomegalovirus infection. Other factors, such as c-kit ligand (Steel factor) or flt-3 ligand, are being tested.[183] [184]

Infections

The principles of infection prophylaxis have been described previously. [39] One additional modality is the use of IV immunoglobulin (IVIG). Patients who receive prophylactic IVIG after transplantation experience fewer infections while IVIG is administered. However, after discontinuation of IVIG administration, these patients appear to have a higher rate of infection than patients not given IVIG. [185] Apparently, the passive immunity provided by IVIG suppresses and delays recovery of the patients active immune response.

The use of IVIG is also of interest in the context of GVHD. Although IVIG was administered originally with the aim of infection prophylaxis, results suggested that patients so treated had a reduced incidence of GVHD. This was confirmed in a prospective, randomized study. [186] The effect was most prominent in HLA-identical transplant recipients older than 20 years of age. The mechanism is not well understood, but may involve Fc receptor-mediated effects on inflammatory cytokine production (e.g., secretion of IL-1ra is enhanced by macrophages when their Fc receptors are cross-linked), the presence of neutralizing antibodies to cytokines, the presence of anti-idiotype antibodies in the IVIG preparation, or a combination of these processes.

To what extent immunity toward herpes virus (in donor, recipient, or both) affects GVHD has remained controversial. [187] Studies in Europe have suggested that increased viral burden in the recipient contributes to GVHD, and the presence of processed

viral antigens, which are known to elicit vigorous T-cell responses under certain conditions, could act as additional minor histocompatibility antigens. [188]

Delayed Complications

The longest surviving patients have now been followed for up to 25 or 30 years post-transplantation, and most are leading normal lives; some, however, have experienced late complications (Table 85-9). Complications are related either to pretransplantation events, the conditioning regimen (irradiation), or transplant-associated events (chronic GVHD, immunodeficiency). [189] [190] Potentially life-threatening problems include infections and pulmonary dysfunction, particularly bronchiolitis obliterans, which is usually associated with chronic GVHD. [191] Autoimmune disorders may be due to adoptive transfer (from a donor who is affected), may be related to GVHD, or may be idiopathic. [192] Conversely, as discussed earlier, patients with aplastic anemia or leukemia who also had an autoimmune disorder noted improvement or complete resolution of their autoimmune disease after transplantation. These observations provide a further illustration of the effect of

transplantation on immunity in general and autoimmunity in particular, an insight that is now being applied to the treatment of autoimmune disorders. [193] [194]

The use of fractionated rather than single-dose TBI as part of the conditioning regimen has reduced the frequency and severity of transplant-related complications such as interstitial pneumonitis, cataracts, and impairment of growth and development. [56] It is desirable to avoid irradiation completely, at least in very young children, where growth and development of the skeleton, as well as the central nervous system, occur at an exponential rate.

Systematic psychosocial studies investigating the effects of transplantation on personal development, family dynamics, and partner relationships are only now being pursued. Active rehabilitation is necessary in many instances. [195] [196]

SUMMARY

Hematopoietic stem cell transplantation has been developed into curative therapy for many nonmalignant disorders. Results are best with HLA-identical sibling (or syngeneic) transplants, whereas outcome may be inferior with transplants from HLA-nonidentical related or from unrelated donors. A major problem is GVHD, especially with its chronic manifestations, which are also responsible for systemic or organ-specific late complications. Because, in contrast to malignant diseases, there is no potential benefit of GVHD in the form of a graft-versus-tumor effect, every effort must be directed at preventing GVHD. To what extent the application of gene transfer to transplantation for nonmalignant disorders will affect long-term outcome remains to be seen.

Chapter 86 - Results of Allogeneic Stem Cell Transplantation for Malignant Disorders

Mary M. Horowitz

The first successful allogeneic hematopoietic stem cell transplantations (allogeneic stem cell transplants or allotransplants) were done in 1968, using bone marrow from human leukocyte antigen (HLA)-identical sibling donors, in three children with congenital immune deficiencies. [1] [2] [3] [4] In the 1970s, most transplantations were done for nonmalignant disorders. However, in the mid-1970s, Thomas and colleagues reported long-term leukemia-free survival (LFS) after HLA-identical sibling transplantation in some patients with refractory acute leukemia. [5] [6] Better outcome was subsequently demonstrated in patients transplanted in first or second remission.[7] [8] [9] [10] Durable cytogenetic remissions and long-term LFS after identical twin and allogeneic transplants for chronic myeloid leukemia (CML) were reported in the late 1970s and early 1980s. [11] [12] [13] Use of allogeneic stem cell transplants (SCT) to treat leukemia increased dramatically in the 1980s. By 1985, approximately 75% of transplantations were performed for therapy for leukemia, with approximately equal numbers for CML, acute myeloid leukemia (AML), and acute lymphoblastic leukemia (ALL); over 90% received stem cells from HLA-identical sibling donors. Allogeneic transplantation is now increasingly applied in other hematologic and nonhematologic cancers. An estimated 15,00020,000 allogeneic SCTs were done in 1997, based on data reported to the International Bone Marrow Transplant Registry (IBMTR). The most common indications are shown in Figure 86-1 . These are consistent with data reported for Europe by the European Blood and Marrow Transplant Group (EBMTG).[14] Seventy-five percent of allogeneic SCTs are performed or therapy for leukemia or preleukemia: 25% for CML, 25% AML, 15% for ALL, 7% for myelodysplastic syndromes (MDS), and 3% for other leukemias. Twelve percent are for other cancers, including non-Hodgkin lymphoma (NHL; 7%), multiple myeloma (4%), and Hodgkin disease (1%). The remainder are for aplastic anemia, immune deficiencies, and other nonmalignant disorders. Use of allogeneic SCTs for cancer treatment is usually restricted to young patients. The median age of patients receiving transplants for malignancies in 1997 was 33 years; only 6% were older than 50 years.

GRAFT-VERSUS-LEUKEMIA EFFECTS

Allogeneic SCT involves administration of high (myeloablative) doses of chemotherapy with or without radiation followed by infusion of hematopoietic stem cells from a healthy donor. Stem cells may be collected from bone marrow or from blood.[15] [16] [17] [18] The purpose of high-dose therapy (conditioning) is twofold: to eradicate malignant cells and to eliminate host immune cells capable of rejecting donor stem cells. The ability to restore hematopoiesis with donor stem cells allow administration of substantially higher doses of cytotoxic therapy than is otherwise possible. Dose-response effects of various anticancer agents can thus be exploited (see Chap. 87).

Donor cells also play an important antitumor role. This was first suggested more than 30 years ago by Barnes et al. [19] They studied leukemic mice treated with high-dose total-body irradiation (TBI) and compared those receiving syngeneic (identical

Figure 86-1 Indications for allogeneic blood and marrow transplantation, worldwide, in 1997. CML, chronic myeloid leukemia; AML, acute myeloid leukemia; MDS, myelodysplastic syndromes; ALL, acute lymphoblastic leukemia; NHL, non-Hodgkin lymphoma; HD, Hodgkin disease; MM, multiple myeloma.

twin) and allogeneic bone marrow infusions. The mice receiving syngeneic marrow died quickly of leukemia. Those receiving allogeneic cells survived longer but eventually acquired fatal graft-versus-host disease (GVHD). Importantly, they had no evidence of leukemia at death. Mathé and colleagues [20] proposed the term adoptive immunotherapy for the antitumor effect of allogeneic cells. Antitumor effects could be specific (i.e., after sensitization of the donor [21] or the donors cells[22] to antigens present on malignant cells) or nonspecific (i.e., associated with GVHD, an immune reaction of donor lymphocytes against normal and malignant host cells presumably triggered by differences in major or minor histocompatibility antigens [23] [24] [25]). The term graft-versus-leukemia (GVL) was coined by Bortin and coworkers[26] [27] to indicate the adoptive immunotherapeutic effect of transplanted allogeneic hematopoietic cells against leukemia cells. In some animal models, the GVL effect could be distinguished from GVHD, whereas in others, the two were inseparable. [26] [27] [28] [29] [30] [31] Clinical evidence for the importance of GVL in eradicating leukemia includes (1) lower incidence of leukemia relapse in allograft recipients with acute or chronic GVHD than in those without GVHD; [23] [24] [25] [32] [33] [34] [35] [36] [37] (2) higher relapse rates after identical twin versus allogeneic stem cell transplantations; [25] [38] [39] (3) high relapse rates after T-cell-depleted transplants; [25] [40] [41] [42] [43] [44] and (4) durable cytogenetic and molecular remissions induced after post-transplantation relapse by infusion of donor leukocytes without other antileukemia chemotherapy.[45] [46] [47] [48] [49] [50] [51]

Clinical evidence for graft-mediated antitumor effects is strongest for leukemia, but is also supported by data reported in NHL, Hodgkin disease, and multiple myeloma.[52] [53] [54] [55] [56] [57] Investigators at Johns Hopkins report lower relapse rates in patients in whom GVHD developed than in those in whom GVHD did not develop after allotransplantations for lymphoma. [52] Complete remissions can be effected by donor lymphocyte infusions in patients relapsing after allogeneic SCTs for lymphoma and multiple myeloma.[50] [51] [55] [56] [57] Some data suggest lower relapse rates with allogeneic than autologous SCTs for lymphoma and multiple myeloma. However, in the latter setting, relapse from reinfused malignant cells in autografts cannot be excluded. [53] [58]

PROGNOSTIC FACTORS FOR TRANSPLANTATION OUTCOME

Although allogeneic SCT has efficacy in several cancers, the procedure carries a substantial risk of morbidity and mortality. Transplant-related mortality may result from toxicity of pretransplantation conditioning to lung, liver, and other organs, infection or bleeding related to cytopenias, GVHD, and infection related to delayed immune reconstitution, especially in the setting of GVHD or its treatment. In addition, many patients have recurrence of their primary disease despite intensive conditioning and GVL. Causes of death after allogeneic transplantation for malignancies are shown in Table 86-1 . The prognosis of transplant recipients is influenced by several factors associated with risk of transplant-related mortality or cancer recurrence. Some of these are disease specific and discussed in the following section on Results in Specific Malignancies. A few generalizations are possible. First, transplant-related mortality is lower with HLA-identical sibling transplants than with alternative related or unrelated donor transplants because of less graft failure and less GVHD. [59] [60] [61] [62] [63] [64] [65] [66] [67] Among alternative donor transplants, those from more closely matched donors tend to have lower risks of GVHD and transplant-related mortality. [61] [62] [63] [66] [67] Second, outcome is better when transplantation is done early in the course of a malignancy. Transplantations done for advanced disease are associated with higher risks of both relapse and transplant-related mortality. High transplant-related mortality in this setting probably reflects poorer clinical status and more extensive prior treatment of patients transplanted for advanced disease. This does not mean, necessarily, that transplantation should always be done early. Some patients with newly diagnosed cancers, such as children with standard-risk ALL, have an excellent prognosis with nontransplantation therapy. Appropriate timing of transplantation requires consideration of likely outcomes with transplantation and nontransplantation therapies. However, even when not used as first-line therapy, transplantations should not be inordinately delayed, because patients with refractory disease or severe complications from extensive prior therapy are unlikely to benefit. The possibility and appropriate timing of transplantation should be considered early in planning management strategies for patients with diseases potentially treatable by allografting. This includes determining the availability of suitable related or unrelated donors. [68] Third, factors affecting the risk of transplant-related mortality influence the outcome of transplantation for all malignancies. Transplant-related mortality is lower, and consequently survival is higher, in patients who are young, cytomegalovirus negative, and have good performance scores and no active infection. Finally, in most but not all settings, factors associated with increased likelihood of relapse or progression after conventional therapy also predict increased risk of post-transplantation relapse or progression. Importantly, patients whose disease does not respond to conventional therapy are significantly less likely to have durable remissions after transplantation than those with responsive disease.

RESULTS IN SPECIFIC MALIGNANCIES

Chronic Myeloid Leukemia

The incidence of CML is 12/100,000 population; the median age at onset is >60 years. [69] Approximately 35% of patients are <55 years of age at diagnosis. With nontransplantation treatment, complete remissions occur in a minority of patients, and

TABLE 86-1 -- Causes of Death After Allogeneic Stem Cell Transplantations Done in 19901996 and Reported to the International Bone Marrow Transplant Registry

Indication for Transplantation	No. Transplanted	No. of Deaths	Primary Cause of Death					
			Primary Disease	GVHD	IPn	Infection	Organ Toxicity	Other
CML	5,503	1,664	14%	25%	9%	22%	13%	17%
AML	5,290	1,811	37%	13%	5%	18%	12%	15%

few, if any patients are cured. Reported median survivals range from 3 to >8 years. [70] [71] [72] [73] [74] Eighty to 90% of patients die of causes related to CML. Allogeneic stem cell transplantation using a related or unrelated donor can cure a substantial proportion of patients with CML. [12] [13] [33] [40] [41] [42] [66] [75] [76] [77] [78] [79] Follow-up of survivors transplanted >20 years ago confirms the durability of posttransplantation morphologic and cytogenetic remissions.

A study of 10 countries in Europe, North America, Australia, and New Zealand, covering the years 19891991, suggested that approximately 3040% of people with CML younger than 55 years of age receive allografts. [80] This proportion likely increased in subsequent years with more widespread use of transplants from unrelated donors. According to data reported to the IBMTR, there are approximately 3,500 allogeneic SCTs for CML yearly. Seventy to 75% of these are from related and the rest from unrelated donors. Eight-five percent of HLA-identical sibling transplantations are done in the first chronic phase, 15% in the second chronic or accelerated phase, and 5% in the blast phase. Corresponding figures for unrelated donor transplants are 70% in chronic phase, 5% in accelerated or second chronic phase, and 25% in blast phase, reflecting time needed for donor identification and work-up and reluctance to risk the higher transplant-related mortality of an unrelated donor transplantation early in the course of CML. The median interval from diagnosis to transplantation is 9 months for HLA-identical sibling transplantations and 21 months for unrelated donor transplantations. The median age of transplant recipients is 36 years; 10% are <20 years of age and 10% are >50 years of age.

The most common conditioning regimen used before transplantation for CML is high-dose busulfan (416 mg/kg) and cyclophosphamide (120200 mg/kg), accounting for approximately 55% of CML transplants reported to the IBMTR in 1997. Studies comparing busulfan and cyclophosphamide to TBI and cyclophosphamide in CML suggest similar relapse and transplant-related mortality with the two approaches. [81] [82] The former is in general simpler and less expensive to administer. A randomized trial addressing the question of whether intensifying pretransplantation conditioning reduces relapse and increases survival after allografts for CML found fewer relapses but more transplant-related mortality with 15.75 versus 12 Gy TBI; LFS was similar. [83] Transplantations for CML using unrelated donor transplants are more likely to include TBI in the conditioning regimen, as are transplantations using T-cell-depleted bone marrow. Post-transplantation cyclosporine and methotrexate is the most frequent GVHD prophylaxis regimen, accounting for approximately 70% of transplantations for CML. [84] [85] [86]

The high-dose therapy given for pretransplantation conditioning likely cures some patients with CML, accounting for long-term LFS of 3050% of patients receiving identical twin transplants. [38] [39] However, there is strong evidence for the importance of GVL effects in preventing CML relapse after transplantation. Patients with GVHD, particularly chronic GVHD, after HLA-identical sibling transplantation for CML, have significantly lower risks of relapse than those without GVHD. [24] [25] Recipients of identical twin transplants for CML in whom GVHD does not develop also have significantly higher risks of post-transplantation relapse than recipients of allogeneic transplants. [25] [39] Development of clinically evident GVHD is apparently not necessary for a GVL effect in CML, because patients receiving allogeneic grafts in whom acute or chronic GVHD does not develop have lower relapse rates than those receiving identical twin transplants. [25] [39] GVL effects of allografts in CML are substantially reduced by removing T lymphocytes from the donor bone marrow, an effective strategy for reducing GVHD that was introduced in the 1980s. [40] [41] [42] [44] [87] Relapse rates after T-cell-depleted HLA-identical sibling transplantation are similar to rates after identical twin transplantation. This is not fully explained by a lower incidence of GVHD because relapse rates are high in T-cell-depleted transplant recipients in whom GVHD

Figure 86-2 Actuarial probabilities of relapse after HLA-identical sibling transplantation for chronic myeloid leukemia.

develops. [25] The high relapse rate after T-cell-depleted transplantation for CML is one reason there has not been widespread adoption of this strategy, although it is very effective in preventing GVHD. Approximately 5% of HLA-identical sibling transplantations and approximately 10% of unrelated donor transplantations for CML use T-cell-depleted bone marrow. Some data suggest that GVL effects may be preserved despite T-cell depletion in unrelated donor transplantation. [88] Techniques suggested to reduce relapse risk after T-cell-depleted transplants are intensification of the conditioning regimen and selective depletion of T-cell subsets. [44] [89] [90] [91] [92] [93] [94] [95] An effective GVL response can be established by infusing donor lymphocytes in many patients who relapse after an HLA-identical sibling transplantation for CML. The subsequent hematologic, cytogenetic, and molecular remissions appear durable. [45] [46] [47] [48] [50] [51] Some strategies being explored for minimizing transplant-related mortality (especially GVHD-related mortality) while maintaining antileukemia efficacy of allotransplants for CML include T-cell depleting donor bone marrow with subsequent infusion of donor lymphocytes, either at the time of a post-transplantation relapse or prophylactically after toxicity from the conditioning regimen has resolved. [90]

The strongest determinants of outcome after allogeneic SCTs for CML are donor type and phase of disease at time of transplantation. Among 4,114 recipients of HLA-identical sibling transplantations done between 1990 and 1996, reported to the IBMTR, 3-year actuarial probabilities of relapse (95% confidence intervals) are 17% (1519%) for 3,359 patients transplanted in the first chronic phase, 42% (3747%) for 583 in the accelerated phase, and 44% (3553%) for 172 in the blast phase (Fig. 86-2). Three-year probabilities of LFS are 58% (5660%), 34% (3038%) and 29% (2236%), respectively (Fig. 86-3). Patients relapsing

Figure 86-3 Actuarial probabilities of leukemia-free survival (LFS) after HLA-identical sibling transplantation for chronic myeloid leukemia.

Figure 86-4 Actuarial probabilities of survival after HLA-identical sibling transplantation for chronic myeloid leukemia.

after an HLA-identical sibling transplantation for CML often survive for long periods with conventional treatment. [96] Many achieve durable remissions with infusion of donor lymphocytes (see earlier). Consequently, 3-year survival rates after transplantation are somewhat higher than LFS rates: 67% (6569%) in the chronic phase, 41% (3745%) in the accelerated phase, and 29% (2236%) in the blast phase (Fig. 86-4). Unrelated donor transplantation for CML carries a higher transplant-related mortality rate than HLA-identical sibling transplantation. However, a significant proportion of patients become long-term survivors. Among 1,338 unrelated donor transplantations done between 1990 and 1996 reported to the IBMTR, 3-year survival rates were 45% (4149%) for 909 patients transplanted in the chronic phase, 28% (2234%) for 337 transplanted in the accelerated or second chronic phase, and 30% (2040%) for 92 transplanted in the blast phase. The survival rates of patients receiving an unrelated donor transplant in the blast phase may be misleading because many patients with transformation to the blast phase die before an unrelated donor transplantation can be performed or are deemed ineligible based on the refractory nature of their disease. Survival rates as high as 74% are reported with HLA-matched (using molecular HLA typing techniques), unrelated donor transplantation done early after diagnosis. [67] The timing of transplantation influences the outcome of related and unrelated donor transplantations for CML. Survival rates are significantly higher when transplantation is done <1 year after diagnosis (Fig. 86-5).

Several disease-related features at diagnosis, such as white blood cell count, percentage circulating blasts, hemoglobin, and spleen size, predict survival duration in patients with chronic-phase

Figure 86-5 Actuarial probabilities of leukemia-free survival (LFS) after HLA-identical sibling and unrelated donor transplantation for chronic myeloid leukemia, by interval between diagnosis and transplantation.

CML who receive nontransplantation therapy. [97] [98] [99] [100] These factors are associated with the rate of transformation to the acute or blast phase, which is the cause of death in most patients receiving nontransplantation treatment. In contrast, relatively few deaths after HLA-identical sibling transplantation for chronic-phase CML result from leukemia, particularly if the transplants are not T-cell depleted. Most deaths are from transplant-related complications such as regimen-related toxicity, GVHD, and infection (see Table 86-1). Consequently, prognostic factors for survival after allogeneic transplantation for chronic-phase CML are those that influence the risk of transplant-related complications, such as donor type, older age, donor parity, and prior treatment. [101] Splenomegaly is not associated with more relapses, although it may lead to delayed engraftment. [102] Studies of pretransplantation splenic irradiation or splenectomy do not show a survival benefit. [103] [104] [105]

The type of initial therapy given for CML can affect the outcome of a subsequent transplantation. Patients receiving busulfan, once frequently used to control leukocyte counts and symptoms, have higher risks of transplant-related mortality after HLA-identical sibling transplantation than patients receiving hydroxyurea. [76] Whether interferon- affects transplantation outcome is uncertain. Conflicting observations are reported. [106] [107] [108] [109] Recent data in over 209 patients receiving interferon- before an HLA-identical sibling transplantation suggest no adverse effect on outcome. [108] Another study of 184 patients receiving unrelated donor transplants shows higher risks of severe GVHD and GVHD-related death in those receiving interferon for 6 or more months. [109]

Timing of transplantation, even among patients who remain in the chronic phase, also affects transplantation outcome. Several studies demonstrate a better outcome of HLA-identical sibling transplantation when done within 1 year of diagnosis [13] [67] [76] (see Fig. 86-5). The adverse effects of delaying transplantation include both increased transplant-related mortality and increased relapse. Survival after unrelated donor transplantation is also lower when transplantation is delayed. [66] [67] This makes decisions about initial therapy for CML difficult. CML has a long natural history, with few patients dying in the first 12 years after diagnosis; patients with major cytogenetic responses to interferon have long expected survivals. Consequently, delaying transplantation to determine the interferon response is an appealing strategy. This is especially so for patients without an HLA-identical sibling donor or with risk factors for transplant-related complications. However, the delay, and possibly interferon exposure, may adversely affect transplantation outcome. Recent studies comparing large databases of nontransplant and transplant recipients suggest that early transplantation (transplant <1 year after diagnosis) yields the largest number of long-term survivors and longest average survivals for patients younger than 50 years of age. [110] [111] An exception might be patients 4050 years of age without an HLA-identical sibling donor and with features predicting good prognosis with nontransplantation treatment. [110]

Acute Myeloid Leukemia

The incidence of AML is 23/100,000 population in the United States. [69] The median age at onset is >60 years; approximately 35% of patients are <55 years of age at diagnosis. [65] Using current induction regimens, 6080% of patients achieve complete remission, and 2050% of these become long-term leukemia-free survivors after further consolidation therapy. [112] [113] Patients failing to achieve remission with primary induction therapy or relapsing after an initial remission have a poor prognosis, with almost all dying of causes related to AML. Allogeneic transplantation is an effective treatment for AML, with LFS rates as high as 80% in young patients transplanted in first remission. [114] [115] [116]

The international survey cited previously indicated that approximately 25% of patients diagnosed with AML in 19891991 in the 10 countries studied received allotransplants. [117] The survey also revealed wide variation in this proportion among countries, reflecting different strategies for applying transplantation (i.e., as consolidation vs. salvage therapy). IBMTR data indicate approximately 3,500 allogeneic SCTs for AML yearly. Approximately 80% of these are from related and the rest from unrelated donors. Five to 10% of HLA-identical sibling transplantations are done in patients never achieving first remission, 60% as consolidation therapy in first remission, 1015% in first relapse, 1015% in second remission, and <5% in a subsequent relapse or remission. Few unrelated donor transplantations are done in patients never achieving remission. Twenty-five percent of unrelated donor transplantations are done in first remission, 20% in first relapse, 30% in second remission, 10% in a subsequent relapse, and 5% in a subsequent remission. The median interval from diagnosis to transplantation is 6 months for HLA-identical sibling transplantation and 12 months for unrelated donor transplantation. The median age of transplant recipients is 31 years; 30% are <20 years of age and 5% are >50 years of age.

As for CML, the most common conditioning regimen used before transplantation for AML is busulfan and cyclophosphamide, accounting for 45% of AML transplantations reported to the IBMTR in 1997. Randomized trials comparing busulfan and cyclophosphamide to TBI and cyclophosphamide in AML suggest similar relapse and similar or somewhat higher transplant-related mortality rates with the busulfan regimen. [118] [119] [120] [121] One randomized trial in AML demonstrated decreased relapse risk with intensification of the pretransplantation conditioning regimen. [122] In this study, an increase in the TBI dose from 12 to 15.75 Gy decreased the relapse rate from 35 to 12%. However, the potential survival benefit was offset by a comparable increase in transplant-related mortality. Post-transplantation cyclosporine and methotrexate is the most frequent GVHD prophylaxis regimen, and is used in approximately 65% of transplantations for AML.

The GVL effect is important in preventing relapse after transplantation for AML. As in CML, patients in whom GVHD develops, particularly chronic GVHD, after HLA-identical sibling transplantation for AML have significantly lower risks of relapse than those without GVHD. [24] [25] [37] [123] Recipients of identical twin transplantation

for AML also have significantly higher risks of post-transplantation relapse than recipients of allogeneic transplants, with or without GVHD, demonstrating an important GVL effect even in the absence of clinically detectable GVHD. [38] [39] The effect of T-cell depletion of donor bone marrow on relapse risk is not as dramatic in AML as in CML. Although relapse rates are higher after T-cell-depleted transplantation than non-T-cell-depleted transplantation for AML, the decrease is entirely consistent with reduction of GVHD and GVHD-associated GVL effects. [44] Donor lymphocyte infusions are effective in reinducing durable remissions in a minority (approximately 25%) of patients relapsing after receiving allografts for AML. [50] [51]

As in CML, the strongest determinants of outcome after allogeneic transplantation for AML are donor type and phase of disease at time of transplantation. Patients in first remission have the best transplantation outcomes. Those with more advanced disease have lower probabilities of LFS because of higher risks of both relapse and transplant-related mortality. Among 4,171 recipients of HLA-identical sibling transplantations done between 1990 and 1996, reported to the IBMTR, 3-year actuarial probabilities of relapse were 24% (2226%) for 2,651 patients transplanted in first complete remission, 41% (3646%) for 571 transplanted in second or subsequent remission, and 58% (5462%) for 949 transplanted in relapse (Fig. 86-6). Three-year probabilities of LFS were 59% (5761%), 40%

Figure 86-6 Actuarial probabilities of relapse after HLA-identical sibling transplantation for acute myeloid leukemia. CR, complete remission.

(3545%), and 27% (2434%), respectively (Fig. 86-7). Salvage therapy infrequently produces durable remissions after post-transplantation relapse, although some patients may be successfully treated with chemotherapy or donor lymphocyte infusions. [50] [51] Unrelated donor transplantations have higher transplant-related mortality but lower relapse rates than HLA-identical sibling transplantations. Among 743 unrelated donor transplantations done between 1990 and 1996 reported to the IBMTR, 3-year LFS rates were 51% (4755%) for 188 patients transplanted in first remission, 35% (3139%) for 249 transplanted in second or subsequent remission, and 18% (1620%) for 306 transplanted in relapse (Fig. 86-8).

Several disease-related features such as high white blood cell count at diagnosis, M4b-7 FAB classification, cytogenetic abnormalities such as t(9;22) and abnormalities of chromosomes 5 and 7, and first remission durations of <1 year, known predictors of poor response to conventional therapy, also predict poorer transplantation outcome. [116] [124] [125] [126] In addition, transplantation outcome is influenced by factors associated with risk of transplant-related complications, such as age and cytomegalovirus status. Among patients transplanted in first remission, transplantation outcome is not affected by the type or amount of prior consolidation therapy. [127]

There is general agreement that most patients younger than approximately 55 years of age who fail conventional therapy and who have good performance status should be treated with allogeneic SCT if an appropriate related or unrelated donor is available. Although there are no formal comparisons of transplantation versus conventional therapy in this setting, transplantation can salvage 1530% of patients with advanced

Figure 86-7 Actuarial probabilities of leukemia-free survival (LFS) after HLA-identical sibling transplantation for acute myeloid leukemia. CR, complete remission.

Figure 86-8 Actuarial probabilities of leukemia-free survival (LFS) after unrelated donor transplantation for acute myeloid leukemia. CR, complete remission.

disease, including those never achieving remission with conventional therapy. [128] [129] [130] [131] A study comparing two observational databases, one of chemotherapy recipients and the other of patients receiving HLA-identical sibling transplants for AML in second remission, found a significant advantage for transplantation in younger but not in older patients. [129] The use of allogeneic transplantation in first remission is common but still somewhat controversial. Between 20 and 50% of patients achieving first remission have long-term LFS with conventional consolidation therapy. Several randomized and nonrandomized studies indicate significantly higher LFS for patients receiving HLA-identical sibling transplants, although others indicate no advantage. [132] [133] [134] [135] [136] [137] [138] [139] [140] [141] [142] [143] [144] [145] [146] [147] Few demonstrate overall survival advantages because some patients relapsing after conventional therapy achieve long-term survival with a transplant in first relapse or second remission. [129] [130] A strategy of performing HLA-identical sibling transplantation in first remission only for patients with adverse prognostic factors is advocated by some, with transplantation reserved for first relapse or second remission in other patients, but a differential benefit of transplantation by prognostic factors is not proven. On the other hand, there are currently few transplantations done in first remission of M3-AML, presumably because of the good results possible with all-trans retinoic acid. [148] Studies directly comparing unrelated donor transplantation with conventional chemotherapy for AML in first remission are lacking. Most unrelated donor transplantations in first remission are in patients with adverse prognostic factors such as high leukocyte counts, adverse cytogenetic abnormalities, or requiring more than two cycles of induction therapy to achieve remission. Long-term LFS rates between 40 and 60% are reported in young patients. [59] [66] [149] [150] Among children (<16 years of age), there is little difference in reported results of unrelated donor and HLA-identical sibling transplantation.

Myelodysplastic Syndromes

Myelodysplastic syndrome (MDS) is a clonal hematologic disorder with a high likelihood of transformation to acute leukemia. [151] [152] De novo MDS, the more common form, is a disease of older adults, with a median age of onset in the eighth decade of life. Less than 10% of patients are younger than 55 years of age at diagnosis. MDS may also develop after treatment for other cancers, particularly in patients receiving alkylator agents or epipodophyllotoxins. [153] Treatment depends on the clinical syndrome. Patients with cytopenias are usually treated conservatively with transfusions and hematopoietic growth factors; those with transformation may receive standard antileukemia regimens. Response to the latter is poor, with fewer than 60% achieving remissions, and the median remission duration is <12 months. [154] Allogeneic SCT is not extensively used in MDS because most patients are older than the generally accepted upper age limits for allografts. However, long-term disease-free survival, and presumably cure, is possible with allogeneic SCT, with reported 5-year LFS rates ranging from 10 to 60%. [151] [154] [155] [156] [157] [158] [159] [160] [161] [162] [163] [164] [166]

Data from the IBMTR indicate approximately 1,000 allogeneic SCTs for MDS yearly. Approximately 75% of these are from related donors. Thirty percent of HLA-identical sibling transplantations are done in patients with refractory anemia (RA) and 70% in those with refractory anemia with excess blasts (RAEB), refractory anemia with excess blasts in transformation (RAEBT), or chronic myelomonocytic leukemia (CMML). Corresponding figures for unrelated donor transplantations are 20% and 80%. The median interval from diagnosis to transplantation is 6 months for HLA-identical sibling transplants and 11 months for unrelated donor transplants. The median age of transplant recipients is 36 years. Twenty percent are younger than 20 years of age, and 14% are older than 50 years. This is in striking contrast to the age distribution of all patients with MDS.

The most common conditioning regimen used before transplantation for MDS is busulfan and cyclophosphamide, accounting for approximately half of MDS transplantations reported to the IBMTR in 1997. The need for intensive pretransplantation conditioning was demonstrated by Appelbaum and colleagues, who showed higher risks of graft failure and relapse when transplantations for RA were done with less intensive regimens, similar to those used for aplastic anemia. [162] The relative benefits of TBI versus non-TBI regimens are uncertain, although one retrospective study suggested an advantage for TBI. [163] Post-transplantation cyclosporine and methotrexate is the most frequent GVHD prophylaxis regimen, and is used in approximately 65% of transplantations for MDS.

The importance of graft-mediated immune effects (i.e., GVL) in preventing relapse after allotransplantation for MDS is uncertain. Donor lymphocyte infusions are sometimes effective in reinducing durable remissions after post-transplantation recurrence. [50] [51]

Outcome of allotransplantations for MDS depends in part on FAB classification. Patients with RA or RA with ringed sideroblasts (RARS) have lower recurrence rates and better survival rates than those with RAEB or RAEBT. Among 619 recipients of HLA-identical sibling transplants done between 1990 and 1996 and reported to the IBMTR, 3-year actuarial probabilities of relapse were 8% (313%) for 180 patients with RA or RARS and 39% (3246%) for 439 with RAEB, RAEBT, or CMML (Fig. 86-9). Three-year probabilities of disease-free survival were 58% (5064%) and 38% (3343%), respectively (Fig. 86-10). Salvage therapy

Figure 86-9 Actuarial probabilities of relapse after HLA-identical sibling transplantation for myelodysplastic syndromes. RA, refractory anemia; RARS, refractory anemia with ringed sideroblasts; RAEB, refractory anemia with excess blasts; RAEBT, refractory anemia with excess blasts in transformation; CMML, chronic myelomonocytic leukemia.

Figure 86-10 Actuarial probabilities of disease-free survival (DFS) after HLA-identical sibling and unrelated donor transplantation for myelodysplastic syndromes. RA, refractory anemia; RARS, refractory anemia with ringed sideroblasts; RAEB, refractory anemia with excess blasts; RAEBT, refractory anemia with excess blasts in transformation; CMML, chronic myelomonocytic leukemia.

infrequently produces durable remissions after post-transplantation relapse. Among 170 unrelated donor transplantations done between 1990 and 1996 and reported to the IBMTR, 3-year disease-free survival rates were 15% (030%) for 30 patients with RA or RARS and 27% (1836%) for 135 with RAEB, RAEBT, or CMML (Fig. 86-10). Survival rates as high as 4050% are reported in some series. [161] Prognosis is better in younger than in older patients and in those transplanted sooner rather than later after diagnosis. Results appear similar whether the MDS is de novo or secondary to prior anticancer treatment, assuming similar morphologic, cytogenetic, and patient characteristics. [164]

Because patients with MDS tend to be older and may have prolonged survival with conservative therapy, especially if presenting only with RA and not requiring transfusions, the role and timing of transplantation is controversial. However, allogeneic SCT offers the only chance for cure and should be considered for young patients with disease features predicting short survival or with evidence of transformation to acute leukemia. These include patients with therapy-related MDS, platelet transfusion dependence, severe neutropenia, excess or increasing percentages of marrow blasts, or clonal cytogenetic abnormalities. There is little evidence that intensive nontransplantation chemotherapy improves the outcome of subsequent allografting.

Acute Lymphoblastic Leukemia

The incidence of ALL is 12/100,000 population. The median age at onset is 11 years. However, the age distribution is bimodal, with peaks in childhood and older adulthood. Approximately 60% of patients are younger than 20 years and 20% are older than 55 years of age at diagnosis. [69] Most patients with ALL, approximately 70% of children and 35% of adults, are cured with conventional chemotherapy. [166] [167] [168] Consequently, transplantation is usually reserved for patients failing conventional therapy (i.e., in relapse or second or subsequent remission) or for patients in first remission with prognostic factors predicting a high risk of failure with conventional therapy. [116] [166] [167] [168] [169] [170] [171] [172] [173] [174] The most frequent indications for transplantation in first remission are older age, high leukocyte count at diagnosis, poor-prognosis chromosome abnormalities such as t(9;22) or t(4;11), extramedullary leukemia, and difficulty obtaining a first remission. Allogeneic SCT is an effective treatment for ALL, with LFS rates 60% in young patients transplanted in first remission. [171] [172] [174] [175]

The international survey cited previously indicated that only 510% of patients diagnosed with ALL in 19891991 received allotransplants. [117] As in AML, there was wide variation among countries, reflecting different strategies for timing of transplantation. IBMTR data indicate approximately 2,500 allogeneic SCTs for ALL yearly. Approximately 70% of these are from related and the rest from unrelated donors. Fewer than 5% of HLA-identical sibling transplantations are done in patients never achieving first remission, 40% as consolidation therapy in first remission, 10% in first relapse, 35% in second remission, 5% in a subsequent relapse, and 10% in a subsequent remission. Few unrelated donor transplantations are done for patients never in remission. Approximately 20% of unrelated donor transplantations are done in first remission, 10% in first relapse, 40% in second remission, 10% in a subsequent relapse, and 20% in a subsequent remission. The median interval from diagnosis to transplantation is 10 months for HLA-identical sibling transplants and 24 months for unrelated donor transplants. The median age of transplant recipients is 18 years; 45% are <16 years of age, 15% are 1619 years, and <5% are >50 years of age. Most (75%) patients receiving transplants in first remission are >16 years of age.

The most common conditioning regimen used before transplantation for ALL is TBI and cyclophosphamide, with or without other drugs, accounting for 60% of ALL transplantations reported to the IBMTR in 1997. Although there is concern about the effect of TBI on growth and development in young children and on the risk of second cancers, some studies suggest that transplant-related mortality is higher and LFS lower with non-TBI regimens, particularly busulfan and cyclophosphamide, in ALL. [176] [177] Other studies show no difference. [178] [179] Post-transplantation cyclosporine and methotrexate is the most frequent GVHD prophylaxis regimen and is used in approximately 60% of transplantations for ALL.

Graft-versus-leukemia effects are important in ALL, although not as striking as in CML and AML. [25] [44] [180] Although GVHD decreases relapse risk, relapse rates are not as markedly increased after identical twin or T-cell-depleted transplantation as they are in CML. [25] [44] Donor lymphocyte infusions are only rarely effective in reinducing durable remissions in patients relapsing after allografts for ALL. [50] [51]

As in other leukemias, LFS after allogeneic SCT for ALL depends on the phase of disease at time of transplantation. Patients in first remission have the best transplantation outcomes. Those with more advanced disease have lower probabilities of LFS because of higher risks of both relapse and transplant-related mortality. Among 2,894 recipients of HLA-identical sibling transplants for ALL done between 1990 and 1996 and reported to the IBMTR, 3-year actuarial probabilities of relapse were 29% (2632%) for 1,213 patients transplanted in first remission, 55% (5258%) for 1,212 in second or subsequent remission, and 66% (6171%) for 469 not in remission (Fig. 86-11).

Figure 86-11 Actuarial probabilities of relapse after HLA-identical sibling transplantation for acute lymphoblastic leukemia. CR, complete remission.

Figure 86-12 Actuarial probabilities of leukemia-free survival (LFS) after HLA-identical sibling transplantation for acute lymphoblastic leukemia. CR, complete remission.

Three-year probabilities of LFS were 53% (5056%), 40% (3743%), and 21% (1725%), respectively (Fig. 86-12). Unrelated donor transplantation has a higher transplant-related mortality rate than HLA-identical sibling transplantation. Among 939 unrelated donor transplantations for ALL done between 1990 and 1996 and reported to the IBMTR, 3-year LFS rates were 42% (3846%) for 215 patients transplanted in first remission, 34% (3236%) for 537 transplanted in second or subsequent remission, and 16% (1318%) for 187 transplanted in relapse (Fig. 86-13). Among patients <20 years of age, available data suggest that LFS is similar with HLA-identical sibling and unrelated donor transplantation. [149] [181]

Several disease-related features such as age at onset, high white blood cell count at diagnosis, non-T-cell phenotype, cytogenetic abnormalities such as t(9;22) and t(4;11), a prolonged time to achieve first remission, and first remission durations of <1 year, all of which predict poor response to conventional therapy, also predict poorer transplantation outcome. [116] [170] [171] [172] [173] [175] Allogeneic transplantation is an effective and accepted treatment for relapsed ALL. A matched-pair analysis comparing 255 children (18 years of age) receiving HLA-identical sibling transplants with 255 children on chemotherapy protocols of the U.S. Pediatric Oncology Group for ALL in second remission, demonstrates a significant advantage for transplantation in this setting. [182] An advantage is seen in children with short and long first remissions. Although formal comparisons of transplantation and chemotherapy are not available in adults relapsing after first remission, transplantation can salvage 1545% transplanted in first relapse or second remission, substantially more than would be expected with conventional therapy. Long-term LFS in patients receiving HLA-identical sibling transplants after

Figure 86-13 Actuarial probabilities of leukemia-free survival (LFS) after unrelated donor transplantation for acute lymphoblastic leukemia. CR, complete remission.

failing to achieve a first remission with conventional therapy is also well documented. [128] [183] The role of transplantation in first remission for patients with high-risk ALL is controversial. Long-term LFS rates of 3040% in patients with Philadelphia chromosome-positive ALL after allogeneic SCT in first remission are reported in several

series, and transplantation in these patients seems appropriate because long-term remissions are unusual with conventional therapy. [184] [185] Some prospective and retrospective comparative studies fail to show a significant LFS advantage for adults receiving HLA-identical sibling transplants for ALL in first remission, with lower relapse rates offset by high transplant-related mortality rates. [186] [187] [188] Two other studies suggest an advantage for some patients, one in patients with high-risk features (i.e., t[9;22], null or undifferentiated phenotype, high leukocyte count, age >30 years at onset, and >4 weeks to achieve first remission), and the other in patients <30 years of age at time of treatment. [189] [190] There are no published comparisons of unrelated donor transplantation with conventional therapy for ALL. A comparison of unrelated donor transplantation with autologous transplantation showed superior LFS with unrelated donor transplantation in some groups of patients, particularly those beyond first remission. [191] Unrelated donor transplantation is usually reserved for patients failing conventional therapy or with poor prognosis cytogenetic abnormalities. The ability to use this approach effectively depends on the efficiency of identifying and collecting cells from unrelated donors because many patients with advanced or high-risk ALL have rapid disease progression. [68]

Chronic Lymphocytic Leukemia

Chronic lymphocytic leukemia (CLL) is a common hematologic malignancy affecting 34/100,000 population in the United States. [69] Like MDS, CLL is primarily a disease of older adults. Median age at onset is 70 years, with approximately 15% of patients <55 years of age at diagnosis. [69] Treatment and prognosis depend on the presenting stage. [192] [193] Many patients have asymptomatic lymphocytosis and require no immediate treatment. Their survival may be similar to that of an age-matched normal population. Those with cytopenias, lymphadenopathy, or splenomegaly have a worse prognosis. Allogeneic SCT can cure some of these patients, although experience with the procedure in CLL is not nearly as extensive as with the other leukemias. [194]

Data from the IBMTR indicate approximately 150 allogeneic SCTs for CLL annually. Eighty-five percent are from related donors. The median interval from diagnosis to transplantation is approximately 40 months. The median age of transplant recipients is 46 years; 25% are older than 50 years of age.

The most common conditioning regimen used before transplantation for CLL is TBI and cyclophosphamide, accounting for 70% of CLL transplantations reported to the IBMTR in 1997. Post-transplantation cyclosporine and methotrexate is the most frequent GVHD prophylaxis regimen and is used in approximately 60% of transplantations for MDS. The importance of graft-mediated immune effects (i.e., GVL) in preventing relapse after allografting for CLL is unknown, although one case report suggests an anti-CLL effect of GVHD. [195]

A review of 54 HLA-identical sibling transplantations for CLL reported to the IBMTR or the EBMTG showed 46% (95% confidence interval, 3260%) survival at 3 years. [196] Transplant-related mortality was high; 46% of patients died of treatment-related causes. Most of these patients had long-standing or advanced disease. Details of prior treatment were not available for all patients, but most had received multiple courses of chemotherapy. The authors concluded that transplantation should be considered for young patients with a poor prognosis receiving conventional chemotherapy. A more recent study suggested that transplant-related mortality may be reduced and survival

increased by prior treatment with fludarabine. [197] Among 138 recipients of HLA-identical sibling transplants between 1990 and 1996 and reported to the IBMTR, 3-year actuarial probabilities of relapse and survival were 20% (1525%) and 41% (3646%), respectively. Causes of death are shown in Table 86-1 .

Because patients with CLL tend to be older and may have prolonged survival with conservative therapy, especially if presenting with stage 0 or 1 disease, the role and timing of transplantation are controversial. Symptomatic patients can achieve good responses and prolonged survival with alkylating agents or fludarabine; however, neither of these approaches is curative. Allogeneic SCT should be considered for younger patients with disease features predicting short survival, that is, patients with Rai stages IIIV disease or those failing to respond to or relapsing after fludarabine.

Non-Hodgkin Lymphoma

The incidence of NHL is approximately 15/100,000 population in the United States. [69] The median age at onset is 65 years, with approximately 35% of patients younger than 55 years of age at diagnosis. [69] Prognosis depends on histologic subtype, age at onset, and other patient- and disease-related features. [198] [199] Approximately 60% of patients achieve complete remission with combination chemotherapy. Patients with low-grade histologic types may have prolonged remissions or survival but rarely are cured with conventional chemotherapy. Approximately 40% of those with intermediate- and high-grade histologic types are cured with intensive chemotherapy, with or without radiation, but most eventually have recurrence and die of their disease. Most hematopoietic stem cell transplantations for NHL use autologous cells collected from the blood or bone marrow. [194] Autografting cures a substantial proportion of patients with high-risk intermediate-grade and immunoblastic lymphoma, but is less effective for low-grade and lymphoblastic lymphomas (see Chap. 87). Only 10% of transplantations for NHL use allogeneic donor cells. Centers usually reserve allogeneic SCT for patients with a high likelihood of relapse after autografting or from whom an adequate autologous graft cannot be obtained. [194] [200] [201] This includes patients with low-grade or lymphoblastic NHL, tumors refractory to conventional chemotherapy, extensive marrow involvement, co-existing myelodysplasia, or poor marrow reserve or prior pelvic irradiation. Some patients relapsing after an autograft for NHL can achieve long-term disease-free survival with allogeneic SCT. [202] IBMTR data indicate approximately 1,000 allogeneic SCTs for NHL are done yearly. Approximately 90% of these are from related donors. Eighty percent of the HLA-identical sibling transplantations and 15% of the unrelated donor transplantations are for low-grade lymphoma. Twenty-five percent of HLA-identical sibling transplantations are done in patients never achieving first remission, 25% as consolidation therapy for high-risk NHL in first remission, 20% in first relapse, 20% in second remission, and 10% for more advanced disease. Thirty percent of unrelated donor transplantations are done for patients never in remission, 10% are done in first remission, 20% in first relapse, 25% in second remission, and 20% for more advanced disease. The median interval from diagnosis to transplantation is 13 months for HLA-identical sibling transplantation and 18 months for unrelated donor transplantation. Median age of transplant recipients is 33 years; 20% are <20 years of age and 5% are >50 years.

The most common conditioning regimen used before allogeneic SCT for NHL is TBI and cyclophosphamide, accounting for 45% of NHL transplantations reported to the IBMTR in 1997. Patients who received local radiation therapy for their lymphoma are often not candidates for TBI. A variety of high-dose chemotherapy regimens are also used, including busulfan and cyclophosphamide and regimens commonly used for autografting, such as cyclophosphamide, carmustine, and etoposide (CBV),

Figure 86-14 Actuarial probabilities of survival after HLA-identical sibling transplantation for low-grade non-Hodgkin lymphoma.

and carmustine, etoposide, cytarabine, and cyclophosphamide (BEAC). Data on relative efficacy of different conditioning regimens are lacking. Post-transplantation cyclosporine and methotrexate is the most frequent GVHD prophylaxis regimen, and is used in approximately 60% of transplantations for NHL.

Graft-versus-lymphoma effects may play a role in preventing relapse after transplantation for NHL. One observation supporting this is the lower relapse rate after allogeneic versus autologous transplantation. [52] [53] [203] It is possible that some of this difference results from reinfusion of lymphoma cells in autologous grafts. [53] However, among allograft recipients, patients with GVHD have lower relapse rates than those without GVHD. [53] Unfortunately, lower relapse rates after allografts do not result in higher survival rates because of offsetting higher rates of transplant-related mortality. As in ALL, donor leukocyte infusions are only occasionally effective in patients with recurrent NHL after an allograft. [51] [204]

Because of the selection practices noted previously, results of allogeneic SCT for NHL must be interpreted with the understanding that these patients represent a group with an extremely poor prognosis with nontransplantation treatment. Allogeneic SCT can produce durable remissions and possibly cure in patients with low-grade lymphoma. [200] [201] [205] [206] Several small studies and one review of over 100 patients suggest long-term disease-free survival in 5060% of patients receiving HLA-identical sibling transplants for low-grade lymphoma, despite the fact that many of the patients in these series had failed prior chemotherapy regimens. Among 189 recipients of HLA-identical sibling transplants for low-grade lymphoma done between 1990 and 1996 and reported to the IBMTR, 3-year actuarial probabilities of survival are 46% (3755%) for 36 patients transplanted in remission and 43% (3848%) for 153 patients not in remission (Fig. 86-14). Among 220 recipients of HLA-identical sibling transplants for intermediate and immunoblastic lymphoma, 3-year survival rates are 38% (3046%) for 43 patients in remission at time of transplantation and 29% (2533%) for 177 not in remission (Fig. 86-15). Causes of death are shown in Table 86-1 . Factors associated with better prognosis include low-grade histologic type, chemotherapy-sensitive disease, and absence of B symptoms. [201]

Which patients with NHL might best benefit from allogeneic SCT versus autografting or chemotherapy is uncertain. Good candidates might be young patients with low-grade or lymphoblastic lymphoma. Patients with advanced refractory disease are unlikely to benefit.

Hodgkin Disease

The incidence of Hodgkin disease is 23/100,00 in the United States; the median age at onset is 35 years, and 75% of patients are <55 years of age at diagnosis. [69] Most patients are cured with

Figure 86-15 Actuarial probabilities of survival after HLA-identical sibling transplantation for intermediate- and high-grade non-Hodgkin lymphoma.

conventional chemotherapy or radiation therapy. However, for the 2030% who fail conventional therapy, hematopoietic stem cell transplantation is effective salvage therapy. Autografts are commonly used in patients with advanced Hodgkin disease. [194] Five-year disease-free survival rates are 4070% for patients transplanted in remission and 1020% for those with advanced disease (see Chap. 87). This contrasts with survival rates of <550% with salvage chemotherapy. [207] [208] [209] [210] In both Hodgkin disease and NHL, there are several possible advantages of allogeneic SCT in advanced or recurrent disease: (1) advanced donor hematopoietic cells have not been exposed to chemotherapy, (2) there is no risk of lymphoma cells in the graft, and (3) there may be a graft-versus-lymphoma effect. However, relatively few allogeneic SCTs for Hodgkin disease are done, approximately 150 yearly. Ninety percent are from related donors. As in NHL, most are in extensively treated, poor-risk patients.[211] The median interval between diagnosis and transplantation is 30 months.

A recent study from the IBMTR examining outcome of 100 HLA-identical sibling transplantations for Hodgkin disease done between 1982 and 1992, showed high transplant-related mortality rates (61%) in large part due to a high incidence of pulmonary complications. [211] Most received their transplants after extensive prior nontransplantation treatment. The 3-year disease-free survival rate was 15%. A matched-pair analysis of autologous and allogeneic SCT for Hodgkin disease showed fewer relapses but more transplant-related deaths with allografts; survival was similar. [212] Among 108 HLA-identical sibling transplantations for Hodgkin disease done between 1990 and 1996 and reported to the IBMTR, the 3-year probability of disease-free survival is 16 ± 7% (Fig. 86-16).

Figure 86-16 Actuarial probabilities of survival after HLA-identical sibling transplantation for Hodgkin disease.

Multiple Myeloma

The incidence of multiple myeloma is approximately 4/100,000 in the United States. [69] It is a disease of older adults, with a median age at onset of approximately 70 years.[69] Only 15% of patients are younger than 55 years of age at diagnosis and therefore candidates for allogeneic SCT. The most common treatment strategy for multiple myeloma is melphalan and prednisone; response is common but complete remissions unusual. [213] The median survival is approximately 3 years. Most hematopoietic stem cell transplants for multiple myeloma use autologous cells; a recent prospective, randomized trial demonstrated prolonged survival with this approach compared with standard chemotherapy.[214] However, complete remissions after autografting are unusual and cures, if any, are rare. Some studies using polymerase chain reaction (PCR) techniques to ascertain presence of minimal residual disease suggest that although myeloma cells may persist for months or years after allogeneic SCT, at least some patients eventually become PCR negative and remain so for years. [215] Long-term (>4 years) disease-free survival is estimated to occur in 1040% of allograft recipients, although few patients have been followed this long posttransplantation. [216] [217] [218] [219] [220]

Relatively few allogeneic SCTs for multiple myeloma have been performed. IBMTR data indicate approximately 500 allogeneic SCTs for myeloma in 1997. More than 90% of these are from related and the rest from unrelated donors. Most patients who receive allotransplants for myeloma have advanced disease and have failed multiple prior chemotherapy regimens.[216] [217] [218] [219] [220] According to IBMTR data, the median interval from diagnosis to transplantation is 13 months for HLA-identical sibling transplantation and 16 months for unrelated donor transplantation. Median age of transplant recipients is 45 years; 20% are >50 years.

Transplantation regimens used for multiple myeloma are heterogeneous. Approximately 50% of patients receive TBI. The relative benefits of various conditioning regimens are unknown, although reported results do not differ dramatically with different regimens. Post-transplantation cyclosporine and methotrexate is the most frequent GVHD prophylaxis regimen, and is used in approximately 65% of transplantations for multiple myeloma.

The importance of graft-versus-myeloma effects in preventing relapse after allografting for multiple myeloma is uncertain. No decreased relapse rates in association with GVHD or increased relapse rates with T-cell-depleted transplants are reported. However, relapse rates after allografting are lower than after autografting, and there are several reports of donor lymphocyte infusions successfully inducing remissions after post-transplantation relapse. [55] [56] [57] [58]

Between 40 and 70% of patients receiving allografts for multiple myeloma achieve a clinical complete remission. [216] [217] [218] [219] [220] Many of these patients relapse. Transplant-related mortality is high, between 20 and 45%. The 3-year probability of survival after 674 HLA-identical sibling transplantations done between 1991 and 1996 and reported to the IBMTR is 37% (3539%). The 3-year survival rate after 39 unrelated donor transplantations for multiple myeloma is 24% (1632%). Factors associated with better transplantation outcomes are stage 1 disease at diagnosis, no more than one course of previous treatment, lower-stage disease at transplantation, low $_2$ -microglobulin levels, IgG rather than IgA or Bence-Jones myeloma, shorter time from diagnosis to transplantation, and female sex. [218] [219] [220] Not surprisingly, patients who achieve a complete remission after transplantation have a higher probability of long-term survival. Few patients have received unrelated donor transplants for multiple myeloma. There are some long-term survivors, but the role of alternative donor transplantation is uncertain.

The relative benefit of autologous and allogeneic SCTs for

multiple myeloma was studied in a matched-pair fashion by several investigators. Although relapse rates after allografts are lower than after autografts, they are offset by high transplant-related mortality. Long-term survival rates are similar. [58] [221] High-dose therapy with stem cell rescue should be considered for most young patients with myeloma. The choice of allogeneic versus autologous SCT depends on evaluation of individual risk factors for disease progression versus transplant-related toxicity, availability of a suitable donor, and development of allograft approaches with reduced toxicity.

Other Cancers

Allogeneic SCT has been used in patients with various other cancers, each accounting for <0.5% of cases reported to the IBMTR yearly. These include neuroblastoma, soft tissue and bone sarcomas, melanoma, and, recently, breast cancer. Although successful outcomes are reported in some patients, the role of allogeneic SCT in these diseases is difficult to assess because of the small number of patients treated. Extrapolating from experience with the leukemias, it may be rational to apply allogeneic SCT to diseases sensitive to chemotherapy but unlikely to be cured with chemotherapy in patients at low risk of transplant-related mortality.

LATE EFFECTS OF ALLOGENEIC STEM CELL TRANSPLANTATION

There are now over 20,000 people surviving 5 or more years after allogeneic SCT, and that number will grow rapidly. Most of these survivors lead normal lives, but allograft recipients remain at risk for late complications long after transplantation. [222] [223] These include late infections, abnormalities of growth and development, infertility and sexual dysfunction, thyroid disorders, chronic lung disease, cataracts, and avascular necrosis. Some of these are related to high-dose preparative regimens, some to immunosuppressive effects of GVHD and its treatment, and some to prior nontransplantation treatment. There is also an increased incidence of lymphoproliferative disorders and solid tumors in transplant recipients compared with the general population. [224] [225] [226] [227] These second cancers may not all be due to the transplant per se but to the chemotherapy or radiation preceding transplantation. Regardless, life-long surveillance is necessary, as is increased awareness of late complications among the many nontransplant physicians who will care for these patients.

Chapter 87 - Results of Autologous Stem Cell Transplantation for Hematologic Malignancies

Auayporn P. Nademanee
Anthony S. Stein
Stephen J. Forman

Since the late 1960s, combination chemotherapy regimens have been developed for treatment of most hematologic malignancies. These regimens use agents with relatively nonoverlapping toxicities and are based on the concept of superior disease control with combinations of single agents to decrease the emergence of drug resistance.[1] These chemotherapy regimens were designed to maximize objective clinical responses while minimizing toxicity. Conventional-dose chemotherapy regimens vary based on the tumor being treated.

Although conventional-dose chemotherapy produces frequent responses in patients with a wide variety of hematologic malignancies, for many patients these chemotherapy regimens produce responses that last only for short intervals, with relapse ensuing, ultimately leading to the death of the patient. For these reasons, the development and evaluation of new treatment strategies have focused on intensification of dose as a means of overcoming resistance to chemotherapy. In laboratory models of a variety of tumors, delivery of the highest possible doses of chemotherapy is a requirement for achieving long-term control. [2] These studies also indicate that resistance to a variety of cytotoxic agents can be overcome with a 5- to 10-fold escalation in the dose of drugs used to treat the malignancy.

Delivery of dose-intensive therapy is facilitated by the harvest of either marrow or peripheral blood stem cells to provide autologous hematologic stem cell support after delivery of high-dose chemotherapy or radiation and chemotherapy (see Chap. 92). Autologous hematopoietic stem cell support or autologous stem cell transplantation (SCT) shortens the duration of hematologic toxicity as a limiting step in the chemotherapy or radiation dose intensification and makes other organ toxicities the major limitation to increasing the dose. Table 87-1 shows the list of chemotherapy drugs commonly used in autologous SCT regimens and their dose-limiting organ toxicity.

TABLE 87-1 -- Agents Used in Autologous Transplant Regimens and Their Dose-Limiting Toxicity

Agent	Toxicities
Etoposide	Mucositis, skin
Cyclophosphamide	Cardiac failure, pulmonary failure, hemorrhagic cystitis
Cisplatinum	Renal failure, hearing loss
Carmustine	Interstitial pneumonitis, seizures
Total-body irradiation	Interstitial pneumonitis, enteritis
Melphalan	Mucositis
Busulfan	Veno-occlusive disease of liver, interstitial pneumonitis, seizures

RATIONALE FOR HIGH-DOSE THERAPY

Hryniuk and Bush introduced the concept of dose intensity (drug dose administered in mg/m ^{2} /week) for the purposes of being able to quantify the dose response effect.[3] The dose response effect is defined as the correlation of the effect of a drug with increasing doses. It was their hypothesis that dose intensity correlated with response, which in turn correlated with survival. Several assumptions are inherent in this hypothesis and include:

1. All drugs in a given regimen are therapeutically equivalent.
2. Synergy and cross-resistance between drugs do not play an active role.
3. The area under the curve is more important than peak drug concentrations.
4. Scheduling has no importance other than what is reflected in total dose intensity.

This suggests that chemotherapy regimens should be designed to maximize dose intensity and focus on the overall dose administered over time rather than achieving the highest peak dose. Laboratory models and clinical observations have demonstrated a dose-response relationship against a variety of tumors, leading to the concept that the highest possible doses should be incorporated into the design of the regimen. [4] [5] Where possible, combinations of active, non-cross-resistant agents should be used to decrease the emergence of drug resistance. This latter consideration is based on studies by Skipper that estimate a spontaneous rate of mutation conferring resistance to a single drug to be on the order of 1 in 10 ^{6} or 1 in 10^7 cancer cells.[2] The implication of this is that spontaneous mutations are highest in patients at diagnosis or at relapse (high tumor burden). The agents used in the regimen need to have different dose-limiting toxicities to avoid dose reduction and prevent additive toxicity. This would facilitate the delivery of full, single-dose therapies of the drug. To minimize the rapid emergence of resistance, combinations of drugs in high-dose regimens with different mechanisms of action would limit the emergence of cross-resistance.

Table 87-2 lists the malignant hematologic diseases that have been treated using high-dose chemotherapy or chemoradiation therapy and autologous SCT. Unlike allogeneic SCT, where the preparatory regimen provides both cytoreduction to reduce or eliminate the tumor burden and immunosuppression to facilitate engraftment, the regimen used for autologous SCT is designed to provide maximal antitumor activity limited only by the nonhematologic toxicity of the regimen.

CONTRIBUTION OF THE GRAFT TO RELAPSE

The major cause of relapse in patients undergoing autologous SCT for hematologic malignancy is persistent disease in the host. Even under the best of graft conditions, namely, a syngeneic (identical twin) graft, the cure rate is not 100%, and emphasizes

AUTOLOGOUS TRANSPLANTATION THERAPY FOR THE HEMATOLOGIC MALIGNANCIES

Autologous stem cell transplantation therapy for the hematologic malignancies offers several advantages over donor transplantation for the same disorders. Identification of a willing, human leukocyte antigen-matched donor is unnecessary. Graft-versus-host disease and its attendant problems of organ damage, immunosuppression, and infection do not occur. Consequently, hospitalization and convalescence are shortened and transplant-related mortality is diminished. On the other hand, the autologous stem cell inoculum may be contaminated with clonogenic malignant cells capable of engraftment and shown by several molecular marker studies sometimes to be responsible for persistent or recurrent disease. The autologous graft also lacks effector cells capable of mounting an allogeneic graft-versus-tumor response. These allogeneic effector cells engraft and circulate in the recipient after transplantation, suppressing emergence of malignant hematopoietic clones of recipient origin that have survived the preparative regimen. The graft-versus-tumor effect is most notable in donor transplantation therapy for chronic myeloid leukemia, but has been observed in acute nonlymphocytic leukemia (ANLL) and acute lymphocytic leukemia, and may occur in multiple myeloma and the lymphomas.

Nevertheless, autologous stem cell transplantation can be a powerful antitumor therapy, yielding up to 50% long-term, disease-free survival rates in selected populations such as patients with first-remission ANLL and patients coming to autologous transplantation with therapy-responsive lymphomas. Major reduction of tumor burden accomplished by autologous stem cell transplantation may also set the stage for additional innovative antitumor therapy, such as transplantation of stem cells transduced with chemotherapy-resistant genes, or use of interleukin-2-stimulated effector cells in the post-transplantation interval.

the contribution of the body burden of disease to relapse. [6] However, the high likelihood of reinfusing tumor cells, even from a remission marrow of a hematologically based tumor, has led to the development of methods designed to eradicate tumor cells from the autologous graft with the goal of achieving clinical results comparable with syngeneic transplantation. Intuitively, it would seem that all sources of autologous stem cells from patients with hematologic malignancy might contain cells that contribute to relapse, and studies of stem cell products have documented the presence of tumor cells in the grafts, including leukemia, myeloma, lymphoma, and chronic myeloid leukemia (CML).[7] [8] [9] [10] The success of autologous SCT for hematologic malignancy depends in part on whether any clonogenic cells remaining

TABLE 87-2 -- Autologous Transplantation for Hematologic Malignancies

Acute myelogenous leukemia: first and subsequent remission
Lymphoma: intermediate, high and low grade; high risk, relapse
Chronic lymphocytic leukemia
Hodgkin disease: induction failure, second remission and relapse
Multiple myeloma: chemosensitive, responsive disease
Chronic myeloid leukemia: chronic phase
Acute lymphoblastic leukemia: high-risk first remission, second remission

in the reinfused stem cell product can cause relapse. Although laboratory studies show the efficacy of purging to reduce tumor cell contamination, the benefit of purging of tumor cells in human transplant studies has remained controversial. Although retrospective analyses give some indication as to the value of purging, no prospective, randomized trials addressing the efficacy of ex vivo purging have been reported. [11]

Most trials have tested either chemotherapeutic agents or monoclonal antibodies against differentiation antigens on B-hematopoietic tumor cells as purging methods. These analyses suggest that purging reduces the number of clonogenic cells but often delays engraftment. [12] [13] The most direct evidence of the contribution of the infusion of autologous tumor cells to relapse resulted from an approach using gene therapy. Brenner et al. incubated a third of harvested marrow mononuclear cells from two children undergoing autologous stem cell transplantation for acute myeloid leukemia (AML) with the L and L-6 retroviral vector. [14] This vector contained the selectable neomycin resistance gene that marked approximately 5% of cultured progenitor cells. Patients underwent transplantation with infusion of both marked and unmarked marrow cells. At the time of the relapse, some of the leukemia cells contained the neomycin-resistant gene, demonstrating that these leukemia cells were present in the reinfused graft and could be detected at relapse. This has also been observed in patients with CML undergoing autologous transplantation. [15] Studies in patients with lymphoma have correlated the ability to deplete contaminating malignant lymphoma cells from the graft with overall disease-free survival after transplantation.[16] Thus, tumor cell contamination of the stem cell graft can, under some circumstances, be the cause of treatment failure in patients undergoing autologous stem cell transplantation for hematologic malignancy.

ACUTE MYELOID LEUKEMIA

The first successful case of autologous SCT for AML was reported in 1977 for a patient with relapsed AML with a chloroma. [17] Initially, autologous transplantation applied the same clinical approach previously used for patients undergoing allogeneic transplantation. Patients with advanced disease were treated with high-dose chemotherapy and then received infusion of their own marrow, usually collected during remission instead of marrow from a human leukocyte antigen (HLA)-identical sibling. Although this approach produced a high remission rate, there were few, if any, cures. Similar to the strategy with allogeneic transplantation, autologous transplantation was used earlier in the clinical course of the disease to enable high-dose consolidation therapy for patients who were in complete remission, usually in patients who lacked a histocompatible sibling donor or were of older age. The high-dose chemoradiation therapy regimens that have been used for autologous transplantation for AML are generally derived from those used for allogeneic transplantation. The most common regimens used for the treatment of AML include total-body irradiation (TBI) and cyclophosphamide, TBI with etoposide and cyclophosphamide, and busulfan and cyclophosphamide. [18] [19] [20] [21] [22]

Studies using unpurged marrow, purged marrow, and peripheral blood as a source of hematopoietic stem cells have reported disease-free survival rates for patients with AML transplanted in first remission of 3470%, 4176%, and 3580%, respectively. [23] Although each trial demonstrates the efficacy of autologous transplantation, they have been criticized for including patients with varying subtypes of disease (e.g., cytogenetics, French-American-British [FAB] classification type, white blood cells [WBC] at diagnosis) who had received widely varying induction therapies and types and numbers of consolidation cycles before hematopoietic cell transplantation, and had different durations of complete remission (CR) before transplantation. In addition, there are differences in the stem cell product manipulation and in preparative regimens. Nevertheless, numerous phase II and phase III autologous transplantation trials for AML have shown autologous SCT to be a useful alternative for patients who lack a sibling donor or are of older age. Most trials show a similar outcome for autologous SCT compared with allogeneic SCT, and a higher cure rate compared with chemotherapy. [24] The most common cause of treatment failure after autologous SCT for AML is relapse. Risk features for relapse in first remission include cytogenetic subtype, elevated WBC at diagnosis, and number of chemotherapy cycles required to achieve a first remission. [23] Figure 87-1 (Figure Not Available) shows a survival curve from a randomized trial comparing allogeneic and autologous SCT to standard chemotherapy, demonstrating the relative efficacy of autologous SCT in the treatment of this disease.

The role of autologous transplantation in second remission is better defined than in first remission because the cure rate with conventional therapy for such patients is very low. Under these circumstances, most patients have undergone transplantation using either chemically or immunologically purged marrow cells. Trials using marrow purged with 4-hydroperoxycyclophosphamide, maphosphamide, or monoclonal antibody have demonstrated a disease-free survival rate of 1956% and a relapse rate of 2575%. [12] [25] A study comparing autologous transplantation with unrelated donor transplantation for advanced leukemia has been conducted. [26] The relapse rates were lower with unrelated donor transplantation; however, the disease-free survival rate was not significantly different between the two types of transplant. These studies indicate that autologous transplantation is a reasonable alternative for patients who do not have a suitable donor and for older patients who achieve a second remission and may not be candidates for allogeneic transplantation.

As described in Chapter 54 , patients with newly diagnosed AML have significantly higher chances of long-term disease-free survival than two decades ago, largely because of better induction chemotherapy regimens, supportive care, and the selective use of allogeneic transplantation. Studies with autologous transplantation indicate that this option is a reasonable

Figure 87-1 (Figure Not Available) Kaplan-Meier estimates of disease-free survival for patients in first remission of acute myeloid leukemia assigned to allogeneic bone marrow transplantation (BMT; dotted line, n = 168), autologous BMT (dashed line, n = 128), or intensive consolidation chemotherapy (solid line, n = 126). Percentages represent estimated disease-free survival rates ± standard error. *(Reprinted with permission from Zittoun RA, Mandelli F, Willemze R et al: Autologous or allogeneic bone marrow transplantation compared with intensive chemotherapy in acute myelogenous leukemia. therapeutic choice, particularly for those patients who have poor-prognosis cytogenetic abnormalities in whom chemotherapy is unlikely to have a major impact on disease-free survival. Importantly, knowledge of the molecular biologic characteristics of the patients leukemia can be used to determine the appropriate therapy and whether the transplantation should be performed during first or subsequent remission. For those patients who do not undergo a transplantation in first remission and suffer a relapse, the opportunity to undergo transplantation requires that stem cells were collected during first remission or that a second remission is achieved and stem cells can be procured.

HODGKIN DISEASE

High-dose therapy followed by autologous SCT can produce long-term disease-free survival in selected patients with advanced refractory Hodgkin disease. [27] Reports from a number of single institutions and cooperative group trials indicate that 3065% of selected patients with Hodgkin disease can become long-term disease-free survivors when treated with autologous transplantation. [27] The primary indications for transplantation have been patients who had a relapse or failed to achieve a remission after treatment with multiagent chemotherapy. This includes patients who never achieved a CR with chemotherapy or were in untreated first relapse, sensitive relapse, or later CR. Therefore, most reports contain a heterogeneous group of patients with variation in the extent of disease at presentation, duration of response to therapy, use of reinduction therapy, prior use of radiation therapy, and the presence of B-cell symptoms.

Although several trials have examined the role of autologous transplantation in patients who failed to achieve a remission or had a relapse after chemotherapy, there have not been good prospective trials directly comparing salvage second-line therapy to chemotherapy followed by high-dose chemoradiation therapy and autologous transplantation. Recent investigations have compared a group of patients who received salvage chemotherapy and were matched for disease and treatment characteristics to a group of patients receiving an autologous transplant. Patients were matched for risk factors, including initial advanced disease, age, failure to achieve a CR with initial chemotherapy, and first relapse after chemotherapy-induced remission. [28] Overall survival, event-free survival, and freedom from progression at 4 years favored patients who received an autologous transplant compared with conventional salvage therapy (Fig. 87-2). This study, along with others, has identified numerous prognostic factors that influence the cure rate after transplantation [29] [30] [31] [32] [33] [34] (Table 87-3).

A recent international effort analyzing a large number of patients with Hodgkin disease suggested that there are disease characteristics that predict a high likelihood of relapse after conventional therapy. Several factors were identified, each of which reduced tumor control by 78%. [35] Among these poor prognostic factors at diagnosis are anemia (hemoglobin <10.5 g/dl), stage IV disease, male sex, age >45 years, albumin <4 mg/dl, WBC >15,000/l, and lymphocyte count <600/l or <8%. Patients with four or more of these features have a poor prognosis and

could benefit from early autologous transplantation. Pilot trials for the use of high-dose chemotherapy and transplantation as part of the initial management of Hodgkin disease have been conducted with very encouraging results. [36] Randomized trials comparing early versus late transplantation are being developed to answer this question in this group of patients at high risk for relapse.

The preparative regimens used in autologous transplantation for Hodgkin disease have focused on combination chemotherapy, most commonly carmustine, cyclophosphamide, and etoposide (CBV). [29] [30] [31] [32] [33] [34] Augmented CBV regimens have been shown to improve long-term disease control in phase II trials. Given its known effectiveness in the treatment of Hodgkin disease, some programs have also used TBI or total lymphoid irradiation. [33] However, many patients who require transplantation have had prior mediastinal mantle radiation, thus precluding the use of TBI as a component of the treatment regimen. The combination of TBI and prior mantle radiation increases prohibitively the risk of cardiac and pulmonary toxicity. In some cases, irradiation directed to site of bulky or refractory disease can be used after transplantation.

NON-HODGKIN LYMPHOMA

Like other tumors, the basis for high-dose chemotherapy and autologous stem cell transplantation in non-Hodgkin lymphoma (NHL) is that resistance to standard therapy can be overcome by escalation of doses of drugs or radiation beyond limiting marrow toxicity. The initial reports of successful incorporation of high-dose therapy with autologous transplantation were from the National Cancer Institute, where BACT (carmustine, cytarabine, cyclophosphamide, and thioguanine) chemotherapy followed by autologous SCT eradicated lymphoma in some patients with high-grade lymphoma previously considered incurable. [37] These observations led to the development of several trials, including a randomized trial documenting the efficacy of autologous transplantation in patients with lymphoma.

Several investigations have reported a cure rate of 3540% in patients with chemotherapy-sensitive, diffuse, aggressive non-Hodgkin lymphoma with high-dose therapy or autologous transplantation. [38] These studies were received with great enthusiasm because, under ordinary circumstances, <10% of patients with relapsed lymphoma can be cured with conventional salvage therapy (see Chap. 70). Eventually, an international randomized trial demonstrated that second-line chemotherapy with cisplatin, cytarabine, and decadron (DHAP) followed by consolidation with high-dose chemotherapy with carmustine, etoposide, cytarabine, and cyclophosphamide (BEAC) and autologous transplantation was more effective than continued conventional chemotherapy alone. [39] The 5-year event-free survival rate was 46% for transplantation patients versus 12% for chemotherapy-only patients (Fig. 87-3). This study was limited to patients younger than 60 years of age who had achieved a CR after primary therapy, had no known marrow or central nervous system involvement, and had responded to second-line therapy.

The issue of chemosensitivity appears to play an important part in the overall long-term disease-free survival of patients with lymphoma who undergo autologous transplantation. Patients refractory to initial therapy often responded to transplantation but had a relapse relatively quickly. [40] In addition, those patients with lymphoma who had responded to primary treatment but proved resistant to second-line treatment also had a relatively low response rate. In contrast, patients responding to conventional therapy did well after subsequent autologous transplantation. Figure 87-4 (Figure Not Available) shows the long-term disease-free survival rates for patients with advanced lymphoma depending on their remission status and sensitivity to chemotherapy.

Some investigators have attempted to identify patients who

Figure 87-3 Event-free survival in 109 patients with recurrent, chemotherapy-sensitive non-Hodgkin lymphoma randomized to high-dose therapy and autologous transplantation (n = 55) or conventional treatment (n = 54). had poor prognostic features at diagnosis and who were at high risk for relapse even with achievement of a CR. These phase II studies showed that early transplantation while in first remission resulted in high rates of disease-free survival in patients who would be expected to have had a greater chance of relapse with standard therapy[41] (Fig. 87-5). A large phase III trial comparing chemotherapy with chemotherapy followed by transplantation in patients with intermediate high-grade lymphoma who had one or more unfavorable prognostic features did not show a significant difference in event-free overall survival rates in the study arms.[42] However, an analysis limited to these poor-risk subsets demonstrated significant benefit in disease-free survival for patients with high-dose therapy and autologous transplantation.[43] The 5-year disease-free survival rate after autologous transplantation was 59% and superior to that with chemotherapy (39%; $P = 0.01$) in the poor-risk patient subsets.

Those patients who achieve only a partial remission with primary chemotherapy are rarely cured by further chemotherapy. Dose escalation theoretically may result in a durable response in drug-sensitive subjects and has been shown to be an effective approach. Therefore, patients who achieve only a partial

remission but are sensitive to chemotherapy are appropriate candidates for transplantation before tumor regrowth.

A number of phase II trials have been conducted to determine the curative potential of high-dose therapy and autologous transplantation in patients with low-grade lymphomas.[44] [45] [46] [47] Even if the approach was noncurative, the prolongation of remission itself would be a worthwhile goal for this group of patients. Similar to diffuse, aggressive, high-grade lymphoma, selection of appropriate patients is crucial for the success of high-dose therapy and autologous transplantation in low-grade lymphoma. The long natural history of patients with low-grade lymphoma makes it difficult to determine if a proportion of malignant patients are cured or had their survival prolonged by high-dose therapy and autologous transplantation. Figure 87-6 illustrates what is considered to be the best available historical comparison for patients with recurrent low-grade lymphoma. This analysis from St. Bartholomews Hospital in London

Figure 87-6 Freedom from progression in 41 patients with follicular lymphoma in second remission treated with cyclophosphamide and total-body irradiation plus autologous bone marrow transplantation (ABMT) compared with 34 historical control patients treated with chemotherapy at St. Bartholomews Hospital. *(Reprinted with permission from Rohatiner AZ, Johnson PW, Price CG et al.[44])*

showed that freedom from recurrence and survival rates for patients treated with cyclophosphamide and fractionated TBI plus purged autologous marrow cells were improved compared with chemotherapy control patients matched for remission status. Although there was a statistically significant advantage in disease control with a high-dose approach, this did not translate into a survival benefit. [47]

Similar to large cell lymphoma, several groups have attempted to identify patients with low-grade lymphoma with poor-risk features who should undergo

transplantation during first remission. Disease-free survival rates in these studies were extended compared with remission durations expected with chemotherapy, and overall survival rates to date have been excellent. [48] [49] Based on available data, patients with low-grade lymphoma with brief initial remissions or in complete second remissions with standard treatment who represent groups of patients with very short survivals after relapse are the most appropriate candidates for high-dose therapy and autologous transplantation. In addition, those patients who present with poor prognostic features, similar to the criteria used for intermediate-grade lymphoma, might also be suitable candidates for clinical trials.

OTHER TYPES OF LYMPHOMA

Autologous stem cell transplantation has been used for patients with various other subtypes of poor-prognosis lymphoma, including lymphoblastic lymphoma, Burkitt lymphoma, and mantle cell lymphoma.[38] The success of transplantation with these histologic subtypes is related to the extent of disease at the time of diagnosis and the response to conventional therapy.

CHRONIC LYMPHOCYTIC LEUKEMIA

Although a large number of patients have undergone autologous transplantation for acute leukemia, CML, myeloma, lymphoma, and Hodgkin disease, there have been relatively few studies addressing the issue of autologous transplantation in chronic lymphocytic leukemia. [50] [51] [52] This subject has been limited by the older age of the population and the higher degree of contamination in the blood and marrow needed to procure stem cells for support of high-dose therapy. Therefore, patients undergoing transplantation represent a highly select group, namely, those patients who had a very good response to therapy and for whom stem cells could be collected. Although the complete response rate was high, the overall impact on disease-free survival is difficult to ascertain. Nevertheless, the studies suggest that it is feasible to perform the procedure in selected patients. The most important issue to pursuing autologous transplantation for chronic lymphocytic leukemia would be better induction therapies that increase the CR or near-CR rate, similar to what has been seen in other hematologic malignancies.

CHRONIC MYELOID LEUKEMIA

Chronic myeloid leukemia is a malignancy of the hematopoietic stem cell that is caused by the Philadelphia chromosome, resulting from a translocation between the *c-bcr* gene located on chromosome 22 and the *c-abl* gene located on chromosome 9 (see Chap. 62). The resulting p210 oncoprotein is sufficient for malignant transformation of hematopoietic stem cells.[53] CML is invariably lethal and, with the exception of allogeneic transplantation, there has been no curative approach developed for this disease. Conventional therapy has been focused on the use of agents to control blood counts and reduce spleen size, improving symptoms and quality of life.[54] Recently, therapy with interferon- alone or in combination with cytosine arabinoside induced hematologic remissions in up to 80% of patients. [55] [56] Approximately 30% of patients treated with interferon- achieve a complete or major cytogenetic response. [55] [56] These

cytogenetic responses are associated with superior survival rates. [55] [56] Studies also indicate that acquisition of the hematopoietic response without a concomitant major cytogenetic response does not, in and of itself, significantly affect survival. Therefore, the ability to achieve partial or complete reconstitution of normal hematopoiesis is a requirement for improved disease-free survival in this disease.

There is considerable evidence that normal, Philadelphia chromosome-negative (Ph) stem cells coexist in the marrow of patients with CML. [57] In some patients at presentation, both a Ph+ and Ph population can be detected. [57] Patients who have had higher doses of busulfan or induction chemotherapy regenerate with Ph hematopoiesis, albeit transiently. [58] [59] [60] These clinical observations have also been corroborated by a number of in vitro studies showing that Ph progenitors coexist with Ph+ cells, and long-term culture accentuates this kinetic difference (see Chap. 70).

A large number of studies have focused on approaches to enrich the benign progenitor population by negative or positive selection. The relative difference in the compartment size between the diseased cells and normal cells has made this difficult and has limited the success of autografting patients with CML. Initial transplantations were performed in blast crisis using marrow that was cryopreserved during the chronic phase. The re-establishment of the chronic phase after transplantation was usually short lived, with recurrence of blast crisis. [61] Subsequently, other investigators, using unmanipulated autologous peripheral blood stem cells in patients with CML, showed that major cytogenetic responses could be achieved and that the actuarial survival rates were higher than expected with conventional chemotherapy.[62] [63] The encouraging results seen after transplantation with these unmanipulated, highly contaminated cell populations led to the development of stem cell manipulations to augment the ratio of normal to abnormal cells. These have included the use of 4-hydroperoxycyclophosphamide, interferon, ex vivo marrow culture, antisense oligonucleotides directed against *bcr-abl,* antisense oligonucleotides directed against *c-myb,* as well as in vivo selection by priming and mobilization of stem cells after recovery from chemotherapy.[64] [65] [66] [67] [68] [69] [70] For those patients treated in the early chronic phase, the pilot data appear encouraging for obtaining a graft that is less contaminated. As noted previously, studies of genetically modified stem cells in CML have documented the contribution of the graft to relapse after transplantation.[15] Improvements in long-term disease-free survival using autologous transplantation will require attention both to the body burden of leukemia as well as to the contaminating cells in the stem cell graft. Newer approaches to modify the graft include the use of genetically modified antisense sequences, ribozymes, and tyrosine kinase inhibitors, as well as exploitation of abnormal in vitro growth characteristics of malignant CML progenitor cells. [71] [72] [73] [74] [75] Some investigators have focused on phenotypic separation of benign progenitor cells based on the concept that the normal hematopoietic stem cell is present in the CD34 fraction of marrow or blood.[76] [77] Interestingly, once the disease progresses, this stem cell compartment decreases in size, possibly explaining the benefit of early transplantation for improved disease-free survival in patients treated with aggressive chemotherapy. Because CML is one of the foremost examples of disease for which a graft-versus-tumor effect is effective, other investigators have focused on the identification of immunologic approaches to purge CML marrow, including interleukin-2, the co-incubation of natural killer and cytokine-induced killer (CIK) cells, as well as the development of antigen-specific T cells recognizing tumor-derived immunogenic peptide.[78] [79] [80] [81]

Studies to date indicate that autologous transplantation for CML, although not curative, is probably capable of improving survival. Figure 87-7 (Figure Not Available) compiles the results of 200 consecutive autologous transplantations performed with purged or unpurged

Figure 87-7 (Figure Not Available) Survival by disease stage with autologous transplantation for chronic myeloid leukemia: chronic phase (n = 141); accelerated phase (n = 30), blast crisis (n = 27). *(Update provided by Verfaillie CM, Bhatia R, McGlave PB: Autologous hematopoietic cell transplantation in chronic myeloid leukemia. marrow or blood grafts at 8 different institutions in Europe and North America between June, 1984 and June, 1992. [82] The median survival of 142 patients with chronic-phase CML has not been reached, suggesting that autografting may provide prolonged survival that may exceed that associated with conventional therapy. The results are clearly improved if the patient undergoes transplantation in the early course of the disease rather than awaiting acceleration or blast crisis. Because most patients eventually show hematologic or cytogenetic relapse, this improved survival is probably not due to elimination of the Philadelphia clone but to a reduction in the overall tumor cell burden and delay of progression of the disease. It is likely that in future trials the use of intensive therapies earlier in the course of the disease will have the best chance of improving disease-free survival, an observation that has also been seen with interferon therapy, where the drug is less effective after the patient has had the disease for more than a year.

MULTIPLE MYELOMA

Multiple myeloma is part of a spectrum of disorders referred to as *plasma cell dyscrasias,* which include benign conditions such as monoclonal gammopathy (see Chap. 76) and account for approximately 10% of hematologic tumors, with a median age at diagnosis of approximately 65 years. Symptomatic multiple myeloma requires initiation of systemic therapy using either melphalan and prednisone or combination chemotherapy, most commonly vincristine, doxorubicin (Adriamycin), and decadron (VAD). Very few patients achieve a true CR and the median survival is approximately 36 months.

High-dose cytotoxic therapy combined with autologous transplantation was first considered for multiple myeloma in 1986, resulting in some patients having prolonged survival with minimal disease activity.[83] In 1983, investigators from the Royal Marsden Hospital explored high-dose melphalan alone at a dose of 140 mg/m ^{2} .[84] The observation of true CRs after this procedure performed without hematopoietic growth factor and stem cell support led to the introduction of autologous transplantation in the mid-1980s, initially in support of higher-dose melphalan or melphalan combined with TBI. [85] [86] An underlying hypothesis in these trials was that the reinfusion of typically hypoproliferative tumor cells with low in vitro clonogenic potential would not contribute significantly to disease recurrence

despite their presence in the graft. This has led to studies focused on high-dose therapy given during the early phase of disease as well as the exploration of multiple cycles of high-dose therapy, each supported by stem cells.

A number of phase II studies indicated a high response rate as well as apparent improved disease-free survival rates in patients undergoing high-dose therapy for multiple myeloma.[87] [88] [89] [90] These studies have achieved a 4050% CR rate with a median duration of progression-free survival of 2436 months. [91] Patients with chemosensitive tumor cells or who are less heavily pretreated have the most favorable outcome. The major favorable prognostic features associated with event-free survival and overall survival after autologous transplantations include low levels of $_2$ -microglobulin and CR before transplantation; the absence of unfavorable cytogenetics (i.e., abnormalities of chromosomes 11 and 13); <12 months of standard therapy preceding transplantation; and non-IgA myeloma. Combinations of these important prognostic variables allow a risk-based therapeutic approach to patients with multiple myeloma. Most important, a recently completed national French trial of 200 patients with multiple myeloma demonstrated the efficacy of high-dose therapy in improving the outcome of these patients. [92] In this trial, patients received two courses of vincristine, melphalan, cyclophosphamide, and prednisone (VMCP) alternating with vincristine, carmustine, doxorubicin, and prednisone (VBAP), and were then randomized to receive either conventional chemotherapy (eight additional courses of VMCP/VBAP) or high-dose therapy (melphalan and TBI) followed by autologous transplantation. The transplantation patients demonstrated significantly higher response rates, event-free survival, and overall survival rates compared with those treated with conventional therapy. Response rates in the high-dose and conventional arms were 81% and 57%, respectively. The 5-year probabilities of event-free survival and overall survival was 28% and 52%, respectively, in recipients of high-dose therapy, and only 10% and 12% in patients treated with conventional therapy: The treatment-related mortality was comparable between the two groups (Fig. 87-8). Attempts to improve this outcome include the use of autologous BMT, either depleted of tumor cells or processed to select normal hematopoietic progenitor cells, as well as the use of multiple autologous transplantations and biologic therapy. [93] [94] [95]

ACUTE LYMPHOBLASTIC LEUKEMIA

Improvements in induction and consolidation therapy for both adults and children with acute lymphoblastic leukemia (ALL) have resulted in improved disease-free survival, particularly in those with certain subgroups of disease. [96] [97] [98] For those patients with high-risk features, including the Philadelphia chromosome, high WBC count at diagnosis, and longer time to achieve remission, allogeneic transplantation has also been successfully used to prevent disease recurrence. [99] However, most patients with high-risk ALL or those with second CR do not have a readily available histocompatible related or unrelated donor. The experience of autologous transplantation, both in single institutional studies as well as in larger, randomized trials, has been less than in patients with AML and has focused in general on children with the disease, usually in second remission. One controlled trial has compared autologous transplantation with allogeneic transplantation in ALL. [100] Kersey and colleagues transplanted 91 patients with high-risk, refractory leukemia; 45 patients without a matched donor received an autologous purged transplant, whereas 46 patients who had a donor underwent allogeneic transplantation after preparation with fractionated TBI and cyclophosphamide. [100] It was noteworthy that although the overall 4-year disease-free survival rates did not differ significantly in the two groups, the causes of failure differed. Allogeneic recipients experienced a high mortality rate

Figure 87-8 Overall survival according to treatment group in patients with multiple myeloma, 60 years of age or younger, who were treated with either conventional-dose or high-dose chemotherapy. *(Re-printed with permission from Attal M, Harousseau JL, Stoppa AM et al: Autologous bone marrow transplantation versus conventional chemotherapy in multiple myeloma: a prospective randomized trial. N Engl J Med 335:91, 1996. Copyright © 1996 Massachusetts Medical Society. All rights reserved.)*

from transplantation complications, but few relapses. Autologous transplant recipients experienced a very high relapse rate.

Most centers that have pursued autologous transplantation for ALL have used in vitro purging with antibodies to B- or T-cell early differentiation antigens. [101] [102] [103] Transplantation in first remission has been used primarily in children with very high-risk features. [104] In this group, disease-free survival rates for transplantation range from 30 to 60% with variable follow-up. The European Cooperative Group for Bone Marrow Transplantation has reported the results of autologous transplantation for over 500 patients with ALL.[105] Disease-free survival rates for patients with standard risk (n = 173) and high risk (n = 41) autografted in second remission were 31% at 5 years and 23% at 30 months, respectively. For children who underwent autologous transplantation in second remission, the survival rate was 42%. In the analysis of different patient groups and treatment, disease-free survival was better in patients receiving purged versus unpurged marrow and in patients receiving fractionated versus single-dose TBI. Others have noted that the single most important predictor of outcome after autologous transplantation was the duration of the initial remission.[106] In one series, the event-free survival rate was 44% for patients with a long first remission of at least 24 months, compared with 5% among those patients who had a shorter first remission but who received the same conditioning regimen. Some investigators recently have reported more encouraging results with the addition of etoposide to a conventional regimen of cyclophosphamide and TBI. [107] In most series, adult patients had a higher relapse rate compared with pediatric patients, resulting in inferior disease-free survival for adult patients. [108]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

LONG-TERM COMPLICATIONS OF AUTOLOGOUS TRANSPLANTATION

Most patients recover from the acute effects of the high-dose regimens used in the treatment of their disease. This has been

facilitated by the use of stem cells obtained from the peripheral blood after mobilization with chemotherapy and/or hematopoietic growth factors, peritransplant growth factor support, antifungal agents, and transfusions.

Cataracts

Cataracts are a complication that usually results from the use of TBI in the preparatory regimen. An analysis from the European Bone Marrow Transplant Registry indicated that cataracts developed only in those patients who received TBI. [109] [110] Depending on the degree of impairment of visual acuity, lens replacement can be performed with excellent results.

Secondary Malignancies

Most surveys of patients undergoing autologous transplantation for treatment of malignancy have not documented an increase in the incidence of secondary malignancies. The follow-up for those patients is shorter than for allogeneic recipients, in whom an increase in solid tumors has been observed, so all long-term transplantation survivors should be followed for the development of new malignancies.

The most important long-term complication of autologous SCT is the development of myelodysplastic syndrome (MDS) or secondary leukemia. [111] [112] [113] The incidence of secondary acute leukemia and MDS, although difficult to assess, appears to be substantially lower in patients undergoing transplantation for AML than in those receiving similar preparative regimens for lymphoma and Hodgkin disease. This finding has been attributed to the type of prior therapy that is used in patients with Hodgkin disease, lymphoma, and myeloma (e.g., alkylating agents, topoisomerase I and II inhibitors), as opposed to patients with acute leukemia whose therapy is built around the use of anthracycline and cytosine arabinoside. MDS is reported to occur in 615% of patients undergoing autologous SCT for lymphoma or Hodgkin disease.[114] The most significant factor for the development of this problem is the amount of therapy the patient has received before SCT. In principle, patients who receive marrow grafts incubated with cytotoxic agents may be at risk for secondary leukemia. Despite this concern, the experience to date is probably sufficient to indicate that there is not a dramatic increase in secondary hematopoietic tumors in the recipients of chemotherapy-treated autologous grafts. [115]

Infertility

One of the major complications of high-dose chemoradiation therapy for the treatment of hematologic malignancy is infertility, a frequent concern expressed by young patients who are being evaluated for transplantation. [116] With current methods, men are sometimes able to collect viable sperm for future use and women are able, under some circumstances, to cryopreserve fertilized ova for implantation after transplantation. New techniques involving the harvesting of and storage of ova before fertilization will further expand the possibilities for female patients. Despite these technical advances, the expense is often limiting, and there is not always sufficient time to collect sperm or fertilized eggs before proceeding to urgently needed antitumor therapy. Prior therapy can reduce the quality and quantity of viable sperm necessary for storage.

Impairment of ovarian function after radiation depends on the radiation dose and the patients age. [117] Patients who are young and receive TBI can, on rare occasions, recover ovarian function and fertility. Nevertheless, for most patients receiving high-dose radiation therapy-containing regimens, infertility is a long-term problem.

More than 90% of men given TBI are azoospermic and have elevated follicle-stimulating hormone levels. There is less effect on testosterone levels, with some patients having normal levels of luteinizing hormone and testosterone. However, some patients demonstrate hypogonadism requiring replacement therapy (transdermal testosterone patches or intramuscular injections). Women in whom an early menopause develops can usually be treated with hormone replacement therapy to avoid secondary problems of osteoporosis, coronary artery disease, and sexual dysfunction. The effect of these therapies on sexual satisfaction is an important one. As the number of long-term survivors undergoing autologous transplantation increases, the issues of fertility and normal sexual function are becoming increasingly important problems.[116]

Chapter 88 - Clinical Results of Autologous Stem Cell Transplantation for Solid Tumors in Adults

Yago Nieto
Elizabeth J. Shpall

INTRODUCTION

Autologous bone marrow or peripheral blood progenitor cells (PBPCs) are used as hematopoietic stem cell support in patients with solid tumors after the administration of high-dose chemotherapy (HDC). This process is also known as autologous stem cell transplantation (ASCT). The HDC regimens that are responsible for the eradication of tumor cells typically use two or three drugs that meet the following criteria: known activity at conventional doses in the tumor in question, a steep dose-response effect, and often myelosuppression as the major standard dose-limiting toxicity. When doses are further escalated, the myelosuppression is surmounted by the infusion of the patients own stem cells, which are collected and cryopreserved prior to HDC administration. Thus, ASCT allows a 210-fold increase in the doses of the drugs used. In this setting, extramedullary organ toxicities become dose limiting. [1] The goal of this strategy

is to achieve more tumor cell killing than standard-dose therapy, which will hopefully result in improvements in long-term disease-free survival (DFS).

A potential obstacle to the successful use of ASCT in diseases that often involve the bone marrow, such as breast cancer, is the possibility of infusing an autograft contaminated with tumor cells. This has prompted research efforts directed at effectively purging cancer cells from the stem cell product before transplant using alternative sources of stem cells, such as peripheral blood, and identifying patients for treatment who are less likely to have marrow metastases.

BREAST CANCER

Metastatic Breast Cancer

Metastatic breast cancer is considered incurable for the majority of patients who receive standard chemotherapy. [2] Although in many cases the tumor responds initially to chemotherapy, additional cycles become substantially less active and eventually the tumor ceases to respond.

Retrospectively, Hryniuk and Bush showed that within the conventional range, dose intensity correlates with antitumor activity and clinical outcome. [3] Prospective studies testing dose reduction below the standard range, in an attempt to reduce toxicity, produced less antitumor effect and compromised palliation. [4] A minor increase of dose intensity, however, does not improve results. [5] To overcome tumor cell resistance to the degree that would have a significant clinical impact, a substantial dose escalation beyond normal bone marrow tolerance is needed. This clinically relevant dose escalation, which exceeds normal bone marrow tolerance, requires subsequent autologous stem cell support.

The first HDC trials for patients with breast cancer were initiated in the mid 1980s. As with all other therapies that have a curative intent, minor dose reductions result in a critical compromise of the antitumor efficacy; [6] therefore, the maximally tolerated doses of the drugs were used. Alkylating agents constituted the backbone of the HDC regimens based on their activity against breast cancer, steep dose-response effect, non-cross-resistance, and nonoverlapping extramedullary toxicities. [7] The use in these trials of multiple drug combinations was supported by in vitro data and results from standard-dose treatment in other more chemosensitive diseases [7] (Table 88-1).

A sequential series of trials demonstrated that ASCT as salvage treatment for patients with refractory metastatic breast cancer produced a high response rate. [8] [9] [10] However, the responses were short-lived and had no impact on survival. Results improved when ASCT was used as initial therapy for patients with metastatic disease. [11] High-dose chemotherapy was then used as consolidation after aggressive standard-dose induction chemotherapy. [12] [13] [14] Induction regimens, such as AFM (Adriamycin, 5-fluorouracil, and methotrexate), [15] were designed to provide substantial cytoreduction prior to ASCT. Phase II trials testing the strategy of induction followed by

TABLE 88-1 -- Initial High-Dose Combinations of Alkylating Agents

Regimen	Composition	Author
CCB	Cyclophosphamide 5,625 mg/m^2 Cisplatin 165 mg/m^2 BCNU 600 mg/m^2	Peters WP et al. [8]
CTCb	Cyclophosphamide 6,000 mg/m^2 Thiotepa 500 mg/m^2 Carboplatin 800 mg/m^2	Eder JP et al. [10]
CT	Cyclophosphamide 7,500 mg/m^2 Thiotepa 675 mg/m^2	Williams SF et al. [143]

Figure 88-1 Relapse-free survival curve of the whole population of stage IV breast cancer patients treated with HDC at the University of Colorado Bone Marrow Transplant Program.

ASCT consistently demonstrated that 1525% of patients remained free of disease long-term as shown in Figure 88-1 . [12] [13] [14] Autologous SCT was most effective at a time of minimal tumor burden. Adequate local treatment (surgery or radiotherapy) to pre-transplant sites of bulky disease was added as part of the overall strategy. The mortality rate in these HDC trials has decreased from 20% initially to a current 25%, similar to what is often reported for standard-dose regimens (Table 88-2).

New High-Dose Chemotherapy Regimens

Current research efforts are directed at improving the antitumor activity of ASCT. An important strategy to deliver a single potent treatment pre-transplant is the optimization of ASCT regimens by adding more active drugs. The most active single agents against breast cancer are doxorubicin and the taxanes, paclitaxel and docetaxel. [2] Doxorubicin is an essential component of the pre-HDC induction combinations, but because of the potential for cardiotoxicity, it is not included in most ASCT regimens. Paclitaxel, while not an alkylator, has an in vitro and clinically established dose-response effect, [16] [17] [18] and, at standard doses, produces dose-limiting myelosuppression. [19] A phase I study conducted at the University of Colorado escalated paclitaxel with fixed doses of cyclophosphamide and cisplatin, up to a maximum tolerated dose of 775 mg/m^2 . [20] The resulting regimen of cyclophosphamide, cisplatin, and paclitaxel, is presently under evaluation in a phase II trial of patients with metastatic breast cancer. [21] High-dose paclitaxel has been incorporated into other ASCT regimens. [22] [23] Dose escalation of docetaxel with ASCT is being explored at the University of Colorado BMT Program.

Tandem or Multiple Transplants

A different strategy assumes that more than one cycle of ASCT is needed to eradicate the tumor. Dunphy et al. [24] used two cycles of high-dose myelosuppressive, but not myeloablative, therapy with DFS rates of 25% reported at 2 years, which is comparable to those reported with a single cycle of myeloablative HDC. Multiple rapid cycles of chemotherapy with ASCT are being investigated by workers at a number of institutions. [25] [26] The feasibility of delivering tandem cycles of myeloablative chemotherapy has been demonstrated in several studies. [27] [28] [29] The value of administering two cycles of the same HDC regimen is unclear because antitumor activity seems to decrease substantially after the first cycle. [29] The use of two different non-cross-resistant combinations administered sequentially has been explored.

TABLE 88-2 -- Sequential Strategies Used in Phase II Trials of High-Dose Chemotherapy for Metastatic Breast Cancer

Strategy	Regimens Used	No. of Patients	Complete Response (%)	Long-term Disease-Free Survival (%)
Refractory disease	CCB [9]	23	26	0
	CTCb [10]	16	6	0
Up-front Rx for MBC	CCB [11]	22	54	14
Consolidation after induction	AFM CCB[12]	45	57	22[a]
				26[b]
	AFM CTCb[13]	29	45	17
	LOMAC/FCAP CT[14]	62	32	13[a]
				17[b]

MBC, metastatic breast cancer; LOMAC/FCAP, cyclophosphamide, Adriamycin, vincristine, methotrexate with leucovorin rescue/fluorouracil, cisplatin, Adriamycin, and cyclophosphamide.

[a]DFS based on intent-to-treat analyses.
[b]DFS for patients actually treated with HDC.

Ayash et al.[30] treated chemosensitive breast cancer patients with high-dose melphalan (140180 mg/m ^{2}) followed, within a median of 35 days, by high-dose cyclophosphamide, thiotepa, carboplatin (CTCb) with ASCT after both cycles. With a median follow-up of 16 months after the second cell reinfusion, the DFS of 34% appears similar to results achieved with a single ASCT treatment. The reverse sequence of cyclophosphamide and thiotepa (CT) followed by melphalan, reported by Bitran et al.[31] with longer median intervals between cycles (median, 105 days vs. 35 days in the Ayash study), produced a DFS rate of 56% at a median follow-up of 25 months from the first reinfusion. Whether the Bitran and Ayash studies produced significantly different results is unclear, given the small size of the studies with DFS ranges that overlap. Theoretically, the longer interval between cycles of the Bitran study could potentially allow the acquired drug resistance to revert after the first cycle.

Is High-Dose Chemotherapy with Autologous Stem Cell Transplantation Better Than Standard-Dose Chemotherapy for Metastatic Breast Cancer?

Autologous stem cell transplant consistently yields a 1520% rate for long-term DFS for patients with chemosensitive metastatic breast cancer. This seems substantially higher than the long-term results, ranging from 03%, for standard-dose chemotherapy in this patient population. [32] [33] [34] However, the effect of patient selection bias, based on more extensive staging for patients on ASCT trials, age, performance status, and chemosensitivity, cannot be excluded, underscoring the need for prospective randomized trials.

Bezwoda et al.[35] randomized patients with metastatic breast cancer to receive, as first-line therapy for metastatic disease, two cycles of high-dose cyclophosphamide, mitoxantrone, and etoposide (HD-CNV) with ASCT support or six to eight cycles of standard-dose cyclophosphamide, mitoxantrone, and vincristine (CNV). Patients on the high-dose arm had significantly higher response, complete response (CR), DFS, and overall survival (OS), as well as a longer median duration of response than patients on the standard-dose arm of the trial. Although neither arm of the study used typical chemotherapy regimens, this trial showed, in a prospective fashion, higher antitumor activity and a survival advantage for the ASCT arm.

Peters et al.[36] reported the preliminary results of a large randomized trial that compared the immediate versus the delayed use of ASCT in metastatic breast cancer patients in CR following standard-dose induction chemotherapy. Four hundred twenty-three patients with metastatic breast cancer received AFM; 98 (23%) achieved a CR and were randomized to either immediate ASCT with cyclophosphamide, cisplatin, and BCNU (CCB) or observation. Patients relapsing during observation were transplanted, if feasible, with CCB. The median DFS was longer for patients immediately transplanted compared with those randomized to observation (11 vs. 3.6 months, $p < 0.01$).

However, patients transplanted at relapse had superior OS than those who underwent an immediate transplant (38 vs. 23 months, $p < 0.05$). Although this trial was not designed to directly compare ASCT and standard-dose therapy, its results indicate that ASCT may improve DFS and OS in patients with chemosensitive metastatic breast cancer.

Which Metastatic Breast Cancer Patients Are Most Likely to Benefit from Autologous Stem Cell Transplantation?

Dunphy and colleagues [37] identified liver metastases, soft tissue site, and prior adjuvant chemotherapy as independent negative predictors of OS after ASCT. Ayash et al.[38] reported that a single metastatic site and attainment of a CR to induction chemotherapy were the most significant positive predictors for DFS. Doroshow and colleagues[39] obtained the longest DFS rates in patients transplanted in CR, without a history of liver metastases, with fewer number of prior chemotherapy cycles and fewer sites of disease. A univariate analysis by Antman et al. [40] reported that age <40 was significantly associated with shorter DFS and OS rates. Patients treated with ASCT at the University of Colorado for a relapse within a previously irradiated field consistently have a poor outcome (University of Colorado Bone Marrow Transplant Program, unpublished observations). In summary, patients with metastatic breast cancer with a minimal tumor burden, no liver involvement, and chemosensitive disease are those who most likely benefit from ASCT.

A prospective phase II study was initiated in 1990 at the University of Colorado for breast cancer patients with no evidence of disease, defined as only one site of disease, that can either be resected before or encompassed within a radiation field after ASCT (University of Colorado Bone Marrow Transplant Program, unpublished observations). The latest review demonstrated that 55% of 40 patients remain free of disease at a median follow-up of 45 months. The minimal tumor burden and the potential benefit of local therapy to the site of macroscopic disease may be responsible for an improved outcome in that group of stage IV patients (Fig. 88-2).

High-risk Primary Breast Cancer

Once the high activity of ASCT regimens was seen in metastatic breast cancer, the next step was to test this strategy in high-risk primary breast cancer, where the majority of patients will eventually relapse, despite conventional adjuvant therapy. Dose intensity has a greater impact on survival in the adjuvant setting compared with the metastatic setting.[41] [42]

Peters et al. [43] at Duke University conducted the first trial of

Figure 88-2 Relapse-free survival curve of clinical trial conducted at the University of Colorado Bone Marrow Transplant Program on stage IV patients with no evidence of disease. Wedges indicate censored patients.

ASCT in patients with 10 or more (10+) involved axillary lymph nodes. At a median follow-up of 6 years, 65% of 85 evaluable patients remain free of disease. [44] Gianni and colleagues from the National Cancer Institute in Milan used a sequential high-dose single-agent approach in the same patient population. After a median follow-up of 4 years, DFS is 57%.[45] The results of both trials appear superior to standard adjuvant therapy where relapse rates of 6085% are commonly reported for 10+ node patients. Two large cooperative group randomized trials that compare conventional-dose chemotherapy to ASCT are underway to confirm the efficacy demonstrated in the single-arm ASCT trials.

The University of Colorado has piloted the use of ASCT earlier in stage II/III patients with four to nine involved axillary nodes, whose long-term DFS ranges from

4576% with standard-dose adjuvant chemotherapy. Fifty-four patients received four cycles of standard-dose chemotherapy followed by CCB with stem cell support. An actuarial 4-year DFS of 71% was demonstrated at a median follow-up of 31 months.[46] These results stimulated the initiation of a randomized trial that is presently comparing ASCT in four cycles of conventional adriamycin-containing chemotherapy followed by CCB or CTCb versus a dose-intensive nonmyeloablative sequential approach with three cycles each of adriamycin, taxol, and cyclophosphamide plus granulocyte colony-stimulating factor support, developed at the Memorial Sloan-Kettering Cancer Center.[47]

Inflammatory Breast Cancer

Inflammatory breast cancer (IBC) is a very aggressive type of presentation, with a high incidence of local and systemic recurrences, following standard therapy. With the use of multimodal therapy, including doxorubicin-based neoadjuvant chemotherapy, surgery, and radiotherapy, approximately 30% of the patients remain free of disease at 5 years.[48] Systemic relapses still occur in the majority of those with IBC.[49] High-dose chemotherapy has recently been included in the treatment, in varying schedules. Single-institution phase II ASCT trials conducted at the Dana Farber Cancer Institute [50] and the University of Colorado[51] tested CTCb before and CCB after mastectomy, respectively. In both studies patients were initially treated with neoadjuvant Adriamycin-based standard-dose chemotherapy and radiotherapy was added at the end. Preliminary results demonstrate that >70% of patients in both studies remain recurrence free at a median 2 years following transplant. The DFS curves of patients treated at the University of Colorado BMT Program in the different clinical trials of HDC for high-risk primary breast cancer are shown in Figure 88-3 .

Predictive Factors for Relapse After High-Dose Chemotherapy for Primary Breast Cancer

Somlo et al.[52] studied prognostic indicators of relapse in 114 patients with high-risk breast cancer treated with ASCT. In their univariate analyses, the risk of relapse was lower for progesterone receptor (PR)-positive (but not estrogen receptor [ER]-positive) tumors and higher for patients with IBC. PR positivity was the only prognostic factor independently associated with improved DFS in multivariate analyses.

Retrospective review of 176 high-risk patients treated with ASCT at the University of Colorado shows that tumor size, tumor grade, clinical inflammatory presentation, ER and PR negativity, and both the absolute number of positive lymph nodes and the ratio between the number of positive nodes and the total number of lymph nodes sampled (nodal ratio) were statistically associated with relapse in the univariate analyses. In a multivariate analysis, tumor size, ER/PR combined status (only considered negative if both ER and PR are negative), and the nodal ratio remained as independent predictors of relapse. A predictive model with these three tumor-related parameters was subsequently developed to identify a subset of patients with a high probability of relapse after ASCT. [53]

Purging of Stem Cell Grafts

Hematopoietic progenitor cells obtained from the peripheral blood after chemotherapy and/or growth factor priming (peripheral blood progenitor cells or PBPCs) have replaced bone marrow as the primary source of hematopoietic progenitors for ASCT. Although tumor burden may be lower in PBPCs than in bone marrow fractions, [54] current immunocytochemical techniques detect breast cancer cells in PBPC fractions of 1040% of stage IV patients and 520% of patients with stage II disease. [55] Higher relapse rates have been reported for breast cancer patients who received autologous PBPC grafts contaminated with malignant cells, identified in a long-term culture assay, compared to those with no identifiable tumor cells in their graft. [56] [57] Because the majority of patients with stage IV disease relapse in sites of previous bulk disease, the contribution to relapse of

Figure 88-3 Relapse-free survival curves of patients who have received high-dose chemotherapy at the University of Colorado Bone Marrow Transplant Program, included in the 10+ (black curve), 49 positive nodes (solid color curve), and inflammatory breast cancer (IBC) (shaded curve) groups. The number of censored patients within each time interval is indicated.

tumor in the stem cell graft cannot be evaluated in that setting. Whether breast cancer cells in the graft contribute to relapse after transplant remains unclear and will have to be determined in the adjuvant setting. Studies addressing this issue are being designed.

Negative Purging Procedures

Negative purging procedures, either pharmacologic [58] or immunologic,[59] have been used primarily to purge the bone marrow of patients with breast cancer. These procedures can damage or deplete the normal progenitors, delay engraftment, and thereby increase the patients risk of myelosuppressive complications. When immunologic PBPC purging was studied in breast cancer patients, tumor cell removal was achieved without prolongation of the engraftment rates compared with historical controls.[60] However, pharmacologic purging of the marrow,[58] as well as the combination of pharmacologic plus immunologic purging, [59] produced marked delays in engraftment of both neutrophils and platelets. Because of its potential toxicity to the normal hematopoietic cells, negative purging of PBPCs, particularly with chemotherapy, is not commonly performed.

Positive or CD34 Selection

The CD34 antigen is expressed on 0.53% of normal bone marrow cells and PBPCs, including both the committed and probably the long-term reconstituting progenitor cells. CD34 does not appear to be expressed on breast cancer cells. [61] The University of Colorado Bone Marrow Transplant Program has reported data on a series of patients with breast cancer who received ASCT with HDC and a CD34-selected marrow or PBPC graft. [62] The stem cells were CD34 selected with an immunoadsorption device and effectively reconstituted immediate and long-term hematopoiesis in 155 patients. An average two-log (range 1 to >4 logs) tumor cell depletion was achieved following the procedure. The patients who received CD34+ PBPCs, with or without marrow, experienced neutrophil and platelet recovery rates that were identical with those of patients who received unmanipulated stem cell grafts. Long-term follow-up showed that the durability of engraftment, immune reconstitution, and progression-free and OS, were also comparable to those parameters in patients who received unmanipulated hematopoietic cell fractions. [63]

Because the majority of patients with breast cancer still had detectable cancer cells present in their stem cell grafts following CD34 selection, maximally effective purging may require a combination of positive and negative selection procedures.

Future Directions

Ongoing clinical trials of allogenic stem cell transplantation for breast cancer are presently exploring its potential graft-versus-tumor effect. If such an immune-mediated effect can be demonstrated, it could enhance the therapeutic potential of HDC.

Radioimmunotherapy, active in low-grade B-cell non-Hodgkin lymphoma, [64] [65] holds promise for patients with breast cancer. At the University of Colorado a phase I PBPC-supported trial is presently exploring the dose escalation of yttrium 90, conjugated to humanized BrE-3 monoclonal antibody, directed to an epitope of the human milk fat globulin (MUC-1). Preliminary results suggest a high anti-breast cancer activity with this therapy.

OVARIAN CARCINOMA

Improvements are needed in the treatment of advanced ovarian cancer. After initial optimal debulking surgery followed by conventional-dose chemotherapy with paclitaxel and cisplatin, 50% of stage III patients will be rendered disease free when evaluated by second-look laparotomy. Only half of these patients are ultimately cured of their disease. Therefore, optimal treatment cures only 25% of women with stage III diseases. For patients with residual disease at second-look surgery and for those who relapse, standard-dose salvage therapy, while prolonging survival, is not curative. Women with stage IV disease have a 5-year survival rate of <5%. [66]

Rationale for Dose Intensity in Ovarian Cancer

In vitro models suggest that a fivefold escalation in dose is required to overcome drug resistance in ovarian cancer. [67] Alkylating agents exhibit a steep dose-response relationship and synergistic cytotoxicity against ovarian cancer cell lines. [68] Retrospective dose-intensity analysis of 33 different clinical trials of platinum-containing chemotherapy for ovarian carcinoma demonstrated that response and survival correlate with dose intensity. [69]

Moderate dose escalation of the platinum compounds in patients refractory to standard-dose cisplatin can produce a 2030% response rate. However as with patients with metastatic breast cancer, most randomized trials that have explored minor cisplatin dose escalations have failed to show a survival advantage. [70] Because alkylators are among the most active and widely used agents for the treatment of ovarian cancer, the exploration of ASCT with major escalation in chemotherapy doses seemed warranted.

High-Dose Chemotherapy and Autologous Stem Cell Transplantation for Patients with Relapse

In a phase I/II trial of ASCT with intravenous chemotherapy plus intraperitoneal cisplatin conducted at Duke University in those with refractory ovarian carcinoma, 75% of the patients experienced pathologically documented partial response of median 6-month duration. [71] At the University of Colorado, that regimen was subsequently modified, by changing the route of cisplatin administration from intraperitoneal to intravenous and then increasing the doses of chemotherapy. [72]

Stiff et al.[73] from Loyola University, developed an ASCT regimen that includes mitoxantrone, cyclophosphamide, and a 120-hour continuous infusion of carboplatin. In 30 relapsed patients, 20 of whom were refractory to cisplatin, the response rate was 89%. Complete clinical responses occurred in 88% of the cisplatin-sensitive patients and in 47% of the cisplatin-resistant-group (p = 0.06). Median OS was 29 months for the whole population, with a 3-year DFS rate of 23%. [74] A subsequent analysis of those 30 relapsed patients identified cisplatin sensitivity and low tumor burden at the time of HDC as the most significant prognostic factors for survival after ASCT.[75] Patients with <1 cm disease at high-dose study entry, had a 10.3-month median progression-free survival versus 5.2 months for those with >1 cm (p = 0.04). Median DFS was 10.1 months for cisplatin-sensitive patients versus 5.1 months for those in refractory relapse (p = 0.03). At a median follow-up of 12 months, 80% of cisplatin-sensitive patients were alive versus <50% of those with resistant disease. The authors concluded that survival for patients with resistant relapse is similar to that for patients treated with conventional chemotherapy and HDC. Results from the universities of Duke/Colorado and Loyola studies in relapsed/refractory patients are summarized in Table 88-3 .

A Southwest Oncology Group randomized phase II trial for stage III/IV patients with residual disease (up to 3 cm) after cisplatin-based chemotherapy, conducted to compare the toxicity of the Duke/Colorado and Loyola regimens, has completed accrual. Analysis of this ambitious study will help shape future

efforts in ASCT therapy of advanced ovarian carcinoma patients.

Autologous Stem Cell Transplantation as Front-Line Therapy for Advanced Ovarian Carcinoma

The Europeans have pioneered the use of ASCT as part of the front-line treatment for stage III/IV ovarian cancer. In most studies, patients are initially surgically debulked, treated with cisplatin-based chemotherapy (generally six cycles), followed by second-look surgery. High-dose chemotherapy with stem cell support is then used as consolidation.

The French Melphalan-based Trials

Viens et al.[76] reported their results in 28 ovarian cancer patients (17 with stage III and 11 with stage IV disease) with initial cytoreductive surgery. Residual tumor was <2 cm in 6 patients and >2 cm in 22 patients. All patients received six courses of cisplatin-based chemotherapy. Twenty-two patients (78%) had second-look surgery performed. Pathologic complete responses (pCR) were documented in 10 patients, microscopic disease in 2 patients, and persistent macroscopic tumors in the remaining 10 patients. Subsequently, patients received ASCT with a melphalan-containing HDC combination. The toxic death rate was 4%. The expected OS and DFS rates at 3 years are 72.5% and 52.5%, respectively.

Legros et al.[77] treated 53 patients (38 with stage III and 15 with stage IV disease) with similar ASCT consolidation after surgical debulking, six courses of conventional cisplatin-based chemotherapy, and second-look surgery. Nineteen patients had a pCR at second-look, 7 patients had microscopic disease, and 22 had macroscopic disease, most of whom underwent complete redebulking. Intensive chemotherapy consisted of melphalan 140 mg/m^2 (23 patients) or carboplatin at

1,0001,500 mg/m^2 plus cyclophosphamide at 6 g/m^2 (30 patients). With a median follow-up of 80 months, reported OS and DFS rates are 60% and 23%, respectively.

A retrospective analysis of 35 patients treated at both institutions correlated the status at transplant, following second-look surgery, with progression-free survival. [78] Although patient-selection bias may have influenced results, ASCT seems to improve OS and DFS when compared to historical controls (Table 88-4).

TABLE 88-4 -- Patient Outcome According to Status at Second-look Surgery

Status at Second Look	No. of Patients	PFS (8+ to 35+ mo FU)
Residual disease >2 cm	16	31%
Residual disease <2 cm	10	30%
No residual disease (pCR)	9	66%

PFS, progression-free survival; FU, follow-up; pCR, pathologic complete remission.

Other Studies with Autologous Stem Cell Transplantation as Consolidation for Up-Front Therapy

Benedetti-Panicci et al. [79] treated 20 stage III/IV patients, having 0.52 cm residual tumor, with two cycles of a cisplatin-based regimen, followed by ASCT with cisplatin (100 mg/m^2), etoposide (650 mg/m^2), and carboplatin (1,800 mg/m^2). Second-look surgery revealed a 37% pCR rate, whereas 26% of the patients had microscopic and 21% macroscopic disease. With a median follow-up of 4 years, OS and DFS rates for the whole group are 62% and 57%, respectively. Eighty-five percent of patients in pCR and 60% of those who had their disease completely resected at second-look surgery remain free of disease (Table 88-5).

In summary, ASCT may prolong DFS and OS, both in chemosensitive relapses and as up-front therapy for advanced disease, particularly in patients with minimal disease or negative second-look after the standard therapy. A cooperative group study that compares ASCT with high-dose therapy to the best conventional treatment for patients with advanced disease has been initiated in the United States. After four to six cycles of a platinum compound plus taxol and a second-look procedure, patients with at least a partial response and no tumor nodule >1 cm without surgical cytoreduction are randomized to six additional cycles of carboplatin-taxol or ASCT with the Loyola regimen of cyclophosphamide, mitoxantrone, and carboplatin.

NONSEMINOMATOUS GERM CELL TUMORS (NSGCT)

First-line standard-dose cisplatin-based combinations yield long-term DFS rates of 90% in good-risk patients with advanced-disease, which decreases to 5560% in poor-risk patients.[80] Standard-dose salvage regimens, including ifosfamide and cisplatin, cure about 25% of patients in first relapse. Patients in second relapse are incurable with standard treatment. Therefore, in parallel studies directed at reducing the toxicity of therapy for good-risk patients, ASCT was explored for those indications where conventional chemotherapy offered less satisfactory results.

Autologous Stem Cell Transplantation for Refractory or Relapsed Nonseminomatous Germ Cell Tumors

Nichols and colleagues at Indiana University developed a highly active combination of carboplatin at 1,500 mg/m ^{2} and etoposide at 1,200 mg/m^2 (CE), that was used as a tandem transplant with stem cell support after each of the two cycles.[81] Long-term follow-up showed that 15% of 40 refractory patients were free of disease.[82] These two drugs became the core of ASCT regimens for NSGCT. A subsequent Eastern Cooperative Oncology Group trial confirmed their curative potential and feasibility within a multicenter setting.[83]

Autologous stem cell transplant was then administered earlier in the course of disease, to patients in first relapse. Motzer

and colleagues from Memorial Sloan-Kettering showed that ASCT is better tolerated when refractory patients are treated early in the course of their disease, rather than when disease is progressing.[84] Subsequent trials confirmed improved outcome for ASCT used in first relapse, with a 38% long-term DFS rate.[85] [86] As with other solid tumors, improved supportive measures progressively decreased the toxic death rate from 21% in the initial study by Nichols et al. [81] to 03% in these last trials.

The addition of a third drug to the two-drug CE combination has been explored. While short infusions of high-dose ifosfamide are often nephrotoxic, [87] a protracted 22-hour infusion of this drug at 10 g/m ^{2} can be administered safely with CE, as shown by Siegert et al.[88] Motzer et al.[89] gave 60150 mg/kg of cyclophosphamide, 1,500 mg/m^2 of carboplatin, and 1,200 mg/m^2 of etoposide (CEC) to 58 refractory patients. The CR rate attained was 40%, and the DFS rate was 21% at a median follow-up of 28 months; the toxic death rate in that trial was 12%.

In an attempt to increase their activity, doses of carboplatin and etoposide were escalated further. Their respective maximally tolerated doses were established at 2,100 mg/m^2 and 2,250 mg/m^2 per cycle.[90] Dose-limiting toxicities were neurologic and mucosal. In the phase II trial of this tandem two-drug regimen, 52% of 25 patients treated in first relapse remained disease-free at a median follow-up of 26 months.[91]

A randomized trial for relapsed patients that compares conventional salvage chemotherapy with ASCT as consolidation after standard chemotherapy is presently underway in Europe.

Up-front Autologous Stem Cell Transplantation for Poor-risk Nonseminomatous Germ Cell Tumors

A European randomized trial, conducted from 1988 through 1991 in 115 patients, failed to show a therapeutic benefit for early high-dose therapy for poor-risk patients.[92] Previously untreated patients were randomized to receive three or four cycles of vinblastine, etoposide, bleomycin, and high-dose cisplatin (200 mg/m ^{2}) (PveBV), or two cycles of PveBV followed by one cycle of a stem-cell-supported HDC regimen that included cisplatin at 200 mg/m ^{2} , etoposide at 1,500 mg/m^2 , and cyclophosphamide at 6,400 mg/m^2 (PEC). This study has been extensively criticized. The patients on the high-dose arm received less total cisplatin than those on the standard-dose arm. PEC, which was a state-of-the-art high-dose regimen in 1986, when the trial was initiated, is considered substandard by modern criteria. The cisplatin dose of 200 mg/m^2 is therapeutically similar to 100 mg/m^2 .[93] It is possible that a higher dose escalation of the platinum compound is necessary to overcome resistance in NSGCTs. Long-term follow-up suggests that carboplatin, which can be escalated more than four-fold, may be more efficacious in refractory tumors than

cisplatin-based combinations, such as PEC, where only moderate dose escalations of cisplatin can be achieved.

Motzer and colleagues administered ASCT as initial treatment to patients with advanced poor-prognostic disease, per Memorial Sloan-Kettering criteria, who had a reduced clearance of tumor markers with standard-dose chemotherapy that included vinblastine, cyclophosphamide, dactinomycin, bleomycin, and cisplatin (VAB-6).[94] Reduced clearance of tumor markers, defined as prolonged half-life of either -fetoprotein or human chorionic gonadotropin (HCG), >7 days and >3 days, respectively, was used as an early indicator of cisplatin resistance. A total of 28 patients received VAB-6 as initial therapy, and 22 of them were switched, after two cycles, to ASCT with two cycles of CE. The CR rate for patients in this trial was 56%, and 46% of patients were recurrence free at a median follow-up of 31 months. The toxic death rate was 5%.

In a continuation study,[95] these investigators substituted VIP (etoposide, ifosfamide, and cisplatin) for VAB-6 as initial therapy for 30 patients. Fourteen of them experienced slow decline

of markers after two cycles of VIP and were treated with two cycles of high-dose CEC. With a 0% toxic death rate, 57% of patients achieved a CR, and 50% remained free of disease at median follow-up of 30 months. Administering ASCT to poor-risk patients showing a slow decline in tumor markers yielded longer survival when retrospectively compared with historical controls treated with conventional-dose chemotherapy at the same institution (p = 0.001). [95]

An ongoing Intergroup randomized trial is addressing the use of up-front ASCT. Untreated poor-prognosis patients, by the International Classification, [96] are randomized to a standard-dose arm that includes four cycles of BEP (bleomycin, etoposide, and cisplatin), or the high-dose arm, which includes two cycles of BEP followed by two cycles of high-dose CEC with ASCT.

Predictive Factors for Nonseminomatous Germ Cell Tumors Treated with Autologous Stem Cell Transplantation

Beyer et al.[97] constructed a prognostic model for relapsed or refractory NSGCT treated with ASCT, based on 310 patients treated with CE-based high-dose regimens in several European and American institutions. Chemorefractoriness was defined as tumor progression while on cisplatin, progression within 4 weeks after prior response, or disease stabilization. Multivariate analysis identified chemorefractoriness, mediastinal primary tumor; and HCG >1000 U/L at ASCT, as independent negative risk factors for relapse and survival. The model assigns patients to three risk categories, according to the presence of those variables, with DFS at 2 years after ASCT of 51%, 27%, and 5%, respectively.

Broun et al.[98] of Indiana University reported that none of 12 patients with a primary mediastinal tumor who received ASCT remained free of disease long-term. Motzer et al.[89] reported that in their series of 58 patients with refractory disease, those with pretreatment levels of HCG <100 times the upper normal limit, and those with retroperitoneal as opposed to nonretroperitoneal metastases, experienced a longer median OS rate.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

SMALL-CELL LUNG CANCER

Small-cell lung cancer (SCLC) is an aggressive tumor, which is typically responsive to initial conventional-dose chemotherapy. In patients with limited SCLC, 80100% respond and 5070% achieve a CR.[99] For patients with extensive disease, the response rate is 6080%, with a CR rate of 2040%. However, despite this chemosensitivity, the overwhelming majority of patients relapse. Only 10% of patients with limited and <1% of those with extensive SCLC remain free of disease long-term.[100] Different treatment strategies, within the conventional-dose range, have been evaluated in patients with SCLC. The use of alternating non-cross-resistant combinations is not more active than the use of only one regimen. [101] Moderate increases of dose produce a higher response rate at the expense of significant toxicity and with no impact on survival. [102] [103]

These discouraging results and the fact that SCLC appeared to be chemosensitive prompted the investigation of ASCT in that disease in the early 1980s. The initial studies used ASCT as front-line therapy. Farha et al. [104] treated 14 patients with limited and extensive disease with two cycles of high-dose cyclophosphamide, etoposide, vincristine, and Adriamycin with ASCT. The CR, DFS, and OS rates were no better than those achieved with standard therapy. Souhami and colleagues conducted a series of studies in an attempt to identify a superior ASCT regimen. Initial treatment with single-agent cyclophosphamide, [105] cyclophosphamide and etoposide,[106] cyclophosphamide as consolidation of prior standard-dose induction therapy, [107] and finally, initial high-dose combination chemotherapy with carboplatin, etoposide, and cyclophosphamide or melphalan, were evaluated in consecutive phase II trials, with no improvement in clinical outcome compared to historical controls.

The next generation of studies tested late intensification to consolidate a response obtained with conventional induction treatment. The most encouraging results were achieved by Spitzer et al., [108] who administered two cycles of high-dose cyclophosphamide, Adriamycin, etoposide, vincristine, and methotrexate to 32 limited SCLC patients. At a median follow-up of 4 years, the OS was 19%. Thirty-eight percent of the patients transplanted in CR, and 11% of those who were converted from partial response to CR after ASCT, remained disease free at the same time point.

Humblet et al.[109] reported the only prospective, randomized trial using late intensification in limited- and extensive-stage SCLC. Patients who responded to induction chemotherapy were randomized to an additional cycle of the same conventional-dose combination or to high-dose cyclophosphamide, BCNU, and etoposide with ASCT. Although patients received cranial irradiation, no chest radiotherapy was delivered. The transplant arm had significant higher response and DFS rates, but OS was not significantly different between both groups, in part due to a high transplant-related mortality rate of 17%. The majority of relapses occurred in sites of previous disease, particularly in the lungs. All patients in both arms with extensive disease relapsed following therapy.

The third generation of studies addressed the problem of chest relapses, which was the major site of failure after ASCT. Bulky chest disease at diagnosis may imply intrinsic drug resistance, the presence of a chemorefractory non-small cell subpopulation (10% of patients), and poor drug perfusion. Because chest radiotherapy was included as part of standard of care for limited stage disease, [110] subsequent ASCT studies also included intensive thoracic radiotherapy, to a total dose 50 Gy, along with prophylactic cranial irradiation as an essential component of the therapeutic strategy for limited-stage disease. Another refinement in most recent studies is an improvement of ASCT regimens. Finally, only patients with limited-stage disease were considered for ASCT because there seems to be no benefit from ASCT for patients with extensive disease.

Elias et al.[111] used CCB for 19 patients who had responded to induction therapy (6 CR, 13 partial response). After HDC, 15 of 19 patients were in CR. Once patients recovered their marrow function, chest and cranial radiotherapy was delivered. Median DFS was 12 months, and OS was 53% at 2 years. The toxic death rate was 5%. The degree of response to induction chemotherapy (CR vs. partial response) was a critical factor because 57% of the patients transplanted in CR remained recurrence free at 2 years.

Brugger et al.[112] shortened induction chemotherapy cycles in an attempt to prevent the appearance of cell resistances. Fifteen of 18 patients with limited disease who responded to two cycles of etoposide, ifosfamide, cisplatin, and epirubicin were consolidated with higher doses of a similar combination, with carboplatin replacing cisplatin, plus ASCT. Subsequently, chest and cranial radiotherapy were delivered. At a short follow-up of 14 months 69% of the patients were disease free. Future research will confirm whether or not results can truly be improved when effective induction is combined with modern concurrent chest radiotherapy, followed by optimal ASCT in patients with limited-stage disease.

Contamination of Stem Cell Products with Malignant Cells in Small-cell Lung Cancer

Bilateral bone marrow aspirations and biopsies diagnose bone marrow involvement in 1734% of patients with extensive SCLC. [113] Fewer than 5% of patients present with bone marrow

metastases as the only site of extrathoracic disease. [114] However, the use of monoclonal antibodies has demonstrated marrow involvement in 50% and 77% of patients with limited and extended disease, respectively. [115] Reinoculation of clonogenic tumor cells is a potential source of relapse in SCLC, although most series show the lung as the primary site of failure. It is, however, unclear whether local relapses are entirely due to insufficient cytoreduction that cause local regrowth or if infused cancer cells contribute by homing to chest sites. If future strategies improve control of the bulky local and micrometastatic disease, the issue of seeding viable tumor will be of utmost importance.

Although the widespread use of PBPCs as the source of stem cells decreases the risk of tumor contamination, it does not ensure the reinfusion of a tumor-free cell product. Large-scale immunomagnetic purging can remove up to 3.6 logs of SCLC cells, as shown by Ball et al. [116] Clinical studies are warranted to explore the impact of in vitro purging of the stem cell product, when used in conjunction with highly effective systemic and local therapy.

MELANOMA

As a consequence of the disappointing results using standard therapy for the treatment of metastatic melanoma, HDC with ASCT has been investigated intermittently for over 30 years in patients with this disease. [117] Early phase II clinical trials with high-dose single agents in advanced melanoma identified BCNU, melphalan, and thiotepa as the drugs where dose escalation provided the greatest increase in antitumor activity; response rates of 4055%, and CR rates of approximately 10% were reported, which appeared to be superior to responses obtained with conventional-dose therapy. [118] [119] [120] Responses from high-dose single agents, however, were brief, with a median duration of 3 months, and 15% of the patients had responses that lasted for >1 year. These trials identified patients with more limited disease, confined to skin or lymph nodes, as the ones more likely to respond, as opposed to those with visceral disease.

Subsequent studies with different drug regimens, including melphalan-BCNU, [121] CCB,[122] or diethyl-triazeno-imidazole-carboxamide (DTIC)-melphalan or ifosfamide,[123] demonstrated high response rates, but did not substantially improve long-term DFS or OS rates.

Because melanoma is one of the most immunogenic human tumors, the combined use of immunotherapy with ASCT is an attractive strategy for this disease. The use of PBPCs, which produce a more rapid immune reconstitution than bone marrow, may be necessary for subsequent biologic therapy to be effective. The use of adoptive immunotherapy has proved to be tolerable after ASCT, [124] and clinical trials evaluating this strategy are underway.

Because metastatic melanoma patients with limited disease appeared to benefit most from ASCT, it seemed logical to explore its use in the adjuvant setting for high-risk patients. A small randomized trial conducted at Duke University compared immediate treatment with CCB plus ASCT to observation with CCB at relapse, in 39 patients with melanoma involving a primary skin site and five or more proximate lymph nodes at initial diagnosis. [125] Time to progression was 35 weeks for patients on the HDC arm versus 16 weeks for those on the observation arm, which was not statistically significant. No differences in OS were noted, which was partly due to the successful salvage with HDC of relapsed patients, with a 66% response rate and a 33% CR rate.

Future directions include exploring the use of ASCT in poor-prognosis melanoma patients with less extensive disease. Examples include patients with recurrent disease that can be rendered disease free by standard local or systemic treatment. Although ASCT cannot be considered standard treatment for melanoma, it remains a useful tool to cytoreduce the tumor and attain a minimal residual disease state that may allow biologic therapies to be effective.

BRAIN TUMORS

After surgery and radiotherapy for malignant tumors of the central nervous system (CNS), most patients experience a median survival of <1 year and die within 18 months of diagnosis. The addition of chemotherapy offers a modest survival advantage, especially for younger patients and for those with anaplastic astrocytoma, as opposed to glioblastoma multiforme.[126] Still, the majority of patients die within the first 2 years. Standard salvage therapy is ineffective for relapsed brain tumors. The existence of the blood-brain barrier limits the therapeutic armamentarium to small, lipid-soluble and nonpolar drugs. Of these, BCNU has the highest activity against glial tumors and constitutes the mainstay of standard chemotherapy for brain neoplasms. [127]

Initially ASCT for brain tumors used BCNU, [128] [129] [130] as well as other drugs with adequate CNS penetration and evidence of antitumor activity at standard doses, such as thiotepa.[131] Subsequently, drugs such as cyclophosphamide, etoposide, or carboplatin, suitable for ASCT and exhibiting good CNS penetration at high doses, were also tested.

In the first trials using high-dose BCNU for patients with refractory and progressive high-grade glioma, close to 50% of the patients responded, although most responses were short-lived.[128] [129] Based on these results, high-dose BCNU was subsequently tested as part of first-line therapy, along with surgery and radiotherapy, which initially seemed to improve survival when compared to historical controls. [130] However, when patients treated with ASCT were compared to matched patients from historical series treated with conventional therapy, the outcomes were similar. [132]

More recent studies have used combination chemotherapy. Thiotepa-etoposide has produced response rates of 2030% and 1428% long-term DFS in patients with recurrent brain tumors.[133] [134] Survival was significantly improved in patients treated with minimal residual disease. Innovative approaches include the combination of ASCT with intra-arterial chemotherapy, which in single-institution studies has shown promising results for selected patients. [135]

Since the initial trials, minimal data have been reported using ASCT for brain glial tumors in adults. Future prospects will require more active agents and the possible synergy between ASCT and biologic therapies that, as with melanoma, will require major prior cytoreduction.

OTHER SOLID TUMORS

A few single-institution series with small numbers of patients have been reported on the use of ASCT for metastatic soft tissue sarcoma. When used as initial therapy for untreated patients[136] or salvage treatment for refractory disease,[137] CRs are reported, but they do not correlate with a survival benefit. However, when used as consolidation for selected patients who have responded to induction treatment, particularly those in CR, approximately 30% achieve long-term DFS. [138] [139] [140]

More than 100 patients with metastatic colorectal cancer have been treated with ASCT, most commonly with single-agent alkylators, and in particular melphalan. [141] [142] Although the overall response rate is approximately 50%, the CR rate is low, and there is neither an OS or DFS benefit for these patients.

Patients treated with ASCT for gastric, pancreatic, nasopharyngeal, uterine, cervical, head and neck, renal cell, and bladder carcinomas have been reported. The majority of those patients

TABLE 88-6 -- Summarized Results of High-Dose Chemotherapy with Autologous Stem Cell Transplantation for Breast Cancer, Ovarian Carcinoma, and Nonseminomatous Germ Cell Tumor

Tumor Setting	Long-term DFS	References
Breast		
High-risk 49 nodes	>70%	[46]
High-risk 10+ nodes	5665%	[44] [45]
High-risk inflammatory	>70%	[50] [51]
Metastatic, chemosensitive disease	1525%	[12] [13] [14]
Ovary		
Relapsed refractory disease	<5%	[72] [74]
As part of multimodal first-line therapy for poor-risk disease	2555%	[76] [77] [79]
NSGCT		
Refractory	15%	[83]
First relapse	3540%	[84] [85]
Second relapse	15%	[82]
Up-front for poor-risk disease	50%	[95]

DFS, disease-free survival; NSGCT, nonseminomatous germ cell tumor.

were included in phase I ASCT trials. Response rates are typically low, and the responses are short-lived.

CONCLUSIONS

Over the past 10 years, ASCT for the treatment of patients with solid tumors has been characterized by a steady decrease in treatment-related mortality, as well as a steady improvement in the activity of high-dose regimens. The use of ASCT in combination with standard-dose induction chemotherapy, radiotherapy, and surgery has also been increasing. The addition of effective immunotherapy to ASCT holds promise, not only for the demonstrably immunogenic tumors like melanoma, but also for breast cancer, where clinical trials are in progress.

Encouraging data from ASCT trials conducted in patients with solid tumors, are summarized in Table 88-6 . These were primarily phase II trials conducted at single institutions.

Several ongoing prospective randomized trials comparing the best standard therapy to widely used high-dose regimens are actively accruing patients in North America and Europe. The next few years will likely bring exciting advances in use of HDC for patients with the solid tumors discussed in this chapter.

Chapter 89 - Unrelated Donor Stem Cell Transplantation Therapy

Nancy A. Kernan
Dennis L. Confer

INTRODUCTION

Allogeneic stem cell transplantation (SCT) is an accepted form of treatment that can provide a cure for patients with hematologic cancers, syndromes of bone marrow failure, and congenital disorders of the lymphohematopoietic system. [1] [2] Before the establishment of several large donor registries, however, this approach was largely restricted to patients with an HLA-identical or HLA one-antigen mismatched family member who was willing to be a donor. [3] [4] During the 1980s and 1990s, investigators explored the use of other sources of hematopoietic stem cells (HSC) including haploidentical HLA-matched family members and phenotypically HLA-matched placental cord blood or marrow from unrelated donors. Stem cell transplants from haploidentical family members with more than an HLA one-antigen mismatch are associated with a very high risk of transplantation-related complications such as graft rejection or graft-versus-host disease (GVHD). The introduction of T-cell depletion for prevention of GVHD permitted successful transplantations in children with severe combined immunodeficiency, [5] but was largely unsuccessful in patients with leukemia. More recently published studies indicate that graft rejection can be prevented by additional immunosuppression for leukemic recipients of marrow grafts derived from haploidentical family members.[6] [7] However, these observations await confirmation in larger multicenter studies.

The first successful transplantations using stem cells obtained from unrelated donors were reported in the mid-1970s. [8] [9] [10] [11] [12] Despite these successes, the use of marrow from closely HLA-matched unrelated donors was limited by the lack of accessible donor registries of sufficient size to permit identification of a donor. The worlds oldest registry of volunteer unrelated marrow donors, the Anthony Nolan Bone Marrow Trust, was established in 1974 by the mother of a child with Wiskott-Aldrich syndrome. By 1983 more than 50,000 HLA typed volunteers were available through this registry. [13] In 1986 the National Marrow Donor Program (NMDP) was established in the United States to facilitate donor searches and marrow procurement for patients lacking an HLA-identical related donor. [14] The NMDP is a nonprofit corporation and holds a contract from the U.S. Department of Health and Human Services to operate the congressionally mandated National Bone Marrow Donor Registry. As of early 1998 the cumulative number of HLA-A and -B typed donors registered with the NMDP through U.S. and international donor centers exceeded 3.1 million (Table 89-1) and the NMDP could facilitate approximately 110 transplants per month. Worldwide there are now more than 4.5 million unrelated donors listed in 43 registries in 34 countries. The majority of donors has been typed only for HLA-A and -B. HLA-DR typing is available on about 1.8 million donors worldwide, of which, 1.3 million are registered in the NMDP (Table 89-1).

In the late 1980s, Bone Marrow Donors Worldwide (BMDW) was organized to provide a centralized capacity for international identification of volunteer unrelated donors.[15] BMDW maintains a database of summary HLA typing data on donors from around the world and also provides a search process for rapid identification of donors with specific HLA types. The entire BMDW database is currently available on-line via the World Wide Web (http://bmdw.leidenuniv.nl/).

In general, unrelated donors are volunteers between the ages of 18 and 61 years who are in good health, not pregnant, and not excessively overweight. Although transplant physicians may search multiple registries, most recipients of unrelated stem cells in the United States have their donor identified and their marrow procurement facilitated by the NMDP. At present,

TABLE 89-1 -- Donors in the National Marrow Donor Program Registry

Racial or Ethnic Group	Number HLA-A, -B and -DR Typed	Total Number
American Indian/Alaska Native	28,730	41,262
Asian/Pacific Islander	127,311	177,563

Total donors	1,324,027	3,101,314

Source: National Marrow Donor Program, February 28, 1998.

Figure 89-1 Steps in the National Marrow Donor Program search process. The search process begins with preliminary searches that are available at no charge to any licensed physician. Formal searches are initiated and managed by NMDP Transplant Centers. Donors are identified through confirmatory typing performed on donors who are HLA-A, -B, and -DR matched with the proposed recipient. Once the optimal donor is identified, a request for donor work-up is submitted.

the unrelated donor transplant approach is limited by logistical difficulties in identifying a suitably HLA-matched donor and by the relatively high rate of morbidity and treatment-related mortality associated with the unrelated donor stem cell transplant procedure.

Any physician can request a free preliminary search of the NMDP Registry (Fig. 89-1). However, a formal search must be initiated by a member of the NMDP Transplant Center. The purpose of the formal search is to narrow the list of prospective donors to the single donor who is deemed most suitable for the proposed recipient. When HLA-A, -B and -DR matched potential donors are available, the Transplant Center will repeat the HLA typing on selected donors to confirm that the Registry typing is correct and to obtain the typing at a higher level of resolution (as described in the following sections). If the proposed recipients only potential matches reside among the HLA-A, -B typed donors, it is first necessary to complete HLA-DR typing in an attempt to identify an HLA-DR matched donor. In the NMDP

experience, it is uncommon that HLA-DR typing leads to identification of a suitable donor and subsequent transplantation; only 5% of NMDP transplants use donors selected from the HLA-A, -B typed pool.

If the formal search leads to identification of an acceptable match and the patient remains eligible for SCT, a work-up of the donor begins. This includes a detailed medical history and physical examination, laboratory testing to assess the health of the donor and the potential for transmission of infectious diseases, as well as thorough counseling of the donor. If the medical evaluation confirms the donors good health, and the donor agrees to proceed, the donor signs an Intent to Donate form and a marrow collection date is scheduled. For the convenience of the donor and in order to maintain confidentiality, the marrow is harvested at a member Collection Center that is located near the donors home. The freshly collected marrow is transported by courier to the recipients institution for transplantation, usually within 24 hours.

Currently 80% of all preliminary searches submitted to the NMDP identify at least one potential HLA-A, -B, and -DR identical match. Among patients who initiated a formal search in 1995 and 1996 and subsequently received an SCT facilitated by the NMDP, 5% of SCTs occurred within 1.9 months of the initiation of a formal search and 50% were within 4.0 months (Table 89-2). One must consider the length of time involved in the search process in deciding to search for an unrelated donor. Although

TABLE 89-2 -- Time from Formal Search to Transplant (Searches Begun in 1995 and 1996)

5% were within 1.9 months
50% were within 4.0 months
95% were within 16.8 months

Percentiles adjusted by Kaplan-Meier method based on transplants occurring within 24 months of formal search.

the time interval may be acceptable for patients with stable phase chronic myeloid leukemia (CML), patients with advanced leukemia or unstable medical conditions are likely to require alternative therapy before a donor is identified and may be too ill to undergo a transplantation at the time a donor is ready for harvest.

The decision to undertake an unrelated donor stem cell transplantation is complex and involves many factors that are independent of donor availability. These include the quality of the HLA match, recipient factors, and donor factors. The patients diagnosis, stage of disease, age, and major organ function at the time the donor is ready for harvest are the major factors. Secondary factors include the donors age, donors prior exposure to cytomegalovirus, and the donors pregnancy and transfusion history.

HISTOCOMPATIBILITY AND DONOR SELECTION

The major human histocompatibility complex, the HLA antigen system, is the primary immunologic barrier to successful stem cell transplantation. The HLA antigens are effective stimulators and targets of GVHD and graft rejection. Clinical outcomes of stem cell transplantation, particularly those involving unrelated donors, are dependent on optimizing the histocompatibility matching between the patient and the donor. The HLA genes are clustered in a short region on chromosome 6. The cluster of genes constitutes an HLA haplotype and tends to be inherited en bloc, which accounts for the 25% likelihood of HLA matching between any two siblings (Fig. 89-2).

Figure 89-2 Inheritance of HLA haplotypes. The HLA genes, clustered in a short stretch on chromosome 6, are inherited en bloc. Mothers two HLA haplotypes (arbitrarily labeled I and II) can combine with Fathers (arbitrarily labeled A and B) in only four ways: I-A, I-B, II-A, and II-B. Thus, between any two siblings, the likelihood of a match is 25%. With n siblings, the likelihood of a match is 1 the likelihood of no match, or 1 $(0.75)^n$.

TABLE 89-3 -- Patients Proceeding to Unrelated Marrow Transplantation, 19871998

Racial or Ethnic Group	Formal Searches	Transplantation
American Indian/Alaska Native	103	35 (34%)

Hispanic/Latino	1,209	349 (29%)
Black, including African American	1,229	245 (20%)
Asian/Pacific Islander	700	147 (21%)
All others	2,011	341 (17%)
Total patients	21,534	6,721 (31%)

Source: National Marrow Donor Program, February 28, 1998.

The emergence of unrelated donor SCT as a therapeutic option for many patients has had an important influence on the development of HLA typing methods to identify histocompatibility alleles. [16] In the 1980s and early 1990s, HLA compatibility was determined by serology for HLA-A, -B, and -DR, and by the mixed lymphocyte culture (MLC). The MLC proved not to predict the development of GVHD or transplantation outcome, [17] and the test is no longer used for donor selection in most transplant centers. Techniques such as one-dimensional isoelectric focusing and DNA sequencing demonstrated that there are several polymorphisms within a single serologic specificity. Unrelated donors who are selected to be phenotypically HLA-identical by serology, may be HLA-non-identical when tested using DNA-based techniques. There is marked genotypic polymorphism for both HLA-A and HLA-B. As many as 83 HLA-A alleles and 186 HLA-B are represented by 29 HLA-A and 59 HLA-B serotypes.[18] These genotypic polymorphisms are unimportant for transplantation between HLA-identical siblings. HLA-matched siblings, who inherit identical parental chromosomes and thus, polymorphisms, are always genotypically identical (Fig. 89-2). In unrelated donor transplantation, however, these differences are biologically important because donor-recipient pairs mismatched for HLA-DR at the allelic level correlate with a higher incidence of severe GVHD and a higher risk of transplant-related mortality. [19] [20] One study has suggested that allelic disparities at the HLA-A and -B loci detected by DNA-based techniques may also be associated with a higher incidence of GVHD. [21] In a recently completed study, it was demonstrated that only 53% of donors matched by serology for HLA-A and -B and DNA typing for HLA-DR remained HLA-A, -B, and DRB1 matched when tested by DNA techniques for each of these loci. [22]

HLA genes are not randomly distributed. Rather, linkage disequilibrium occurs, resulting in common (frequently observed) and uncommon HLA haplotypes within and between various racial and ethnic groups. Patients with one or two common haplotypes are far more likely to identify a matched unrelated donor than a patient with two uncommon haplotypes, and an individual is most likely to find a donor within his or her own racial and ethnic group. An analysis of the NMDP Registry disclosed the highest rate of HLA polymorphism among black donors and the lowest rates among Asian/Pacific Islander and Caucasian donors. [23] Among minority racial and ethnic groups, the HLA polymorphism and limited numbers of registered donors (Table 89-1) reduce access to unrelated donor transplantation. The percentage of formal searches of the NMDP resulting in a transplantation procedure is outlined in Table 89-3 . Higher percentages of Caucasian and Hispanic patients undergo transplantation than African Americans and Asian/ Pacific Islanders.

To date, most reports of clinical outcome have included patients and donors typed by serology at HLA-A, -B, and -DR. In the more recent reports patients and donors have been typed by serology for HLA-A and HLA-B, and DNA-based typing techniques for HLA-DRB1. If retrospective studies confirm improved clinical outcome for patients matched at HLA-A, -B, and -DRB1 with their donors as determined by DNA-based methods, it is likely that future donors will be selected based on their DNA genotypes rather than by phenotypes determined by serology. It is unlikely that fully DNA-matched donors will be identified for many patients; therefore, it will be necessary to determine which mismatched allele combinations may be tolerated. Alternatively, transplantation physicians may need to devise approaches such as T-cell depletion for prevention of GVHD to be used when the donor and recipient are not HLA-identical.

OUTCOME OF UNRELATED DONOR STEM CELL TRANSPLANTATION

Factors Affecting Transplant Outcome

Many factors affect transplantation outcome (Table 89-4). As reviewed previously, unrelated donor recipient pairs are usually phenotypically but not genotypically matched at HLA class I (HLA-A, -B, -C) and HLA class II loci (HLA-DR and -DQ). Additionally, multiple mismatches exist for minor histocompatibility antigens. [24] These are not currently easily defined and are not routinely identified for either family member or unrelated stem cell transplant donor-recipient pairs. Although disease stage at transplant is the dominant prognostic factor, within a homogeneous group of patients transplanted with the same disease category, the age of the patient and the level of histocompatibility between the patient and the donor are probably the most important factors affecting outcome of the transplant.

The probability of graft failure after an infusion of stem cells from a family member correlates with the degree of HLA incompatibility [4] [25] [26] and the use of T-cell depletion to prevent acute and chronic GVHD. [17] [26] [27] [28] All studies involving unrelated donor SCT have reported a higher incidence of nonengraftment and secondary graft failure following an unrelated donor transplant as compared to an HLA-identical sibling donor transplantation. [6] [17] [29] In most studies the probability of engraftment is 9095%. [17] [27] [30] HLA disparity between the patient and the donor is the single most important factor affecting the probability of engraftment. [17] [31] [32] [33] [34] The rates of primary and secondary graft failure are highest in recipients of unrelated donor stem cells with serological mismatch at HLA-A or -B. Little evidence exists concerning the role of HLA-C locus antigens in SCT. However, one study suggests that HLA-C mismatch is associated with a higher incidence of graft failure after an unrelated transplant [33] and others have demonstrated that disparities at HLA-C are associated with both graft rejection and GVHD following unrelated donor SCT. [34] [35]

The major effect of donor-recipient HLA disparity is on the incidence and severity of GVHD and the risk of transplant-related mortality associated with this complication. The probability of developing severe acute GVHD is 6595%. [17] [30] [31] The level of disparity in the class II region (HLA-DR and -DQ)

TABLE 89-4 -- Factors Affecting Transplant Outcome

Diagnosis and stage of disease
HLA match grade
Age of recipient
Age of donor
Time from diagnosis to transplant
Prior cytomegalovirus (CMV) exposure

TABLE 89-5 -- Transplants by Diagnosis (Malignant Diseases as of July 1997)

Disease	Number (%)
Chronic myelogenous leukemia	2,078 (35%)

Plasma cell disorders	68 (1%)
Hodgkin disease	18 (<1%)
Other malignancy	6 (<1%)

is the single most important variable affecting the development of GVHD. [19] [20] Matching HLA-DRB1 alleles of the donor and recipient decreases the risk of acute GVHD and improves survival after unrelated donor SCT. [19] [20] [30] Matching for HLA-DRB1 and -DQB can reduce the risk of Grade II to IV acute GVHD following an unmodified stem cell allograft from 7338% among recipients mismatched for either allele. [36] Interestingly, this effect was not observed among recipients of T-cell depleted allografts, as all recipients experienced a low level of GVHD (10%) in this study. [36] The overall incidence of chronic GVHD in most studies is approximately 50%. [17] [30] [31] The extent of HLA matching has had no detectable association with the risk of clinical chronic GVHD. However, the risk is independently associated with grafts derived from women with a history of pregnancy and is increased in older patients, especially those with CML. [30] [37]

Several reports indicate that both recipient and donor age correlate directly with the risk of GVHD, transplantation-related mortality, or both. [17] [30] [31] [37] [38] Younger patients tolerate GVHD and its treatment better than older patients. There is a significant association between graft failure and increasing donor age. [32] The explanation for this observation is unclear. But the impact of graft failure is significant as only 25% of individuals with graft failure survive long-term. [39]

Even when patients have engrafted without significant GVHD, recipients of unrelated allografts are at very high risk of developing serious infectious complications. [17] [40] [41] [42] Death from serious infections is significantly more frequent following unrelated donor stem cell allografts; cytomegalovirus (CMV) is the most common viral infection observed. [41] Before the use of ganciclovir prophylaxis at the time of engraftment, systemic CMV infections were almost uniformly fatal.

Outcome for Patients with Malignant Disorders

The majority of unrelated donor stem cell transplants are performed for patients with a malignant disorder. The diagnoses requiring transplant therapy reported to the

NMDP are outlined in Table 89-5 . The timing of the procedure in relation to disease phase or stage correlates strongly with outcome. [17] [43] [44]

Chronic Myeloid Leukemia

The majority of unrelated allografts have been performed for treatment of CML. Multiple studies have shown this approach to be curative for CML. [17] [30] [37] [45] [46] The Kaplan-Meier survival estimates for NMDP recipients with CML transplanted between 1987 and July 1997 are shown in Table 89-6 and Figure 89-3 . These include all donor recipient pairs regardless of their level of HLA disparity. The best results reported to date have been observed for patients in primary chronic phase, less than 50 years of age who received an allograft from an HLA-matched donor defined by serologic methods for HLA-A and -B and DNA typing methods for HLA-DRB1. The Kaplan-Meier estimate of survival at five years for these patients is 74% (95% confidence interval of 6280%). [30] An unmodified unrelated allograft is probably not indicated for patients in blastic phase CML. However, in one report approximately 50% of recipients of marrow depleted of T cells with the monoclonal antibody T10B9 and complement while in accelerated or blastic phase survive long-term. [45] Preliminary analysis of the first 196 unrelated donor BMTs for CML facilitated by the NMDP indicated that T-cell depletion of the stem cell graft reduces early mortality, but has not yet been shown to improve long-term survival

TABLE 89-6 -- NMDP Transplant Outcomes for Chronic Myelogenous Leukemia (July 1997)

Disease	Number of Transplants	2-Year Survivala[a] with 95% CI
CML 1st chronic phase (CP)	1,106	46% ± 3%
CML 2nd CP and accelerated phase	451	26% ± 5%
CML blast phase	106	11% ± 6%

[a]Kaplan-Meier estimate.

Figure 89-3 Kaplan-Meier survival estimates of unrelated donor stem cell transplant therapy for chronic myeloid leukemia. Results are shown for 1,663 patients transplanted between 1987 and July 1997. Patients are stratified by stage of disease. Survival of patients with less-advanced disease is superior. (Tick marks represent the time of most recent follow-up for surviving patients.)

TABLE 89-7 -- NMDP Transplant Outcomes for Acute Leukemias (July 1997)

Disease	Number of Transplants	2-Year Survivala[a] with 95% CI
AML 1st complete remission (CR)	158	39% ± 9%
AML 2nd CR	241	33% ± 7%
AML 3rd or greater CR or relapse	522	15% ± 4%
ALL 1st CR	187	43% ± 8%
ALL 2nd CR	312	40% ± 6%
ALL 3rd or greater CR	192	28% ± 7%
ALL relapse	253	12% ± 5%

[a]Kaplan-Meier estimate.

(*P* = 0.1).[37] For children with CML, unrelated allografts are clearly curative with disease-free survival estimates of 5080% depending upon the stage of disease and level of HLA disparity between the patient and the donor. [47] [48] [49]

Following an unrelated allograft for CML, the probability of relapse is very low (<10%). [30] [37] [45] A low relapse rate is observed even with the use of partial T-cell depletion for prevention of GVHD.[45]

As treatment with an unrelated allograft can be curative for patients with CML, but is associated with 2030% early mortality, timing of the procedure is now the major issue. Results of transplants performed early in the course of the disease, particularly in chronic phase patients within the first year of diagnosis, are superior to those performed later.[30] [37] However, present treatment approaches using interferon have produced clinical and sometimes cytogenetic remission, which can delay the progression of disease and prolong survival. Despite these advances, a recent decision analysis reported by Lee et al. supports the use of early transplantation from unrelated donors for most patients with CML. [50]

Acute Leukemia

Analysis of the first 156 patients with acute leukemia whose unrelated allograft was facilitated by the NMDP, revealed that among patients with acute leukemia in first or second remission, the probability of disease-free survival was 0.45 ± 0.13, which was superior to that among patients with more advanced disease (0.19 ± 0.08), *P* < 0.001.[17] Since that publication, additional patients within each category of disease and stage have received unrelated allografts (Table 89-7).

The Kaplan-Meier survival estimates for NMDP recipients with acute lymphoblastic leukemia (ALL) transplanted between 1987 and July 1997 are shown in Figure 89-4 . Survival is stratified by disease. In virtually every series, younger patients treated in first or second remission experience superior survival rates. [47] [51] [52] [53] [54] In fact, several series have demonstrated results identical to those expected for children with ALL transplanted with stem cells derived from a sibling donor. [55] [56] [57] [58]

The Kaplan-Meier survival estimates for NMDP recipients with acute myelogenous leukemia (AML) are depicted in Figure 89-5 . Remission at the time of transplantation is the most favorable prognostic factor. In one series, a higher cell dose was found to be favorable especially in patients transplanted in remission. [44] Patients receiving a mononuclear cell dose greater than the median (3.65×10^8 cells/kg) experienced a more rapid engraftment, less severe GVHD, and a lower non-relapse mortality.

An unrelated donor allograft is not usually the first line therapy for patients with acute leukemia. Improvements in conventional induction and maintenance chemotherapy have increased the numbers of patients cured by these therapies. Certain prognostic factors, however, can identify patients likely to fail front-line therapy. Patients with Philadelphia positive ALL and patients induced into a first remission with difficulty should be considered for an unrelated donor allograft. [52]

Outcome for Nonmalignant Disorders

Myelodysplasia (MDS) and Aplastic Anemia (AA)

Transplants performed for nonmalignant disorders are outlined in Table 89-8 . Figure 89-6 and Table 89-9 depict the Kaplan-Meier survival estimates for NMDP patients with MDS and AA. These results are representative of other published series of patients, even children, with these diseases. [59] [60] [61] [62] [63] The probability of survival after an unrelated allograft is probably superior to that with other available therapies, since in qualifying for transplantation protocols involving unrelated

donors, it is likely that these patients had not responded to immunosuppression or cytokine therapy.

Other Nonmalignant Disorders

The most frequent diagnoses encountered in this group of patients are immunodeficiency disorders including severe

Figure 89-4 Kaplan-Meier survival estimates of unrelated donor stem cell transplant for acute lymphoid leukemia. Results are shown for 921 patients transplanted between 1987 and July 1997. Patients are stratified by stage of disease. Survival of patients in first or second remission is superior to that of patients with more advanced disease. (Tick marks represent the time of most recent follow-up for surviving patients.)

Figure 89-5 Kaplan-Meier survival estimates of unrelated donor stem cell transplant for acute myeloid leukemia. Results are shown for 944 patients transplanted between 1987 and July 1997. Patients are stratified by stage of disease. Survival of patients in first or second remission is superior to that of patients with more advanced disease. (Tick marks represent the time of most recent follow-up for surviving patients.)

TABLE 89-8 -- Transplants by Diagnosis (Nonmalignant Diseases, July 1997)

Severe aplastic anemia	263 (4%)
Inherited metabolic disorders	157 (3%)
Inherited immune system disorders	120 (2%)
Inherited erythrocytic disorders	73 (1%)
Histiocytic disorders	54 (1%)
Other nonmalignant diseases	23 (<1%)
Inherited platelet disorders	6 (<1%)

TABLE 89-9 -- NMDP Transplant Outcomes for Nonmalignant Diseases

Disease	Number of Transplants	2-Year Survival[a] with 95% CI
Severe aplastic anemia	212	39% ± 7%
Myelodysplastic and related syndromes	386	34% ± 5%
Other nonmalignant diseases	332	45% ± 6%

[a]Kaplan-Meier estimate.

Figure 89-6 Kaplan-Meier survival estimates of unrelated donor stem cell transplant for severe aplastic anemia, other nonmalignant diseases, and for myelodysplastic syndromes and related disorders. Results are shown for patients transplanted between 1987 and July 1997. The number of patients transplanted in each category is shown. (Tick marks represent the time of most recent follow-up for surviving patients.)

combined immunodeficiency (SCID) and Wiskott-Aldrich syndrome (WAS), Fanconi Anemia (FA) and metabolic disorders including Hurlers syndrome and adrenoleukodystrophy. Kaplan-Meier survival estimates for these disorders are presented in Figure 89-6 and Table 89-9 . The results of unrelated donor allografts have been particularly promising for patients with SCID and WAS. Up to 75% of patients survive disease-free long-term. [64]

SUMMARY

The majority of people who are candidates for allogeneic stem cell transplantation lack HLA-matched sibling donors. For these individuals, alternative stem cell sources include autologous stem cells, partially matched related donors, unrelated donor cord blood, and volunteer unrelated stem cell donors. The last of these has been made feasible through the emergence of internationally active registries of HLA-typed volunteers. Transplants using unrelated stem cell donors produce successful outcomes, but not without significant risks of transplant-related morbidity and mortality. Improvements in the availability and matching of donors, advances in HLA typing technologies, and refinement of transplantation procedures are the keys to improved safety and effectiveness of unrelated donor SCT.

Chapter 90 - Placental and Umbilical Cord Blood Transplantation

John E. Wagner
Joanne Kurtzberg

INTRODUCTION

Transplantation of allogeneic hematopoietic stem cells (HSC) derived either from bone marrow or placental-umbilical cord blood (P-UCB) has been successfully used in the treatment of patients with high-risk or recurrent hematologic malignancies, bone marrow failure syndromes, selected hereditary immunodeficiency states, and metabolic disorders. A major limitation to the successful use of hematopoietic stem cell transplant (SCT) therapy has been the unavailability of suitable donors. Although there are currently more than 1.5 million human leukocyte antigen (HLA)-A-, B-, and DR-typed marrow donors registered in marrow donor registries worldwide, 50% of all patients requiring transplant therapy are still unable to find a suitably HLA-matched donor. [1] Furthermore, patients of racial and ethnic populations of non-Northern European descent [1] have an even lower probability of finding a suitable donor. To alleviate the shortage of suitable donors and reduce the length of the marrow donor search process, Rubinstein et al. (New York), Bertolini et al. (Milano), and Wernet et al. (Dusseldorf) initiated Placental Blood Banking Programs almost simultaneously in 1993. [2] As of December 1997, approximately 10,000 HLA-A-, B-, and DR-typed P-UCB grafts have been collected, tested, and cryopreserved for clinical use in transplantation worldwide.

In 1996, Kurtzberg et al. [3] and Wagner et al. [4] reported preliminary clinical results of unrelated donor P-UCB transplantation in 25 and 18 patients, respectively. Together, the clinical data suggested that banked unrelated donor P-UCB contained sufficient numbers of HSC and progenitor cells to achieve engraftment with lower than anticipated risk of acute graft-versus-host disease (GVHD) at least in children and smaller or younger adults. More recently, Gluckman et al. [5] reported the results of unrelated donor P-UCB transplantation in 65 patients, as reported to the EuroCord Registry. Gluckman et al. [5] reported that (1) higher graft nucleated cell dose and HLA identity predicted more rapid rate of neutrophil engraftment, (2) recipients cytomegalovirus (CMV) seropositive status predicted higher risk of acute GVHD, and (3) recipients CMV seronegative status and higher graft nucleated cell dose predicted better survival after unrelated donor P-UCB transplantation.

As a result of these observations, numerous laboratory investigators have initiated studies to understand the biologic characteristics of the primitive hematopoietic progenitors in P-UCB as well as the immune system in the neonate. Ontologically, hematopoiesis begins in the ventral aspect of the fetal aorta [6] and primitive yolk sac early after conception. Following a brief hepatic phase, it enters the bone marrow space at the end of the second gestational trimester where it remains almost exclusively throughout adulthood. [7] [8] It has long been known that human P-UCB contains hematopoietic progenitor cells at high frequency. The frequency of granulocyte-macrophage progenitor cells equals or exceeds that of adult bone marrow. [9] [10] [11] [12] Within hours of birth, however, the progenitors abruptly leave the neonatal circulation [11] and are present only at very low frequency as in unmobilized adult peripheral blood.

As of March 1998, P-UCB from sibling and unrelated donors has been used to reconstitute hematopoiesis in an estimated 600 patients with malignant and nonmalignant disorders. What still

remains to be defined is the breadth of applicability of this HSC source. Specifically:

1. Are there adequate numbers of HSC and progenitor cells to routinely engraft adult-size recipients?
2. Is the neonatal immune system sufficiently different from that of the adult to allow greater HLA disparity between donor and recipient without concomitant increases in graft rejection, GVHD, or opportunistic infection?

This chapter reviews the current state of knowledge regarding properties of the hematopoietic cells present in P-UCB and the neonatal immune system as well as the clinical results with P-UCB transplantation. Factors potentially influencing the probability of hematopoietic recovery and engraftment, risk of GVHD, and survival are also discussed.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

HISTORICAL BACKGROUND

Use of human P-UCB as a source of transplantable HSC was first suggested in 1983 by Professor Edward A. Boyse in conversations with Dr. Hal Broxmeyer and Ms. Judith Bard. In 198485, the hypothesis that P-UCB contained long-term reconstituting HSC was first tested in a murine model. [13] [14] In the first of four experiments, 7-week-old (B6 × A-T1a^{b})F1 hybrid males were irradiated with 862.8 cGy and then transplanted with heparinized whole blood obtained from near-term (B6-T1a ^{a} × A)F1 mouse embryos. Thirty-day survivors were subsequently typed for the T1a markers distinguishing donor from recipient lymphohematopoietic cells. Animals demonstrated repopulation with donor cells, showing that lethally irradiated mice could be reconstituted with blood from near-term embryos. Three additional experiments evaluated the engraftment potential of (1) smaller volumes of blood from near-term embryos, (2) blood from neonatal donors <24 hours of age, and (3) smaller volumes of blood from neonatal donors. Together, these studies demonstrated that near-term and neonatal blood contained sufficient numbers of stem and progenitor cells to allow early lymphohematopoietic recovery and engraftment of donor cells.

While Boyse et al. [14] provided data supporting the hypothesis that small quantities of neonatal blood were sufficient for at least short-term hematopoietic recovery of donor origin in a murine model, Broxmeyer et al. [11] [12] established practical and efficient methods of collecting and storing P-UCB for clinical use. Broxmeyer et al. [11] [12] evaluated the nucleated cell and progenitor content and sterility of >100 P-UCB specimens before and after cryopreservation. Hematopoietic progenitors from P-UCB remained viable at 4°C or 25°C for at least 3 days after collection. This observation confirmed that cell viability during transport between hospitals would not be compromised before cryopreservation. Moreover, the collection of P-UCB proved to be remarkably simple. Obstetricians and nurse midwives previously untrained in the collection of P-UCB learned the collection technique in a matter of minutes. These early results suggested that P-UCB could be easily obtained and would be a sufficient source of HSC and progenitor cells for an autologous or allogeneic recipient.

An international collaboration, including Drs. Eliane Gluckman, Hal Broxmeyer, Arleen Auerbach, Gordon Douglas, Joanne Kurtzberg and others, led to the first human P-UCB transplant in Paris on October 6, 1988. [15] These investigators were the first to demonstrate unequivocally that the pluripotential HSC existed in human P-UCB. This conclusion was based on the observation that in a child with Fanconi anemia, complete chimerism was sustained after transplantation in multiple lymphohematopoietic lineages.

CHARACTERIZATION OF P-UCB PROGENITOR CELLS

Characterization of the hematopoietic progenitor cell population circulating in P-UCB has revealed similarities and differences with those in adult marrow. Saeland et al.[16] extensively characterized the CD34+ population in P-UCB. Besides the lack of a distinct subpopulation of CD10+/CD34+ B-cell precursors typically found in adult marrow, expression of adhesion receptors (e.g., leukocyte function-associated antigens 1 and 3, intercellular adhesion molecule-1, hematopoietic cell adhesion molecule, and leukocyte adhesion molecule) and other differentiation antigens (e.g., CD33, HLA-DR) were remarkably similar between P-UCB and adult marrow.

Through physical and immunologic parameters, it has been possible to separate primitive from more committed progenitors. It has long been known that immunofluorescent staining with anti-CD34 and anti-HLA-DR allows separation of more committed hematopoietic progenitors (CD34+/HLA-DR+ cells) from a more primitive (CD34+/HLA-DR) subpopulation in adult marrow. Traycoff et al. [17] demonstrated that there is a higher proportion of HLA-DR cells expressing the CD34+ phenotype in P-UCB. Notably, high proliferative potential colony-forming cells (HPP-CFC) and long-term culture-initiating cells (LTC-IC) in P-UCB did not segregate with the HLA-DR subpopulation of CD34+ cells. In contrast to adult marrow, the majority of HPP-CFC were detected in the CD34+/HLA-DR+ subpopulation (ninefold greater than the number found in the HLA-DR subpopulation) and the quantity of LTC-IC, as measured by production of burst forming unit-erythroid (BFU-E) and colony forming unit-granulocyte, macrophage (CFU-GM) after 5 weeks in culture, was consistently higher in the CD34+/HLA-DR+ subpopulation. Similarly, Dugan et al.[18] have demonstrated that the frequency of LTC-IC by limiting dilution analysis is identical between the two subpopulations of CD34+ cells segregated on the basis of HLA-DR expression (i.e., 1:100). In summary, these findings indicate that the primitive hematopoietic progenitor cells in P-UCB express both CD34 and HLA-DR suggesting that neonatal primitive progenitor cells do not share the same phenotypic properties of adult marrow primitive progenitors.

In contrast to the results with HLA-DR, Hao et al.[19] and Cardoso et al.[20] found that CD38 distinguishes subpopulations of hematopoietic progenitor cells. The CD34+CD38 immunophenotype defines a rare, quiescent CD34+ subpopulation in P-UCB as in adult marrow that can be distinguished functionally from the CD34+CD38+ population by sustained clonogenicity in extended long-term culture assay (8 weeks). In contrast to CD34+CD38 cells in adult marrow, Hao et al. [19] showed that CD34+CD38 P-UCB cells continue to proliferate well beyond 8 weeks. Importantly, the extended LTC-IC population (5%) was less efficiently transduced by retrovirus vectors as compared to the standard 5-week LTC-IC (4060%). P-UCB CD34+CD38 cells apparently proliferate more rapidly in response to cytokine stimulation in vitro and each CD34+ cell generates a significantly greater number of progeny as compared to adult marrow counterparts.

The proliferative response of purified candidate stem cell populations in adult marrow, fetal liver, and P-UCB were evaluated by Lansdorp et al. [21] When cells with the $CD34+CD45RA^{lo}$ -$CD71^{lc}$ phenotype were cultured in serum-free medium supplemented with a mixture of cytokines that include interleukin (IL)-3, IL-6, stem cell factor (SCF), and erythropoietin striking differences were observed between the number of CD34+ cells recovered from each of the cultures every 710 days. Throughout the culture period, the number of CD34+ bone marrow cells remained relatively constant at input values. In marked contrast, CD34+ P-UCB cells increased several hundred-fold (and several thousand-fold for CD34+ fetal liver cells). The purified cells also differed markedly in their response to various growth factors. PKH26-labeled CD34+ cells from bone marrow remained brightly labeled after 7 days in culture, whereas CD34+ cells from P-UCB demonstrated markedly decreased fluorescence over the same period, indicating that marrow CD34+

cells are relatively quiescent during this period, whereas P-UCB CD34+ cells are highly proliferative. Additionally, Carow et al. [22] demonstrated P-UCB multipotential CFU-granulocyte, erythrocyte, monocyte, macrophage (GEMM) progenitors had extensive replating capacity, which contrasts with that of adult marrow. Importantly, the addition of P-UCB plasma to the culture medium resulted in extensive secondary replating potential suggesting that other factors were present in P-UCB plasma not found in adult blood plasma or in artificial media supplemented with recombinant growth factors. These differences may have important implications for the use of P-UCB over marrow stem cells in gene therapy and ex vivo HSC expansion protocols.

Broxmeyer et al. [12] have attempted to determine the suitability of P-UCB as a graft for adult recipients. They reported that the total numbers of CFU-GM in a typical P-UCB graft and unpurged autologous marrow graft are remarkably similar. Although the numbers of nucleated cells and progenitors in P-UCB specimens are lower than that expected for allogeneic marrow grafts, Broxmeyer et al.[12] showed that progenitors in P-UCB had a greater capacity for expansion than marrow in short-term liquid culture in the presence of specific cytokines. Moore et al. [23] also found that a marked expansion of P-UCB progenitors could be achieved without expenditure of the primitive, LTC-IC compartment.

Numerous investigators have shown that P-UCB CD34+ cells have a greater proliferative potential and have different growth factor requirements compared to adult marrow CD34+ cells. Traycoff et al.[17] reported that SCF, IL-3, IL-6, and erythropoietin resulted in 2,500-fold increase in cell number at 9 weeks with peak production of CFU-GM and BFU-E at weeks 3 and 4 of long-term culture, respectively. Cardoso et al. [20] evaluated CD34+/CD38 P-UCB cells in liquid suspension culture containing IL-3, IL-6, granulocyte colony-stimulating factor (G-CSF), SCF, and anti-transforming growth factor (TGF-). As reported with adult marrow, the CD34+/CD38 subpopulation was significantly more effective in generating CFU-GM, BFU-E, and CFU-GEMM after long-term culture than the CD38+ subpopulation. Notably, the total CFU-GM production of the CD34+/CD38 subpopulation of P-UCB was 7.6-fold greater than the corresponding population in adult marrow.

In the severe combined immune deficiency (SCID-Hu) mouse model, P-UCB appears to have a higher engrafting capability than cells from adult marrow. These SCID repopulating cells (SRC) are found only in a fraction of cells expressing high levels of CD34 antigen and lacking CD38 antigen on their cell surface. Although there is no proven in vitro assay for the true pluripotential HSC, the SRC appears to identify a primitive progenitor. Through the use of limiting dilution analysis, the concentration of SRC in P-UCB is 1 in 9.3×10^5 cells, which is significantly greater in concentration than the 1 in 3×10^6 found in adult marrow or 1 in 6×10^6 found in G-CSF mobilized adult peripheral blood. Notably, there is 1 SRC per 600 CD34+/CD38 P-UCB cells. [24]

In summary, all assays used thus far appear to point to an increased concentration of primitive hematopoietic progenitors in P-UCB as compared to adult marrow. Moreover, recent studies suggest that P-UCB progenitors may be less mature by virtue of telomere length [25] and have a greater capacity for extensive proliferation. Analysis of cell cycle kinetics demonstrates that P-UCB progenitors are in a quiescent state but respond rapidly to stimulation by hematopoietic growth factors in sharp contrast to adult marrow progenitors that are highly proliferative.

How these characteristics potentially affect transplant outcome, capacity for ex vivo progenitor cell expansion, or efficiency of retrovirus-mediated transduction remain to be determined. Various investigators have demonstrated that culture of adult marrow CD34+ cells in the presence of multiple cytokines results in expansion of hematopoietic progenitors even in the absence of stroma. Although primitive progenitors can be induced to differentiate in such cultures, Verfaillie et al. [26] [27] showed that maintenance and extensive proliferation of LTC-IC from adult marrow is poor in stroma-free conditions but markedly improved by the presence of stroma-conditioned media supplemented by IL-3 and macrophage inhibitory protein-1a (MIP-1a). Using various starting populations and ex vivo culture conditions potentially useful for the expansion of primitive and committed hematopoietic progenitor cells in P-UCB, Han et al. [28] evaluated the ability to expand the number of colony-forming cells (CFC) and LTC-IC. As with adult marrow, the use of stroma-conditioned media supplemented by IL-3 and MIP-1a was superior to stroma-free

conditions supplemented with various cytokines with regard to LTC-IC maintenance and progenitor expansion. In contrast, fold expansion of CFU-GM was greatest for CD34+ P-UCB cells cultured without stroma in the presence of SCF, IL-3, IL-6, IL-1, G-CSF, and MIP-1a. Although these data suggest that it is possible to expand both primitive and committed progenitors in P-UCB, additional work is required using clinically available reagents as well as determining the effect of prior cryopreservation. Transplants using P-UCB cells expanded ex vivo under clinical study conditions, however, must be performed to document safety of the expansion procedure and efficacy with regard to hematopoietic recovery and engraftment.

The data presented in the preceding section suggest that methods are available for increasing the number of hematopoietic progenitor cells in P-UCB and for potentially reducing the time to hematopoietic recovery after transplantation. Because it is not known how few HSC are required for engraftment in any size recipient, only guesses can be made using surrogate markers (i.e., number of CFU-GM, SRC, or CD34+ cells). Although it appears that P-UCB grafts may contain sufficient numbers of HSC for adult recipients, time to neutrophil recovery is markedly prolonged (see Clinical Results). This observation clearly represents one of the most compelling arguments for investigating ex vivo expansion strategies with P-UCB. Early clinical trials with ex vivo expanded P-UCB HSC are underway (E. J. Shpall, personal communication).

NEONATAL IMMUNE SYSTEM

Hematopoietic SCT is limited both by the lack of suitable donors, particularly in specific ethnic and racial subpopulations, and high risk of severe, life-threatening complications that arise when donor and recipient are not immunologically identical, namely, GVHD and opportunistic infection. In the past 30 years, research has focused on the development of new immunosuppressive drugs and treatment regimens and strategies for engineering the marrow or peripheral blood graft that will selectively eliminate alloreactive T-cell clones while preserving the short- and long-term engrafting cells. [29] [30] Although it is clear that a severe reduction in T-cell number can effectively prevent severe acute GVHD, it is also clear that T-cell depletion has increased the risks of primary and secondary graft failure, Epstein-Barr virus (EBV)-lymphoproliferative disease and relapse. Additionally, some data suggest that T-cell depletion may increase the risk of opportunistic infection. Together, it remains to be proven whether this approach will translate into improved survival.

Graft-versus-host disease results from the activation of donor-derived T cells that recognize host-specific alloantigens. The clinical syndrome is the culmination of a complex series of events that involves not only triggering of the T-cell receptor and various co-stimulatory molecules but also the release of proinflammatory cytokines. The clonal proliferation of donor T cells and activation of other effector cells (e.g., cytotoxic T cells, natural killer [NK] cells) and release of various cytokines result

in tissue damage and subsequently the manifestations of the disease. Are there qualitative and quantitative differences between the neonatal and adult immune systems that would predict or explain the low risk of GVHD observed after P-UCB transplantation, and do those differences allow greater HLA disparity between the neonatal P-UCB donor and recipient?

Thus far, the clinical observation is that patients transplanted with P-UCB may indeed have a lower than expected incidence of significant acute GVHD as compared with patients who receive adult marrow. Although case-controlled comparisons or randomized trials have not been performed to verify this conclusion, the low rate of GVHD has led to an interest in studying the neonatal immune system. Qualitative and quantitative differences between the adult and neonatal immune system have already been demonstrated. Rainaut et al. [31] have extensively investigated fetal and neonatal blood with regard to cell surface antigen expression. Relative to adult peripheral blood, P-UCB has (1) a significantly greater absolute number of lymphocytes per milliliter (two- to threefold greater), (2) a significantly lower percentage of CD8+ T cells, and (3) a significantly greater CD4:CD8 ratio. Hannet et al. [32] further characterized P-UCB lymphocytes using two-color flow microfluorometric analysis. P-UCB lymphocytes had phenotypic characteristics suggestive of T-cell immaturity. The majority of CD4+ P-UCB lymphocytes co-expressed CD45RA (91% as compared to 40% of adult CD4+ lymphocytes), fewer CD3+ T cells expressed IL-2 receptors (8% versus 18%), and fewer CD3+ T cells expressed the activation marker HLA-DR (2% versus 10%). Clement et al.[33] found that virtually all P-UCB CD4+ T cells co-expressed CD38 (95%) and CD45RA (>90%). They demonstrated that CD4+/CD45RA+ (CD38+) P-UCB T cells had no detectable helper function and their dominant immunoregulatory activity was suppression.

Investigations of the functional immunologic properties of P-UCB lymphocytes have been reported by Roncarolo et al. [34] Purified P-UCB T cells proliferated vigorously when activated by allogeneic antigens in primary mixed lymphocyte reactions (MLR) indicating that P-UCB cells respond normally to activation by alloantigens. In addition, strong proliferative responses were observed when the P-UCB T cells were activated by cross-linked anti-CD3 monoclonal antibodies. Together, these data suggest that T cells in P-UCB can be normally activated via their T-cell receptor and that their proliferative response is normal. Importantly, P-UCB cells had a reduced capacity to stimulate allogeneic cells in primary MLR. The data suggest that this defect may be related to reduced antigen-presenting capacity. P-UCB monocytes express lower levels of HLA-DR, B7, and intercellular adhesion molecule-1 compared to adult monocytes and produce lower levels of IL-10. The exact mechanism underlying the defect in the antigen-presenting capacity of P-UCB, however, remains to be clarified. In addition, P-UCB cells are also impaired in their capacity to generate allogeneic cytotoxic activity in primary MLR. Whether this defect is intrinsic to the cytotoxic T cells or due to other cells or factors preventing the generation of alloantigen-specific cytotoxic T cells is not yet known.

Interestingly, some of these data suggest that P-UCB T cells are capable of an alloreactive response and that their capacity to effect GVHD equals or exceeds that of adult peripheral blood T cells. Therefore, is the low risk of GVHD due to differences in T-cell dose or other factors? Most P-UCB T cells have the naive CD45RA+ phenotype. The alloreactive T-cell repertoire present in P-UCB is composed of unprimed cells, as compared to the repertoire of T cells in adult marrow or peripheral blood in which >50% of the alloreactive T cells are of the primed memory phenotype. On the basis of recent studies, naive, unprimed T cells are highly susceptible to tolerance induction. Studies by Roncarolo et al. [34] indicate that repeated activation of P-UCB T cells with alloantigens in vitro results in the inability of these cells to proliferate or produce cytokines following restimulation with the same antigens. This state of antigen-specific unresponsiveness may be due to an intrinsic property of P-UCB T cells not observed in adult T cells. Roncarolo et al. [34] also showed that NK activity of purified CD56+ P-UCB NK cells against NK-sensitive targets is comparable to that observed with adult NK cells.

As in BMT recipients, most circulating lymphocytes in the early post-transplant period express the CD56 phenotype. Roncarolo et al. [34] further demonstrated that IL-2, IL-6, and tumor necrosis factor- production by P-UCB mononuclear cells following activation was comparable to that observed with adult peripheral blood mononuclear cells. In contrast, interferon- and IL-10 production was significantly decreased and IL-4 and IL-5 were absent. Levels of GM-CSF were in general higher in the supernatants of P-UCB cells. Thus, P-UCB mononuclear cells differ from adult peripheral blood cells at several levels: (1) decreased capacity to stimulate an allogeneic response, (2) impaired cytotoxic effector function, and (3) unique cytokine profile (Table 90-1). Whether these properties account for the reduced capacity of transplanted P-UCB cells to modulate GVHD remains to be determined. However, it is also clear that T-cell dose in an unrelated donor P-UCB graft is lower than that in an unmodified marrow allograft. The median CD3 cell dose in recipients of P-UCB thus far is approximately 8×10^6 CD3+ cells/kg as compared to 3040×10^6 CD3+ cells/kg recipient body weight in a typical marrow allograft. Nonetheless, <2 log reduction of T cells in a marrow graft (i.e., T cell dose $>5 \times 10^5$ /kg) would be considered insufficient for preventing GVHD, particularly in the mismatched or unrelated donor setting. Most studies in SCT would suggest that a CD3 cell dose $<0.1 \times 10^6$ CD3+ cells/kg is required to eliminate the risk of severe acute GVHD. Therefore, it is unlikely that CD3 cell dose alone accounts for the low rate of severe GVHD currently observed after P-UCB transplantation.

Harris et al.[35] analyzed the development of alloreactivity in the infant over the first year of life and assessed the immunologic reactivity of P-UCB cells with lymphocytes from various family members. At birth, P-UCB cells were observed to be immunologically unreactive with cells from the mother and minimally reactive with cells from the father. Moreover, lymphocytes from the mother demonstrated a decreased ability to mediate NK lysis shortly after the time of delivery as well as a depressed alloreactive response. Although the neonatal blood was capable of mediating NK lysis, the infant did not develop the ability to generate an alloantigen-specific cytotoxic response until sometime between birth and 6 months of age. The inability of P-UCB to respond to parental lymphocytes as measured by

MLR and by the inability to generate alloantigen-specific cytotoxic T cells suggests that P-UCB might be partially tolerant particularly with maternal antigens. The idea that the fetus may become partially tolerant to the non-inherited maternal allele (NIMA) was first proposed on the basis of outcomes observed in recipients of parental renal allografts.[36] [37] How such tolerance develops is unknown, but such results are particularly intriguing in view of the clinical results observed in haploidentical sibling donor-recipient pairs (see Clinical Results). If the immune cells in the P-UCB graft are tolerant to HLA antigens on the NIMA, this finding would have wide-reaching implications in defining an acceptable donor in both the related and unrelated donor setting.

SIBLING DONOR P-UCB TRANSPLANTATION

Since the first report of a successful P-UCB transplant in 1989, [15] investigators worldwide have explored the potential of P-UCB as a source of HSC for transplantation. Early on, however, many questions in the form of editorials were raised. Would this HSC source engraft larger recipients [38] or recipients with diseases other than Fanconi anemia? Would lethal GVHD occur because of maternal lymphocyte contamination, previously shown to occur in some neonates with congenital immunodeficiency?[39] Alternatively, would P-UCB lymphocytes be less likely to cause a graft-versus-host reaction because of immunologic naivite and therefore lead to a greater risk of leukemic relapse?

In 1992, the International Cord Blood Transplant Registry was established as a repository of clinical data on outcomes observed in patients transplanted with P-UCB in an attempt to more quickly discern the true risks and benefits of this new HSC source. In 1993, a similar registry was developed in Europe as part of the European Research Project on Cord Blood Transplantation (EuroCord Transplant Registry). This section summarizes reports from both registries on outcomes observed in recipients of P-UCB transplantation from sibling donors.

Clinical Results

Data on patients receiving P-UCB transplants from sibling donors for the treatment of malignant and nonmalignant disorders have been reported previously. [40] [41] [42] As of March 1997, transplant outcomes in 74 patients were reported to the International Cord Blood Transplant Registry by 22 transplant teams. Patients were aged a median of 4.9 years (range, 0.516.3 years). Fifty-six patients received HLA 01 antigen mismatched grafts and 18 HLA 23 antigen mismatched grafts. Prophylaxis for acute GVHD was variable but most often consisted of cyclosporine alone or in combination with methylprednisolone or an anti-T-cell antibody. Hematopoietic growth factors were used early after the infusion of P-UCB in half the patients by study design.

For recipients of HLA 01 antigen mismatched sibling donor P-UCB grafts (n = 62), the actuarial probability of hematopoietic recovery at 60 days after transplantation was 0.91 ± 0.02 (Fig. 90-1). The median times to neutrophil recovery (defined as time to achieve an absolute neutrophil count [ANC] >5 × 10^8 /L) and platelet recovery (defined as platelet count >5 × 10^{10} /L untransfused for 7 days) were 22.0 days (range, 946) and 51 days (range, 15117), respectively. Four patients never had signs of hematopoietic recovery and one patient had early recovery but cells were entirely host in origin. Of the five patients without donor cell engraftment, four had undergone P-UCB transplantation for the treatment of a bone marrow failure syndrome and one for the treatment of Hunter syndrome. Similar results have been reported by Gluckman and colleagues for the EuroCord Transplant Registry. [5] [42] Although the engraftment rate is high for the group as a whole, there is a trend toward greater risk of graft failure in recipients with a prior history of a bone marrow failure syndrome, hemoglobinopathy, or storage disease (Table 90-2). Multivariate analyses with larger patient

Figure 90-1 Probability of neutrophil engraftment (i.e., ANC 5 × 10^8 /L) after HLA 01 antigen mismatched sibling donor P-UCB transplantation.

numbers are required to determine what factors are important in engraftment after sibling donor P-UCB transplantation.

Notably, no correlation between nucleated cell count or hematopoietic progenitor cell content of the P-UCB graft and time to neutrophil recovery or probability of engraftment has been discerned in the sibling donor setting. Moreover, the use of hematopoietic growth factor early after transplantation has not shortened the time to neutrophil recovery after P-UCB transplantation. Whether these observations are due to unique attributes of the neonatal HSC or simply due to small patient numbers or patient selection bias is unknown at this time.

Remarkably, acute GVHD has occurred only rarely in recipients of HLA 01 antigen mismatched P-UCB transplants. The actuarial probability of grade II-IV and grade III-IV GVHD at 100 days after transplantation remains 0.03 ± 0.02 and 0.02 ± 0.02, respectively. Despite the fact that the risk of acute GVHD is lower in young children, the incidence of acute GVHD appears to be lower as compared to similarly aged patients (ages 07 years) transplanted with HLA-identical marrow from sibling donors. Similar results have been reported by Gluckman et al. [5] Case-controlled studies will be required to determine if there is a significantly lower risk of acute GVHD after P-UCB transplantation as compared to BMT using sibling donors. Of the entire cohort of patients with a HLA 01 antigen disparate sibling donor, chronic GVHD has been reported in only three patients to date with no patient having had extensive disease.

Interestingly, moderate to severe GVHD has also been observed infrequently in 15 evaluable patients with haploidentical sibling donors (3 recipients of HLA 23 antigen disparate sibling donor P-UCB were not evaluable due to graft failure or early death). Of the 15 evaluable patients, 2 were mismatched at two antigens and 13 were mismatched at three antigens. Although patient numbers are small, donor-recipient pairs mismatched at the NIMA did appear to be less likely to develop

TABLE 90-2 -- Graft Failure After Sibling Donor UCB Transplant[a] (HLA 01 antigen mismatched)

	Proportion
Severe aplastic anemia	1/7
Fanconi anemia	1/10
Thalassemia	3/10
Sickle cell disease	1/5
Hunter syndrome	2/7

[a]Data from EuroCord Transplant Registry and International Cord Blood Transplant Registry.

grade II-IV GVHD than donor-recipient pairs mismatched at the noninherited paternal allele. This observation supports the hypothesis that partial tolerance may develop to the NIMA during gestation.

At a median follow-up of 2.0 years, the actuarial probability of survival for recipients of HLA 01 antigen mismatched grafts is 0.61 ± 0.12. Causes of death were multifactorial, including graft failure, relapse, interstitial pneumonitis/adult respiratory distress syndrome, veno-occlusive disease, intracranial hemorrhage, and early bacterial sepsis. For the entire cohort, GVHD was listed as a cause of death in only one patient with an HLA-3 antigen mismatched donor graft. The actuarial probability of disease-free survival in those treated for malignancy is 0.41 ± 0.11. Relapse was observed in two patients with relapsed neuroblastoma and in one patient with relapsed acute myelocytic leukemia after prior autologous marrow transplantation, in two patients with juvenile myelomonocytic leukemia, in three patients with acute lymphocytic leukemia (1 in complete response-1 but with the 9;22 translocation; 2 in complete response-2) and in one patient with adult type chronic myelogenous leukemia.

In summary, analysis of registry data and other case reports in the literature [13] [15] [43] [44] [45] [46] [47] [48] [49] [50] [52] [53] [54] demonstrates that engraftment occurs in most patients with greater risk of graft failure possibly in patients with bone marrow failure syndromes, hemoglobinopathy, and storage disease. Moreover, the data suggest that GVHD occurs infrequently in recipients of P-UCB. Results in haploidentical P-UCB transplants support the postulate of partial tolerance to NIMA. Although patient age has clearly been shown to be an important predictor of GVHD, [55] [56] it does not fully explain the very low incidence of grade II-IV disease observed in patients transplanted with P-UCB. Properties of the neonatal immune system that might account for the relative absence of a graft-versus-host reaction are currently being explored and have already been outlined. Importantly, these data also suggest that maternal cell contamination of the P-UCB at the time of collection may be of limited clinical importance. Kurtzberg et al. (presented by Broxmeyer et al. [13]), Wagner et al., [43] and Vilmer et al. [44] have failed to demonstrate maternal cells in the P-UCB grafts by cytogenetic or DNA techniques. Although maternal cell contamination is probably present in most P-UCB grafts, [57] [58] [59] [60] the very low incidence of GVHD observed in transplant recipients suggests that carefully collected P-UCB either contains insignificant numbers of maternal T cells or that maternal T cells are not immunologically competent in this context.

UNRELATED DONOR P-UCB TRANSPLANTATION

As a result of the early successes with P-UCB transplantation from sibling donors, pilot programs for the banking of unrelated donor P-UCB were initiated in many countries around the world. Known benefits of banked P-UCB include rapid availability, absence of donor risk, absence of donor attrition, and very low risk of transmissible infectious diseases, such as CMV and EBV. Although this HSC source may allow us to expand the available donor pool in targeted ethnic and racial minorities, this remains to be proven.

To date, few reports have been published on the use of unrelated donor P-UCB transplantation in the literature. The largest series to date has been reported by Gluckman et al.[5] who summarized the data in the EuroCord Transplant Registry. The clinical results with unrelated donor P-UCB transplantation at Duke and the University of Minnesota, the two largest single center experiences, are also summarized. [61]

Clinical Results: EuroCord Registry

Between 1994 and December 1996, 65 patients were transplanted with unrelated donor P-UCB in Europe and reported to the EuroCord Registry. [5] P-UCB was provided by the Placental Blood Program at the New York Blood Center (n = 45) or a European P-UCB bank (n = 20). HLA typing was performed by serology for class I HLA-A and -B antigens and by low-resolution generic oligotyping for DRB1. Of the 65 patients, only 11 received HLA-matched P-UCB grafts. The clinical results are summarized in the following sections.

Hematopoietic Engraftment

Of the 49 patients with malignant disease, 42 were evaluable for engraftment. Neutrophil recovery of donor origin was documented in 88% by day 56. Similarly, of the 10 patients with bone marrow failure or genetic disease, engraftment occurred in 80%. Among the 65 recipients of unrelated donor P-UCB, factors associated with more rapid neutrophil recovery in multivariate analysis were higher cell dose (>3.7 × 10^7 nucleated cells/kg recipient body weight) and recipient weight <20 kg. Although HLA identity was not associated with neutrophil recovery, there was an association with more rapid platelet recovery. The effect of prophylactic hematopoietic growth factor on neutrophils was not addressed in this report.

GVHD

Grade II-IV acute GVHD was observed in 21 of 46 patients with engraftment after unrelated donor P-UCB transplantation. A lower rate of acute GVHD was observed in CMV-seronegative recipients (p = 0.04); however, there was no association with the degree of HLA disparity.

Survival

With a median follow-up of 10 months, the probability of survival in this group of patients was 29%. Nucleated cell dose (>3.7 × 10^7 /kg [p = 0.07]) and CMV-seronegative status (p = 0.03) were favorable risk factors for survival in multivariate analysis.

Clinical Results: Duke/University of Minnesota

Between August 1993 and August 1997, 144 patients were transplanted with unrelated donor P-UCB at Duke University and the University of Minnesota. For the purpose of this analysis, patients with <42 days follow-up (n = 25), history of prior allogeneic SCT (n = 6), or an immunodeficiency state not requiring lymphomyeloablative therapy (n = 2) were excluded. The remaining 111 patients were treated for various malignant (n = 73) and nonmalignant (n = 38) disorders. Although the median age of recipients was 7.2 years (range, 0.258), 19 patients were >18 years of age. The median weight of patients was 21.6 kg (range, 4.892) and median cell dose was 3.5 × 10^7 /kg (range, 0.733.8).

In this analysis, all unrelated donor P-UCB grafts were identified at the Placental Blood Program of the New York Blood Center (NYBC). Prior to transplantation, confirmatory HLA typing of patient and cryopreserved donor specimens was performed using standard serologic techniques identifying all World Health Organization-recognized specificities for HLA-A and -B antigens and serologic level or high-resolution DNA techniques for HLA-DR antigens. Units were selected to deliver the highest cell dose with the closest matched unit, prioritizing matching at HLA-DR over HLA-A or -B antigens. For purposes of this analysis (in contrast to that reported for the EuroCord Transplant Registry), HLA typing was based on high-resolution oligotyping of DRB1.

Hematopoietic Recovery and Engraftment

For the 111 recipients eligible for this analysis, the median volume collected, nucleated cell dose, and CFU-GM dose in the

Figure 90-2 (A)>5 × 10^8 /L) and **(B)** probability of platelet recovery (i.e., platelet count >5 × 10^{10} L) after HLA 03 antigen mismatched unrelated donor P-UCB transplantation.

P-UCB graft at the time of collection was 84 mL (range, 40214), 3.5 × 10^7 /kg (range, 0.733.8), and 1.6 × 10^4 /kg (range, 0.123), respectively, as reported by the NYBC. The median CD34 and CD3 doses, as determined at the transplant centers at the time the P-UCB graft was thawed, were 1.6 × 10^5 (range, 0.132.9) and 8.0 × 10^6 /kg (range, 0.4101), respectively.

The overall probability of neutrophil recovery by day 42 and platelet recovery by 6 months were 0.83 (range, 0.760.90) and 0.76 (range, 0.690.88), respectively (Fig. 90-2). The median time required to achieve an ANC >5 × 10^8 /L and platelet count >5 × 10^{10} /L was 23 days (range, 1259) and 2.4 months (range, 18), respectively. For both neutrophil and platelet recovery, there was no difference in probability of recovery for patients with 01 versus 23 HLA antigen-disparate grafts. In contrast to previous reports of sibling donor P-UCB transplantation, time to neutrophil recovery strongly correlated with the dose of cryopreserved nucleated cells (correlation coefficient, 0.40 [p < 0.01]) and CFU-GM and dose of thawed CD34 cells. Of note, secondary graft failures have not been observed to date; all patients engrafting

after unrelated donor P-UCB transplantation without relapse continue to have complete chimerism (i.e., persistent mixed chimerism has not been observed).

In univariate analysis, a significantly faster rate of neutrophil and platelet recovery was seen in recipients of a non-total body irradiation (TBI) containing preparative regimen or higher graft cell dose content (nucleated cells, CD34, CFU-GM). A trend could be discerned for more rapid recovery in recipients of prophylactic G-CSF. In Cox regression analysis, among continuous variables, nucleated cell dose, CFU-GM dose, and CD34 cell dose were the only factors significant for predicting neutrophil recovery by day 42 and platelet recovery by 6 months.

GVHD

The overall probabilities of grade II-IV and grade III-IV acute GVHD for the entire group of patients was 0.35 (range, 0.260.44) and 0.12 (range, 0.060.18) by day 100 after unrelated donor P-UCB transplantation, respectively. In univariate analysis, no factor was significantly associated with risk of acute GVHD, including CD3 cell dose or degree of HLA disparity. Probability of acute GVHD was 0.29 (range, 0.160.42) and 0.40 (0.270.53) in recipients of HLA 01 and HLA 23 antigen-disparate grafts, respectively. Moreover, there was no difference in the probability of acute GVHD between patients treated with cyclosporine plus high-dose methylprednisolone (n = 54, 0.34 [range, 0.210.47]) versus lower dose methylprednisolone (n = 38, 0.36 [range, 0.200.52]) versus other regimens (n = 19, 0.36 [range, 0.130.60]) (p = NS). The only factor that approached significance in univariate analysis was nucleated cell dose (<3 vs. >3 × 10^{7}/kg, p = 0.09). In Cox regression analysis, no risk factor was identified for acute GVHD. Notably, the probability of extensive chronic GVHD was 0.04.

Relapse

The probability of relapse in the patients with malignant disease was 0.10 (range, 0.030.17) at 1 year and 0.14 (range, 0.050.23) at 2 years after P-UCB transplantation. In univariate analysis, only prophylactic use of G-CSF was associated with a lower risk of relapse (p < 0.01). Notably, risk of relapse was not significantly different between standard- and high-risk patients (0.16 vs. 0.10, respectively). In Cox regression analysis, however, no factor predicted higher risk of relapse.

Survival

With a median follow-up of 1 year, the probability of survival at 2 years after unrelated donor P-UCB transplantation was 0.44 (range, 0.320.56). In univariate analysis, younger recipient age (<2 years, p = 0.05), harvested graft nucleated cell dose (>3 × 10^{7}/kg, p < 0.01) and thawed graft CD34 dose (>2 × 10^{5}/kg, p < 0.01) were associated with improved survival. However, in Cox regression analysis, CD34 cell dose and age were the most favorable risk factors for survival. Causes of death are shown in Figure 90-3 .

At these two centers, 19 patients >18 years of age have been transplanted with unrelated donor P-UCB. Thirteen had malignant disease (9 high risk) and six had nonmalignant disease. Eight patients had 01 HLA-disparate grafts and 11 had 2-antigen HLA-disparate grafts. The median age and weight of this subset of patients were 26 years (range, 2058) and 68 kg (range, 4392), respectively. The overall probability of neutrophil recovery was 0.86 (range, 0.691.00) at a median of 28 days (range, 1345). Graft failure occurred in 4 patients (2 had Fanconi anemia and 2 had acute leukemia in relapse). The probability of grade II-IV acute GVHD was 0.21 (range, 0.030.39) and probability of survival was 0.62 (range, 0.390.85) with a median follow-up of 6 months (range, 0.228).

Figure 90-3 Causes of death after unrelated donor P-UCB transplantation.

TABLE 90-3 -- Unrelated UCB Transplantation Cinical Results

	NEJM[5] (n = 65)	Blood[62] (n = 272)	Duke/Minnesota (n = 111)
Engraftment			
Probability at 60 days	0.87	0.89	0.83
Days to ANC 500/L		24	23

(IIIIV)		0.23	0.12
Survival			
Probability at 1 year	0.29		0.50

Data from Gluckman et al. [5] and Rubinstein et al.[62]

Summary

The results reported by Gluckman et al.[5] for the EuroCord Registry and Rubinstein et al. [62] for the NYBC database are consistent with the Duke/University of Minnesota database in terms of rates of hematopoietic recovery and engraftment and risks of grade II-IV acute GVHD (Table 90-3). The reasons for differences in survival between the EuroCord Registry and Duke/University of Minnesota are not readily apparent but may be due to differences in patient selection. Importantly, both the EuroCord Registry and Duke/University of Minnesota have independently documented the importance of cell dose in predicting engraftment and survival (Table 90-4). Although degree of HLA-A, -B and -DRB1 disparity has not had an impact on survival according to the EuroCord Registry and Duke/University of Minnesota, this may reflect limited patient sample sizes. More recent data from the NYBC (P. Rubinstein, personal communication) suggest that degree and class of HLA disparity may affect survival with poorer survival in patients with greater degrees of HLA disparity or disparities at HLA-DR.

AUTOLOGOUS P-UCB TRANSPLANTATION

Transplantation of autologous P-UCB has thus far been linked to gene therapy. Review of the literature would suggest that P-UCB HSC may be transduced more efficiently by retroviral vectors than adult marrow HSC. To date, four infants with adenosine deaminase (ADA) deficiency SCID have been transplanted with genetically modified autologous P-UCB HSC collected and genetically modified shortly after birth. [63] [64] No myeloablative regimen was administered to these four infants reasoning that the T-cell progeny of the corrected HSC would have a selective survival advantage over time. In each case, engraftment was documented albeit at low levels with some indication that the proportion of T cells containing the corrected ADA gene is increasing over time.

TABLE 90-4 -- Unrelated Donor UCB Transplantation: Analysis of Risk Factors

Outcome	Predictive Factor	
	NEJM (n = 65)[5]	**Duke/Minna[a] (n = 111)**
Engraftment	Nucleated cell dose	CFU-GM dose
	HLA identity	CD34 dose
Acute GVHD	Recipient	None
	CMV status	
Survival	CMV status nucleated cell dose (p = 0.07)	Nucleated cell dose (p = 0.05)

Data from Gluckman et al. [5]

[a] Unpublished.

To date, there have been no other reports on the use of autologous P-UCB. Clinical protocols, however, currently exist for its use in the treatment of patients with Fanconi anemia (FAC complementation group). As in patients with ADA deficiency, it has also been reasoned that corrected Fanconi HSC will have a survival advantage with eventual replacement of the abnormal Fanconi hematopoiesis. Although several candidate patients exist, such therapy has yet to be used.

ALLOGENEIC PLACENTAL BLOOD BANKING

Documentation of hematologic reconstitution after myeloablative therapy and P-UCB transplantation has resulted in considerable interest in the techniques of P-UCB collection and storage. Although the individual procedures used are not novel, the collection and processing procedures for P-UCB are not the same as those used for bone marrow. Unlike the typical bone marrow collection, the obstetrician or hematologist cannot collect a predetermined volume of P-UCB but rather is restricted to the finite amount available.

A variety of collection methods have been proposed to optimize the collection volume and reduce the risks of microbial and maternal cell contamination. [65] [66] [67] [68] [69] [70] Although no single method has been proven to be substantially better than another, the collection of free-flowing P-UCB into an open collection jar has largely been abandoned. The most important advantage of open collection was ease of collection, requiring no training and little set-up time; however, the most important disadvantage was the greater potential for microbial and maternal cell contamination. In contrast, closed systems using catheters and needles are technically more challenging and not uniformly transferable to obstetricians or midwives who have not had the opportunity to evaluate the system prior to the umbilical cord blood collection. Closed collection systems have been principally used by designated P-UCB collection centers with trained staff.

Different procedures for P-UCB collection, separation, and cryopreservation have been evaluated and reported in anticipation of large-scale banking projects proposed in the United States and Europe. Bertolini et al. [69] have reported on one of the most extensive evaluations of P-UCB collection procedures thus far. Open and closed collection systems, the effect of vaginal versus cesarean section delivery, and the recoveries of CFC and HPP-CFC after density-gradient centrifugation and gelatin sedimentation of both fresh and cryopreserved cell samples were compared. Bertolini et al. [69] failed to demonstrate any statistical differences in the collection volumes of P-UCB recovered during vaginal delivery (in utero, n = 445) or after cesarean section deliveries (ex utero, n = 82). The median volume of blood collected was 72 ± 34 ml and 62 ± 19 ml, respectively. Furthermore, no significant difference in collection volume could be discerned between open and closed collection systems. Expectedly, there appeared to be a lower risk of bacterial contamination for samples collected by venipuncture into a blood collection bag as compared to the open collection method (4% vs. 14%, respectively).

In an attempt to reduce the complication of dimethyl sulfoxide (DMSO) toxicity and ABO incompatibility reaction, red blood cell (RBC) depletion of the P-UCB graft has been evaluated. Broxmeyer et al.[11] first reported significant losses in progenitor recovery with P-UCB after density-gradient centrifugation (Ficoll-Hypaque, 1.077 g/ml, Sigma, St. Louis, MO). Broxmeyer et al.[11] found that CFC were lost by a variety of RBC separation techniques, suggesting that RBC depletion prior to clinical transplantation, even if the recipient and donor were ABO incompatible, should be carefully reconsidered. Others, [68] [69] [70] [71] however, failed to observe the same substantial losses of progenitor cells as assessed by in vitro CFC assays. Harris et al. [68] described a double Ficoll-Hypaque procedure in which the final preparation was virtually devoid of RBC and polymorphonuclear leukocytes but contained virtually all CFC. Bertolini et

al.[69] compared the double Ficoll-Hypaque method proposed by Harris et al., [68] and a 3% gelatin sedimentation method proposed by Nagler et al. [72] P-UCB separation using either Ficoll-Hypaque or gelatin sedimentation resulted in only 814% loss of CFC and HPP-CFC. However, Bertolini et al. [69] also found that the effectiveness of either separation procedure was markedly reduced when P-UCB was stored for more than 12 hours before the procedure. Although the gelatin procedure took less time (1.5 vs. 2.5 hours) relative to the Ficoll-Hypaque method, in one-third of instances, the gelatin procedure failed to result in RBC depletion when performed at room temperature. This technical issue, however, was corrected simply by performing the procedure at 4°C. Rubinstein et al. [73] suggest that the P-UCB graft be placed in a sterile bag and then thawed in a 38°C water bath with gentle agitation. With an equal volume of dextran/albumin solution added after thawing, the cells are centrifuged gently and the supernatant is removed. Together this procedure removes the bulk of RBC ghosts, free hemoglobin, and DMSO, thus reducing some of the risks associated with the procedure. These data suggest that RBC depletion by either density-gradient centrifugation or gelatin sedimentation results in only modest losses of hematopoietic progenitor cells.

Interest in the creation of large-scale unrelated donor P-UCB banks worldwide makes RBC separation a particularly important issue. Cryopreservation of mononuclear cell preparations would (1) reduce the risk of ABO-incompatible reactions (i.e., anaphylaxis and effects secondary to the infusion of free hemoglobin), (2) reduce the volume of the P-UCB graft and thus significantly reduce the space required for banking, (3) potentially improve the ability to manipulate these cells after thawing (e.g., CD34+ selection and ex vivo progenitor cell expansion), and (4) reduce the risk of DMSO-related reactions. Importantly, both density-gradient centrifugation with Ficoll-Hypaque and gelatin sedimentation [46] [47] of P-UCB have been successfully used prior to clinical transplantation without deleterious effects on hematopoietic recovery and engraftment.

As of March 1998, 10,000 P-UCB grafts have been collected, HLA typed, tested for transmissible infectious diseases, and cryopreserved. Recently, three additional P-UCB banks at Duke University, University of California at Los Angeles, and Childrens Hospital of Orange County have been designated and funded by the National Institutes of Health (NIH). These banks have developed a standardized P-UCB banking procedure. In close cooperation with transplant centers, these NIH-sponsored P-UCB banks have developed standardized quality assessment procedures (i.e., quantification of hematopoietic progenitors, sterility, detection of genetic and transmissible infectious diseases); streamlined histocompatibility testing using restricted volumes of the sample from the P-UCB graft; established repositories of viable cells, serum, and DNA on donor and mother for future testing; optimized the cryopreservation and thawing procedure to reduce cell loss and minimize infusion of DMSO and RBC debris; and established a computer network for efficient data storage and retrieval. Currently, P-UCB searches are most commonly accomplished by direct communication with individual P-UCB banks around the world or via NE CORD (consortium of banks in Milano, Dusseldorf, Barcelona). Recently, the National Marrow Donor Program (NMDP) has initiated discussions with various P-UCB banks worldwide to serve as the search coordinating center. Programs, such as the NMDP, could also serve as repositories of outcome data for the P-UCB banks. Clearly, such a construct offers multiple advantages for the P-UCB banks and transplant centers. Searches of both the marrow and P-UCB donor registries simultaneously will allow us to determine how much time is saved in the search process as well as the costs of using banked P-UCB rather than fresh marrow. It is hoped that a uniform search algorithm will be developed. Once it has been demonstrated that unrelated P-UCB reduces the risks of allogeneic stem cell transplant therapy or that it can supplement the pool of unrelated marrow donors, particularly for certain ethnic or racial minorities, it is likely that these repositories of P-UCB will be greatly expanded.

With the creation of unrelated donor P-UCB banks and the increasing awareness of P-UCB transplantation in general, there are increasing requests to store P-UCB for parents of children with leukemia, lymphoma, neuroblastoma, marrow failure syndrome, immunodeficiency state, inborn errors of metabolism, or other diseases potentially treatable by stem cell transplantation. Such a request for storing HLA-matched or partially HLA-matched P-UCB for a specific family member is appropriate and should be considered by the family and the hematologist or oncologist. Although not available at every transplant center, P-UCB testing and storage under such circumstances is widely available and is usually covered by third-party payers.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

AUTOLOGOUS STORAGE OF P-UCB

On the basis of the results with allogeneic P-UCB, repositories of autologous P-UCB have also developed at least in the United States and Canada. It has been suggested that the storage of the infants own P-UCB might be useful in several ways:

1. It might be an optimal source of tumor-free, virus-free HSC if the child should develop a disease amenable to stem cell transplantation later in life.
2. It might be a source of HLA-matched or closely matched HSC for a sibling requiring transplant therapy at some point.
3. It might be an optimal source of HSC for gene therapy should such therapy be needed either for the treatment of a genetic disorder in that child.

It has been suggested that autologous storage of P-UCB HSC is a form of biological insurance.

Biocyte Corporation was founded on the concept that P-UCB would be useful in the treatment of a variety of disorders, including cancers, genetic disorders, and immunodeficiency states. The company holds a US patent[74] for the collection and cryopreservation of P-UCB. The validity of the patent, however, is being considered at this time.

Several companies currently offer this service for a fee to expectant parents as shown in Table 90-5 . The routine collection of autologous P-UCB, as biologic insurance is controversial. The need for such a service is not clear. Several unknown factors need to be considered regarding autologous P-UCB, including the effect of long-term storage on the graft, the absence of graft-versus-leukemia/tumor effect, and preferences of the transplant physician. However, autologous P-UCB may be useful in specific situations, such as a vehicle for gene therapy. It may be worthwhile collecting and storing P-UCB from neonates with a high risk of disease possibly amenable to gene therapy in the future (e.g., Fanconi anemia, ADA deficiency) or in a family with familial cancer risk.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

ETHICAL CONSIDERATIONS

The collection of P-UCB poses a number of ethical issues. If it is considered to be like any other organ or tissue, then consent must be obtained by the tissue donor. In the case of P-UCB, the donor is always a minor, and therefore, consent must be obtained from the infants mother. The questions that arise include:

TABLE 90-5 -- **Commercial UCB Banks**

Cord Blood Registry San Bruno, CA	International Cord Blood Foundation San Francisco, CA
CorCell Philadelphia, PA	Stem Cell Sciences, Inc. New York, NY
Cryo-Cell International Safety Harbor, FL	United States Center for Cord Blood Altamonte Springs, FL
CryoTech, Inc. Roseville, MN	Viacord, Inc. Boston, MA

When should consent be obtained from the mother, and secondly, will the infant donor at 21 years of age have any rights to the P-UCB that was previously given to the unrelated P-UCB registry? Although the second issue must be addressed by the legal agencies, current practice would dictate that consent from the donors mother should be obtained before labor or at least at some finite period of time after delivery.

Alternatively, P-UCB may be considered to be discarded tissue. If so, consent is not required. The collection of P-UCB from the delivered placenta poses no risk to mother or infant. However, if P-UCB is to be considered discarded tissue and consent is not required, what do we do about the issue of testing for human immunodeficiency virus and how do we protect the rights of individuals whose religious and cultural practices would not allow the collection and transplantation of P-UCB? Although P-UCB offers several real and potential advantages as an alternate source of HSC, it also opens a new set of issues that need to be considered before large-scale collection of this tissue worldwide.

Other related issues that need to be addressed include the commercial aspects of P-UCB collection and storage, and the ability to back track and perform additional donor testing before the use of a P-UCB graft. By necessity, these and other issues need to be considered by medical ethicists and the physicians offering this treatment option.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

REGULATORY ISSUES

With the development of numerous P-UCB banks around the world, some form of regulation is necessary. The transplant physician is often not able to assess the quality of the banking practices at an individual site. Over the past 5 years P-UCB has moved from the status of biologic waste to a potentially important source of HSC. Clinical experience has already demonstrated that P-UCB contains sufficient numbers of HSC to engraft at least small recipients consistently. As a result, banks have been developed or are being considered throughout the United States and Europe as well as many countries in South America and Asia. Moreover, the potential for storing the childs own P-UCB as a form of biologic insurance has also been considered, resulting in the establishment of commercial banks. Hence, there has been an explosion of banking activity, making the need for standard policies and procedures particularly acute. It is likely that P-UCB will be the first source of HSC to be regulated by the US Food and Drug Administration (FDA). [75] [76] Although it is generally agreed that some form of regulation of P-UCB banking is important, the optimum mechanism for such regulation is being debated. In December 1996, the Center for Biologics Evaluation and Research of the US FDA issued a draft document in the *Federal Register* entitled Concerning the Regulation of Placental/Umbilical Cord Blood Stem Cell Products Intended for Transplantation or Further Manufacturing into Injectable Products, which defined cells in P-UCB as biologic products subject to Investigational New Drug regulations during clinical development. This incited considerable debate within the HSC transplant field and was formally opposed by various groups, including the Foundation for the Accreditation of Hematopoietic Cell Therapy, the International Society of Hematotherapy and Graft Engineering, American Association of Blood Banks, the American Society of Bone Marrow Transplantation, and the American Society of Clinical Oncology because of the potential of such a process for restricting research and development in the field of HSC and because of an inability to characterize the essential components of the HSC product.

In February 1997, the US FDA issued a document entitled Proposed Approach to Regulation of Cellular and Tissue-Based Products, which proposes a new regulatory framework based on a tiered approach to the regulation of traditional and new products that both protect the public as well as allow for the development of new therapies and products with minimal regulatory burden. However, central to the proposal is that all banks involved in P-UCB HSC therapy be registered with the US FDA. Products that are more than mimimally manipulated or experimental treatment plans will be subject to more regulation. Key elements of the regulation of P-UCB include use of good manufacturing practice, adequate testing for transmissible diseases, and development of product standards. The US FDA states that it intends to invite professional groups and individuals to submit data and standards to the FDA Tissue Reference Group that would define the essential elements of the HSC product for safety and effectiveness. Once sufficient data are available to develop processing and product standards that ensure safety, purity, and potency, the US FDA would issue a product license on the basis of certification by the applicant that such applicable standards have been met.

Although there will be debate on the optimal procedures for handling P-UCB, there is already extensive experience in handling blood and marrow. Many of the procedures for obtaining consent, collection, testing, cryopreservation, RBC depletion, histocompatibility testing, and sample labeling are likely to be extracted from existing operating manuals for blood. A major problem, however, will be in the definition of suitable product. Moreover, the definition of suitable product may vary depending on the type of recipientself, sibling, or unrelated.

Although it is clear that P-UCB should be considered as a viable source of HSC for transplantation, we are still in the learning phase. Just as the transplant physician requires assurances that the P-UCB graft product has been processed and stored properly, the director of P-UCB bank may require assurances that the transplant team will use the graft properly. Clinical outcome data may affect the P-UCB banks methods of processing and graft characterization. Policies for defining the qualifications of transplant teams and the appropriate use of P-UCB should not be overlooked. In the past, similar issues had to be addressed by the NMDP. Perhaps existing societies, such as the International Society of Hematotherapy and Graft Engineering and the American Society of Bone Marrow Transplantation, will aid in addressing these difficult issues.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

ALLOCATION OF P-UCB

A decision algorithm for choosing P-UCB as an appropriate source of HSC for a particular patient must be based on what is known and not known about this and other HSC sources. What do we know about P-UCB?

1. P-UCB contains sufficient numbers of HSC and progenitor cells for engraftment in most recipients weighing <50 kg.
2. P-UCB collection inflicts no risk to the mother or infant donor. [77]
3. P-UCB banking eliminates the risk of donor attrition observed by all marrow donor registries.
4. P-UCB is rarely contaminated by CMV[78] [79] and EBV.[80]
5. P-UCB can cause severe GVHD.

What do we think we know about P-UCB based on existing clinical data?

1. P-UCB transplantation appears to be associated with a lower rate of acute GVHD as compared to transplant using stem cell obtained from marrow.
2. P-UCB banking appears to shorten the interval between search initiation and time of donor cell acquisition by about 1 month, as compared to marrow collection.
3. Targeted P-UCB collection should reduce the shortage of racial and ethnic minority representation.

What dont we know about P-UCB because of lack of clinical data?

1. Is the P-UCB stem cell content sufficient for successful engraftment of adult-sized recipients?

2. Is P-UCB transplant associated with a low risk of relapse as with adult unrelated donor marrow transplant?
3. Will P-UCB increase the number of stem cell transplants for patients of racial and ethnic minority heritage?

TREATMENT ALGORITHM

Although other attributes could be added to these lists of what we do and do not know, the attributes described will help guide the creation of a decision algorithm for appropriately choosing P-UCB over adult marrow or peripheral blood.

When deciding whether P-UCB is more or less appropriate for a particular patient, several factors need to be assessed (Fig. 90-4). What is known about P-UCB transplantation and marrow SCT results for the disease being considered? Young patients with chronic myelogenous leukemia in chronic phase [81] and Wiskott-Aldrich syndrome (age <5 years[82]), for example, do well after adult unrelated donor marrow SCT. In contrast, older patients (age >35 years), regardless of disease, do poorly after adult unrelated donor marrow SCT.[83] [84] It could be argued that patients with chronic myelogenous leukemia or Wiskott-Aldrich syndrome, who are predicted to do well after marrow SCT, should be offered P-UCB only if no suitable marrow donor can be

Figure 90-4 Advantages and disadvantages of transplantation of P-UCB versus adult marrow.

found. In contrast, older adults should be reasonable candidates for such phase I-II trials evaluating new approaches to reduce the proven risks of unrelated donor marrow SCT in these populations. Other factors that are potentially involved in the decision process might include urgency of the transplant and cost.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

SUMMARY

Placental-umbilical cord blood is now considered to be a clinically useful source of HSC for transplantation. Multiple reports clearly document that donor-derived multilineage hematopoiesis after P-UCB transplantation is sustained with the longest follow-up of nearly 10 years. Unfortunately, it is still unknown what dose of nucleated cells or CD34+ cells is the absolute minimum required for engraftment and the absence of well-controlled trials prevent any conclusion regarding which HSC source is optimal for a given patient. Future studies are planned that will retrospectively compare transplant outcomes after P-UCB and adult marrow SCT.

It is clear that P-UCB is immediately available and risk of herpes virus contamination is low. Furthermore, the available clinical data suggest that the risks of grade III-IV acute GVHD and extensive chronic GVHD are remarkably low. Recent studies repetitively demonstrate the importance of graft cell dose in terms of engraftment, nonrelapse mortality, and survival. Whether the degree or class of HLA disparity has any impact on outcome has yet to be determined. Although early results fail to demonstrate an association, limited numbers of patients prevent any definitive statement on this issue. Nonetheless, these data at least suggest that P-UCB banks should focus on the collection of grafts containing larger cell doses and choice of P-UCB graft should be based primarily on cell dose and secondarily on HLA match.

Chapter 91 - Preparative Regimens for Stem Cell Transplantation

Edward A. Copelan
Sam L. Penza

INTRODUCTION

Recurrence of malignancy and death due to complications of the preparative regimen are the major causes of treatment failure following hematopoietic stem cell transplantation (SCT). Limitations of current preparative regimens are largely responsible; improvement is needed. This chapter describes the development of current preparative regimens, assesses their virtues and liabilities, and describes potential directions for research.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

PRECLINICAL STUDIES

Animal Studies Using Irradiation

Initial studies of SCT evolved from animal investigations that had been designed to analyze organ damage following irradiation exposure. These studies were undertaken in the hope that methods for protection from and treatment of radiation injury could be developed. Animals exposed to very high doses of radiation developed lethal cutaneous and gastrointestinal toxicities. At lower but still lethal doses, sustained marrow impairment resulted in death from infection or bleeding. Studies in mice demonstrated that otherwise lethal exposure to irradiation could be circumvented by lead protection of the spleen. [1] The subsequent demonstration that infusion of syngeneic spleen or marrow cells could protect mice and guinea pigs from lethal doses of irradiation [2] led to canine studies and later human studies using marrow as a source of stem cells.[3] [4] [5] [6] Canine studies helped elucidate the problems of graft-versus-host disease (GVHD) and graft rejection and helped to define histocompatibility antigens.

In animal models as well as in humans, SCT proved a feasible treatment for whole-body radiation exposures of 300 to 1,500 Gy. Donnall Thomas envisioned, from these studies of radiation toxicity, a radically different approach to the treatment of hematologic malignancies. This approach would not depend on an increased susceptibility of malignant cells (compared to normal hematopoietic cells) to drug therapy. Advantages of total-body irradiation (TBI) responsible for its continued use in animal and human studies of transplantation include speed of delivery, lack of metabolites that interfere with the function of transplanted cells, and potent immunosuppressive effects in multiple animal models and in humans. Characteristics favoring its use in the treatment of leukemia include its antileukemic effectiveness, the lack of cross-resistance with chemotherapeutic agents, the ability to reach privileged sites (including the central nervous system, where drugs may not penetrate well), its effectiveness regardless of blood supply, and the potential for shielding or boosting specific areas of the body. [8]

Preparative regimens for allogeneic SCT in disease states should immunosuppress the recipient sufficiently to prevent rejection of donor cells and destroy malignant or defective hematopoietic progenitor cells as well as normal hematopoietic progenitors. They should also cause minimal short- and long-term toxicity. The usefulness of a preparative regimen in a specific disorder depends on its ability to fulfill these functions.

Total-body irradiation remains the most important conditioning agent for patients with hematologic malignancies receiving allografts. When dogs are exposed to TBI doses of 4 Gy or more, they generally die from complications of marrow failure. [7] However, when dogs receive infusions of autologous stem cells following similar or higher radiation doses, they consistently survive. [7] [8] [9] Successful engraftment of stem cells from allogeneic litter mates that are dog leukocyte antigen-identical requires substantially higher TBI doses of approximately 9 Gy. Transplantation from unrelated or mismatched donors requires doses >15 Gy. [10] In histocompatible rats, dogs, and monkeys, substantially higher doses of irradiation (up to 15 Gy) are required when split into fractions over 4 days, compared to that necessary to ensure engraftment when irradiation is administered as a single dose (in which case 9 Gy is sufficient). [11]

Animal Studies Using Chemotherapy

Studies using chemotherapy agents alone as preparation for allogeneic SCT proceeded in parallel with investigations using TBI. The initial stimuli for the development of radiation-free regimens were lack of adequate facilities for administration of TBI and concern over the short- and long-term toxicity of radiation. Animal models, which had been essential to the development of transplantation using TBI, were also crucial in the development of preparation without irradiation.

In 1962, Cree reported successful allogeneic SCT in rabbits using aminochlorambucil as a single agent. [12] Cyclophosphamide (Cy) was subsequently shown to permit engraftment of allogeneic stem cells in mice and rats.[13] [14] Two hundred mg/kg of Cy was needed to ensure consistent and permanent engraftment of stem cells from Lewis rats into histoincompatible ACI donors.[15] Subsequent studies in rhesus monkeys demonstrated engraftment with cyclophosphamide doses of 180 mg/kg over 2 days. Larger total doses were required when the Cy was administered over 4 days.[16] Thus, high doses of Cy administered over short periods of time proved sufficiently immunosuppressive to ensure engraftment; similar doses over shorter periods of time were much more effective than those spread over longer intervals.

In addition to the immunosuppressive requirement, injury to normal hematopoietic cells is important for permitting engraftment in animal models. Infused marrow cells preferentially engraft in irradiated body parts versus those that have been shielded. [17] Drugs such as busulfan (Bu) and dimethylbusulfan cause profound granulocytopenia and thrombocytopenia without substantial immediate effect on lymphocyte levels or humoral antibody response. [18] [19] [20] These agents are not sufficiently immunosuppressive to permit allogeneic engraftment. However, they helped achieve engraftment with the addition of agents such as antilymphocyte serum.[21]

In rat studies, 200 mg/kg of Cy was needed to permit engraftment; however, with the addition of 30 mg/kg of Bu, 150 mg/kg of Cy proved sufficient. Further, the combination resulted in more rapid and complete engraftment than Cy alone. [15] [22] [23]

EARLY HUMAN STUDIES

Initial Studies Using TBI and Cyclophosphamide

Two patients with acute lymphoblastic leukemia (ALL) prepared for syngeneic transplantation with only TBI developed a

recurrence of leukemia after the transplant.[24] Cyclophosphamide was added to TBI to deliver additional antileukemia therapy. Thomas et al [25] published their results using a combination of TBI and Cy in 1977. In that study, 100 patients with advanced leukemia were transplanted using marrow from HLA-identical siblings following preparation with TBI and Cy. Thirteen percent became long-term leukemia-free survivors. This innovative study set the stage for the application of SCT to a number of malignant and nonmalignant disorders over the last 20 years.

Thomas [26] used dual 60_{co} sources to achieve homogeneous TBI. Sustained engraftment required a single exposure of 10 Gy. Administration of TBI in a single exposure, followed shortly by the infusion of marrow, minimized the duration of neutropenia and thrombocytopenia. However, when high-dose TBI is administered in a single dose, it must be given at a low dose rate to prevent the development of interstitial pneumonia, [27] [28] the dose-limiting toxicity of single-dose TBI. Increasing the number of fractions in which TBI is administered reduces lung damage.[26] Hematopoietic cells repair DNA damage less effectively than other tissues. Thus, administration of TBI in multiple fractions accentuates marrow toxicity and attenuates the injury to other organs, a circumstance advantageous to the treatment of hematologic disorders.

Fractionation of irradiation over several days was considered in patients who were in better clinical condition and could tolerate a longer period of neutropenia and thrombocytopenia. Using Cy and fractionated irradiation, Thomas et al [29] [30] achieved leukemia-free survival in 50% of patients in first remission from acute myelogenous leukemia (AML). Patients who received 2 Gy/day for 6 consecutive days had a better outcome than patients who received 10 Gy in a single exposure (Fig. 911). Using a hyperfractioned regimen given 3 times per day over a 4-day period, investigators from Memorial-Sloan Kettering reported a lower incidence of interstitial pneumonia and of relapse of acute leukemia than they previously achieved with a single-dose regimen. [31] [32] These observations established the advantages of a fractionated schedule of TBI. Techniques of administration, dose rates, fractionation schedules, and total doses have varied widely. Variations in technique are frequently related to the equipment available and the preference of the radiation therapist. With rare exceptions, direct comparisons of different approaches have not been performed. Further complicating interpretations of results with different techniques are other important

Figure 91-1 Kaplan-Meier product limit estimates for event-free survival of patients with acute myelogenous leukemia in first remission, given Cy 60 mg/kg on each of 2 days, randomized to receive 2 Gy on each of 6 days (n = 26) or 10 Gy (n = 27) in one exposure followed by an infusion of stem cells from an HLA-identical sibling. *(From Thomas ED: Total body irradiation regimens for marrow grafting. I. J Radiation Oncology, Biology, Physics 19:1286, 1990, with permission from Elsevier Science.)*

variables, such as the underlying disease and stage, the condition of the patient, the method for prevention of GVHD, and other supportive care measures.

Initial Studies in Leukemia Using Busulfan and Cyclophosphamide

In 1969, Santos et al[33] reported fatal cardiac toxicity in patients undergoing allogeneic marrow transplantation after a preparative regimen of Cy, 60 mg/kg, on each of 4 consecutive days. The dose was then lowered to 50 mg/kg daily for 4 consecutive days. Twelve of 24 patients with advanced leukemia prepared with this regimen died from transplant-related complications; the other patients died from leukemia recurrence. [34] Santos et al subsequently performed a series of dose-finding studies with busulfan in patients with AML. At 20 mg/kg of Bu, mucositis and hepatic veno-occlusive disease (VOD), occurred frequently and were dose-limiting. [35] Others had also demonstrated significant toxicity with 20 mg/kg of Bu as a single agent. [36] Bu, 16 mg/kg, was the dose chosen to be used with Cy, 200 mg/kg, in patients with AML for initial studies at Johns Hopkins. This proved to be an extremely effective regimen; however, the incidence of transplant-related complications was high. [37] More effective supportive care measures, such as the use of cyclosporine to prevent GVHD, later led to improved results. [38]

Reasoning that the huge dose of Cy added little therapeutic effectiveness but was responsible for significant toxicity, investigators at Ohio State chose to decrease the dose of Cy to 60 mg/kg on each of 2 consecutive days.[39] This dose was identical to that traditionally used in Cy/TBI regimens. This little BuCy (or BuCy2) regimen was studied in a variety of diseases. Following pilot studies at Ohio State, several multi-institutional trials were performed in AML, [40] chronic myelogenous leukemia (CML),[41] and ALL.[42] Multiple myeloma,[43] Hodgkins disease, [44] and non-Hodgkins lymphoma[45] were also investigated.

In the series of multi-institutional trials, BuCy2 consistently permitted engraftment of HLA-genotypically identical stem cells in patients with hematologic malignancies.[40] [41] [42] Only 3 of 281 patients undergoing such transplants failed to engraft. Intriguingly, all 10 patients with hematologic malignancies given busulfan, 16 mg/kg, and only 90 mg/kg of Cy engrafted with HLA-identical sibling allografts, [46] further demonstrating the important role of Bu in permitting engraftment. Clearly, however, BuCy2 is not as immunosuppressive as Cy/TBI regimens. An increased incidence of graft failure occurs following BuCy preparation for transplantation using T-depleted marrow from HLA-nonidentical family members, or from unrelated donors.[47] In the setting of unmanipulated marrow, failure to engraft using nonT-depleted marrow from unrelated donors is rare after preparation with BuCy, but probably more frequent than with TBI-containing regimens. [48] [49]

TOXICITY OF PREPARATIVE REGIMENS

The incidence of complications reported following SCT appears to be more closely related to the criteria for diagnosis of that complication at a given center than to the regimen used. Accordingly, one must interpret with care comparisons of published series of patients receiving different preparative therapies at different institutions. However, this type of comparison is often the only information available. Also, because of patient numbers and thoroughness of study or reporting, these data may be superior (for this purpose) to data obtained in randomized trials.

Attempts to analyze the toxicity resulting from specific preparative regimens have been complicated by a variety of factors, most prominently the development of injury to multiple organs that occurs following transplantation for reasons other than the

preparative regimen. These include GVHD (and its prevention and treatment), the underlying disease and its prior treatment, and the administration of drugs with the potential to damage organs.

Bearman et al[50] developed a grading system in an attempt to distinguish toxicity related to the preparative regimen from that due to other transplant-related complications. Toxicity directly related to the preparative regimen is labeled regimen-related toxicity. The system was designed for high-dose preparation for transplantation, not for lower-dose chemotherapy. Such a system permits comparison of different preparative regimens. It attempts to grade the effect of the preparative regimen on eight organs: gut, liver, lungs, kidney, mucosa, heart, bladder, and central nervous system (Table 911). Toxicity is graded weekly for 4 weeks and then on day 100 for the lungs. Grade I toxicities are mild and reversible without intervention. Grade II toxicities are moderate but generally require intervention or interfere with therapy. Grade III represents life-threatening toxicity, which often requires intensive supportive care (e.g., mechanical ventilation). Patients who die from regimen-related toxicity on or before day 28 (for pulmonary toxicity, before day 100) are labeled grade IV. Toxicity that can be attributed to other transplant-related complications (e.g., GVHD, infection, bleeding, or drugs) is excluded. Cumulative toxicity is the sum of the highest toxicity scores observed in each organ system.

In Bearmans analysis, severe regimen-related toxicity was most common in the liver, kidneys, and lungs. All but 2 of 19 patients with Grade III toxicity died within the first 100 days. For these 2, the highest-grade toxicity was mucositis. Half of the patients who developed Grade III toxicity died directly from toxicity. Less cumulative toxicity was associated with better survival. The total dose of irradiation administered was the most significant risk factor identified for development of regimen-related toxicity. Recipients of allografts showed a significantly increased incidence of Grade III or IV toxicity compared with autograft recipients. Those with advanced disease also had a significantly increased incidence of severe toxicity and death within 100 days of transplantation [51] (Fig. 912). The use of methotrexate

TABLE 91-1 -- Regimen-Related Toxicity According to Organ System[a]

	Grade I	Grade II	Grade III
Cardiac toxicity	Mild EKG abnormality, not requiring medical intervention; or noted heart enlargement on CXR with no clinical symptoms	Moderate EKG abnormalities requiring and responding to medical intervention; or requiring continuous monitoring without treatment; or congestive heart failure responsive to digitalis or diuretics	Severe EKG abnormalities with no or only partial response to medical intervention; or heart failure with no or only minor response to medical intervention; or decrease in voltage by more than 50%
Bladder toxicity	Macroscopic hematuria after 2 days from last chemotherapy dose with no subjective symptoms fo cystitis and not caused by infection	Macroscopic hematuria after 7 days from last chemotherapy dose not caused by infection; or hematuria after 2 days with subjective symptoms of cystitis not caused by infection	Hemorrhagic cystitis with frank blood, necessitating invasive local intervention with installation of sclerosing agents, nephrostomy, or other surgical procedure
Renal toxicity	Increase in creatinine up to twice the baseline value (usually the last recorded before start of conditioning)	Increase in creatinine above twice baseline but not requiring dialysis	Requirement for dialysis
Pulmonary toxicity	Dyspnea without CXR changes not caused by infection or congestive heart failure; or CXR showing isolated infiltrate or mild interstitial changes without symptoms not caused by infection or congestive heart failure	CXR with extensive localized infiltrate or moderate interstitial changes combined with dyspnea and not caused by infection or CHF; or decrease of P_{O_2} (>10% from baseline) but not requiring mechanical ventilation or >50% O_2 on mask and not caused by infection or CHF	Interstitial changes requiring mechanical ventilatory support or >50% oxygen on mask and not caused by infection or CHF
Hepatic toxicity	Mild hepatic dysfunction with 2.0 mg% bilirubin 6.0 mg%; or weight gain >2.5% and <5% from baseline, of noncardiac origin; or SGOT increase > 2-fold but < 5-fold from lowest preconditioning	Moderate hepatic dysfunction with bilirubin >6 mg% <20 mg%; or SGOT increase >5-fold from preconditioning; or clinical ascites or image documented ascites >100 ml; or weight gain >5% from baseline of noncardiac origin	Severe hepatic dysfunction with bilirubin >20 mg%; or hepatic encephalopathy; or ascites compromising respiratory function
CNS toxicity	Somnolence but the patient is easily arousable and oriented after arousal	Somnolence with confusion after arousal; or other new objective CNS symptoms with no loss of consciousness not more easily explained by other medication, bleeding, or CNS infection	Seizures or coma not explained (documented) by other medication, CNS infection, or bleeding
Stomatitis	Pain and/or ulceration not requiring a continuous IV narcotic drug	Pain and/or ulceration requiring a continuous IV narcotic drug (morphine drip)	Severe ulceration and/or mucositis requiring preventive intubation; or resulting in documented aspiration pneumonia with or without intubation
GI toxicity	Watery stools >500 ml but <2,000 ml every day not related to infection	Watery stools >2,000 ml every day not related to infection; or macroscopic hemorrhagic stools with no effect on cardiovascular status not caused by infection; or subileus not related to infection	Ileus requiring nasogastric suction and/or surgery and not related to infection; or hemorrhagic enterocolitis affecting cardiovascular status and requiring transfusion

CXR, chest x-ray; IV, intravenous.

From Bearman S, Appelbaum F, Buckner C et al: Regimen-related toxicity in patients undergoing bone marrow transplantation. J Clin Oncol 6:1564, 1988, with permission.

[a]Grade IV regimen-related toxicity is defined as fatal toxicity.

Figure 91-2 Actuarial probability of survival 100 days after transplant for good-risk and poor-risk lymphoma patients (p = 0.003). *(From Bearman S, Appelbaum F, Back A et al: Regimen-related toxicity and early post-transplant survival in patients undergoing marrow transplantation for lymphoma. J Clin Oncol 7:82, 1989, with permission.)*

in addition to cyclosporine resulted in a higher incidence of Grade III or IV toxicity, indicating that drugs used after the transplant can contribute to regimen-related toxicity. This study established a scoring system that may be useful in attempting to compare toxicities for preparative regimens. It also emphasizes the influence of factors other than the preparative regimen itself on what is defined, even under rigorous scrutiny, as regimen-related toxicity.

Nevill et al[52] from Vancouver used this grading system to analyze the regimen-related toxicity of Bu, 16 mg/kg, and Cy, 120 mg/kg, in patients undergoing allogeneic transplantation for hematologic malignancies. Stomatitis and hepatic toxicity were the most frequently observed toxicities. Sixty-three percent of patients developed Grade II or higher stomatitis and 44% Grade II or higher hepatic regimen-related toxicity. Grade II or greater toxicity was rare in other organ systems, occurring in <10% of patients. Only 17% of patients developed Grade III or IV regimen-related toxicity. Hepatic regimen-related toxicity of grade II or higher was significantly more common in patients who received methotrexate for prevention of GVHD. Amphotericin B administration and prolonged administration of antibiotics were associated with Grades II to IV hepatic toxicity. This is especially interesting in view of reports demonstrating that the use of growth factors to accelerate hematopoietic recovery is associated with a reduction in hepatic regimen-related toxicity. [53] The extent of the hepatic toxicity seen in this study was similar to that observed with a TBI-containing regimen at the same center.[54] The incidence of hemorrhagic cystitis of 21% in the same study group is approximately twice that reported with radiation and Cy. Pulmonary and cardiac toxicity occurred only rarely with BuCy, consistent with reports by other investigators using the same BuCy regimen. [40] [41] [42]

Hepatic Veno-occlusive Disease

Hepatic VOD results from obstruction of intrahepatic venules and surrounding centralobular hepatocytes and sinusoids. [55] [56] [57] [58] [59] It is the most common life-threatening regimen-related toxicity. It usually occurs within 4 weeks of transplantation. Diagnosis is made by the development of hepatomegaly, right upper quadrant pain, jaundice, and ascites. [60] A variety of risk factors for the development of hepatic VOD exist. The preparative regimen is critical. Single-dose irradiation is associated with a much higher incidence of VOD than fractionated regimens. [61] [62] [63] A higher risk of VOD is similarly associated with higher total doses of radiation.[50] [57] [64] [65]

Most, but not all, centers using both BuCy regimens and TBI-containing regimens report a higher incidence of hepatic VOD with BuCy. [56] [65] [66] Most studies find an approximately 4050% incidence of hepatic VOD using BuCy, an incidence increased by prior use of Bu [66] or nitrosurea[67] in addition to those factors previously mentioned.

To determine the incidence and clinical course of VOD, McDonald et al [65] reviewed 355 consecutive patients undergoing allotransplant and found a 54% incidence of VOD. Interestingly, this study found that multiorgan failure was significantly more common among patients with VOD, and half of the patients who developed severe VOD developed renal failure, cardiac failure, and pulmonary failure. In addition to BuCy, the use of BCV (BCNU, Cy, and VP16) was associated with a high incidence of severe VOD.

While few deaths are directly attributed to hepatic VOD, one study of Bu-treated patients demonstrated that those whose bilirubin rose to >10 mg/dl within 100 days of transplantation had a 91% treatment-related mortality rate. [68] The treatment-related mortality rate for all others was 20%. Of 29 such patients who came to autopsy, 18 had hepatic VOD and 4 had massive hepatic necrosis. Thus, in the early post-transplant period, a high bilirubin level was associated with hepatic VOD and was an extremely poor prognostic sign.

Data from the Pesaro team indicate the pivotal importance of underlying hepatic disease in the development of regimen-related toxicity following transplantation in patients with thalassemia. The consequences of iron overload and hepatitis have been well described in these patients. [69] [70] Patients who undergo SCT for leukemia also commonly have iron overload. Data are much more limited in defining the role of iron overload in hepatic or other complications of transplantation. It appears likely, however, that iron overload contributes significantly to hepatic injury following transplantation. [71] [72] [73] Toxicity attributed to the preparative regimen may be strongly related to an underappreciated or unexplored underlying condition, such as iron overload.

Interstitial Pneumonia

Interstitial pneumonia occurs less frequently with BuCy than with Cy/TBI. In a study from Seattle of patients at high risk of interstitial pneumonia because of prior chest radiation, 32% of individuals transplanted with Cy/TBI experienced interstitial pneumonia, while only 5% of patients receiving BuCy developed interstitial pneumonia.[74] Factors present before transplant clearly predispose individuals to develop specific toxicities after transplantation; the actual risk results from a complex relationship between predisposing factors and the preparative regimen.

Other Regimen-Related Toxicities

Similar complexities in other organ systems have led some to conclude that assessment of toxicity due to the preparative regimen is too difficult to draw meaningful conclusions from the limited number of patients generally studied for this purpose. While grading systems are clearly imperfect, attempts at objective analysis are essential. They have led to useful conclusions regarding differences between regimens and in determination of optimal dosing of new regimens. Ideally, future randomized trials of preparative regimens will include uniform grading of regimen-related toxicities.

DELAYED TOXICITY OF PREPARATIVE REGIMENS

Chronic GVHD is the best-studied delayed complication of allogeneic SCT. More intense regimens have been associated with a higher incidence of GVHD, [75] [76] [77] but the mechanism is not clear.

The frequency and severity of infections following allogeneic SCT is related to GVHD and sometimes to immunodeficiencies. IgG2 and IgG4 subclass deficiencies may occur in the presence or absence of chronic GVHD. Subclass deficiency has been reported in irradiated as well as nonirradiated transplant recipients. [78] [79]

A variety of other problems, many of which are multifactorial in etiology, appear to be strongly related to the preparative regimen used. Chronic pulmonary disease, neuroendocrine dysfunction, impaired growth and development, cataracts, infertility, and secondary malignancies are among the most important delayed effects that appear to be effected by the preparative regimen used. [80] [81] Unfortunately, delayed effects have not been well reported for many preparative regimens. The most recognized and best-studied delayed effects have developed following TBI, which clearly causes profound late complications.

Chronic Pulmonary Disease

Chronic pulmonary disease appears in 10% of patients who have undergone allogeneic transplantation. Both restrictive and obstructive disease occurs. Obstructive airway disease is less reversible following allogeneic transplantation and is frequently associated with GVHD. It occurs after radiation-free as well as radiation-containing regimens. [82] [83] Few long-term studies have been performed. A study of 34 allogeneic transplant patients compared those receiving Cy alone, Bu and Cy, or Cy plus TBI. [83] Unlike patients who received Cy alone, patients who received Bu or TBI demonstrated a progressive decrease in diffusing capacity following allogeneic transplant. The extent of the deterioration was greater in the group receiving TBI, although the difference did not reach statistical significance in this small group of patients. Many patients demonstrated gradual improvement of lung function over several years following their initial deterioration.

Endocrine Dysfunction

Hypothyroidism is observed in >30% of individuals receiving single-dose TBI and in >15% of those receiving fractionated TBI. It does not occur commonly following Cy or BuCy. [84] [85] [86]

Future growth is an important concern following high-dose therapy in children. Deficiency in growth hormone production is observed in roughly 50% of children receiving high-dose TBI and up to 90% of those who receive cranial irradiation in addition to TBI. Together with direct effects of radiation on bone, growth factor deficiency leads to impaired longitudinal growth. [86] In contrast, children receiving only Cy show normal longitudinal growth. The effect of Bu on growth is controversial. It was first reported not to affect growth or other endocrine functions. [87] However, others found growth impairment similar to that in children who received Cy/TBI. [86] [88] One recent analysis found that in very young children who do not develop GVHD and/or receive high-dose corticosteroids, which impair growth, Bu does not significantly impair growth. [89] Studies of thalassemia patients indicate decreased growth velocity in children aged 1011 prepared for transplantation with BuCy, while younger children had normal growth velocity. [90]

Children who receive only Cy show normal sexual development. [91] Girls prepared with single-dose TBI have a significant delay in menarche, and boys commonly fail to produce sperm. [92] [93] [94] [95] [96] Men and women almost universally develop primary gonadal failure following TBI. There are only rare reports of women who have become pregnant following TBI. In contrast, following Cy alone, many younger women recover ovarian function and deliver normal children. [91] Similar doses in older patients (where the number of oocytes is less) may result in ovarian failure. Only rare patients have recovered sperm production 68 years following transplantation with TBI, [96] and few have fathered children. Only 5 of 323 men evaluated for 12 years following TBI demonstrated return of spermatogenesis; none of these 5 patients had received fractionated TBI. [97] Infertility is generally not a problem in Cy-conditioned patients, and fathering of children appears to be much more frequent in males given Bu [98] than in those receiving irradiation. Aspermia occurs following transplantation, but recovery was observed in two of six men evaluated >2 years out from transplant in one study and one of five in another. [97] [98]

Cataracts

Cataracts occur in 80% of patients who receive single-dose TBI and >30% of those who receive fractionated TBI. [99] The incidence of cataracts in patients receiving only Cy appears to be <20%. [99] Busulfan can cause cataracts; the incidence appears to be approximately 20%. [47]

Second Malignancies

Several recent analyses have attempted to determine the incidence of second malignancies following SCT. [100] [101] [102] Some studies have demonstrated a high risk of lymphoproliferative disorders following allogeneic transplantation. [103] [104] The use of potent immunosuppressive treatments is an important risk factor. A lower incidence of lymphoproliferative disorders occurs in patients conditioned with non-TBI regimens. [100]

A recent analysis of nearly 20,000 stem cell transplant recipients, including 3,200 who survived for 5 years, demonstrated a high incidence of cancers following transplantation. [102] The risk increased to 6.7% at 15 years and was highest in children whose transplants occurred prior to age 10 (Table 912). Melanoma and cancer of the buccal cavity, brain, liver, thyroid, bone, and connective tissue occurred with significantly increased frequency. The risk of cancer rose with the dose of radiation; the risk for those receiving the highest dose of radiation approached four times that for those who did not receive radiation (Table 913). The incidence of lymphoproliferative disorders, in the same cohort, was <1.5%, and no cases were observed 10 or more years following transplantation.

TABLE 91-2 -- Ratio of Observed to Expected Cases and Absolute Excess Risk of New Invasive Cancers According to Age at Transplantation

Age at Transplantation	No. of Patients	PersonYears at Risk	OBS	EXP	OBS:EXP (95% CI)	Excess Risk[a]
<10 yr	2,745	7,989	22	0.6	36.6 (22.9554)	26.8
1019 yr	4,178	12,008	8	1.7	4.6 (2.09.1)	5.2
2029 yr	4,948	11,996	21	4.6	4.6 (2.87.0)	13.7

3039 yr	4,474	8,914	13	9.4	1.4 (0.72.4)	4.1
40 yr	2,884	4,457	16	13.5	1.2 (0.71.9)	5.7

[a]The model used for general risk factors was a Poisson regression model stratified according to the primary disease and time since transplantation and adjusted for age at transplantation.
[b]The radiation-dose model was a Poisson regression model stratified and adjusted as indicated for the general model but including the radiation-dose variables. The model excludes data on patients with unknown radiation doses.
[c]P values for trend are for the comparison between TBI-dose categories and no radiation.

Recipients of transplants, in particular those who underwent transplantation at a young age and those who received high doses of TBI, have an increased incidence of cancer. The incidence increases sharply with time. Stem cell transplant recipients should be followed carefully to detect premalignant lesions and early cancer. Furthermore, patients who have undergone SCT should avoid carcinogenic exposures, such as tobacco.

MODERN PREPARATIVE REGIMENS

Cy/TBI

Bearman identified TBI as the most significant risk factor for regimen-related toxicity. Patients who receive Cy alone experience less stomatitis, enteritis, infection-related deaths, life-threatening GVHD, and interstitial pneumonia than patients who receive regimens containing Cy/TBI. [105] [106] [107] When TBI doses are escalated, the incidence of transplant-related mortality goes up, [26] [51] [108] [109] [110] while the incidence of leukemic relapse declines. Randomized studies by the Seattle group in AML[109] and CML[110] yielded similar results. Patients with AML in first remission (Fig. 913) and CML in chronic phase (Fig. 914) were randomized to receive preparation for allotransplant with Cy, 120 mg/kg, combined with either 2 Gy per day on each of 6 consecutive days or 2.25 Gy per day for 7 days, a total dose of 12 Gy versus 15.75 Gy. In each trial, patients who received the higher irradiation dose demonstrated a substantially lower incidence of recurrent leukemia but a higher frequency of transplant-related complications and death. They exhibited a higher incidence of interstitial pneumonia, hepatic VOD, renal failure and mucositis. Attempts to intensify preparative regimens have consistently

Figure 91-3 (A) Mortality in patients not relapsing after stem cell transplantation (p = 0.04). Patients who relapsed were censored at the time of relapse. **(B)** Probability of relapse (p = 0.06). **(C)** Probability of surviving relapse-free after transplantation. *(From Clift R, Buckner C, Appelbaum F et al: Allogeneic marrow transplantation in patients with acute myeloid leukemia in first remission: a randomized trial of two irradiation regimens. Blood 76:1869, 1990, with permission.)*

been associated with less leukemic relapse but an increased frequency and severity of transplant-related complications.

The toxicity of Cy/TBI regimens is significantly greater in end-stage allotransplant recipients, such as those studied initially by Thomas et al, [25] than in patients receiving allotransplants in first remission, studied later by Thomas et al. [29] [30] Similar results have been widely supported by the International Bone Marrow Transplant Registry, as well as a variety of single institutions and multi-institutional groups. [37] [40] [41] [51] [111] [112]

Figure 91-4 (A) Probability of relapse after transplantation during the chronic phase of CML for patients receiving 12 Gy or 15.75 Gy of total body irradiation (p = 0.008). **(B)** Probability of developing Grade II or worse acute GVHD after transplantation in the chronic phase of CML for patients receiving 12 Gy or 15.75 Gy of total body irradiation (p = 0.15). **(C)** Probability of survival after transplantation during chronic phase of CML for patients receiving 12 Gy or 15.75 Gy of total body irradiation. *(From Clift R, Buckner C, Appelbaum F et al: Allogeneic marrow transplantation in patients with chronic myeloid leukemia in the chronic phase: a randomized trial of two irradiation regimens. Blood 77:1663, 1991, with permission.)*

Patients in first remission from AML who receive HLA-identical stem cell grafts from siblings have leukemia-free survival rates of approximately 5060% they have been as high as 70% in some studies.[111] [112] [113] [114] Patients in second remission or in an untreated first relapse appear to have an approximately 30% leukemia-free survival rate at 5 years.[38] [47] [112] Those beyond second remission or with refractory disease have a 1020% leukemia-free survival rate, similar to that originally described by Thomas et al in a similar patient population. [25] [47] [112]

Patients with CML in the chronic phase of disease transplanted within a year of diagnosis (thus having generally received relatively minimal prior chemotherapy) have a mortality rate of approximately 15% when Cy/TBI preparation is used. The sustained disease-free survival rate is approximately 70% in patients under age 40. Patients with more advanced disease, including those who have had the disease for >1 year or those with accelerated or blastic phase disease, have a substantially lower incidence of leukemia-free survival. [110] [115]

Thomas et al [116] demonstrated that patients with ALL who underwent transplantation in second or subsequent remission had a lower incidence of transplant-related toxicity and leukemic relapse and improved survival compared to patients transplanted in relapse. Transplantation in ALL is now most frequently performed in second remission and most frequently using Cy/TBI regimens. Disease-free survival has ranged from approximately 3050%, depending on patient age, specific cytogenetic abnormalities, and other risk factors.[116] [117] [118] [119] [120] [121] [122] [123] [124] In patients with more advanced disease, disease-free survival is usually around 20%; leukemic relapse is the most common cause of failure.

Allogeneic SCT has been performed with increasing frequency and effectiveness is well-documented in selected patients with ALL in first remission who are at high risk for relapse (e.g., those with the Philadelphia chromosome). [125] [126] [127] The effectiveness of allogeneic transplantation results from the preparative regimen and the antileukemic activity of donor cells.[124] The superior effectiveness of Cy/TBI and transplantation is balanced by regimen-related toxicity, delayed effects of the preparative regimen, and GVHD. Leukemia-free survival rates of 4060% have been reported. [124] [128] [129] [130] The International Bone Marrow Transplantation Registry observed a decrease in treatment-related mortality following allotransplant in patients in first remission from 39 ± 19% to 27 ± 8% between 1980 and 1989. [131] Leukemia-free survival improved from 42 ± 20% to 57 ± 8% over the same period. Throughout, Cy/TBI remained the most frequently administered regimen.

The Cy/TBI regimen has been effective and widely used in non-Hodgkins lymphoma, Hodgkin disease, multiple myeloma, thalassemia, and other nonmalignant disorders. It has served as the standard to which all other regimens should be compared.

While preparation with Cy, 120 mg/kg, and TBI (9201575 cGy) consistently permits engraftment of stem cells from HLA-identical siblings, >10% of HLA-haplo-identical partially matched donors rejected grafts.[132] Patients given single doses or high total doses had lower rejection rates than those who received fractionated lower doses (e.g., 1,200 Gy) over intervals (e.g., 6 days).

TBI with Agents Substituted for Cyclophosphamide

Drugs other than Cy have been added to TBI, such as cytosine arabinoside, melphalan, and etoposide. TBI is a potent immunosuppressive agent, as is Cy. Immunosuppression provided by Cy/TBI regimens is effective but exceeds what is sufficient for consistent engraftment in many circumstances. The antitumor effect provided by this combination might be improved by substitution of an agent with a more potent antitumor effect. This has been attempted where the high level of immunosuppression is unnecessary, such as in transplants involving HLA-identical siblings.

Melphalan may be more effective than Cy in the treatment of many hematologic malignancies. A variety of trials have used melphalan in doses up to 180 mg/m ^{2} .

have been combined with TBI up to 1,485 cGy.[133] [134] [135] In a randomized study of patients with AML in first remission, those receiving melphalan, 110 mg/m ^{2} , and TBI had a lower relapse rate than patients receiving Cy, 120 mg/kg, plus TBI. Unfortunately, transplant-related deaths occurred more frequently in the melphalan group, and leukemia-free survival rates were similar.[135] Stomatitis and hepatic VOD were dose-limiting toxicities of melphalan and TBI.

High doses of cytosine arabinoside have also been substituted for Cy. Initial studies of cytosine with fractionated TBI reported excellent results in children with ALL.[136] Other studies have reported results similar to those achieved with Cy/TBI. [137] [138] The use of cytosine arabinoside and TBI has been associated with increased toxicity compared to Cy/TBI and has not improved results in AML.[139] Skin and central nervous system toxicity have limited dose escalation of cytosine arabinoside and TBI.

The most promising results involving the substitution of another drug for Cy have occurred with etoposide. Etoposide-plus-TBI regimens have yielded favorable results in a number of hematologic disorders. A phase I/II study using a total dose of 1,320 cGy TBI delivered in 11 fractions over 4 days achieved a maximum tolerated etoposide dose of 60 mg/kg.[140] Stomatitis and hepatic and pulmonary toxicity were dose-limiting. In the initial study, 43% of patients with advanced acute leukemia achieved sustained disease-free survival. The relapse rate was only 32 ± 20%. A phase II trial using this regimen in 69 patients with AML and ALL in remission and CML in chronic phase demonstrated that 55% of patients were leukemia-free survivors at 3 years. [141] The City of Hope and Stanford reported a disease-free survival of 61% for 57 high-risk patients with ALL who underwent allogeneic transplantation in first remission. [130]

A confounding factor in the etoposide-and-TBI trials is that the majority of patients received cyclosporine and corticosteroids for prevention of GVHD. In comparable studies performed with Cy/TBI, the majority of patients received cyclosporine and methotrexate. The combination of cyclosporine and corticosteroids does not have a long-term beneficial effect on disease-free survival; this is largely attributable to an increased incidence of chronic GVHD and of fungal infections. [42] [142] However, when evaluating acute toxicity, it would appear that substitution of corticosteroids for methotrexate results in fewer and less severe acute toxicities, including VOD. Thus, comparisons of regimen-related toxicity for Cy/TBI versus TBI/etoposide are difficult.

Cyclophosphamide Plus Antithymocyte Globulin

In aplastic anemia, there is no requirement for myeloablation, only for immunosuppression. Storb et al [143] [144] performed allogeneic SCT in patients with severe aplastic anemia after the administration of 200 mg/kg of Cy. While engraftment consistently occurred in patients who had not been sensitized by prior transfusion, graft failure rates were high in patients who had received transfusions (as had a vast majority of patients). [143] [144] [145]

Additional immunosuppression has been achieved by adding TBI, total lymphoid irradiation (TLI), or thoracoabdominal irradiation. [146] [147] [148] [149] The addition of irradiation has been associated with an increased incidence and severity of transplant-related complications. Other concerns include the increased incidence of second malignancies and other long-term sequelae following radiation.

The addition of antithymocyte globulin (ATG) to Cy has been associated with survival rates >90% in patients receiving stem cell transplants from HLA-identical siblings.[150] Unfortunately, in the setting of matched unrelated donors, the combination of antithymocyte globulin and Cy is not sufficiently immunosuppressive to permit consistent engraftment.[151] Radiation in a variety of doses and delivery formats has been used; the best approach is uncertain.

Busulfan Plus Cyclophosphamide in Thalassemia

Successful treatment of aplastic anemia with allotransplant in the 1970s led to consideration of this approach in patients with other nonmalignant marrow disorders, such as thalassemia. In 1982, the first successful allograft in a patient with thalassemia was published. [152] Lucarelli and his team in Pesaro have had the most extensive experience with the use of SCT in thalassemia.[69] [70] [153] [154] [155] The Pesaro group described the results of transplantation in 805 thalassemia patients aged 135. Patients were treated with Bu, 14 mg/kg, and Cy, 200 mg/kg, and cyclosporine alone. The following risk factors were defined: poor quality of previous iron chelation therapy, hepatomegaly, and portal fibrosis on liver biopsy. Patients with none of these risk factors were categorized as class 1, and those with three risk factors class 3; all others were class 2. Class 1 patients had a very high probability of cure and very low morbidity and mortality. The long-term event-free survival rate in patients aged <17, transplanted from HLA-identical donors, was 90%. Class 3 patients aged <17, transplanted from HLA-identical siblings, had a success rate of 50%. Severe cardiac and liver toxicity occurred commonly in class 3 patients. When the Cy dose was decreased from 200 mg to 160 mg and short-course methotrexate was used, results were more encouraging, although additional patients and longer follow-up are needed. These results emphasize the very high probability of cure with minimal morbidity and mortality when transplantation is performed early in the course of disease. The Bu dose of 14 mg/kg is lower than that generally used in hematologic malignancies.

Busulfan Plus Cyclophosphamide in Hematologic Malignancies

The effectiveness of BuCy regimens has now been evaluated in a number of malignant diseases. Studies of AML in first remission using Bu, 16 mg/kg combined with either Cy, 120 mg/kg or Cy, 200 mg/kg,[38] have generally resulted in leukemia-free survival rates of about 60% and relapse rates of approximately 20%, similar to results reported from studies using Cy/TBI. However, the only randomized study of first-remission patients with AML was the GEGMO study by Blaise et al, [114] which demonstrated increased relapse rates and decreased survival in patients receiving BuCy compared to those receiving Cy/TBI. Proponents of BuCy have not yet established that it is as effective as Cy/TBI in patients with AML in first remission; in particular, patients with M4 or M5 FAB subclasses appear to have higher relapse rates following BuCy.[40]

The original multi-institutional study of BuCy2 in CML in 1992 described leukemia-free survival rates similar to those reported for Cy/TBI in chronic, accelerated, and blastic phase disease.[41] Chronic-phase patients had an approximately 58% 3-year leukemia-free survival. Relapse rates appeared lower than were generally reported with Cy/TBI. The relapse rate was reported as 3% at 3 years in chronic-phase patients, 12% in accelerated-phase patients, and 27% in blastic-phase patients. A single study of BuCy, 200 mg/kg, demonstrated a lower survival in chronic-phase patients, but these patients were generally older and received only one drug for GVHD prophylaxis.[156] The relative effectiveness of big BuCy versus little BuCy remains unknown and unstudied.

Randomized trials of BuCy versus Cy/TBI in CML in chronic-phase patients have been published from Seattle in 1994 [157] and from the French Society of Bone Marrow Grafts in 1995.[158] The Seattle study compared 73 patients in chronic phase transplanted following BuCy2 to 69 patients transplanted following Cy/TBI. Three-year probabilities of survival were identical at 80%; relapse rates were identical at 13%; event-free survival was 71% in the BuCy group and 68% in the Cy/TBI group (Fig. 915). This study concluded that survival and relapse rates were equivalent. There was no difference in speed

Figure 91-5 The probabilities of event-free survival and of developing persistent cytogenetic relapse for patients transplanted after the Cy/TBI or BuCy regimens are shown. *(From Clift R, Buckner C, Thomas W et al: Marrow transplantation for chronic myeloid leukemia: a randomized study comparing cyclophosphamide and total body irradiation with busulfan and cyclophosphamide. Blood 84:2040, 1994, with permission.)*

of engraftment or the incidence of VOD, but the TBI group had an increased incidence of creatinine elevation and an increased frequency of acute GVHD (Fig. 916). Thus, BuCy was better tolerated and was recommended. The French Society of Bone Marrow Graft reported results in 120 patients randomized to Cy/TBI or BuCy. Similar survival and disease-free survival rates were observed in the two groups. Like the original investigators, however, they found low relapse rates with BuCy (4.4 ± 6.7%), a significantly lower rate than that observed with Cy/TBI.

Because of widespread interest in avoiding radiation-related complications in children, there is a high level of interest in BuCy and other radiation-free regimens in

childhood malignancies in general, particularly in ALL. Bu does not appear to be very immunosuppressive and does not immediately, dramatically affect lymphocyte count.[18] [19] [20] Many investigators have reasoned that BuCy would not be an effective regimen in ALL. However, following BuCy, the kinetics of reconstitution, both lymphoid and hematopoietic, in animals and humans is similar

Figure 91-6 The probabilities of developing Grade II or worse acute GVHD for patients transplanted after the Cy/TBI or BuCy regimens are shown. *(From Clift R, Buckner C, Thomas W et al: Marrow transplantation for chronic myeloid leukemia: a randomized study comparing cyclophosphamide and total body irradiation with busulfan and cyclophosphamide. Blood 84:2039, 1994, with permission.)*

to that following Cy/TBI transplants.[159] [160] Multi-institutional studies have generally demonstrated results with BuCy similar to those reported with Cy/TBI in adults with ALL.[40] [161] Sufficient data are not available, however, to make a meaningful conclusion. Expression of CD3 surface antigens in T-lineage ALL is associated with resistance to radiation.[162] Whether a radiation-free regimen might be more effective than TBI in this group is worthy of investigation.

The Nordic BMT Group reported the results of a prospective randomized study of HLA-identical sibling transplants in 167 patients with leukemia. [163] They found a higher incidence of VOD and hemorrhagic cystitis in patients receiving BuCy compared to Cy/TBI and a significant difference in transplant-related mortality in patients with advanced disease, with a rate of 62% in BuCy patients and 12% in those receiving Cy/TBI. Interestingly, in low-risk patients BuCy was very well tolerated and effective; disease-free survival was superior (though not significantly so) among BuCy patients in this category. Disease-free survival did not differ when all patients were considered.

Blume et al reported somewhat contrasting results in a Southwest Oncology Group trial comparing BuCy to VP16/TBI in a heterogeneous group of patients undergoing allogeneic transplantation from HLA-identical siblings. [164] Overall outcome was similar in these two groups. In contrast to the Nordic study, however, the low-risk patients appeared to fare better with the radiation-containing regimens and the high-risk patients fared better with BuCy. Thus, even with well-conducted, prospective, randomized studies, the relative merits and limitations of these three regimens are not fully understood.

The heterogeneity of results achieved with BuCy (as well as other regimens) may result from a variety of circumstances, including different dosing (e.g., ideal versus real body weight), dosing schedules of other drugs (e.g., dilantin, which affects Bu metabolism), as well as the learning curve in using a new regimen.

Mephalan and etoposide have also been used in combination with Bu. However, because of the limited immunosuppressive capacity of Bu, the immunosuppressive capability of these regimens is limited and their application is likely only to patients with HLA-identical sibling donors. Five patients who had relapsed after prior allotransplants were prepared for second transplants with Bu and etoposide. All engrafted and obtained complete remission. [165] Extensive study of this regimen in the autologous setting has yielded favorable results. [166] Its use in the allogeneic setting merits further study.

A pilot study of Bu and melphalan prior to allogeneic transplantation in advanced hematologic malignancies demonstrated engraftment in 24 of 25 patients receiving stem cells from HLA-identical siblings. Antileukemic activity in this study was promising. [167]

Cyclophosphamide and TBI Plus Additional Agents

For patients with advanced leukemia, relapse remains the most frequent cause of failure following allogeneic transplantation. Higher doses of radiation or other agents have been used; however, reports of favorable antileukemic effectiveness have been offset by increased toxicity. Attempts have been made to add combinations of chemotherapy agents without significant overlapping toxicity to TBI. Peterson et al [168] performed a careful phase I study designed to determine the maximum tolerated dose of Bu and Cy to be combined with 12 Gy of fractionated irradiation. Doses of 8.7 mg/kg of Bu and 69 mg/kg of Cy in conjunction with TBI led to severe regimen-related toxicity in 5 of 18 patients, while none of 15 patients treated with 6.9 mg/kg of Bu and 47 mg/kg of Cy developed severe regimen-related toxicity. A phase II study of Bu, 7 mg/kg, Cy, 50 mg/kg, and TBI, 12 Gy, in patients with morphologically advanced myelodysplasia demonstrated trends toward lower relapse rates but

higher transplant-related mortality compared to historical controls prepared with Cy, 120 mg/kg, and TBI. [169]

Similarly, it was found that 44 mg/kg of etoposide could be combined with 103 mg/kg of Cy and 12 Gy of fractionated TBI. [170] [171] A separate study indicated that etoposide administered as a continuous infusion was well tolerated. At present, the relative merits of these regimens have not been adequately examined.

The Stanford group developed a different regimen of 1,320 cGy TBI in 11 fractions, 60 mg/kg of etoposide, and 60 mg/kg of Cy followed by allotransplant from matched sibling donors.[172] Preliminary studies have demonstrated the regimen to be well-tolerated and effective. The long-term effectiveness of this preparative regimen is currently being evaluated.

Busulfan Plus Cyclophosphamide and Etoposide

Based on data in nontransplant settings where combinations of chemotherapeutic agents have been more effective than single agents, investigators have explored combinations of multiple drugs as preparative therapy for transplantation. Combinations of Bu, etoposide, and Cy have been used in various doses and schedules. This is a logical combination because of the synergistic activity of etoposide and Cy. Vaughan et al [173] reported that 11 of 24 (46%) of patients with advanced leukemias or lymphoma died of transplant-related complications using Busulfan, 16 mg/kg, Cy, 120 mg/kg, and etoposide, 60 mg/kg. While this degree of transplant-related mortality would be considered prohibitive by many investigators, the relapse rate in this study was only 20% and disease-free survival was 40% at a median follow-up of >1 year. Although the follow-up is too short to make a significant conclusion, this study raises a critical issue: what degree of transplant-related mortality is tolerable if disease-free survival with a given regimen is favorable? Investigators at John Hopkins used Bu, 16 mg/kg, etoposide, 30 mg/kg, and Cy, 150 mg/kg, over 8 days in patients with advanced lymphoid and hematologic malignancies. In a phase I trial, stomatitis and VOD were dose-limiting at etoposide doses of 40 mg/kg.[174] At 30 mg/kg, most patients developed grade I or II mucositis. VOD was diagnosed in 30% of patients and was the major factor contributing to death. These investigators reported a trend toward improved disease-free survival with this new regimen compared to historic controls. Based on dose escalation trials indicating markedly lower toxicity of 14 mg/kg of Bu compared to 16 mg/kg, investigators at Ohio State have used Bu, 14 mg/kg, etoposide, 50 mg/kg, and Cy, 120 mg/kg, in >100 patients who have undergone allogeneic transplantation from sibling or matched unrelated donors with favorable preliminary results. [48] [175]

While selected initial data are promising, there has been no clear demonstration that the addition of etoposide to BuCy or Cy/TBI represents a significant improvement. Another multidrug combination used in allogeneic transplantation is Cy, BCNU, and etoposide. This regimen has generally been used in patients with Hodgkin disease, non-Hodgkin lymphoma, and acute lymphoblastic lymphoma. [176] Good results in allogeneic transplants have been reported. Reports of late pulmonary fibrosis have dampened enthusiasm for this regimen, [177] but this requires more extensive study.

T-Cell Depletion

Removal of T cells from the donor graft is associated with an increased risk of graft failure. More intense preparative regimens have been required to prevent rejection. This has been accomplished by the administration of higher doses of radiation, adding additional chemotherapy (e.g., thiotepa), adding additional immunosuppression (e.g., ATG), or combinations of the above. Regimens such as BuCy2 provide inadequate immunosuppression in this situation.

PROMISING AREAS OF CLINICAL RESEARCH

In general, Cy/TBI, BuCy, and TBI/VP16 are associated with tolerable regimen-related toxicity and acceptable results in allograft recipients with acute leukemia in first remission and CML in chronic phase. Patients with more advanced disease, however, develop more transplant-related complications and have higher relapse rates. Shortcomings of these preparative regimens limit the proportion of patients who can be cured. Dramatic improvement in preparative regimens is needed. Investigators are attempting to improve the effectiveness of existing regimens without producing more toxicity, a difficult task in view of prior experiences. The following section will address selected areas of current research that may well advance the field.

Targeting Plasma Levels of Drugs

In multiple studies, Bu has shown wide inter- and intrapatient variability in its disposition, leading to varying plasma concentrations. [178] [179] Age, hepatic function, underlying disease, and drug interactions have all been shown to play important roles. Pharmacokinetic studies in children have shown lower plasma levels for a fixed mg/kg dose in children than in adults. Children <age 6 have demonstrated higher plasma levels and greater success when doses are based on body surface area. [180] [181] Interestingly, graft rejection, acute complications, and relapse rates have all been related to plasma Bu levels. In a multivariate analysis of 42 patients transplanted in Seattle, only the average steady-state ($\mathbf{C}_{ss}$) level of Bu was shown to be significant in predicting graft rejection. [179] Forty-two patients were administered 1630 mg/kg of Bu and Cy. Bu levels were analyzed using gas chromatography. When $\mathbf{C}_{ss}$ levels of Bu were <200 ng/ml, all 4 such patients rejected their grafts. At levels of 200600 ng/ml, 4 of 11 patients rejected, and at levels >600 ng/ml, only 1 (a one antigen mismatched, unrelated donor) of 23 patients rejected the graft. In addition, the data from Seattle indicated that partially matched, unrelated donors required higher $\mathbf{C}_{ss}$ levels of Bu (i.e., >600 ng/ml) than HLA-matched siblings, who required a level of only 200 ng/ml. The higher $\mathbf{C}_{ss}$ Bu levels required in the HLA partially matched setting strongly suggest that Bu has immunosuppressive activity.

Significant regimen-related toxicity was seen at higher Bu levels. Only 1 of 31 patients who had an average Bu $\mathbf{C}_{ss}$ <900 ng/ml had Grade III or IV regimen-related toxicity, while 4 of 11 patients who had a $\mathbf{C}_{ss}$ >900 ng/ml had Grade III or IV regimen-related toxicity (Fig. 917). [179] Regimen-related toxicity was

Figure 91-7 Relationship between regimen-related toxicity score and busulfan average concentration at steady-state P = 0.717; P = 0.0001. *(From Hutchinson F: Graft rejection and toxicity following bone marrow transplantation in relation to busulfan pharmacokinetics. Bone Marrow Transplant 16:36, 1995, with permission.)*

chiefly VOD and adult respiratory distress syndrome. The group at Johns Hopkins demonstrated a significantly higher incidence of VOD when Bu levels are high. [180] [181] [182] Lastly, patients with a low $\mathbf{C}_{ss}$ of Bu had statistically higher relapse rates. [183] Maintaining Bu $\mathbf{C}_{ss}$ within a narrow range, defined according to the underlying disorder, stage, or source of donor cells, could lower the incidence of rejection, severe toxicity, and relapse. Limiting toxicity might also permit the addition of other agents, such as directed irradiation. The use of phenytoin has complicated attempts to target specific Bu plasma levels and adjust future doses based on first-dose pharmacokinetics. Patients receiving Bu and phenytoin appear to have increased Bu clearance and decreased area under the curves for Bu following the eighth or ninth dose compared to the first dose. [183]

Cyclophosphamide is converted to 4-hydroxycyclophosphamide (HCY), a reaction responsible for its toxicity. This reaction is catalyzed by peroxidases and cytochrome P450. HCY enters cells spontaneously and is metabolized to acrolein and phosphoramide mustard, a DNA alkylator. [184] [185] [186] Analysis of Cy and HCY by high-performance liquid chromatography demonstrates extensive variability in the disposition of Cy and HCY. Slattery et al [183] reported 3.7-fold variability in the range of exposure to HCY in seven patients receiving Cy, 120 mg/kg, and TBI. A sevenfold difference was observed in the ratio of the area under the curve for HCY compared to the area under the curve for Cy, an expression of the ability to form and eliminate HCY. In patients treated with Bu followed by Cy, a greater clearance of Cy and a greater area under the curve of HCY compared to Cy was seen. The use of Bu prior to Cy results in a greater exposure to HCY (Fig. 918). [186] Further, the area under the curve of HCY was shown to correlate with the average $\mathbf{C}_{ss}$ of Bu. In part, the immunosuppressive capability of Bu may result from its effect on Cy metabolism. In addition, a relationship was seen between exposure to Cy metabolites and hepatic VOD. [186] Greater attention and understanding of the pharmacokinetics of Bu and Cy, as well as other agents, promises safer and more effective

Figure 91-8 Relationship between AUC_{HCY} and AUC_{CY} in BuCy patients (, R^2 = .171, P = .356) and Cy/TBI patients (, R^2 = .116, P = .455 with UPN 8807 and R^2 = .740, P = .028 without UPN 8807). *(From Slattery J, Kalhorn G, McDonald K et al: Conditioning regimen-dependent disposition of cyclophosphamide and hydroxycyclophosphamide in human marrow transplantation patients. J Clin Oncol 14:1484, 1996, with permission.)*

preparation for transplantation. Better understanding of specific metabolic pathways in individual patients could lead to dose adjustment and might also influence the choice of agents.

Directed Irradiation

Hematologic malignancies appear to have steep dose-response relationships to irradiation, as has been previously presented. Doses of TBI are limited by toxicity to the lungs, liver, and gastrointestinal tract.

Investigators have used a variety of techniques to deliver higher doses of radiotherapy to the marrow than to normal organs. Radioactive iron (Fe) is taken up by the erythropoietic marrow, where it irradiates adjacent cells. The marrow of patients treated with ^{52} Fe demonstrated nearly twice the radiation absorbed as did the liver. [187] In combination with standard preparative therapy, this offers a method for selective delivery of radiation to the marrow.

A logical approach to ensure selective delivery of irradiation to malignant cells is to use monoclonal antibodies directed against antigens on tumor cells, conjugated to drugs, toxins, or radionuclides. Unconjugated monoclonal antibodies have demonstrated limited capacity to kill malignant cells. [188] Conjugates of toxins with monoclonal antibodies to lymphoid or myeloid antigens have demonstrated safety and occasional complete responses in patients with malignancies. [189] [190] [191] The delivery of radiation to sites of disease using monoclonal antibodies conjugated to radionuclides has been successful in animal and human studies. [192] [193] [194] [195] [196] Studies in acute leukemia have used I-131-labeled anti-CD33 antibody [197] and most recently I-131-labeled anti-CD45 antibody. [198] CD45 is present in greater amounts on leukemic blasts and does not modulate (as does CD33). Preliminary studies have demonstrated that roughly threefold higher doses of irradiation can be delivered

to leukemic sites than to the liver and lungs. [198] While this technique has been used predominately with standard Cy/TBI, it may be more logical to combine it with a chemotherapy-only regimen. Targeting areas of distribution of malignant cells, without significant exposure of other organs, is a logical and promising approach to improving preparative regimens.

Nonmyeloablative Regimens

Storb et al[199] achieved stable mixed hematopoietic chimerism in DLA-identical litter mates using a sublethal irradiation dose of 200 cGy TBI with the immunosuppressive agents cyclosporine and mycophenolate mofetil. [199] This regimen is not myeloablative, is relatively nontoxic, and does not cause prolonged pancytopenia. A regimen including 200 cGy of TBI, cyclosporine, and mycophenolate with infusion of peripheral blood stem cells is under investigation in Seattle. Sequential lymphocyte infusions at successfully higher doses will be used. The study will initially be performed in patients with CML who are >65 years, or in patients <66 years with organ dysfunction precluding conventional allografting. This novel approach will use nonablative, immunosuppressive therapy to attain hematopoietic chimerism, then rely on a graft-versus-leukemia effect of donor lymphocytes.

Chapter 92 - Practical Aspects of Stem Cell Collection

Scott D. Rowley

INTRODUCTION

Peripheral blood stem cells (PBSC) have virtually replaced bone marrow as the hematopoietic stem cell (HSC) component for autologous transplantation, and their use is undergoing phase III studies in allogeneic transplantation. The ease of collection and the rapid engraftment kinetics of PBSC compared to bone marrow are widely recognized. Median times to achieve an absolute neutrophil count (ANC) >500/l are typically about 1214 days, and platelet recovery is even faster. [1] [2] [3] [4] [5] [6] Although graft-versus-host disease (GVHD) prophylaxis with methotrexate will slow engraftment, the kinetics of engraftment for the allogeneic PBSC recipient are similar to that experienced by the recipient of autologous PBSC. [7] [8] [9] [10] [11] [12] [13] The rapid engraftment kinetics are widely recognized despite the paucity of direct comparative trials between marrow and PBSC as sources of HSC. Beyer et al.[14] reported such a phase III study of 47 patients treated for germ cell tumor. Although all patients received granulocyte colony-stimulating factor (G-CSF) after transplantation, and despite the small number of patients enrolled, the recipients of PBSC achieved an ANC of >500/l 1 day faster, and a sustained platelet count of >20,000/l 7 days faster than the patients receiving marrow. [14]

There are also disadvantages to the use of PBSC components as a source of HSC for autologous or allogeneic transplantation. These include the usual need for multiple days of collection (especially for autologous transplantation), the current need for sophisticated flow cytometric analysis of the components (or hematopoietic cell cultures) to ensure adequacy of HSC content, the inability to collect adequate components from all patients and donors, the risks associated with administration of hematopoietic cytokines and the apheresis procedures, and the risks of infusion if the components are cryopreserved.

The presence of HSC in the peripheral circulation was suggested by animal studies as early as 1951. [15] Although the nature of the survival agent was not recognized at that time, parabiosis experiments demonstrated that some factor in the blood of a healthy animal was able to rescue another animal from the effects of lethal irradiation. Subsequently, the presence of HSC in the peripheral blood and the use of these cells to rescue animals from the marrow-lethal effects of radiation were demonstrated in a number of animal models.[16] [17] Experience in human PBSC transplantation began for patients with chronic myelogenous leukemia because of the high number of clonogenic cells circulating in the peripheral blood of those patients. [18] The concentration of HSC in the peripheral blood is normally very low. Thus, very large quantities of blood must be processed to collect a quantity of HSC equivalent to what could be collected in a bone marrow harvest. For this reason, PBSC transplantation was limited initially to a few centers that explored this source of HSC for patients who were otherwise ineligible for marrow harvesting. Some transplant centers used the transient increase in circulating HSC during recovery from marrow hypoplasia-producing chemotherapy. [19] [20] [21] Others collected cells from the patient or donor without any preceding perturbation of the host. [22] [23] [24] These early reports noted that engraftment could be faster after infusion of PBSC components compared to marrow cell transplantation. However, because of the occasionally limited quantity of HSC collected from the peripheral blood, the kinetics of engraftment for some patients was considerably slower (Table 92-1). Moreover, in a significant proportion of patients the desired quantity of cells could not be collected. The effective mobilization of HSC into the peripheral blood and the reliability of flow cytometric technique to assess quality of the collection are the direct bases for the rapid and widespread adoption of PBSC.

MOBILIZATION OF HSC INTO THE PERIPHERAL BLOOD

The discovery that administration of hematopoietic cytokines caused a transient increase (mobilization) of HSC in the peripheral blood enabled the collection of much greater numbers of PBSC, or peripheral blood progenitor cells (PBPC) as they are sometimes called when collected after mobilization with growth factor and/or chemotherapy.[1] [25] [26] [27] No randomized studies comparing the engraftment of cytokine-mobilized HSC to those collected during steady state or after chemotherapy mobilization have been reported although retrospective studies demonstrated

the much quicker engraftment of cytokine-mobilized HSC (Table 92-1).[28] Cytokine-mobilized PBSC components contain much greater numbers of cells expressing the CD34 antigen (CD34+ cells) that, along with myeloid progenitor cells grown in culture (colony-forming units-granulocyte/macrophage [CFU-GM]), serve as surrogate markers for the engraftment capacity of the stem cell component. It cannot be stated with certainty if it is merely the quantity of cells or some characteristic imparted by chemotherapy or cytokine mobilization that accounts for the rapid engraftment. CD34+ cells isolated from the peripheral blood differ in many characteristics from those isolated from marrow. However, the dose of CD34+ cells infused predicts the kinetics of engraftment with patient groups receiving higher quantities showing a higher probability of quicker engraftment. [29] [30] Although most transplant centers will probably accept components containing at least 12×10^6 CD34+ cells/kg recipient weight, cell doses of 2.55×10^6 CD34+ cells/kg are desirable, and earlier engraftment will be observed with even higher doses. [29] [30] Administration of G-CSF after transplantation will further speed the recovery of granulocytes, [31] [32] [33] but it may have a detrimental affect on platelet engraftment for patients receiving components containing low numbers of CD34+ cells. [29]

A variety of mobilization schemes have been developed for both patients and donors. Before the availability of hematopoietic cytokines, it was noted that marrow hypoplasia-producing chemotherapy such as that used as induction therapy for acute leukemia results in a transient increase in the number of HSC circulating in the peripheral blood. This approach was used by a variety of transplant programs to obtain PBSC for patients with leukemia or other diagnoses. Juttner and colleagues demonstrated rapid engraftment for patients receiving chemotherapy-mobilized PBSC (median 11 and 12 days to achieve an ANC >500/l and platelet count >50,000/l) as long as the dose of CFU-GM exceeded 63.0×10^6 /kg. [19] This finding that the CFU-GM quantity infused roughly correlated with the speed or success of engraftment was also found by Fermand and coworkers for chemotherapy-mobilized patients with multiple myeloma [20] and by Brice and associates for patients with non-Hodgkin lymphoma and Hodgkin disease.[21] However, Juttner also described a proportion of patients who received low doses of CFU-GM and experienced prolonged post-transplant aplasias or a secondary drop in blood counts 34 weeks after infusion. [19] Moreover, some patients, mostly those with progressive disease, marrow infiltration, or extensive prior exposure to alkylating agents or radiation therapy, failed to exhibit this response to chemotherapy and had inadequate collections for transplantation. [21] [34] The timing of apheresis was considered crucial with maximal numbers of CFU-GM in the peripheral blood when leukcocyte and platelet counts rose simultaneously during early recovery from chemotherapy. [35] [36]

It was subsequently discovered that the administration of granulocyte/macrophage colony-stimulating factor (GM-CSF) or G-CSF during the recovery from chemotherapy increased the numbers of circulating progenitor cells to levels as much as 1,000-fold higher than what was present in the blood before treatment. [1] [25] [26] [27] This started the exploration of efficacious mobilization regimens using hematopoietic cytokines, cytokine combinations, or chemotherapy plus cytokines.

Cytokine Mobilization

The ability of recombinant hematopoietic cytokines to increase the level of myeloid progenitor cells in the blood as well as mature blood cells was reported in 1988 by different groups for both G-CSF and GM-CSF. [26] [27] Subsequently, a number of different investigators reported the collection of PBSC from patients after chemotherapy and GM-CSF or G-CSF mobilization.[3] [25] [37] [38] Chemotherapy is not required to increase the numbers of HSC in the peripheral blood and many patients and all donors are treated with hematopoietic cytokines alone. Various recombinant human hematopoietic cytokines including fusion molecules increase the quantity of CD34+ cells in the peripheral blood as discussed below. Direct comparisons between cytokines of the ability to mobilize CD34+ cells are few. Furthermore, many of the single-arm cytokine studies were conducted in patient groups rather than normal donors, and the effect of prior therapy on HSC mobilization is a

confounding variable that hinders the comparison of these phase II studies.

G-CSF

At present, G-CSF is the cytokine most commonly used because of its efficacy compared to other cytokines and its relatively benign toxicity profile. Filgastrim (r-metHuG-CSF) and lenograstim (rHuG-CSF) are the two forms of this cytokine available for clinical use. [39] There is slight, if any difference between these two cytokines in the ability to mobilize PBSC. Watts et al. [40] studied 20 healthy volunteers and found that the peak levels of CFU-GM in the peripheral blood were 28% higher after treatment with the glycosylated molecule (lenograstim). In contrast, De Arriba et al. [41] treated 30 women with breast cancer in a randomized study of these two drugs using dosages containing bioequivalent units of activity and found no difference in the

mobilization of CD34+ cells. The two forms have similar biologic activity and will not be further distinguished in this discussion.

Mobilization of Hematopoietic Stem Cells Using G-CSF

Granulocyte colony-stimulating factor is the most potent cytokine currently available for the mobilization of HSC. In a randomized study of healthy volunteers comparing G-CSF, GM-CSF, and the combination of both, Lane and coworkers reported an average 0.99% CD34+ cells in the peripheral blood of healthy donors treated with 10 g/kg/day of G-CSF compared to 0.25% for donors treated with the same dose of GM-CSF. [42] The quantity of CD34+ cells in the peripheral blood before treatment averaged 1.6/l. After GM-CSF treatment, this increased to 3/l, but with G-CSF, the level increased to 61/l. Each group underwent one leukapheresis on the fifth day of treatment and the collections from donors treated with G-CSF averaged 119 × 10^6 CD34+ cells compared to 12.6 × 10^6 for the GM-CSF-treated donors.

There is a distinct time course of appearance of CD34+ cells during the administration of G-CSF, with the maximal level of CD34+ cells occurring on day 5 after 4 days of G-CSF administration. [43] [44] Smaller numbers of CD34+ are present on days 4 and 6 and the level falls rapidly on subsequent days despite a continual rise in white blood cells (WBC).

The number of CD34+ cells collected after G-CSF treatment is proportional to the number of these cells in the peripheral blood before the initiation of this cytokine. [12] Although doses as low as 5 g/kg/day have been used for allogeneic PBSC transplantation, [45] there is a dose response to G-CSF with higher average levels of CD34+ cells being achieved with 10 g/kg/day compared to 5 g/kg/day. [46] The average collection from one group of healthy donors treated with 10 g/kg/day averaged 4 × 10^8 CD34+ cells. [46] With this dose of G-CSF and appropriate apheresis technique, adequate numbers of CD34+ cells can be collected in one procedure for transplantation of most patients. Waller and coworkers studied twice daily administration of G-CSF to healthy donors and found greater yields of CD34+ cells in the apheresis component. [47] However, the total amount of G-CSF administered was also doubled so it is not clear if the twice daily administration or the higher dose is responsible for this observation. A similar dose-response relationship is observed in autologous patients and may extend to doses as high as 40 g/kg/day. [48] Patients, especially those previously treated with chemotherapy or radiotherapy (see following), will generally have lower quantities of CD34+ cells mobilized. However, previous treatment with chemotherapy does not preclude the use of G-CSF. De Luca et al. [49] noted a median 76-fold increase in CFU-GM for a population of 30 patients who were previously extensively treated for B-cell malignancies. Older donors will also have lower levels of CD34+ cells mobilized into the peripheral blood after G-CSF administration. [50]

Lymphocytes are also increased in the peripheral blood. [51] Murine studies suggest that G-CSF priming changes the cytokine response of these cells, [52] may decrease the risk of acute GVHD, [53] and may increase the graft-versus-leukemia effect. [54] The potential influence of these changes in outcome of allogeneic (or autologous) transplantation is not clear.

Toxicity and Complications of G-CSF

The toxicity of G-CSF has been most clearly defined in studies of allogeneic donors. [45] [46] [55] The autologous patient will experience a similar toxicity profile but with the added complications of the underlying malignancy and its treatment.

Virtually all recipients of G-CSF will develop somatic complaints of which skeletal pain is most prominent (Table 92-2). The somatic complaints are generally tolerable and few donors

TABLE 92-2 -- Incidence of Somatic Complaints for Normal Donors Treated with G-CSF

	Anderlini	Stroncek	Bishop
No. of donors	43	85	41

Data from Bishop et al.,[45] Stroncek et al.,[46] and Anderlini et al.[55]

will require reduction in dose or discontinuation of the medicine. At present, long-term health risks for the donor appear to be minimal. Few serious complications of the mobilization regimen and donation process have been reported. [56] [57] One donor experienced splenic rupture that appeared to be temporally related to the donation process. Another donor with known coronary artery disease experienced a myocardial infarction after the first of two intended donations. A third donor succumbed to a cerebral vascular accident several days after donation and discontinuation of the cytokine. Any relationship of these events for these last two donors to the donation process is purely speculative because similar events have not been reported for autologous donors or others receiving these cytokines. Also of concern is the possibility that cytokine administration will increase the risk of marrow dysplasia or malignancy. Although this is of theoretical concern in that the cytokines used are known to stimulate the growth of leukemic cells, no clinical evidence suggests that these agents will induce abnormalities in the hematopoietic cell. There are no reports of an increased risk of myelodysplasia or hematologic malignancies in either healthy donors or patients who have been treated with short courses of G-CSF.

Administration of G-CSF results in a number of changes in blood counts and chemistries. [46] [55] Alanine aminotransferase, lactate dehydrogenase, and alkaline phosphatase levels will increase and the levels of blood urea nitrogen and bilirubin may decrease. The elevation in alkaline phosphatase is primarily of bone origin and -glutamyltransferase levels remain normal. These abnormalities of serum chemistries will resolve within 2 weeks after discontinuation of this medication. G-CSF administration will also result in a decrease in platelet count, especially if the cytokine is administered over many days. [46] WBC counts fall rapidly after discontinuation of G-CSF. In about 10% of donors, the WBC count may fall to abnormal levels (but generally remain above 1,000/l), reaching a nadir at 1014 days after discontinuation of the cytokine before stabilizing at normal levels.

GM-CSF

Much of the early experience with the use of hematopoietic cytokines for the mobilization of HSC involved GM-CSF and chemotherapy. [1] [25] [27] The increase in CFU-GM in the peripheral blood can increase by as much as 1,000-fold in this setting. [1] Moreover, at least for some patients, the combination of cyclophosphamide and GM-CSF is more effective than mobilization with G-CSF alone. [58] GM-CSF is not as potent as G-CSF. Haas et al. [59] treated 12 patients with 250 g/m^2 /day of GM-CSF and observed only an 8.5-fold increase in the number of CFU-GM in the peripheral blood (to a median of 1,347 CFU-GM/ml). [59]

As with G-CSF, there is also a dose-response relationship in mobilization of PBSC with GM-CSF over a range of 0.320 g/kg/day without a plateau being observed. [60] In this latter study, however, the average increase in CFU-GM in the blood at this highest dose level was again only 8.4-fold.

Administration of GM-CSF results in similar somatic complaints and liver function abnormalities reported after G-CSF administration. [61] In addition, 4480% of patients will experience fever, sometimes after each dose, and generalized or local skin reactions. Lieschke and Burgess noted that doses >20 g/kg/day are poorly tolerated because of fluid retention, pleural and pericardial inflammation, and venous thrombosis. [62] A first-dose reaction characterized by hypoxia and hypotension occurring within 3 hours after administration has been described for some recipients, especially after intravenous administration. [63]

Other Hematopoietic Cytokines

Recognition of the mobilization potential of G-CSF led many investigators to study other hematopoietic cytokines for their capacities to mobilize HSC into the peripheral blood. Used as single agents, these cytokines resulted in only about a 5- to 10-fold increase in circulating CFU-GM or CD34+ cells.

Macrophage Colony-Stimulating Factor

Few studies have been conducted investigating the efficacy of macrophage colony-stimulating factor (M-CSF) on the mobilization of PBSC. In one study involving six patients with acute myelogenous leukemia treated with two cycles of consolidation therapy, there was no significant difference in the number of CFU-GM in the peripheral blood after either cycle despite the addition of M-CSF at a dose of 8 × 10 ^{6} U/day during the second. [64] Although, based on this experience, M-CSF is unlikely to have a major effect on the mobilization of HSC, interpretation of this study is hindered by the fact that this was not a randomized study, all patients received the cytokine only during the second consolidation cycle, and the chemotherapy regimens differed for the two consolidation cycles.

Erythropoietin

Recombinant human erythropoietin has a mild mobilization effect. Pettengell et al. [65] treated 11 patients with malignant lymphoma with either 300 or 450 IU/kg thrice weekly for 2 weeks and found a 4.6-fold increase in CD34+ cells. The peak level of these cells was found on days 58 of administration of this cytokine.

Interleukin-3

Interleukin-3 (IL-3) has been studied primarily as a component of sequential cytokine mobilization with either GM-CSF or G-CSF. [66] [67] [68] In the nonhuman primate treated with 33 g/kg/day, IL-3 administration results in about a 12-fold increase in the number of circulating CFU-GM. [69] In contrast, Ganser and coworkers treated patients with advanced malignancies with 60250 g/m^2 /day of IL-3 for 15 days and found minimal increase in circulating CFU-GM on day 8 and a decrease for some patients on day 15. [66] Geissler et al. [68] reported similar findings.

PIXY 321

This fusion molecule of GM-CSF and IL-3 was studied by Bishop et al. [70] in 13 patients with malignant lymphoma in a phase I study involving doses of 250750 g/m^2 /day by continuous infusion. Peak levels of CFU-GM in the blood were found on days 46 of treatment. Although there was a mild increase in CFU-GM in the blood, there was not a consistent increase in CD34+ cells.

Stem Cell Factor

Most clinical studies of stem cell factor (SCF) report the use of this agent in combination with other cytokines (see below). Limited reports of SCF by itself are available, and this cytokine appears to result in a dose-dependent 6- to 10-fold mobilization of CFU-GM. [71] [72] Considerable dose-dependent toxicity including angioedema, urticaria, pruritis, and laryngospasm, presumably from degranulation of mast cells, has also been observed. [73] [74]

Combinations of Cytokines

The mechanisms by which any of these cytokines causes the mobilization of PBSC is not known. Multiple mechanisms are probably involved, including both an effect on proliferation of HSC as well as release of these cells from the marrow. It is conceivable, therefore, that combining different cytokines could result in additive or synergistic effect. Limited studies have been conducted to date and there is considerable potential to explore different cytokines with variations both in dose and schedule.

G-CSF Plus GM-CSF

The addition of G-CSF to GM-CSF greatly increases the number of HSC mobilized. The converse is not true. Winters et al. [75] treated patients with a variety of malignancies to regimens of GM-CSF or G-CSF (both at 5 g/kg/day) to which the other cytokine was added at day 7 of treatment and both continued through day 12. A third group received both cytokines (at 5 g/kg/day) simultaneously throughout the treatment. Apheresis was conducted on days 5, 7, 11, and 13. The simultaneous use of both cytokines achieved a much greater mobilization of CFU-GM on day 5 than either of the cytokines used singly to that point. The addition of GM-CSF on day 7 resulted in greater numbers of CFU-GM being collected in subsequent apheresis procedures than were collected on day 5, although the effect was not very great. In contrast, the addition of G-CSF on day 7 to patients treated with GM-CSF resulted in a strong release of CFU-GM 4 days later. Ho et al. [76] similarly studied the administration of GM-CSF or G-CSF at doses of 10 g/kg/day, or both cytokines together at doses of 5 g/kg/day each and found that G-CSF alone achieved greater mobilization than GM-CSF or both drugs given in combination at a lower dose.

SCF Plus G-CSF

By itself, SCF is a relatively weak mobilizing agent. Studies in dogs and baboons found that animals administered the combination of SCF and G-CSF had a 3.5- to 21.6-fold increase in progenitor cells in the blood. [77] [78] The clinical effect has been much more modest. Moskowitz and colleagues reported data on 38 patients with non-Hodgkin lymphoma randomized to SCF at 520 g/kg/day plus G-CSF 10 g/kg/day or to G-CSF alone. [79] They found no difference between the cohorts in mononuclear cells, CD34+ cells, or CFU-GM contents of the components collected by apheresis. However, patients with extensive prior therapy had increased numbers of CD34+ cells if given combination therapy, although the difference was not significant for this small number of patients. Begley et al. [80] conducted a similar phase I study of concurrent SCF and G-CSF in 62 women with early-stage breast cancer and found, in contrast, a significantly higher level of CD34+ cells in the blood of recipients treated with G-CSF plus SCF at 10 or 15 g/kg/day compared to G-CSF alone or in combination with SCF at 5 g/kg/day. The duration of mobilization for patients given the combination therapy was much broader with high levels of CFU-GM still being released into the blood several days after

---

discontinuation of the cytokines. Sequential therapy with SCF given 3 days before initiation of G-CSF was even more efficacious, but even for this cohort of patients

the increase in CD34+ cell levels averaged only 2-fold greater than for recipients of G-CSF alone. The combination of SCF and G-GSF is also effective after cyclophosphamide mobilization chemotherapy.[81]

IL-3 Plus G-CSF

Geissler et al.[66] treated six patients with G-CSF at 5 g/kg/day for 5 days followed by a second course consisting of IL-3 at a dose of 5 g/kg/day for 7 days followed by G-CSF again at a dose of 5 g/kg/day for 5 days. They reported a 21-fold increase in CFU-GM in the peripheral blood after G-CSF alone, no increase after the course of IL-3, but a 56-fold increase after the combination. Peak levels of the progenitors in the blood were found on day 5 of G-CSF administration when given alone, but on day 3 if the patient was first treated with IL-3.

IL-3 Plus GM-CSF

Brugger et al.[67] treated 32 patients with etoposide, ifosfamide or cyclophosphamide, and cisplatin. The chemotherapy was followed by GM-CSF for 15 days for one group, by IL-3 for 5 days and then GM-CSF for an additional 10 days for another group, or with no cytokines for a third group. The dosages of the cytokines were not noted. The median peak number of CD34+ cells/l in the blood was 46 for the patients who did not receive either cytokine. The median for patients treated with GM-CSF alone was 426 CD34+ cells/l, and for the group treated with both IL-3 and GM-CSF, 418 CD34+ cells/l. The peak numbers of CFU-GM in the blood of the group receiving both cytokines was almost 2-fold greater than that for the group treated with GM-CSF alone.

Erythropoietin Plus G-CSF

In a retrospective comparison, Olivieri et al.[82] studied the addition of erythropoietin 50 U/kg/day to G-CSF 5 g/kg/day after mobilization chemotherapy with cyclophosphamide, etoposide, or epirubicine. The experimental group consisted of 18 patients with a variety of malignancies. The control group included 16 patients who received G-CSF alone. The groups were matched for diagnosis, previous chemotherapy, disease status, and mobilization chemotherapy agent. They found a 2.8-fold increase in the peak number of CD34+ cells for the group receiving both cytokines, and a 1.7-fold increase in the number of CD34+ cells collected during apheresis.

Chemotherapy Plus Cytokine Mobilization

The number of CFU-GM in the peripheral blood is greatly increased during the early hematologic recovery phase after marrow hypoplasia-producing chemotherapy.[5] [19] [20] [21] [34] [35] [36] A variety of chemotherapeutic regimens have been used for mobilization of PBSC including daunomycin, ara-C, L-thioguanate (DAT),[5] [19] [36] cyclophosphamide, Oncovin, methotrexate, prednisone (COMP), high-dose cyclophosphamide (CY),[34] mitoguazone, ifosfamide, methotrexate, etoposide (MIME),[21] cyclophosphamide, Adriamycin, vincristine (CAV),[20] and CY and etoposide.[83] To et al.[34] demonstrated a 14-fold increase of CFU-GM (compared to levels in healthy donors) in patients with non-Hodgkin lymphoma treated with a single dose of CY at 4 gm ^{2} . However, only 69% of treatment courses achieve the desired mobilization of CFU-GM. As with any mobilization regimen, there was considerable variation among patients in the response to this treatment.

Chemotherapy plus cytokine will generally mobilize greater numbers of PBSC than either alone.[84] Alegre et al.[58] compared the treatment of patients with multiple myeloma with CY 4 g/m^{2} followed by 8 g/kg/day of GM-CSF to a second group of patients treated with G-CSF alone at a dose of 10 g/kg/day. Although G-CSF is the more potent mobilizing cytokine, the patients treated with chemotherapy plus GM-CSF achieved greater numbers of CD34+ cells per apheresis procedure demonstrating the additive potential of chemotherapy mobilization.

A wide variety of different chemotherapy regimens have been used successfully for the mobilization of HSC into the blood. The primary consideration is that the choice of chemotherapy used must meet the treatment needs of the patient. However, evidence also indicates that the choice of chemotherapy regimens will affect the mobilization of HSC. Schwartzberg et al.[83] reported an average daily apheresis yield of 4.0 × 10 ^{7} CD34+ cells in 395 apheresis components collected from 61 patients treated with CY and average yields of 8.3 × 10 ^{7} CD34+ cells in 218 collections from 33 patients treated with both CY and etoposide.[83] (Another group of 24 patients was treated with this latter chemotherapy regimen, but also received 6 g/kg/day of G-CSF. The average CD34+ cell contents for 122 collections from these patients were significantly higher at 38.8 × 10 ^{7} .) The average quantities of CFU-GM paralleled the numbers of CD34+ cells collected. Similarly, Demirer et al.[85] studied the effect of different chemotherapy regimens for the mobilization of HSC for patients with breast cancer. Four regimens were used, all involving CY, but including etoposide with or without cisplatin, or paclitaxel. All patients also received G-CSF. The median quantity of CD34+ cells collected on the first day of apheresis after CY mobilization was 0.9 × 10^{6} /kg of patient weight. The addition of etoposide and then etoposide and cisplatin increased this to 8.1 × 10 ^{6} and 3.5 × 10^{6} CD34+ cells/kg, respectively. The median number of CD34+ cells harvested on the first day of apheresis after CY plus paclitaxel was 11.1 × 10 ^{6} /kg. Over 50% of the women mobilized with this last regimen achieved the target dose of CD34+ cells in one apheresis procedure. Of the 100 women studied, 94 achieved the target dose of >5 × 10^{6} CD34+ cells/kg. Only 4 patients failed to reach a lower but acceptable dose of 2.5 × 10 ^{6} CD34+ cells/kg.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

STRATEGIES FOR THE DIFFICULT-TO-MOBILIZE PATIENT

Most patients achieve the targeted dose of CD34+ cells after the processing of 2030 liters of blood in one to three apheresis procedures. However, about 5% to as many as 30% of patients in various series will have inadequate collections because only small numbers of HSC are present in the peripheral blood despite the administration of hematopoietic cytokines. Different chemotherapy and cytokine regimens will affect the mobilization of HSC. Patient-specific factors predictive for poor mobilization include older age, marrow disease, prior radiotherapy, and prior chemotherapy. [29] [86] [87] [88] [89] The previous administration of marrow-toxic drugs may suppress the subsequent mobilization of HSC.[90] About 50% of patients who fail to achieve the targeted dose of CD34+ cells will achieve this goal on a second attempt. High-dose (15 mg/kg twice daily) G-CSF after a 24-week drug holiday to allow marrow recovery is one strategy. Combination cytokine therapy is also of potential value in this situation, but cytokine combinations have not been tested in groups of patients who previously failed mobilization therapy. Repetition of a chemotherapy plus cytokine regimen will also work, but may be associated with increased toxicity. [89] Consideration should also be given to infusing a lower dose of CD34+ cells (as low as 1×10^6 CD34+ cells/kg) because, although the risk of delayed engraftment is incurred, [29] [30] failure of engraftment has not been reported. [85]

Consideration should be given to collection of PBSC early in the course of treatment for patients who may later be candidates for autologous HSC transplantation. HSC may be cryopreserved

and stored for years without obvious progressive loss of engraftment potential. [91]

DEFINITION OF ADEQUATE COMPONENTS

The quantity of CD34+ cells in a PBSC component varies greatly and depends on the number in the peripheral blood at the time of apheresis, the volume of blood processed, and the efficiency of the apheresis device. Therefore, any definition of an adequate component cannot include a set number of CD34+ cells. Instead, one or more components will be collected to meet the appropriate dose of these cells for transplantation. What dose of CD34+ cells is required for infusion depends on the intended treatment regimen. For marrow-ablative regimens, increasingly higher CD34+ doses result in greater likelihood of rapid engraftment (Figs. 92-1 and 92-2).[29] [30] Lower doses of CD34+ cells appear satisfactory for nonablative regimens.[92] [93] [94] [95] For example, Bokemeyer et al.[94] infused 1×10^6 CD34+ cells per cycle for patients treated with high-dose ifosfamide and doxorubicin. Despite an overall doubling of the ifosfamide dose in this phase I study, the median times between cycles did not differ.

Quantification of hematopoietic progenitors by cell culture has been used by many transplant programs in attempts to determine the adequacy of the bone marrow or PBSC collections for transplantation.[22] [34] [96] Based on delayed engraftment failure in some patients, Juttner and colleagues recommended a minimum dose of CFU-GM of 6.3×10^5 /kg recipient weight. [19] Others have suggested lower doses of 25×10^5 CFU-GM/kg.[97] Patients who receive a dose of CD34+ cells (or CFU-GM) above a certain threshold will engraft. At lower doses of CD34+ cells there is considerable heterogeneity in engraftment speed, especially for platelet engraftment. It is not known why this heterogeneity exists, but it may reflect a weakness in the correlation between CD34+ cells and the cells responsible for engraftment or, more simply, a greater degree of error in the measurement of CD34+ cells at the lower cell concentrations. As the dose of CD34+ cells increases, the engraftment speed becomes more consistent for the population studied.[29] [30] Several investigators showed more rapid granulocyte and platelet engraftment for recipients of products containing a quantity of CD34+ cells above a dose of about 23×10^6 /kg recipient weight.[87] [88] [98] Investigators at the Fred Hutchinson Cancer Research Center found a threshold of 5×10^6 CD34+ cells/kg to achieve reliably prompt platelet engraftment,[99] and studies that include large patient populations found that higher doses of CD34+ cells will

Figure 92-1 The Kaplan-Meier probability of achieving 0.5×10^9 neutrophils/L for $<5.0 \times 10^6$ (-), >5.010.0 $\times 10^6$ (), and $>10 \times 10^6$ (---) CD34+ cells/kg (p = 0.0001). *(Reprinted from Weaver et al.,[30] with permission.)*

Figure 92-2 The Kaplan-Meier probability of achieving 20.0×10^9 platelets/L for $<5.0 \times 10^6$ (-), >5.010.0 $\times 10^6$ (), and $>10 \times 10^6$ (---) CD34+ cells/kg (p = 0.0001). *(Reprinted from Weaver et al.,[30] with permission.)*

result in even higher proportions of patients achieving quick engraftment. [30] Investigators at the Hutchinson Center noted that the dose of CD34+ cells infused was more important than the type of mobilization therapy.

TIMING OF APHERESIS

A major problem with chemotherapy-based mobilization regimens is the difficulty in determining the optimal time to commence HSC collection. It is an obvious point that apheresis devices can only collect those CD34+ cells actually circulating in the peripheral blood. It is possible to estimate the quantity of CD34+ cells that will be collected during apheresis by multiplying the quantity of CD34+ cells in the blood by the total volume of blood processed during the apheresis procedure and by the efficiency of the apheresis device in collecting these cells. If the device has an efficiency of 50% and the patient undergoes a 10-liter exchange, about 5×10^{7} CD34+ cells will be collected for a peripheral blood level of 10 CD34+ cells/l, and 5×10^{8} CD34+ cells for a blood level of CD34+ cells that is 10-fold higher. Although many protocols call for the initiation of apheresis after chemotherapy mobilization when the WBC has recovered to >1,000/l, there is poor, if any, correlation between the peripheral blood WBC or mononuclear cell counts and the CD34+ cells in the peripheral blood. Characteristics that suggest a higher CD34+ cells level are rapidly rising WBC, a shift in differential to immature myeloid cells, circulating nucleated red blood cells (RBC), and platelet transfusion independence. However, it is much more cost effective to obtain an actual measurement of CD34+ cells in the blood and time the apheresis collection when these cells are present in adequate numbers. The published experience from many transplant centers describes a correlation between the CD34+ cells in the peripheral blood and in the harvested component. [87] [98] [100] [101] Figure 92-3 shows such a relationship for patients with lower concentrations of CD34+ cells in the peripheral blood and illustrates the very poor collections that are obtained when the peripheral blood CD34+ count is <10/l. Although there is considerable error in the enumeration of CD34+ cells at levels <5/l, this is not clinically relevant because even a doubling of the CD34+ cells in this range still results in a very poor apheresis yield.

At what level of CD34+ cells in the peripheral blood to start apheresis is a clinical decision. Although levels in the range of 50100/l or greater will reduce the number of apheresis procedures necessary to achieve a target goal of CD34+ cells, each days delay in initiating apheresis also incurs the costs of

Figure 92-3 The relationship between the quantity of CD34+ cells in the peripheral blood and the number collected by apheresis using apheresis and flow cytometry techniques previously described.[2] [29] [209] Shown are data limited to peripheral blood CD34+ cell numbers 50.0/L (n = 157, r = 0.82, p < 0.001).

additional cytokine administration and blood testing. For some patients who have been extensively treated previously and who may show a slowly rising WBC, it may be necessary to accept multiple apheresis procedures to achieve the target goal. Certainly, no patient should undergo apheresis if the peripheral blood count is <5/l (Fig. 92-3). For patients with CD34+ cell counts of 1020/l, it is possible to process more blood per day using large-volume leukapheresis (LVL) techniques and thereby reduce the numbers of days the patient is required to return to the apheresis unit. Most patients will have a rising CD34+ cell count in the peripheral blood so it is generally feasible to start apheresis the day after the patient has achieved a desirable CD34+ level. [101]

The timing of apheresis after G-CSF mobilization differs from the timing after chemotherapy and cytokine mobilization. For both patients and healthy donors, the peak concentration of CD34+ cells occurs on the fifth day of G-CSF administration (after four daily doses). [43] [44] Lower levels are present on day 4, and the concentration continues to fall after day 6 even if cytokine administration is continued and despite a continued rise in the WBC. Thus, PBSC collection should be initiated on day 4 or 5 of G-CSF administration. The kinetics of CD34+ cells in the peripheral blood for patients and donors mobilized with G-CSF alone are so reliable that it is not necessary to monitor peripheral blood levels unless there is concern that the patient has failed to mobilize cells and it is practical to obtain the cell count rapidly enough to initiate apheresis on the same day.

APHERESIS TECHNOLOGY

Apheresis technology is widely used for the collection of platelets from healthy donors and is considered to be without major risk to the donor. The important safety considerations for PBSC collection are the same as for platelet collection and include the venous access to be used for the procedure, the extracorporeal volume of blood during the procedure, and the solutions administered to the donor. However, it must also be acknowledged that PBSC collection for autologous transplantation involves patients with underlying medical conditions who may require considerable nursing care during the procedure. In a retrospective review of >5,000 patient plasmapheresis procedures for the treatment of a variety of diseases, complications of apheresis were observed in 12% of procedures, and 40% of patients experienced at least one complication during a course of therapy. [102] Most of these were mild and transient such as fever, chills, urticaria, hypotension, and reactions to citrate anticoagulants. In contrast, patients and donors undergoing PBSC collection do not require the replacement fluids used during plasmapheresis and will not experience the toxicities associated with plasma protein infusions. However, rare anaphylactic reactions may occur for the pediatric patient who requires blood priming of the extracorporeal circuit, patients treated with angiotensin-converting enzyme inhibitors, [103] or those allergic to ethylene oxide used to sterilize the apheresis disposable set. [104] Goldberg et al. [105] studied the complications occurring during 554 PBSC collections from 75 consecutive patients, 74 of whom had subclavian or jugular venous system catheters placed for apheresis. Patient diagnoses were varied as were the mobilization treatment regimens. A median of nine collections per patient was performed using a discontinous-flow apheresis device. The most common problems were related to the venous catheters with 50% of the patients developing at least one occlusion. Hypocalcemia occurred in 14.6% of patients and hypotension in 13.3%. Sixteen percent of patients experienced infectious complications during the PBSC collection period.

Staffing of the apheresis unit should be appropriate for the medical condition of the patients undergoing apheresis. The collection of PBSC by apheresis performed in the outpatient setting should never be assumed to be a safer alternative for the donor than marrow harvesting conducted in the intensive care setting of the operating room without careful review of the medical support requirements for the individual patient or donor.

Venous Access

Adequate venous access is required for optimal apheresis technique. Continuous-flow apheresis devices require two-lumen access with a stable blood flow capacity generally >20 ml/min. Single-lumen access may be used with discontinous-flow apheresis devices, although at a much slower rate of blood processing. The great majority (90%) of adult allogeneic PBSC donors have adequate arm veins for the procedure to be conducted vein-to-vein. Some allogeneic donors, especially those with small veins and undergoing several daily procedures, may require placement of a temporary venous catheter. Venous access for the patient undergoing collection for autologous PBSC transplantation is much more heterogeneous. Vein-to-vein procedures may be performed, even on several consecutive days, with proper phlebotomy technique and postcollection care of the phlebotomy site. Most patients have received previous chemotherapy or are proceeding directly to transplantation for both of which tunneled access is commonly placed. Ideally, this venous access should be appropriate both for the apheresis procedures and the subsequent transplant. Length, lumen size, and wall stiffness all affect the blood flow that can be achieved through a catheter. For this reason, the commonly used dual-lumen Hickman or Broviac catheters are usually unsuitable for apheresis as are all subcutaneously placed ports. [106] Most triple-lumen catheters are also inadequate because of the small lumen size. If such access is already placed, consideration can be given to replacement with a shorter, stiffer tunneled catheter or to placement of a temporary percutaneous dialysis/apheresis catheter. [107] The catheters designed for dialysis and apheresis have adequate wall thickness to prevent collapse during aspiration of blood as well as a tip design to decrease local recirculation of blood and the resulting decrease in apheresis efficiency. Catheters of 10 Fr or larger size are appropriate for adult patients. Pediatric patients whose blood flow rates are considerably slower may use catheters of 57 Fr size. [108]

Problems directly related to venous access account for a considerable amount of the toxicity associated with PBSC collection. It has been suggested that mobilization with GM-CSF increases

the incidence of catheter occlusion. [109] Haird et al. [110] suggested that catheters placed in the subclavian vein in particular were associated with a high incidence of thrombosis, a complication seen less frequently with translumbar inferior vena cava placement. Goldman et al. [105] reported this complication in 50% of patients. In contrast, Alegre et al. [107] reported only a 1.8% incidence of thrombosis or clotting of catheters, possibly because of differences in cytokine or catheter type and care. Catheter thromboses are easily managed with streptokinase or urokinase instillation by the apheresis unit staff. One randomized study reported that low doses of warfarin decreased the incidence of venous thrombosis associated with indwelling catheters, but this study did not address catheter patency, nor were the patients enrolled in this study treated with hematopoietic cytokines. [111] Consultation with apheresis unit staff about venous access for an individual patient is appropriate. For example, for patients with adequate peripheral veins, a needle may be placed in one arm of the patient for blood draw with simultaneous use of both lumens of a tunneled catheter for return of the blood, thereby avoiding the need for placement of another venous access device.

Apheresis Devices

A number of apheresis devices are available for the separation of HSC from the peripheral blood. These devices may be classified as continuous-flow devices (e.g., Fenwal CS3000, COBE Spectra, Fresenius AS104) or discontinuous-flow devices (e.g., the Haemonetics family of equipment). The discontinuous-flow devices have the advantage of requiring only a single venous access. Continuous-flow devices require two access lines for aspiration and return of blood, but process much greater volumes of blood in a shorter period of time. Devices now available enrich the HSC-containing mononuclear cell fraction, reducing the quantities of granulocytes and platelets collected that may interfere with cryopreservation or other laboratory processing.

All apheresis devices will collect HSC. Which apheresis device is used by the collection center depends primarily on the needs and experience of the center. The CS3000 achieves a greater enrichment of mononuclear cells than the COBE Spectra, [112] reducing the number of granulocytes in the component, but without a difference in the collection efficiency for CD34+ cells. In constrast, the Spectra allows a much higher blood/anticoagulant ratio because additional anticoagulant solution can be added to the collect bag at the initiation of the procedure, thereby avoiding much of the citrate toxicity that may occur with the processing of the large volumes of blood during PBSC collection. Continuous-flow devices are more efficient in the collection of PBSC. In a randomized study comparing the Haemonetics MCS-3P with the COBE Spectra, Morton et al. [113] found that the latter device processed significantly more blood in a shorter period of time and collected over twice as many CD34+ cells and CFU-GM.

Anticoagulation

Anticoagulants are added to the blood during apheresis to prevent clotting of the extracorporeal circuit and clumping of cells in the component. Citrate anticoagulants have a proven record of safety in the apheresis of healthy platelet donors and are used extensively for the collection of PBSC. The major drawback is the risk of a symptomatic decrease in the level of ionized calcium (citrate toxicity), especially during the processing of large volumes of blood. [114] [115] Citrate ions chelate calcium

ions (and other divalent cations such as magnesium), making them unavailable for Ca^{2+} -dependent metabolic reactions. Acid-citrate-dextrose A contains 10.67 g citrate/500 ml volume in the form of trisodium citrate and citric acid. Citrate is diffused throughout the extravascular space and this diffusion is probably the first defense against citrate toxicity. Metabolism by liver, kidney, and muscle also reduces the concentration of citrate. Metabolism of citrate becomes more important during prolonged apheresis procedures such as LVL.

The initial signs of citrate toxicity include circumoral or acral paresthesias and may progress to nausea, vomiting, loss of consciousness, tetany, and seizures. Fatal cardiac dysrythmias have been reported (rarely) for patients undergoing plasmapheresis. [116] Citrate infusions may depress myocardial function, and it has been suggested that this may be worsened by the use of calcium channel blocking medications although reports of such complications for patients or donors undergoing apheresis have not been published. [114] Pediatric patients may not be able to relate the initial symptoms of citrate toxicity, and this should be considered for any change of behavior for these patients during the apheresis procedure.

Citrate toxicity is prevented by limiting the quantity of citrate infused either by decreasing the blood flow rate through the apheresis device or changing the blood/citrate ratio. The COBE Spectra, for example, limits the blood flow rate so that the amount of citrate infused is a maximum of 1.1 ml/min/l of patient blood volume as calculated from the patients gender and size. However, these machine parameters do not account for alterations in electrolytes, plasma protein levels, muscle mass, or renal or hepatic function that may occur for patients receiving chemotherapy. The processing of blood of patients experiencing the initial symptoms of citrate toxicity should be temporarily halted until the symptoms abate and then resumed at a slower rate.

The benefit of oral calcium supplements for these patients is not certain. Heparin may be used as a replacement for some or all of the citrate although to prevent clumping of platelets additional citrate is added to the component. [2] [117] Some centers using citrate anticoagulants will also administer intermittent or continuous infusions of calcium gluconate during the procedure, especially if large volumes of blood are being processed. [95] [118] However, excessive calcium replacement can also induce cardiac dysfunction. [114] Point of care devices that measure the ionized calcium within minutes are now available and greatly simplify obtaining this test. [119] [120]

LARGE-VOLUME LEUKAPHERESIS

The apheresis device has a uniform and fairly reproducible efficiency of collection. Thus, for a consistent quantity of blood processed through the machine, the quantity of CD34+ cells collected is directly related to the number present in the peripheral blood. Greater quantities of CD34+ cells can be collected by increasing the number of these cells in the peripheral circulation or by increasing the volume of blood processed by the device. For those patients with lower CD34+ cell levels, multiple apheresis procedures will be required to achieve the target dose of CD34+ cells needed for transplantation. An alternate approach is to process the same total quantity of blood, but in fewer, longer procedures. Large-volume leukapheresis (LVL) is not formally defined, but in general usage refers to the processing of more than two or three times the patients blood volume.[118] [121] [122] [123] [124] [125] [126] [127] [128] [129] Typically, the quantity of blood processed is six or more times the patients blood volume, often 2536 liters of blood. The advantage of LVL is that this reduces the number of days of cytokine administration and apheresis with associated reduced costs of laboratory processing and testing. The apheresis techniques are the same as those used for the processing of smaller volumes of blood although blood flow rates may be increased to reduce the time required. The risks of LVL are the increased time required and the higher risk of citrate (or other anticoagulant) toxicity. Patients will also incur a proportional drop in platelet counts and may become profoundly thrombocytopenic.

Most reports of LVL describe the collection of more CD34+ cells than are calculated to be present in the peripheral blood at the initiation of the apheresis procedure. Obviously, there is release of cells from the marrow to replace those removed by apheresis. Apheresis of CD34+ cells is a three-compartment system consisting of the extracorporeal circuit of the apheresis device including the collection bag, the peripheral blood, and the marrow. However, it is not obvious that the apheresis technique itself consistently mobilizes CD34+ cells as suggested by the titles of some reports. Initial investigation of LVL in dog and rhesus monkey models and for human patients and healthy donors not receiving cytokine mobilization demonstrated an increase in the number of CFU-GM collected such that a doubling of these cells in the circulation must have occurred during the apheresis procedure. [123] [126] [130] [131] The experience with patients and donors treated with cytokines or chemotherapy plus cytokine is much more variable with reports describing an increase, [122] [123] [125] [126] no change,[120] [128] [129] or even an exhaustion of CD34+ cells from the peripheral blood.[128] [132] Animals receiving hematopoietic cytokine stimulation have a diminished apheresis-associated increase in circulating CFU-GM compared to those animals collected without any mobilization treatment.[131] This increase may also not be evident in patients with poor marrow function resulting from previous, extensive chemotherapy.[127]

Clinically most important is the possibility of exhaustion of HSC such that the processing of the large blood volumes exposes the patient to the risks of anticoagulant toxicity and thrombocytopenia without achieving an increased collection of HSC. Studies at the Fred Hutchinson Cancer Research Center demonstrate a continuous release of CD34+ cells from the marrow (and, presumably, return to the marrow space). Patients having higher levels of CD34+ cells in the peripheral blood appear to have a greater number of these cells circulating between the marrow and peripheral blood compartments (Table 92-3). If this is so, the apheresis device merely serves as a siphon, removing these cells from the blood as they are released from the marrow. If this is an appropriate description of CD34+ cell kinetics, it may be possible to deplete these cells from the blood and marrow by prolonged processing. Also, the model suggests that higher blood flow rates used to shorten the apheresis procedure may be counterproductive for the patient with low CD34+ cell levels in the blood.

The explanation for the increase in CFU-GM circulating in the peripheral blood during the procedure reported by some investigators is obscure. Murea et al. [125] suggested that this phenomenon

TABLE 92-3 -- Replenishment of CD34+ Cells During Large-volume Leukapheresis

UPN	CD34+Cells				
	Blood/l	Blood Total	Harvest Total	Released Total	Released/Min
10605	6.8	34.9	123.5	88.6	0.3
10698	15.6	603.3	1438.1	540.8	2.1
10849	30.7	109.7	211.1	62.6	0.3
10920	37.9	214.2	952.8	57.0	1.6
11128	66.1	280.6	1010.8	532.7	1.9

Shown are the number of CD34+ cells in the peripheral blood or apheresis component for five patients with acute myelogenous leukemia or multiple myeloma undergoing LVL after G-CSF or chemotherapy plus G-CSF mobilization treatment. Blood volumes processed were six times the calculated blood volume of the patient. PBSC collection was performed on the COBE Spectra as previously described.[2] The total number of CD34+ cells in the blood (third column) was calculated from the level of CD34+ cells in the blood and the estimated blood volume of the patient. The total number of CD34+ cells released (fifth column) was calculated from the total number in the apheresis component and the number in the peripheral blood after collection minus the total number in the peripheral blood at the start of the collection procedure. All CD34+ cell quantities (except blood levels reported per l) are $\times 10^{6}$.

may be related to a decrease in divalent cations resulting from the citrate anticoagulant. Divalent cations are necessary for the function of some but not all cell adhesion molecules.[133] A progressive decrease in ionized calcium levels for some patients during the prolonged LVL procedure could, therefore, result in an increase in circulating HSC. This may explain why some investigators using heparin-containing anticoagulation solutions or who concomitantly infuse calcium solutions have not observed this phenonmenon.[128] [129] [132]

Large-volume leukapheresis is appropriate management for the patient or donor who needs to complete apheresis in a limited number of procedures. The quality of the component collected by LVL does not differ from that collected by the processing of smaller volumes of blood, and patients experience the same rapid kinetics of engraftment after infusion of these components.[125]

PEDIATRIC DONORS AND PATIENTS

Peripheral blood stem cells can be collected from pediatric patients including infants. The special challenges of the pediatric patient arise from the fixed extracorporeal blood volume of the apheresis device, the need for venous catheters for blood access, and the management of a patient who may be unwilling or unable to rest quietly for the period of apheresis. It is especially important in management of the pediatric patient that timing of apheresis be optimal to minimize the number of procedures required to achieve the desired quantity of PBSC. Given these considerations, a number of centers have reported successful collection of PBSC from pediatric patients and donors. [95] [117] [132] [134] [135] [136] [137] [138] [139] [140] [141]

Virtually all pediatric patients undergo insertion of a venous catheter adequate for the flow rates expected although older (>12 years) patients may tolerate vein-to-vein procedures. The whole blood flow rate for the pediatric patient is much reduced compared to adult patients and catheters as small as 5 Fr will be adequate. [108] Some centers have used arterial cathethers for blood access. [137]

Appropriate management of fluid balance during the apheresis procedure is critical for the smaller patient. The volume of RBC contained in the extracorporeal circuit of a continuous-flow apheresis device could represent 3050% of the RBC mass of a pediatric donor. Discontinuous-flow devices, although appealing because of the feasibility of performing apheresis with a single-lumen venous access, may result in even higher extracorporeal volumes and should be avoided for the smallest patients. The obvious solution to this problem is to prime the apheresis device with ABO-compatible, irradiated RBC (leukocyte-depleted and cytomegalovirus-negative blood may also be desirable) when the blood in the extracorporeal circuit is expected to exceed 15% of the patients blood volume. Packed RBC units may be diluted with saline or with albumin to reduce the loss of plasma protein that may also occur. The RBC remaining in the extracorporeal circuit at the completion of the run need not be returned (rinseback), [142] [143] [144] although if performed slowly with monitoring of vital signs, rinseback may actually increase the hematocrit after the procedure and otherwise reduce the need for RBC transfusions for these patients. Körbling et al. [139] collected and stored the RBC remaining in the machine after the first days apheresis for use in priming for the second days procedure for allogeneic donors requiring 2 days of apheresis, thereby avoiding the use of homologous blood transfusion. For the intermediate-sized pediatric patient (2550 kg), the apheresis device can be primed with a 5% albumin solution. This will reduce the albumin loss that would otherwise occur. However, clotting proteins and other proteins not contained in this solution may decrease with repetitive apheresis.

The pediatric patient may not exhibit or relate the prodromal symptoms associated with citrate toxicity. Continuous calcium

gluconate infusion may be incorporated into the procedure, or heparin may be added to the citrate anticoagulant solution or used as the sole anticoagulant. [2] [124] [125] [132] Some centers report the use of sedating medications such as chloral hydrate during the procedure. [95] [135] [139] Sedation of the pediatric patient is not necessary, however, [134] [138] [141] and hinders the ability to recognize the symptoms of citrate toxicity. (Some patients may require antihistamine premedication if the apheresis device is primed with RBC.) Centers routinely performing pediatric PBSC collection should design an environment conducive to the management of the pediatric patient and develop support procedures that recognize the unique physical and cognitive features of these patients. [145]

The range in blood volumes for pediatric donors of differing ages is greater than that for the adult donor. Therefore, most centers set a goal for volume processed based on the individuals blood volume instead of a set volume for all patients. The pediatric patient may undergo LVL to achieve the target goal of HSC with fewer procedures. [132] [140] Blood flow rates for the pediatric patient are slower than those for the adult to minimize the risk of citrate reaction. As with adults, the timing of apheresis can be optimized by monitoring the quantity of CD34+ cells in the peripheral blood. [146]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

ALLOGENEIC DONORS

Numerous centers have reported their initial experience with the use of PBSC for syngeneic or allogeneic HSC transplantation. [7] [8] [9] [10] [11] [12] [13] [147] Consistently, these reports describe more rapid engraftment kinetics than previously observed with marrow transplantation. The incidence of acute GVHD appears to be equivalent to that after marrow transplantation despite the 10-fold higher number of T lymphocytes infused. [7] [8] However, chronic GVHD seems to be much more common after PBSC transplantation,[148] especially chronic GVHD involving the skin. Phase III studies are being conducted to assess the toxicity and transplant outcome for this source of HSC compared to marrow. Peripheral blood mononuclear cell components collected from donors either with or without treatment with G-CSF are also effective in reinducing remission for patients who relapsed after allogeneic transplantation. [149] [150] [151]

The apheresis procedure is similarly well tolerated by the allogeneic PBSC donor. In contrast to the collection of PBSC intended for autologous transplantation, the collection for allogeneic transplantation is performed, usually, on a healthy donor. Virtually all allogeneic donors are treated with G-CSF for mobilization of PBSC, and the toxicities incurred with the use of this cytokine are discussed above. The risks to the allogeneic PBSC donor conferred by apheresis should not differ greatly from the risks to the platelet donor if the apheresis techniques are similar. The PBSC donor may undergo larger volume and repetitive exchanges with different anticoagulants compared to the platelet donor. The risk of the larger volume exchange is one of citrate toxicity if the donor is small or if the blood flow rate is increased to achieve this volume in a shorter period of time. Also, larger volume and repetitive exchanges will result in platelet depletion, although the platelets can be collected from the component for infusion back to the donor. [46] [55] The platelet count actually may reach its nadir several days after the completion of the apheresis collections and discontinuation of G-CSF. [46]

Most donations can be obtained using a vein-to-vein procedure. Some donors, especially pediatric donors, may require the placement of a temporary central venous catheter. The risks of catheter placement are well known and will not be repeated here.

Older donors will have more underlying medical conditions, [152] and the risks to the donor with underlying health problems must be fully considered before subjecting the donor to mobilization and apheresis. Standards are now published that describe the evaluation of the donor both for the risk of the donation process as well as the risk of transmission of disease to the recipient. [153] [154] Collection of PBSC is generally an outpatient procedure conducted in the clinic setting. In contrast, marrow harvesting has the luxury of the intensive support capability of the operating room. PBSC collection should never be viewed as a safer alternative to marrow harvesting for the donor with underlying health problems. Anderlini et al. [56] further suggested that G-CSF specifically not be administered to patients with a history of inflammatory ocular disorders, venous thrombosis, autoimmune disorders, or malignancy treated with chemoradiotherapy.

Management of RBC Incompatibility

Management of RBC incompatibility between the PBSC donor and recipient is the same as that for bone marrow transplantation. [155] Marrow processing to reduce the quantity of RBC and careful transfusion practices are used to avoid acute or delayed hemolytic transfusion reactions from the infusion of incompatible RBC or immunocompetent B lymphocytes. Eventually, recipient RBC and isoagglutinins are replaced by donor type. RBC incompatibility may be classified into two categories, one in which the recipient has antibodies directed against donor RBC with the potential of acute hemolysis during the infusion of the component (major incompatibility), and one in which the donor has antibodies against the recipient. Although the latter rarely causes difficulty during infusion of incompatible plasma, B lymphocytes carried in the component can form isoagglutinins resulting in a delayed transfusion reaction 712 days after transplantation. Apheresis devices are commonly used to remove RBC from marrow components for major RBC incompatibility. [156] Infusion of RBC quantities of 10 ml appears to be tolerable. Therefore, secondary processing of a PBSC component collected by the same technology used for the depletion of RBC from marrow grafts and already containing low quantities of RBC is not required. Minor ABO incompatibility can result in delayed transfusion reactions that may be fatal if appropriate blood transfusion support (avoiding the infusion of donor-type RBC) is not initiated before the transplant. Two case reports of severe RBC hemolysis after allogeneic PBSC transplantation have been reported. In the first, transfusion support before the event was not described. [157] The second patient received recipient-type RBC on day 7 after transplantation,[158] which is the point at which donor-derived isoagglutinins will be increasing in the recipient. Although both authors discussed the much greater numbers of B cells in PBSC components as a possible factor in these events, it is not clear from these reports that delayed-type transfusion reactions will be more likely or of greater severity in PBSC recipients.

CELL COUNTING, PROCESSING, AND CRYOPRESERVATION

Tumor Cell Contamination

The probability that tumor cell contamination of the component could contribute to relapse was demonstrated by Brenner et al. and others in studies involving the transplantation of genetically marked marrow cells. [159] [160] [161] Sensitive immunocytostaining techniques, clonal assays, flow cytometric analysis, and polymerase chain reaction amplification of malignant genetic material detect tumor cells in the PBSC components of many patients with a variety of malignancies. [162] [163] [164] [165] In general, the incidence of contamination (number of patients with positive components) and the level of contamination (number of tumor cells per number of normal cells) is much less for PBSC than for marrow components,[162] although this has not been a consistent finding in all

studies. [163] Whether patients transplanted with PBSC have a lower relapse rate compared to those receiving bone marrow is not known, and appropriate phase III studies of this question will be difficult to design and to enroll patients onto. In a retrospective study, Sharp et al. [166] demonstrated similar probabilities of relapse-free survival for recipients of PBSC or marrow components if the components were free of lymphoma cells. In that study, patients with marrow involvement by lymphoma were assigned to transplantation with PBSC. The authors concluded that PBSC transplantation is a sensible approach to the patient with overt marrow involvement. Brugger and coworkers, however, demonstrated that patients with breast cancer involvement of the marrow at the time of chemotherapy mobilization were likely to mobilize tumor cells into the blood. [167] The most disturbing finding of this study is that the tumor cells were detected in the peripheral blood at the same time as CD34+ cells. Investigators at the Johns Hopkins Oncology Center found no difference in the incidence of tumor contamination of PBSC components between patients treated with chemotherapy and cytokines or cytokines alone. [168] The probability of tumor contamination of PBSC components decreases after induction chemotherapy.[169] Patients with marrow involvement may benefit from debulking chemotherapy before collection of PBSC with the caveat that extensive chemotherapy will decrease the yield of PBSC. It is unlikely that tumor cells in the HSC inoculum will benefit the patient, but it is also advisable that, until further data are available, reports of tumor contamination in the collections for individual patients should be interpreted with caution. Purging of PBSC collections should be limited to the research setting culminating in appropriate trials of purging efficacy.

Purging of PBSC Components for Autologous or Allogeneic Transplantation

Components of PBSC can be purged of tumor cells or T lymphocytes using the same techniques developed for marrow although the larger cell quantities collected and the multiple days of collection will increase the cost of this processing. The commercial availability of devices that enrich CD34+ cells has served to focus most purging studies involving PBSC components on this technology. The CD34 glycoprotein is a molecule of about 115-kd size found on lymphohematopoietic stem and progenitor cells including malignant cells derived from these, vascular endothelium, and, possibly, other tissues. [170] The presence of this marker on HSC and progenitor cells enables the enrichment of these cells from peripheral blood, cord blood, or marrow. Enriched populations of CD34+ cells can then be used for transplantation or for further component manufacturing such as gene therapy or cell expansion. Numerically, simple enrichment of CD34+ cells from <1% to levels of 7095% results in a 9099% depletion of CD34 cells, leading many investigators to explore CD34+ cell enrichment as a technique of T-cell depletion to prevent GVHD in allogeneic cell recipients, [171] [172] [173] [174] or tumor depletion to decrease the risk of relapse for autologous component recipients. [175] [176] [177] [178] Engraftment does not appear to be affected by the CD34+ cell enrichment unless low quantities of CD34+ cells are infused. [175]

Positive enrichment of HSC achieves a nonspecific tumor cell depletion as CD34+ cells are separated from the antigen-negative cells. Because this depletion is nonspecific, the degree of purging achieved will equal the depletion of other CD34 cells such as lymphocytes. Typically, this will range from 99.0 to 99.99% depletion. By itself, CD34+ cell enrichment will reduce the number of tumor cells below the level of detection of some assay systems. For example, Shiller et al. [175] reported that five of eight components were negative for myeloma cells after processing, but Lemoli et al. [178] found the persistence of detectable disease in five of six patients tested. The median purity of the CD34+ cells was actually greater in the latter study (77% vs. 89.5%). CD34+ cells can be successfully enriched after thawing using the same techniques used for prefreeze separations. [179] [180] [181] There is a lower cell recovery compared to prefreeze processing, but the post-thaw processed samples do not undergo the potentially damaging osmotic shock that occurs with the infusion of cells cryopreserved in dimethyl sulfoxide (DMSO). Greater depletion of tumor cells can be achieved with combinations of CD34+ cell enrichment followed by depletion of tumor cells. Clinical trials of combination purging techniques are currently being conducted so the utility of this purging cannot be assessed at this time.

Microbial Contamination of PBSC Components

The incidence of culture-positive PBSC components is considerably less than that for marrow. [182] [183] [184] In the prospective study by Attarian et al. of 1,263 PBSC components from 376 sequential patients, bacteria were detected only in 3. [182] Most of these patients were treated with chemotherapy mobilization and about 50% were still receiving antibiotics for the treatment of neutropenic fevers at the time of apheresis. None of the components collected from the patients receiving antibiotics were culture positive. The collection of cells from febrile patients appears acceptable if the patient is clinically stable for apheresis, the timing of apheresis is appropriate as determined by enumeration of CD34+ cells in the blood, and the patient is receiving appropriate therapy. The collecting facility should arrange for microbial culture of the component. Skin flora are the bacteria usually isolated and contaminated components do not need to be destroyed. Infusion of these components is generally without clinical sequelae although serious infections have occurred after the infusion of components contaminated during processing. [182] [183] [184] [185] [186] [187] Any decision regarding the disposition of culture-positive HSC must be made by the patients transplant physician after considering the type of contamination, the anticipated risks from use of the component, and the ability to replace the culture-positive component(s) in a timely manner.

Quantification of CD34+ Cells

Quantification of CD34 antigen-positive cells by flow cytometry has become the standard of care for the management of the PBSC donor because it provides a rapid and clinically relevant assessment of HSC content in the peripheral blood or the PBSC component. This antigen is found on HSC and limited populations of other blood cells,[170] and it can be identified using a variety of commercially available antibodies. If antibodies directly conjugated with dyes are used, the technique requires only about an hour of preparation time. Cell viability using propidium iodide or 7-aminoactinomycin D exclusion can simultaneously be determined if the cells are analyzed while still fresh,[188] or the cells can be fixed after staining for analysis at a later date. Other antibodies may also be added for analysis of CD34 subsets if desired (and if the flow cytometer has proper detectors to detect the different emission wavelengths of the fluorochromes used). [25] Many centers are finding strong correlations between the numbers of CD34+ cells and CFU-GM in the sample, but with a ratio of about 520:1. [10] [189] Thus, CD34 analysis will provide data similar to that obtainable with cell cultures, with the exception that the latter demonstrate the viability of the progenitor cells.

The major difficulty with the analysis of CD34+ cells is the low frequency of these cells. Clinical decisions about the initiation of apheresis are being made at levels of

CD34+ cells as low as 10/l. This may represent a cell frequency that is 0.01% of the nucleated cells in the specimen. This enumeration is possible

because of the multidimensional measurements possible with the flow cytometer. Most cytometers can measure at least five characteristics of each cell including size, granularity, and the presence of up to three different fluorochromes. Thus, the cells of interest can be separated in five-dimensional space achieving discrimination of cells as rare as 1 in 10,000. The difficulties arise from developing an adequate technique that makes optimal use of the cytometer to measure these rare cells. Sources of errors include sampling of the component, cell counting, cytometer calibration and operation, choice of antibody and fluorochrome, lysis technique, and gating strategy. Skilled operators will avoid many of these errors by selecting appropriate antibodies and properly operating the cytometer. However, cytometry provides a proportion of cells and this must be multiplied by the cell count to obtain an absolute number. The steps involved in preparing a specimen for cytometry may alter the proportion of cells in the sample and this error will be translated into an error in the absolute number. [190] The direct relationship between the number of events (CD34+ cells counted) and the precision of this count dictates that large cell numbers be analyzed. [191] Serke et al.[191] found a coefficient of variation of 30% in counting of CFU-GM colonies and of 10% in flow cytometric counting of CD34+ cells. The coefficient of variation in CD34+ cell enumeration could be as high as 65% for specimens containing few cells. This variation was decreased by the analysis of larger cell samples. Clinically, this imprecision may explain some of the range in engraftment kinetics observed for patients receiving low doses of CD34+ cells.

A variety of different cytometry techniques are used in measuring CD34+ cells. These may involve only one antibody although other techniques use two antibodies to obtain better discrimination between the CD34+ and CD34 cells. [192] [193] [194] Gating on cells that are CD45+ helps separate nucleated cells from RBC, platelets, and debris, a step that is otherwise performed using the light scatter characteristics of the cells. [194] Alternately, gating on CD14 cells allows the separation of CD34+ cells from monocytes that nonspecifically bind the CD34 antibody. However, there is considerable variation in results even between laboratories using the same cytometry technique, and no cytometer-based technique has proven to have a lower interlaboratory variability. [193]

Subset analysis will provide additional information but does not appear to be clinically useful at this time. For example, Dercksen et al. [195] reported better correlation between the number of CD34+CD33 cells and time to granulocyte engraftment and between the number of CD34+CD41+ cells and time to platelet engraftment than found with the overall number of CD34+ cells. This group reported a similar finding for the number of CD34+ L-selectin+ cells infused and platelet engraftment. [196] Given the limited range in recovery times when adequate numbers of CD34+ cells are collected and infused, however, this additional information is of limited clinical value.

There is considerable disagreement about which flow cytometry technique is best for the measurement of CD34+ cells. Any particular technique may have advantages over the others in specific settings, but no technique will be adequate if the cytometer is not calibrated and is not clean, if adequate events are not obtained for analysis, and if a uniform gating strategy is not followed. These issues will become moot with the development of automated devices that provide quick and reproducible enumeration of CD34+ cells, leaving the flow cytometer for research use. The ideal technique will provide an actual count of CD34+ cells (instead of a percentage) and be sensitive to CD34+ cell levels at least as low as 10/l (levels below this are generally not clinically relevant). Single platform devices that provide an actual count of CD34+ cells are being evaluated. [197] [198] It may be possible to adapt some hematology analyzers to this purpose. [199]

Progenitor Cell Cultures

Hematopoietic progenitor cells committed to granulocytic, erythroid, or mixed granulocytic and erythroid lineages can be identified using a variety of culture techniques. These techniques require expertise and equipment not available in many clinical laboratories and have other drawbacks that may limit their utility as routine quality control. Other than availability of equipment and expertise, the major limitation is that progenitor cell assays require 1014 days of culture before the results are available. Thus, progenitor cell cultures cannot be used in the day-to-day management of the PBSC donor. No standard culture technique has been adopted by all laboratories, complicating comparisons between laboratories of progenitor cell quantities harvested and infused. The clinical relevance of the culture technique to the transplant population must be determined if the data obtained are to be used in the management of individual patients.

Unlike other measures of component quality, progenitor cell cultures also demonstrate the functional capacity of the cells. Progenitor cell cultures are the only currently available relevant assay of HSC viability other than actual engraftment of the recipient and should be available at the PBSC processing facility for use in quality control or if questions about the viability of a particular component are raised.

Cryopreservation

Hematopoietic stem cells harvested from the peripheral blood, bone marrow, or umbilical cord blood are frozen and stored using the same techniques. The general parameters include cryopreservation in DMSO and a source of plasma protein with or without hydroxyethylstarch, cooling at 13°C/min, and storage at 80°C or colder. [200] Variations on this technique include the concentration at which the cells are frozen, the amount and source of the plasma protein, and the cooling techniques used. [201] [202] Most of these variations probably have little effect on the survival of the HSC as shown by the consistent engraftment of cryopreserved components. However, cryopreservation results in the loss of an undefined but potentially substantial proportion of HSC, and delay in engraftment can occur if the component being frozen has borderline quantities of HSC. [203] [204] There is also a considerable incidence of generally minor toxicity associated with the infusion of cryopreserved cells that must be considered when developing cryopreservation techniques. [205]

Peripheral blood stem cell components differ from marrow components because of the much larger cell quantity, frequently exceeding 4×10^{10} cells found in peripheral blood. Cryopreservation of these cells at a set cell concentration, especially if multiple days of collection are performed, may result in large volumes of cryopreserved material to be infused. DMSO itself has a variety of pharmacologic effects, [206] which may be compounded by the presence of lysed blood cells, foreign proteins from tumor cell-purging procedures, or contaminants from nonpharmaceutical grades of reagents used in the processing. The LD_{50} values (amount of DMSO required to kill 50% of test animals) reported for intravenous infusion of DMSO are 3.19.2 g/kg for mice and 2.5 g/kg for dogs. [207] The acute toxic dose of DMSO for humans has not been determined. A recent report cited two instances of encephalopathy after the infusion of cryopreserved PBSC components. [208] The components for both patients were cryopreserved with a final DMSO concentration of 10%. The volumes infused were 2,254 ml and 1,198 ml, containing 249.7 g and 132.7 g DMSO, respectively. Patient weights were not provided in this report, but the dosage of DMSO probably neared or exceeded 2 g/kg patient weight, at least for the first patient. For this reason, the volume of DMSO infused should be limited to 1 g/kg/day. Patients with larger volumes can receive the cells over >1 day.

Cryopreservation of these cells at the concentrations frequently used for marrow (510×10^{7} nucleated cells/ml) could result in component volumes in excess of 400 ml for each collection. To minimize the volume infused, PBSC may be concentrated before cryopreservation. In one series, the average cell concentration of cryopreserved PBSC was 5.59×10^{8} nucleated cells/ml. [209] High concentrations of RBC and platelets were also frozen. No detrimental effect of cryopreservation at these high cell concentrations on the recovery of nucleated cells, mononuclear cells, or CD34+ cells was found. No clinical studies have addressed the effect of cell concentration on engraftment speed or toxicity of infusion. Of concern, however, is that about 12 patients of several hundred infused at that center developed alterations in mental status including seizures after infusion of PBSC concentrated before cryopreservation (unpublished observations). It is very unlikely these events were related to the small volumes of DMSO infused.

Alternately, the cells can be washed after thawing, with removal of most of the DMSO. [210] The risk is again one of cell loss and it is preferable, if possible, that a strategy be adopted to ensure that not all cells are at risk during a single processing. An effect of post-thaw washing on the speed or success of engraftment after infusion of marrow or PBSC components has not been published. However, investigators at Duke University reported much more rapid engraftment of cord blood components if the cells are washed after thawing. [211] This observation may result from protection of the cells from the extreme osmotic shock occurring during infusion of cells contained in high concentrations of DMSO.

Chapter 93 - Graft-versus-Host Disease and Graft-versus-Leukemia Effect

James L.M. Ferrara

INTRODUCTION

The ability of allogeneic stem cell transplantation (SCT) to cure leukemia is widely recognized. An important therapeutic aspect of SCT in eradicating malignant cells is the graft-versus-leukemia (GVL) effect. The importance of the GVL effect in allogeneic SCT has been recognized since the earliest experiments in stem cell transplantation. Forty years ago Barnes and colleagues noted that leukemic mice treated with a subtherapeutic dose of radiation and a syngeneic (identical twin) graft transplant were more likely to relapse than mice given an allogeneic stem cell transplant. [1] [2] They hypothesized that the allogeneic graft contained cells with immune reactivity necessary for eradicating residual leukemia cells. They also noted that recipients of allogeneic grafts, though less likely to relapse, died of a wasting syndrome now recognized as graft-versus-host disease (GVHD). Thus, in addition to describing GVL, these experiments highlighted for the first time the intricate relationship between GVL and GVHD. Since these early experiments, both GVHD and the GVL effect have been studied extensively, particularly in murine models of transplantation (reviewed by Porter and Antin [3] and Truitt et al. [4]). This chapter reviews the pathophysiology of GVHD and summarizes current understanding of the relationships between GVHD and the GVL effect.

GRAFT-VERSUS-HOST DISEASE: CLINICAL AND PATHOLOGIC ASPECTS

Ten years after the work of Barnes and Loutit, Billingham formulated the requirements for the development of GVHD: the graft must contain immunologically competent cells, the recipient must express tissue antigens that are not present in the transplant donor, and the recipient must be incapable of mounting an effective response to destroy the transplanted cells.[5] According to these criteria, GVHD can develop in various clinical settings when tissues containing immunocompetent cells (blood products, bone marrow, and solid organs) are transferred between persons. The most common setting for the development of GVHD is following allogeneic SCT; without prophylactic immunosuppression, most allogeneic SCTs will be complicated by GVHD.

Acute Graft-versus-Host Disease

Acute GVHD can occur within days (in recipients who are not HLA-matched with the donor or in patients not given any prophylaxis) or as late as 2 months after transplantation. The incidence ranges from less than 10% to more than 80%, depending on the degree of histoincompatibility between donor and recipient, number of T cells in the graft, patients age, and GVHD prophylactic regimen.[6] The principal target organs include the immune system, skin, liver, and intestine. GVHD occurs first and most commonly in the skin as a pruritic maculopapular rash, often on the palms, soles, and ears; frequently it progresses to total-body erythroderma, with bullae formation, rupture along the epidermal-dermal border, and desquamation in severe cases. Gastrointestinal (GI) and liver manifestations often appear later and rarely represent the first and only findings. Intestinal symptoms include anorexia, nausea, diarrhea (often bloody), abdominal pain, and paralytic ileus. Liver dysfunction includes hyperbilirubinemia and increased serum alkaline phosphatase and aminotransferase values. Coagulation studies and the bleeding time may become abnormal, and hepatic failure with ascites and encephalopathy may develop in severe cases. Hepatic GVHD can be distinguished from hepatic veno-occlusive disease by weight gain or pain in the right upper quadrant in the latter. Acute GVHD also results in the delay of immunocompetence. The clinical result is profound immunodeficiency and susceptibility to infections, often further accentuated by the immunosuppressive agents used to treat GVHD.

Pathologically, the sine qua non of acute GVHD is selective epithelial damage of target organs.[7] The epidermis and hair follicles are damaged and sometimes destroyed. Small bile ducts are profoundly affected, with segmental disruption. The destruction of intestinal crypts results in mucosal ulcerations that may be either patchy or diffuse. Other epithelial surfaces, such as the conjunctivae, vagina, and esophagus, are less commonly involved. A peculiarity of GVHD histology is the frequent paucity of mononuclear cell infiltrates; however, as the disease progresses the inflammatory component may be substantial. Recent studies have identified inflammatory cytokines as soluble mediators of GVHD and have suggested that direct contact between target cells and lymphocytes may not be required for the destruction of the target cell (see following sections). There is also a histologic geography of GVHD lesions within target tissues. In the skin, damage is prominent at the tip of rete ridges; in the intestine, at the base of the crypts; and in the liver, in the periductular epithelium. These areas contain a high proportion of stem cells, giving rise to the idea that GVHD targets may be undifferentiated epithelial cells with primitive surface antigens.[8]

The histologic severity of a given lesion is at best semiquantitative,

TABLE 93-1 -- Clinical Classification of Acute GVHD[a]

Organ Involved	Symptoms
Skin	Maculopapular or diffuse erythematous rash that may progress to desquamation
Liver[b]	Elevation of serum bilirubin alone or combined with increased serum activity of hepatic enzymes
Intestinal tract[c]	Diarrhea with or without nausea and vomiting, pain, or ileus

Summary based on Thomas et al.,[25ε] Deeg and Cottler-Fox,[6] and Vogelsang.[25g]

[a]Clinical grading generally considers involvement of skin, liver, and intestinal tract along with performance status on a semiquantitative basis (1+ to 4+). Other manifestations such as conjunctivitis and mucositis are not included in current clinical classification schemes. Overall severity ranges from mild skin involvement only (grade I) to severe multiorgan involvement, usually with fatal outcome (grade IV).
[b]In the presence of veno-occlusive disease, accurate staging of liver GVHD may be difficult or impossible.
[c]Concurrent gastroenteritis of infectious origin may make the diagnosis of GVHD difficult.

and consequently pathologic findings are not used in the grading of GVHD. Standard grading systems generally include clinical changes in the skin, GI tract, liver, and performance status (Table 93-1). Although the severity of GVHD is often difficult to quantify, the overall grade correlates with disease outcome. Although mild GVHD (grade I or II) is associated with little morbidity and almost no mortality, higher grades are associated with decreased survival. With grade IV GVHD, the mortality is almost 100 percent.

Chronic Graft-versus-Host Disease

Chronic GVHD was initially defined as a GVHD syndrome presenting more than 100 days after transplant, either as an extension of acute GVHD (progressive onset), after a disease-free interval (quiescent), or with no precedent (de novo).[9] Chronic GVHD may be limited or extensive (Table 93-2). Any grade of acute GVHD increases the probability of chronic GVHD, although no singular pathologic feature of the former predicts the development of the latter. Its incidence ranges from 30% to 60%, although it may be higher after peripheral blood progenitor transplants. As with acute GVHD, the immune system appears to be affected in all patients, who are highly susceptible to bacterial, viral, fungal, and opportunistic infections. Specific abnormalities of cellular immunity include decreases in the production of antibodies against specific antigens, defects in the number and function of CD4+ T cells, and increases in the number of nonspecific suppresser cells, which further diminish lymphocyte response. Eighty percent of patients have skin changes resembling widespread lichen planus with papulosquamous

TABLE 93-2 -- Grading of Chronic Graft-versus-Host Disease

Type of Disease	Extent of Disease
Limited	Localized skin involvement, liver dysfunction, or both

Extensive	Generalized skin involvement
	Localized skin involvement or liver dysfunction plus any one of the following:
	Chronic aggressive hepatitis, bridging necrosis, cirrhosis
	Eye involvement (results on Schirmers test, <5 mm)
	Involvement of mucosalivary glands
	Mucosal involvement (on lip biopsy)
	Involvement of other target organs

dermatitis, plaques, desquamation, dyspigmentation, and vitiligo. Destruction of dermal appendages leads to alopecia and onychodysplasia. Severe, extensive chronic GVHD later resembles scleroderma, with induration, joint contractures, atrophy, and chronic skin ulcers. Chronic cholestatic liver disease occurs in 80% of patients and often resembles acute GVHD; it rarely progresses to cirrhosis. Severe mucositis of the mouth and esophagus can result in weight loss and malnutrition. GI involvement, however, is infrequent. Chronic GVHD also produces a sicca syndrome, with atrophy and dryness of mucosal surfaces caused by lymphocytic destruction of exocrine glands, which usually affect the eyes, mouth, airways, skin, and esophagus. The hematopoietic system may also be affected, and thrombocytopenia is an unfavorable prognostic factor in patients with chronic GVHD. Important predictors of unfavorable outcome are progressive onset, lichenoid skin changes, elevated serum bilirubin level, continued thrombocytopenia, and failure to respond to 9 months of therapy. [10] [11] Among patients with none of these risk factors, 70% are expected to survive, compared with less than 20% with two or more of these risk factors.

Histologic examination of the immune system reveals involution of thymic epithelium, disappearance of Hassalls corpuscles, depletion of lymphocytes, and absence of secondary germinal centers in lymph nodes. [12] Pathologic skin findings include epidermal atrophy with changes characteristic of lichen planus and striking inflammation around eccrine units. Sclerosis of the dermis and fibrosis of the hypodermis subsequently develop. GI lesions include localized inflammation of the mucosa and stricture formation in the esophagus and small intestine. Histologic findings in the liver are often similar to those that occur in acute GVHD but are more intense, with chronic changes such as fibrosis with hyalinization of portal triads, obliteration of bile ducts, and hepatocellular cholestasis. The endocrine glands of the eyes, mouth, esophagus, and bronchi show destruction focused on centrally draining ducts, with secondary involvement of alveolar components. Findings of bronchiolitis obliterans, similar to those that occur in rejection of lung transplants, are now generally considered a manifestation of chronic GVHD, although their pathogenesis is controversial.

It has become apparent in recent years that the clinical and histologic changes considered characteristic of chronic GVHD can develop 40 or 50 days after transplantation. The time frames of acute and chronic GVHD thus overlap; hence, the time of onset is an arbitrary criterion. It is more meaningful to define the disease on the basis of clinical, histologic, and immunologic findings, although the point at which therapy for chronic GVHD is initiated may be important.

Syngeneic Graft-versus-Host Disease

A GVHD-like syndrome that is usually self-limited and predominantly affects the skin can occur in recipients of syngeneic or autologous transplants. [13] Although the level of severity may be grade II or III, the disease generally resolves promptly with the administration of glucocorticoids and is not life-threatening. Virtually all patients in whom a GVHD-like syndrome develops after syngeneic transplantation have been prepared with intensive conditioning regimens, usually involving irradiation. Experimental studies suggest that such conditioning is essential for the induction of thymic dysfunction, which is necessary for the development of the disease.

PATHOPHYSIOLOGY OF GRAFT-VERSUS-HOST DISEASE

Two important principles help to place the pathophysiology of GVHD in context. The first is that GVHD is not a disease per se; it reflects exaggerated but normal physiologic inflammatory mechanisms that occur in a setting where they are undesirable.

The donor lymphocytes that have been infused into the recipient function appropriately, given the foreign environment they encounter. The second principle is that in SCT, donor lymphocytes are infused into a host that has been profoundly damaged. The effects of the underlying disease, prior infections, and the intensity of a myeloablative conditioning regimen all result in substantial proinflammatory changes in endothelial and epithelial cells. Allogeneic donor cells rapidly encounter not only a foreign environment, but one that has been altered to promote the activation and proliferation of inflammatory cells by the increased expression of adhesion molecules, cytokines, and co-stimulatory proteins. The donor lymphocytes respond to these changes in a fashion that would usually promote the control or resolution of infection. Thus, the pathophysiology of GVHD may be considered a distortion of the cellular responses to viral and gram-negative bacterial infections. The unusual target organ distribution of GVHD supports the close relationship between infection and GVHD. Skin, gut, and liver all share an extensive exposure to endotoxin and other bacterial products that can trigger and amplify local inflammation. This exposure distinguishes them from organs that are not GVHD targets, such as the heart and kidneys. Both heart and kidneys are certainly susceptible to allogeneic cellular injury (e.g., they can be rejected), but they are virtually never target organs of GVHD. The lung is controversial in this regard. Although the lung is not a classic GVHD target, accumulating evidence suggests that it shares some degree of GVHD susceptibility with the skin, gut, and liver. [14] [15] Because of their situation as primary barriers to infection, these target organs have large populations of professional antigen-presenting cells (APCs), such as macrophages and dendritic cells, that may enhance the GVH reaction.

THE CYTOKINE HYPOTHESIS

Recent findings have demonstrated that inappropriate production of cytokines, which are the central regulatory proteins of the immune system, are a primary cause for the induction and maintenance of experimental and clinical GVHD. [16] [17] [18] Dysregulation of the complex cytokine networks that occurs in three sequential steps can be considered a framework for the pathophysiology of acute GVHD.

Phase One

The transplant conditioning regimen is an important determinant of acute GVHD because it damages and activates host tissues, including intestinal mucosa, liver, and other tissues, in a fashion that fosters the attraction and retention of white blood cells. Activated host cells secrete inflammatory cytokines, such as tumor necrosis factor-alpha (TNF-) and interleukin-1 (IL-1). [19] The presence of inflammatory cytokines during this phase may up-regulate adhesion molecules [20] and MHC antigens, [21] [22] [23] [24] [25] thereby enhancing the recognition of host MHC and/or minor histocompatibility agents by mature donor T cells that have been infused with the stem cell inoculum. This process is in accordance with the observation that the enhanced risk of GVHD after clinical SCT is associated with intensive conditioning regimens that cause extensive injury to epithelial and endothelial surfaces, with subsequent release of inflammatory cytokines and increased expression of cell-surface adhesion molecules. [26] [27] [28] The relationship between conditioning intensity, inflammatory cytokines, and GVHD severity has recently been further supported in animal models. [29] Moreover, the risk of inducing severe GVHD appears to be less if the lymphocytes are infused well after the primary tissue injury has resolved. GVHD certainly occurs when donor lymphocytes are infused to induce GVL effects, but there appears to be a time-dependent reduction in risk, suggesting that the late infusion of cells (after 3045 days) results in less GVHD. [30] [31] This reduction may also be due to the fact that by several months after transplantation, host APCs have been replaced, at least in part, with donor APCs.

Phase Two

The second phase of acute GVHD includes antigen presentation, activation of individual T cells, and proliferation and differentiation of responding T-cell clones (Fig. 93-1). These processes have been defined at both cellular and molecular levels. [32] During antigen presentation, large proteins are digested by APCs into smaller fragments; these antigenic peptides bind to HLA (class I or class II) molecules and are displayed on the surface of the APCs as peptide-HLA complexes. T cells recognize this complex via antigen-specific T-cell receptors. In allogeneic interactions such as GVHD, mature donor T cells recognize recipient peptide-HLA complexes (alloantigens) in which both the HLA molecules and the bound peptides may be foreign. These peptides, usually eight to ten amino acids in length, represent minor histocompatibility antigens (mHA) that are largely

Figure 93-1 Pathophysiology of GVHD. During step 1, irradiation and chemotherapy both damage and activate host tissues, including intestinal mucosa, liver, and the skin. Activated cell hosts then secrete inflammatory cytokines (e.g., TNF- and IL-1), which can be measured in the systemic circulation. The cytokine release has important effects on antigen presenting cells (APCs) of the host, including increased expression of adhesion molecules (e.g., ICAM-1, VCAM-1) and of MHC class II antigens. These changes in the APCs enhance the recognition of host MHC and/or minor H antigens by mature donor T cells. During step 2, donor T-cell activation is characterized by proliferation of GVHD T cells and secretion of the Th1 cytokines IL-2 and IFN-. Both of these cytokines play central roles in clonal T-cell expansion, induction of CTL and NK cell responses, and the priming of mononuclear phagocytes. In step 3, mononuclear phagocytes primed by IFN- are triggered by a second signal such as endotoxin (LPS) to secrete cytopathic amounts of IL-I and TNF-. LPS can leak through the intestinal mucosa damaged by the conditioning regimen to stimulate gut-associated lymphoid tissue or Kupffer cells in the liver; LPS that penetrate the epidermis may stimulate keratinocytes, dermal fibroblasts, and macrophages to produce similar cytokines in the skin. This mechanism results in the amplification of local tissue injury and further production of inflammatory effectors such as nitric oxide, which, together with CTL and NK effectors, leads to the observed target tissue destruction in the stem cell transplant host. CTL effectors use Fas/FasL, perforin/granzyme B, and membrane-bound cytokines to lyse target cells.

undefined, but strategies to identify them have recently been successful. [33] [34] [35] Host APCs also provide co-stimulatory activation signals by B7/CD28. [36] In addition to the T-cell receptor, accessory molecules such as CD4, CD8, LFA-1, LFA-2, and CD44 participate in effectortarget cell interactions by intensifying cellular contact and communication. [37] More recently the role of CD40/CD40L interactions has been defined as well. [38] [39] [40]

Alloantigen composition of the host determines which T-cell subset proliferates and differentiates. MHC class II (HLA-DR, DP, DQ) differences stimulate CD4+ T cells; MHC class I (HLA-A, B, C) differences stimulate CD8+ T cells. CD4 and CD8 proteins are co-receptors for constant portions of MHC class II and MHC class I molecules, respectively. In mouse models of GVHD, where genetic differences between multiple strain combinations can be controlled, CD4+ cells induce GVHD to MHC class II differences, and CD8+ cells induce GVHD to MHC class I differences. [41] Thus, both CD4+ and CD8+ T-cell subsets can initiate the afferent phase of GVHD. In the majority of clinical marrow HLA-identical transplants, GVHD may be induced by either subset or simultaneously by both.

Antigen presentation results in the activation of individual T cells. This process involves multiple, rapidly occurring intracellular biochemical changes, including a rise in cytoplasmic free calcium and activation of protein kinase C and tyrosine kinases, [42] [43] which in turn activates transcription of genes for cytokines, such as IL-2, IL-12, interferon- (IFN-) and their receptors. Cytokines produced in response to alloantigens are predominantly secreted by T helper 1 (Th1) subset of T cells, [44] [45] particularly when APCs actively secrete IL-12. [46] Both IL-2 and IFN- have long been implicated in the pathophysiology of acute GVHD (see below), and they play central roles in further T-cell activation and induction of cytotoxic T lymphocytes (CTLs) and natural killer (NK) cell responses. IFN- in particular is essential to the priming of donor and residual host mononuclear phagocytes to produce large amounts of IL-1 and TNF-. The T-cell activation phase is followed by clonal expansion and differentiation. DNA synthesis commences within 24 hours of antigen recognition and is maximal 35 days later. Functional differentiation then occurs as cells produce proteins required for specific effector functions, such as the protein esterases critical to CTLs. [47] The expression of many T-cell surface molecules is altered; receptors for lymphocyte homing and migration may be down-regulated, and other adhesion molecules (e.g., LFA-1) may be up-regulated, thus altering the T-cells trafficking patterns in vivo. [48]

While inflammatory effector functions of mononuclear phagocytes are stimulated by IL-2 and IFN- secreted by activated Th1 cell subsets (see below), these effector functions are inhibited by IL-4 and IL-10, cytokines that are produced by activated Th2 cells. There is now considerable evidence that the preferential expansion of Th2 T cells after allogeneic transplantation is associated with the development of a GVHD syndrome that is similar to chronic GVHD but is associated with less lethality and antibody formation in murine systems. [49] [50] [51] [52] [53]

Phase Three

The third phase of acute GVHD completes the complex cascade (Fig. 93-1). The initial hypothesis that the cytokine function of CTLs directly causes the majority of tissue damage and necrosis in GVHD targets appears to be too limited. [54] Large granular lymphocytes (LGLs) or NK cells appear to be prominent in the effector arm

of GVHD in several animal models, and they may contribute to the pathologic damage, that is, induce the changes of GVHD following the T-cell-mediated GVH reaction.[54] [55] LGLs do not recognize HLA proteins as targets, but they can be recruited and activated by cytokines secreted by T cells. The precise relationship between cytokines induced during the second step and mediators of tissue damage during this third step is an area of active investigation. Mononuclear phagocytes, which have been primed by IFN-, are triggered by a second signal to secrete TNF- and IL-1. This stimulus most frequently is lipopolysaccharide (endotoxin, LPS), which can leak through intestinal mucosa damaged by the conditioning regimen and subsequently stimulate gut-associated lymphocytes and macrophages. [56] LPS reaching skin tissues may also stimulate keratinocytes, dermal fibroblasts, and macrophages to produce similar cytokines in the dermis and epidermis. [57] [58] [59] TNF- can cause direct tissue damage through apoptosis, or programmed cell death. The induction of apoptosis commonly occurs after activation of the TNF-/Fas antigen pathway.[60] Apoptosis is a critical process in GVHD of the GI tract, [61] skin,[62] [63] and possibly endothelial cells [64] after allogeneic SCT. In addition to these proinflammatory cytokines, excess nitric oxide produced by activated macrophages may contribute to the deleterious effects on GVHD target tissues, particularly immunosuppression.[65] [66] [67] Induction of these inflammatory mediators thus synergizes with the cellular damage caused by CTLs and NK cells, [54] [68] resulting in the amplification of local tissue injury and further promotion of an inflammatory response that ultimately leads to target tissue destruction and systemic GVHD in the stem cell transplant host.

Although cytokines play important roles in the morbidity and mortality of systemic GVHD, their relative importance as mediators of damage in GVHD target organs is much less well established. The unusual cluster of GVHD target organs (skin, gut, and liver) is not adequately explained by the systemic release of cytokines. For example, intravenous infusion of TNF- and IL-1 does not cause the lymphomononuclear cell infiltration of the liver and skin that is observed in GVHD. Further, the absence of GVHD toxicity in other visceral organs, such as the kidney, argues against circulating cytokines as the sole cause of tissue-specific damage. The infiltrates seen in GVHD target organs are generally thought to contain T cells responding to alloantigens on host tissues. As mentioned above, LPS leakage through skin or mucosa may act as an adjuvant to the antigens expressed in these tissues, attracting and activating alloreactive donor T cells. A second possibility is that tissue-specific neoantigens are expressed at these sites as the result of ongoing inflammation. Such inflammation may alter the ligands for homing receptors on T cells (e.g., selectins) that enable them to traffic into specific tissues.

In experimental systems, cellular effectors contribute to GVHD (Tables 93-3 , 93-4). The application of gene knockout technology and the identification of pertinent mutant mice strains have provided important tools to dissect these effector mechanisms. Three pathways can be considered as important to GVHD effectors: the perforin/granzyme B pathway, the Fas/FasL pathway, and direct cytokine-mediated injury. Direct cellular cytotoxicity through the perforin/granzyme B pathway is mediated in two ways. Perforin causes membrane pore formation but it is not adequate to cause apoptosis on its own. [69] Granzyme B enters the cell through the perforin-derived pore and causes apoptosis. Granzyme B is particularly important to

TABLE 93-3 -- Cellular Effects of Graft-versus-Host Disease and Graft-versus-Leukemia Effect

CD4 T cells
Th1associated with GVHD/GVL
Th2do not cause acute GVHD, may suppress GVHD/GVL

[a]Have direct effects on target or systemic tissues and indirect effects by activating effector cells and facilitating the production of other inflammatory cytokines.

GVHD induced by MHC class I mismatches, and is less critical in GVHD resulting from MHC class II mismatches, mediated by CD4+ cells. [70] Donor cells from both perforin-deficient and granzyme B-deficient knockout mice can mediate GVHD, but the onset of clinical manifestations is significantly delayed compared with that in control animals. This delay suggests that the perforin/granzyme pathway is an early-acting mechanism, but that an additional late mechanism of cytotoxicity exists. [71] [72] One candidate for a late-acting mechanism is the Fas/FasL interaction. [73] [74] [75] Fas is expressed on numerous cell types, [76] while Fas ligand (FasL) is expressed on activated T cells. Interactions between a Fas-bearing target and a FasL-bearing T cell result in apoptosis of the target cell. Thus, a setting where FasL molecules are up-regulated by cytokines may result in destruction of both specific targets and nonspecific, innocent bystanders that express Fas. When mutant mice that are deficient in FasL (*gld*) are used as stem cell donors, GVHD is attenuated; hepatic and some cutaneous GVHD occurs, but the mice develop cachexia and eventually die.[72] When Fas-deficient mice are crossed with those having perforin or granzyme B knockouts, the use of lymphocytes from these donors further diminishes, but does not eliminate, GVHD. Thus, neither FasL nor perforin is necessary for GVHD, and in the absence of both cellular effectors, GVHD can still occur, suggesting a third pathway for target cell apoptosis. [77] Cytokines such as TNF- are an attractive candidate for this pathway. [71] [78] Metalloproteinase inhibitors, which reduce shedding of both TNF- and FasL by effector cells, suppress both clinical GVHD manifestations and mortality in a murine model of acute GVHD. [79] A recent detailed analysis of a patient with transfusion-associated GVHD supports the hypothesis of multiple effectors in human GVHD. [80]

This conceptual framework of three sequential and interlocking steps helps to explain a number of unique and seemingly unrelated aspects of GVHD. For example, a number of analyses of clinical transplants have noted an increased risk of GVHD associated with advanced-stage leukemia, certain intensive conditioning regimens, and viral infections. [26] [27] [28] Similarly, the reduction in GVHD rates seen in gnotobiotic mice [81] [82] and in patients with aplastic anemia undergoing transplantation in laminar air flow environments with GI tract decontamination[83] may be explained by the reduction of bacterial LPS on the skin and gut. The beneficial effect of protective environments may be less apparent in patients undergoing transplantation for malignancies, because prior therapy and associated infections may have already resulted in an environment that facilitates GVHD. Viral infections are more frequent in patients with GVHD and may trigger the onset of GVHD or worsening of established GVHD. Cytomegalovirus has a particularly close relationship with GVHD, [84] [85] [86] [87] as does herpes simplex virus[88] [89] [90] and possibly human herpesvirus-6.[91] The precise pathophysiology of these connections remains uncertain. Although it has been hypothesized that viral antigen expression on target cells might function as mHAs, direct evidence for this association is lacking. Certainly, viral damage to the intestine or liver may increase the permeability of those organs to bacterial products such as LPS. Alternatively, GVHD targets could be innocent bystanders of virus-induced activated T-cell or NK cell attack. [92] [93] Finally, viral infections may perhaps flare as a result of the intrinsic immunosuppression of GVHD (or of additional immunosuppressive therapy) and may not cause GVHD.

Cytokines

Th1 Cytokines

Th1 cells produce IL-2 and have a pivotal role in controlling and amplifying the immune response against alloantigens, representing step two of the cytokine cascade of acute GVHD (Fig. 93-1). Experimental data show that maximal levels of IL-2 are produced by donor CD4+ T cells in the first 2 days after GVHD induction, with

lower levels observed in splenocytes from GVHD mice until 710 days post transplantation. [94] A similar early and transient increased expression of IL-2 during GVHD was demonstrated in murine GVHD models using RT-PCR techniques for detection of IL-2 mRNA. [50] [95] The addition of low doses of IL-2 during the first week after allogeneic BMT enhanced the severity and mortality of GVHD. [96] [97] [98] The precursor frequency of host-specific IL-2-producing T cells (pHTLs) in the donor predicts the occurrence of GVHD after transplantation between HLA-identical siblings. [99] [100] [101] The critical precursor frequency of host-specific pHTLs seems to be approximately 1/100,000. Patients whose donor bone marrow contained fewer host-specific pHTLs later developed only grade 01 GVHD, whereas patients whose donor bone marrow contained greater frequencies all developed significant, grade II or III GVHD. pHTL cells were detectable as early as day 20 after transplantation, often preceding the onset of acute GVHD by approximately 2 weeks, and persisted until the GVHD resolved.

The primary role of IL-2 likely includes the induction of other cytokines and recruitment of effector cells. [102] Owing to their apparent importance in initiating acute GVHD, IL-2-producing donor T cells have been the target of many experimental designs to control GVHD. The administration of cyclosporine, a powerful inhibitor of IL-2 production, is effective prophylaxis against GVHD. [103] [104] The importance of IL-2 is further underscored by experiments showing that monoclonal antibodies against the IL-2 receptor (IL-2R) are efficient in preventing GVHD in animals or in clinical GVHD when administered shortly after the infusion of T cells. [105] [106] Several studies have shown promising results of monoclonal antibodies directed against IL-2R; in those studies, between 28% and 73% of patients with steroid-resistant GVHD responded. [106] [107] [108] [109] [110] [111] However, a randomized multicenter trial of unrelated donor transplantation did not demonstrate a benefit to the use of humanized anti-Tac when given as prophylaxis. [112] Interestingly, brief administration of high doses of exogenous IL-2 early after SCT protected animals from GVHD mortality. [113] This protective effect, which was augmented by the co-transplantation of syngeneic bone marrow, was not associated with a decrease in either alloengraftment or a GVL effect. [113] [114] [115] Exogenous IL-2 may mediate its protective effect via inhibition of other cytokines, such as IFN-, [116] although this phenomenon has not been well studied in human transplantation.

IFN- is a second Th1 cytokine that is critical to the pathophysiology of acute GVHD. When a method to enumerate cytokine mRNA-containing cells that combined limiting dilution analysis (LDA) and PCR amplification of cDNA was used, IFN- secretion was found to be greatly increased during experimental GVHD. [49] [117] In several models of experimental acute GVHD, lymphocytes produce large amounts of IFN- when restimulated in vitro with mitogen or TCR cross-linking, in contrast to lymphocytes from syngeneic SCT or recipients after T-cell-depleted SCT. [117] [118] [119] [120] [121] [122] During clinical GVHD, a large proportion of T-cell clones isolated from patients also produce IFN-. [123] Increased serum levels of IFN- have also been found after SCT, but the increase was not dramatic, and in a small

number of patients studied, there were no significant differences between patients with and without GVHD. [124]

In vitro, IFN- can directly produce cytopathic effects of GVHD in skin tissue damage. [125] IFN- also mediates GVHD pathology in the GI tract, and the addition of an anti-IFN- monoclonal antibody prevents this damage. [126] Because the expression of MHC molecules is induced by IFN-, it is possible that an increase in these molecules during GVHD [127] might make epithelial target cells in the gut more susceptible to lysis by cytotoxic T cells. [128] Finally, IFN- induces the generation of the nitric oxide, which appears to mediate the suppression of lymphocyte proliferation in several experimental GVHD systems. [118] [129] [130] [131] [132]

The synergy of IFN- with LPS in the activation of mononuclear phagocytes to produce proinflammatory cytokines [133] [134] plays a central role during acute GVHD. A classic study by Nestel and colleagues showed that IFN- is sufficient to produce macrophage priming during a parental to offspring (PF_1) GVHD model. The subsequent administration of LPS to host mice then causes death owing to the increased systemic production of IFN- by macrophages. [56] Recent data have confirmed these observations and demonstrated that the inhibition of IFN- during GVHD by injection of polarized donor T cells (which secrete IL-4 but not IFN-) results in the down-regulation of LPS-triggered TNF- production and reduces GVHD-related mortality. [120] Interestingly, the induction of Th1 cells in humans as measured by expression of the $_2$ chain of the IL-12 receptor is stimulated by IFN- but not by IFN-, suggesting that IFN- may be an important signal for polarity switching. [135] [136] On the other hand, administration of IFN- after marrow grafting does not seem to increase the risk of GVHD. [137] Thus, the relative importance of various IFNs to human GVHD requires further study.

In an interesting set of experiments, injection of IFN- prevented the development of experimental GVHD. [138] These results were surprising because, according to the findings described above, one would expect IFN- to promote rather than to counteract GVHD. These unexpected results may be due to the diametrically opposing effects of local versus systemic actions of IFN-. In addition, IFN- administration early in BMT probably activates residual host elements, such as NK cells, which suppress the activation of donor T cells secreting IFN-, in a manner similar to IL-2s reduction of GVHD (detailed previously).

Th2 Cytokines

The balance of Th1 (IL-2 and IFN-) and Th2 (IL-4 and IL-10) T-cell cytokines in vivo early after BMT may be a critical factor in the development of a systemic inflammatory response in GVHD. Th1 cytokines are associated with the activation of macrophages, the secretion of inflammatory cytokines, the activation of NK and CTL cells, and enhanced production of antibodies of the IgG2a isotope, whereas Th2 cytokines are generally associated with down-regulation of cell-mediated immune responses and enhancement of IgE and IgG1 secretion. A Th1Th2 shift of T-helper cells can down-regulate cell-mediated immune responses and inflammatory processes.

In two recent studies, IL-10 was tested for its use as a prophylactic treatment for the development of severe acute GVHD, but the data have been largely negative. [119] [139] Because IL-4 is more important than IL-10 in directing the Th0 precursor T cells toward a Th2 phenotype, [140] the administration of IL-4 to prevent GVHD has also been tested. Intraperitoneal injections of rIL-4 led to an increase in the severity of GVHD and to enhanced late mortality in a fully allogeneic SCT model. [141] Recipients of IL-4 showed the same histopathologic changes in skin and liver as mice receiving no cytokine. Thus, direct administration of type 2 cytokines appears to be either ineffective or toxic.

Recently, new approaches that encompass a Th1Th2 shift in the cytokine profile of donor T cells prior to SCT have emerged to provide a new way to interrupt the amplification cascade after the allogeneic transplantation. Fowler and co-workers treated donor mice in vivo with a combination of human rIL-2 and murine rIL-4 and were able to generate CD4+ enriched splenic populations with a Th2 cytokine pattern that down-regulated subsequent GVHD. [142] [143]

The pre-incubation of donor T cells in the presence of murine rIL-4 ex vivo during a primary MLR culture to alloantigens also polarized T cells toward a Th2 cytokine phenotype. [120] Transplantation of these polarized Th2 T-cell populations failed to induce acute GVHD to MHC class I or class II antigens. Of great interest are studies of peripheral blood hematopoietic cells collected after mobilization with granulocyte colony-stimulating factor (G-CSF), which suggest that Th1Th2 polarization occurs in lymphocytes exposed to G-CSF. Pretreatment of murine blood cells with G-CSF resulted in less GVHD than in saline-treated controls. [144] [145] [146] This may reflect a change in cellular polarization or alterations in the production of other inflammatory cytokines such as TNF-. [147]

Inflammatory Cytokines

Murine BMT models have provided the strongest evidence of a link between excessive production of inflammatory cytokines and clinical GVHD, and demonstrate that activated macrophages play a key role in the process. [148] TNF- is an inflammatory cytokine that causes an extremely wide variety of biologic effects, including the induction of direct tissue injury and metabolic alterations in muscle and fat tissues leading to cachexia characterized by anorexia and weight loss that ultimately leads to death. [149] [150]

A critical role for TNF- in the pathophysiology of acute GVHD was first suggested by Piguet and colleagues, who observed that mice transplanted with mixtures of allogeneic bone marrow and T cells developed severe skin, gut, and lung lesions that were associated with high levels of TNF- mRNA. [151] [152] Subsequently, the presence of TNF- mRNA was also demonstrated in the skin of mice with GVHD induced to mHAs. [153] Target organ damage could be inhibited by infusion of anti-TNF- antibodies, and mortality could be dramatically reduced by administration of the soluble form of the TNF- receptor, an antagonist of TNF-. [19] More recent data employ the strategy of preventing macrophage shedding of TNF- with metalloproteinase inhibitors, which also reduces the manifestations of acute GVHD. [79] The role of TNF- in GVHD has been elucidated using an experimental murine GVHD model with unirradiated recipients. [56] Injury to the GI tract enables bacterial breakdown products like LPS to enter the circulation and trigger release of cytokines from mononuclear phagocytes throughout the body. It has long been known that pathogen-free mice are protected from GVHD after allogeneic SCT and that recolonization with gram-negative bacteria in the gut leads to increased GVHD severity. [81] [82] [154] The anatomic localization of macrophages to gut-associated lymphoid tissue and the ability of endotoxin to trigger inflammatory cytokine release together provide the most persuasive explanation for the ability of gut decontamination to prevent systemic GVHD.

An important role for TNF- in clinical acute GVHD has been suggested by studies demonstrating elevated levels of TNF- in the serum of patients with acute GVHD and other endothelial complications such as veno-occlusive disease. [155] [156] Importantly, the time of the first appearance of the increased levels was predictive of the severity of regimen-related toxicity and of overall survival. Monoclonal antibodies or F(ab) $_2$ fragments directed at TNF- have been studied either as therapy for steroid-resistant GVHD[157] or for prophylaxis. [158] Although several partial responses were observed, in the majority of patients GVHD flared after discontinuation of treatment. The

prophylactic trial of anti-TNF- monoclonal antibodies showed a delay in the onset of acute GVHD compared with the time of onset in historical controls, but showed only a small decrease in the rate of GVHD. These preliminary data, along with results from animal and laboratory studies, suggest that approaches to limit TNF- secretion will be an important avenue of investigation in SCT.

The second major proinflammatory cytokine that appears to play an important role in the effector phase of acute GVHD is IL-1. This cytokine is mainly produced by activated mononuclear phagocytes and shares with TNF- a wide variety of biologic activities. [159] Secretion of IL-1 appears to occur predominantly during the effector phase of GVHD in the spleen and skin, two major GVHD target organs.[160] A similar increase in mononuclear cell IL-1 mRNA has been shown during clinical acute GVHD.[161] Indirect evidence for a role of IL-1 in GVHD was obtained with administration of this cytokine to hosts in an allogeneic murine SCT model; recipients displayed a wasting syndrome and increased mortality that appeared to be an accelerated form of disease. [141] Investigations of the role of IL-1 in GVHD intensified with the discovery of IL-1 receptor antagonist (IL-1RA). [162] [163] In a murine model of GVHD to multiple minor H antigens, intraperitoneal administration of IL-1RA for 10 days after SCT prevented the development of GVHD in the majority of animals.[153] Two Phase I/II trials have studied specific inhibition of IL-1 in steroid-resistant GVHD.[164] [165] In the first trial, recombinant human IL-1RA was administered to patients with severe GVHD, with an overall response rate of 63%. Since IL-1RA has no intrinsic agonist activity and functions solely as a competitive inhibitor of both IL-1 and IL-1, the observed responses were directly related to decreased activity of IL-1. A subsequent trial using soluble recombinant human IL-1 receptor observed a 57% overall response rate. Taken together, these data strongly suggest that IL-1 is a critical mediator of GVHD.

Additional agents may have immunomodulatory properties whose mechanism of action involves altering the balance of inflammatory and anti-inflammatory proteins. The observation that -globulin administration can ameliorate GVHD [166] may be explained in part by the effects of -globulin on the up-regulation of IL-1RA and soluble TNF receptor.[167] When IgG is bound to macrophages, IL-1RA production is preferentially increased over that of IL-1. [168] Exogenously administered IgG may thus directly modulate the cytokine dysregulation during GVHD.

Interleukin-8 (IL-8), also called neutrophil-activating peptide (NAP-1), may also play a role in GVHD. IL-8 is produced in response to proinflammatory mediators such as endotoxin, IL-1, and TNF-, and its systemic administration inhibits the adhesion of leukocytes to endothelial surfaces. A recent study reports that among patients receiving stem cell transplant for -thalassemia, those with GVHD had significantly higher IL-8 blood levels than those without GVHD. [169] IL-8 may contribute to the immunocompromised status of patients who are already vulnerable to infections because of the underlying GVHD and its treatment. An interesting implication of this observation, which is consistent with the cytokine hypothesis, is that granulocytes and macrophages may contribute to GVHD pathology. Most GVHD occurs after leukocyte recovery. This fact is typically interpreted to reflect the time necessary for lymphocytes to expand to a critical mass. However, it might equally suggest that the inflammatory cytokine network has similar activation and recruitment effects on neutrophils, and that these newly produced cells follow chemotactic signals to injured epithelium, where they contribute to tissue injury by releasing activated oxygen metabolites as well as cytotoxic and proteolytic enzymes.

Chronic Graft-versus-Host Disease

Chronic GVHD is often considered an autoimmune disease because of distinctive similarities to various autoimmune disorders, especially collagen vascular disease. The relationship is difficult to prove clinically, but experimental studies have demonstrated an autoimmune aspect of chronic GVHD pathophysiology. [170] In contrast to T cells from animals with acute GVHD, which are specific for host alloantigens, T cells from animals with chronic GVHD are specific for a public (common) determinant of MHC class II molecules.[171] [172] These T cells are considered autoreactive because they recognize common class II molecule determinants rather than polymorphic major or minor histocompatibility antigens. The autoreactive cells of chronic GVHD are associated with a damaged thymus, which can be injured by acute GVHD, the conditioning regimen, or by age-related involution and atrophy. The normal ability of the thymus to delete autoreactive T cells and to induce tolerance may thus be impaired. Thymic damage may also help to explain syngeneic GVHD, where autoreactive T cells have been identified as well. The pathophysiology of chronic GVHD is generally much less well understood than that of acute GVHD and has undergone less intensive experimental modeling.

Syngeneic Graft-versus-Host Disease

In experimental models, pathologic changes of GVHD have been observed in animals transplanted with stem cells from genetically identical donors (or even with autologous stem cells), findings that substantiated reports of GVHD between identical twins described nearly two decades ago. [173] [174] In optimal models, syngeneic GVHD appears to be mediated by autoreactive lymphocytes directed at MHC class II proteins. Autoreactive T cells are thought to develop in a severely damaged thymic medulla, where MHC class II-bearing cells are deficient or absent. T cells thus escape the usual negative selection (clonal deletion) within the thymus and migrate to the periphery, where they trigger or mediate target organ damage. Other regulatory lymphocytes that would normally inactivate or eliminate such autoreactive cells have themselves been eliminated by total-body irradiation (as part of the preparative regimen). The experimental transfer of normal lymphocytes to these irradiated hosts restores the regulatory mechanism and prevents the autoaggressive process. The effects of cyclosporine are important in these models, particularly with respect to the damage that cyclosporine inflicts on the thymic medulla. [175] Syngeneic GVHD can thus be seen as an imbalance between autoreactive and autoregulatory lymphocytes, an imbalance that results from thymic dysfunction. In experimental animals, cutaneous pathologic findings of syngeneic and chronic GVHD are similar, and it appears that the efferent arms of syngeneic and chronic GVHD are similar if not identical. These observations further the perception of chronic GVHD as an autoimmune disorder.

GRAFT-VERSUS-LEUKEMIA EFFECT

Experimental data show tight linkage between GVHD and the GVL effect, although these entities were separable under some circumstances. There is now substantial evidence that allogeneic stem cell transplantation in humans is associated with a potent GVL reaction, particularly in patients with chronic myelogenous leukemia (CML). Until recently, the evidence for this GVL effect was based on several important but indirect clinical observations. Several case reports of patients with relapse of leukemia after allogeneic SCT noted remissions of the malignancy either on abrupt withdrawal of immunosuppression [176] [177] [178] or during a flare of acute GVHD. [179] These reports provide the rationale for abrupt discontinuation of immunosuppressive therapy to induce a GVL reaction for patients who relapse after SCT, but it is likely that the majority of such patients will not re-enter remission. Further evidence that the donor graft mediates important antileukemic effect comes from observations that relapse rates for recipients of syngeneic stem cells are higher than

relapse rates for recipients of matched sibling grafts. [180] A recent update from Seattle confirms these findings in over 800 patients with advanced leukemia who underwent SCT; the relapse rate for 785 recipients of matched sibling grafts was 62%, compared to 75% in 53 recipients of syngeneic grafts ($P < 0.001$). [181] An even more dramatic effect on relapse rate was reported in a multicenter analysis of SCT recipients with acute myelogenous leukemia (AML) in first remission. In this study the relapse rate after syngeneic SCT was almost 3-fold higher than in recipients of matched sibling grafts (59 ± 20% vs. 18 ± 4%), [182] which was confirmed in a retrospective analysis by the International Bone Marrow Transplant Registry (IBMTR) (Fig. 93-2). [183] The large numbers of patients in this study demonstrated that the risk of relapse after syngeneic SCT remained higher than in recipients of matched sibling marrow grafts without GVHD. A second IBMTR analysis showed that the magnitude of this GVL effect is greater for patients with CML and AML and not statistically significant for patients with ALL in first remission. [184]

Patients who develop GVHD after allogeneic SCT experience relapse less frequently than similar patients who do not develop GVHD, confirming the experimental data showing that GVHD and the GVL effect are tightly linked. GVHD is protective against relapse both for SCT recipients with advanced leukemia [180] [185] [186] and for patients who received transplants in earlier stages of the disease. [183] [187] Initial reports suggested that chronic GVHD was most protective against relapse, [186] but other analyses demonstrate that acute GVHD is also protective. [183] [185] Results from an IBMTR analysis of 2,254 SCT recipients with less advanced leukemia (AML or ALL in first remission or CML in chronic phase) are shown in Figure 93-2 and demonstrate that the risk of relapse after SCT is lowest in patients experiencing acute or chronic (or both) GVHD. [183] As in syngeneic SCT, the magnitude of the GVL effect appears to be disease and stage specific. The Seattle group has reported that GVHD protects against relapse in patients with advanced leukemia, [185] [188] and IBMTR analyses of large patient numbers show a similar effect for patients with less advanced disease. [183]

Donor T cells included in the stem cell graft are critical for acute GVHD, and T-cell depletion of the donor graft by various strategies is one of the most successful means of reducing the incidence and severity of GVHD after allogeneic SCT. [189] [190] [191] [192] [193] [194] [195] Unfortunately, although T-cell depletion results in less treatment-related morbidity and mortality, improved overall survival rates have not been reliably demonstrated. This failure is due in large part to a reciprocal increase in the subsequent relapse

Figure 93-2 Actuarial probability of relapse after stem cell transplantation according to the type of graft and development of GVHD. *(From Horowitz et al., [183] with permission.)*

rate after T-cell depletion, as well as to graft failure and other complications. [187] [191] [196] [197] [198] T-cell depletion particularly increases relapse rates in CML. [183] [187] [196] This observation provides further strong, although indirect, evidence that donor T cells are important mediators not only of GVHD, but also of the GVL properties of the allogeneic stem cell graft.

In many experimental models donor T cells are important components of the GVL response, and cell-mediated cytotoxicity may be mediated through both MHC-restricted and unrestricted pathways. [199] [200] Most experiments implicate CD8+ cells as the vital mediators of the GVL response, [114] [199] [201] but under some conditions both CD4+ and CD8+ cells [15] [115] [200] [202] as well as NK/lymphokine-activated killer (LAK) cells [203] may be necessary for optimal GVL induction. Thus, multiple effector cells can mediate the GVL response in these experimental systems.

It is likely that important effector cells other than T cells can mediate the GVL response. For instance, various cytokines and NK cells can function without MHC restriction to enhance the GVL response in the appropriate setting. IL-2 is a potent inducer of NK cell activity and will potentiate the GVL effect in some murine models, [204] [205] [206] although NK cells are not always required for the GVL effect. [207] Donor-derived T cells appear to be primary effectors of the GVL response in clinical transplantation. The GVL effect of allogeneic SCT appears to be lost when T cells are depleted from the donor graft as GVHD prophylaxis, especially for patients with CML. [183] [187] [196] [198] [208] Many strategies for T-cell purging do not remove other potential effector cells (such as NK cells), [189] [192] [198] further supporting the role of donor T cells as primary mediators of GVL. It has also been possible to identify donor T-cell populations that possess specific cytolytic activity against allogeneic leukemia cells but not nonleukemic targets. [209] [210] After SCT, the number of circulating cytotoxic T-cell precursors directed against the leukemia identified in the peripheral blood may correlate with relapse-free survival. [211] [212]

Most available clinical data implicate CD4+ cells as important effectors of GVL. After SCT, circulating CD4+ cells that will directly lyse cryopreserved leukemic cells can be isolated in some patients. Some of these cells have been isolated and characterized as CD3+, CD4+, TCR+ cells. [210] Other cell lines have been established from patients with CML after allogeneic SCT that selectively lyse Ph+ CML cells; these cells were CD4+ lymphocytes, and specific lysis was inhibited by antibodies against MHC class II molecules. [213] In mice, immunization with a synthetic bcr-abl peptide elicited a CD4+ mediated, MHC class II-restricted response against the bcr-abl peptide. [214] This finding not only suggests that bcr-abl is a potential tumor-specific target for GVL reactivity, it also further supports the concept that CD4+ T cells are likely to be important mediators of the GVL response. For patients with leukemia undergoing allogeneic SCT, selective CD8+ cell depletion of the donor graft has reduced the incidence and severity of GVHD without yet resulting in a significant increase in relapse rates, which suggests that GVL reactivity is intact. [215] Although this finding does not directly prove a GVL effect induced by CD4+ cells, it does suggest that CD8+ cells may be more important in mediating GVHD and not the GVL effect, in contrast to some of the experimental models.

Other mononuclear cells such as NK cells may also have an important role in GVL induction in humans. NK cells routinely lyse the CML-derived cell line K652 in vitro. After SCT, the number and activity of NK cells increase in the peripheral blood, [216] [217] and NK cell isolates can be identified that will lyse cryopreserved host leukemia cells in vitro. [212] [218] Some NK cells derived from patients after SCT can also inhibit leukemic progenitor colony growth. [219] In this context, IL-2 may have a role in GVL induction because IL-2 reproducibly stimulates NK cell number and activity after allogeneic BMT, and its infusion may result in lower relapse rates. [220] [221] [222]

Data are also accumulating to suggest that some leukemic

cells may have specific antigen profiles that make them susceptible to the GVL effect. For instance, CML seems to be uniquely susceptible to T-cell-mediated GVL effects; it is known that p210 bcr-abl can bind to MHC class I [223] [224] [225] and class II molecules, and can serve as the target of T-cell cytotoxicity. [211] [213] [214] [226] Further, in vitro immunization experiments have resulted in generation of T-cell lines specific for the bcr-abl fusion peptide. [226] Similarly, in AML, the RAR- fusion peptide may be found in the MHC class I cleft, [224] and T-cell lines directed against leukemia-specific proteinase 3 have been derived. [227] It is not yet known whether fusion peptides or other leukemia-specific antigens are the target of T-cell attack in clinical situations. It is almost certain that minor histocompatibility differences between donor lymphocytes and host leukemic cells are also important targets for immunologic attack. These minor H antigen differences are clearly important for the GVL response in animal models. [228] [229] In humans, most GVL responses are associated with GVHD, suggesting that the GVL response may be an allogeneic response that is not strictly separate from GVHD. [183] [230]

DONOR LEUKOCYTE INFUSIONS

Until recently the evidence for an important GVL effect in clinical transplantation was strong but largely circumstantial. The use of donor leukocyte infusion (DLI) to treat patients with relapse after allogeneic SCT has recently evolved. Kolb et al. reported that three patients with relapsed CML achieved a complete cytogenetic remission after treatment with IFN- and a DLI from the original donor. [231] These findings have been confirmed in several larger trials. [231] [232] [233] [234] [235] [236] [237] [238] [239] [240] [241] [242] When results from these trials are combined, the complete remission rate for patients treated for relapsed CML is consistently 6080%. [230] In addition, data from 119 patients treated with relapsed CML have been collected and analyzed by the European Group for Blood and Marrow Transplantation (EBMT) [243] and through a survey of 25 North American transplant centers.[244] Although the treatment protocols vary slightly among institutions, the results have been remarkably consistent. Complete cytogenetic and molecular responses are achieved in almost 80% of patients treated with either early relapse (cytogenetic or molecular) or hematologic evidence of chronic phase relapse. Patients with more advanced CML (accelerated phase or blast crisis) are less likely to respond. The magnitude of the GVL effect is highlighted by the finding that the majority of patients who respond achieve a complete molecular remission, which is defined as the absence of detectable cells containing bcr-abl mRNA transcripts when assayed by RT-PCR. Since RT-PCR is capable of detecting one CML cell in 10^6 normal cells,[245] clinical relapse of CML represents a minimum leukemia cell burden of approximately 10[12] cells, a molecular remission may represent a one million-fold reduction by the GVL reaction.

Adoptive immunotherapy with DLI has been associated with significant morbidity. Many patients develop pancytopenia and marrow aplasia, often associated with transfusion requirements, bleeding complications, and infections; these complications of marrow aplasia have been the immediate cause of death in several patients. Marrow aplasia presumably results from the destruction of host leukemia cells before recovery of normal donor hematopoiesis. This idea is supported by the observation that patients treated with donor MNC infusions for cytogenetic or molecular relapse rarely experience pancytopenia. [243] Occasionally, marrow aplasia has been persistent,[234] [239] [246] although this toxicity has been successfully reversed with the infusion of additional donor stem cells in some patients. [234] [239] The other major complication of DLI is acute and chronic GVHD. However, GVHD appears to be closely associated with a clinical response, [230] [247] [248] and despite the relatively high number of T cells administered without the use of GVHD prophylaxis, the severity of GVHD has generally been mild to moderate. No acute GVHD is seen in approximately 3640% of patients, and 1530% have only grade I acute GVHD. Some 2050% of patients experience grade IIIV acute GVHD, but this typically responds to immunosuppressive therapy.

The complications of DLI have resulted in treatment-related mortality rates of 20%. [230] However, GVHD has generally been responsive to immunosuppressive therapy, and the mortality rate from direct complications of GVHD is only 58%. [244] [249] Another 712% of patients have died from infectious complications, either related to marrow aplasia or to immune suppression given as therapy for GVHD. These results compare favorably with the anticipated mortality rate of 40% or higher associated with a second SCT,[250] but strategies to minimize DLI toxicity are still needed.

It is likely that similar effector cells responsible for the GVL effects of SCT also effect GVL associated with donor leukocyte infusions (see later), although this assumption has not been formally proved. Most adoptive therapy protocols administer unfractionated donor mononuclear cell preparations that contain lymphocytes, NK cells, and other leukocyte populations. There is indirect evidence suggesting that T cells are involved in GVL induction after such infusions. An increase in host-reactive T-helper precursor cells was detected in five patients who responded to donor MNC infusions for relapsed CML, while one patient who failed to respond had no detectable increase in the frequency of T-helper precursor cells. [251] There was no consistent increase in host-reactive cytotoxic T-cell precursors in the responding five patients. Jiang et al. found that two patients treated by DLI for relapsed CML had an increase in cytotoxic T-cell precursor frequency against cryopreserved host leukemia cells relative to host lymphocytes. [212] In this analysis, NK cell activity initially decreased but recovered to levels higher than preinfusion values, and this change preceded evidence of the GVL effect. The significance of these phenotypic changes is unclear, but future analysis may help determine which MNC subsets are important for GVL induction in this setting.

The administration of select subsets of donor mononuclear cell fractions is the ideal framework in which to dissect the cellular mechanisms responsible for GVL induction. Donor mononuclear cells depleted of CD8+ T cells given to patients with relapsed CML have been shown to induce a direct GVL reaction with minimal GVHD,[252] [253] further supporting the hypothesis that CD8+ T cells are not critical for GVL, at least for patients with CML. These studies are preliminary, however, and the effect of CD8+ depletion, and other novel manipulations on the duration of clinical response and the overall GVL reaction will have to await further follow-up and comparative trials.

The timing of GVHD and GVL induction in relation to SCT is of great importance to minimize toxic effects and still provide an important antileukemic effect. In dogs, allogeneic lymphocytes can be safely administered only after chimerism has been established. [254] In mice, the allogeneic donor lymphocytes given at the time of BMT result in severe GVHD; when given 21 days after the conditioning therapy, donor lymphocytes will provide a potent GVL effect without inducing severe GVHD. [30] Similar findings have been noted in other murine models. [220] Significant GVHD may be attenuated in this setting because of the separation from the cytokine phases that occurs after SCT,[16] [255] suggesting that DLI may be given safely to patients to prevent relapse if appropriately delayed from the acute toxicity of the transplant.

This strategy of delay is already in clinical trials. [255] [256] This approach may be most useful for recipients of T-cell-depleted grafts, where the high risk of relapse may be acceptable if the transplant can be performed with limited toxicity, with donor leukocytes given at a later time to restore the GVL effects. Slavin and colleagues have given incremental T-cell infusions to patients after T-cell-depleted allogeneic SCT. [255] [257] The infusions of donor T cells resulted in an increase in acute GVHD but had

no effect on event-free survival. There was a non-statistically significant trend toward lower relapse rates, but only in recipients of Campath-1M-treated marrow. Barrett and co-workers have administered varying doses of donor leukocytes at different times after T-cell-depleted SCT, and the results confirm that the timing and dose of DLI are critical determinants for the risk of GVHD. [256] Conclusions regarding the ultimate GVL effects from this strategy will require longer follow-up but will likely alter current transplant strategies, at least in patients with CML.

For patients with CML who relapse after allogeneic SCT, DLI can induce a potent GVL reaction and re-establish complete molecular remissions in the majority of patients. This is perhaps the most successful example of adoptive immunotherapy in the clinical setting and now provides indisputable evidence in humans that allogeneic donor cells mediate the GVL effect. It is now possible to manipulate the donor leukocyte product in an attempt to enhance the efficacy of GVL induction, and future clinical trials will focus on strategies designed to maximize GVL reactivity while limiting toxicity from marrow aplasia, GVHD, and other complications. This technology provides a unique opportunity to understand the detailed mechanisms of the GVL effect. Ultimately, the ability to harness the GVL potential of allogeneic donor cells will have tremendous clinical import for patients with relapsed CML, and it will allow the development of novel cancer therapeutic strategies.

SUMMARY

Complications of SCT, particularly GVHD, remain major barriers to the wider application of allogeneic SCT for a variety of diseases. Recent advances in the understanding of cytokine networks and of the direct mediators of cellular cytotoxicity have led to improved understanding of this complex disease process. GVHD can be considered an exaggerated, undesirable manifestation of a normal inflammatory mechanism in which donor lymphocytes encounter foreign antigens in a milieu that fosters inflammation. Tissue injury related to the conditioning regimen or infection is then amplified by direct cytotoxicity via perforin/granzyme and Fas/FasL pathways, through direct cytokine-induced damage, and by recruitment of secondary effectors such as granulocytes and monocytes. Cytokine dysregulation may further result in the production of secondary mediators such as nitric oxide. The net effect of this complex system is the severe inflammatory manifestations that we recognize as clinical GVHD.

Cytokine modulation may be able to reduce the undesirable inflammatory aspects of GVHD while preserving the benefits of GVL. Multiple cellular effectors may be involved in GVL, although donor T-cell recognition of host antigens is an important element of this process. Cellular immunotherapy such as DLI offers another strategy for separating GVHD and the GVL effect. Both experimental and clinical data suggest that post-transplantation cellular immunotherapy can be performed relatively safely and effectively, and optimization of patient selection, cell dose, and timing of administration may all serve to limit toxicity and enhance the potential GVL effects.

Chapter 94 - Graft Engineering to Enhance Engraftment, Reduce Graft-versus-Host Disease, and Provide a Graft-versus-Tumor Effect

Adrian P. Gee

INTRODUCTION

In the last few years there has been dramatic growth in the use of hematopoietic stem cell transplantation (SCT), with or without high-dose chemotherapy or radiotherapy, for the treatment of marrow failure syndromes, certain genetic disorders, and cancers that are refractory to conventional dose therapy. [1] Although the infusion of hematopoietic progenitor cells (HPC) is required to achieve normal and sustained hematopoiesis and immune function, it carries an associated risk that immunocompetent cells within the graft will recognize and react to antigenic differences expressed by normal tissues and cells of the recipient. [2] [3] The resulting graft-versus-host disease (GVHD) can be severe or fatal and is thought to be triggered primarily by antigens of the human leukocyte antigen (HLA) system, which are encoded by genes on chromosome 6 in humans.[4]

Matching of a related donor and recipient at the HLA-A, -B and -D/DR loci decreases the risk and severity of GVHD; however, fewer than one-third of potential patients have access to such a donor.[4] Several approaches have been taken to find alternative donors for such patients, including the use of HLA-matched unrelated donors obtained through various volunteer registries, [5] partially mismatched related donors,[5] [6] and grafts obtained from the patient himself or herself. [7] The use of these grafts generally carries additional risk, in the form of an increased incidence of GVHD in allogeneic SCT [8] [9] [10] and the potential for disease relapse due to reinfusion of occult viable tumor cells with autologous SCT. [7] [11] As a result, methods have been developed to manipulate or engineer HPC ex vivo, to eliminate the cells that are thought to mediate these clinical sequelae. Purging tumor cells from autologous hematopoietic progenitor cell grafts (autografts) is discussed elsewhere. In this chapter ex vivo manipulation of allogeneic hematopoietic progenitor cell grafts (allografts) is discussed.

GRAFT-VERSUS-HOST DISEASE

A first indication of the identity of the cells mediating GVHD came from animal models in which GVHD was noticeably absent when fetal HPC were transplanted. [12] These grafts lacked mature T lymphocytes, and depletion of these cells from marrow grafts ex vivo in mice and dogs (by treatment with antithymocyte or antilymphocyte antibodies,[13] [14] or with soybean agglutinin [SBA][15]) prevented GVHD and produced stable chimeric engraftment in the recipient animals. This led to clinical studies in which T cells were depleted from HLA-mismatched grafts obtained from the parents of children with leukemia [16] or severe combined immunodeficiency. [17] T cells were removed by incubation with SBA, which agglutinates the majority of mature cells, but spares primitive hematopoietic progenitors. The SBA-negative fraction was then mixed with sheep erythrocytes, which formed rosettes with the residual T cells. These were removed by centrifugation on a density cushion.[18] This approach resulted in a reduction in the incidence and severity of GVHD compared to that previously seen in recipients of unmanipulated grafts.[16] [17] This stimulated a number of studies in which T cell-directed polyclonal and subsequently monoclonal antibodies (MAb) were used to identify and mediate the removal of T cells from grafts.[19]

Graft-versus-host disease occurs in 3050% of HLA-matched sibling transplants where it is believed to be triggered by differences between minor HLA antigens or non-HLA antigens.[9] [20] These are presented, directly or via antigen-presenting cells (APCs) such as monocytes and dendritic cells, [21] to donor T lymphocytes. It has been estimated that in any individual, approximately seven minor histocompatibility loci encode antigens that can cause GVHD, although the total number of these loci in the population is likely to be much higher. [22]

Direct presentation of these antigens in association with multiple histocompatibility complex (MHC) class I antigens (HLA-A, B, and C) predominantly triggers CD8+ T cells, resulting in their clonal expansion. If the antigen is first processed and then presented by APC, the effect is predominantly on CD4+ cells, which in turn stimulate CD8+ cytotoxic cells. Consequently, depletion of CD8+ cells from the graft would be expected to reduce or prevent GVHD, and this has been described in both murine transplant models and human clinical studies. [23] [24] [25] The complex and diverse etiology of GVHD is, however, illustrated by the observation that, in certain mouse strains, GVHD is mediated mainly by CD4+ cells, [26] whereas CD8+ cells both beneficially affect engraftment and reduce disease relapse. [27] It is likely, therefore, that various cell types and a complex array of soluble factors are responsible for the development of GVHD and that multiple interconnected pathways are involved.

This hypothesis forms the core of the cytokine storm theory of Ferrara and colleagues. [28] [29] [30] This proposes that GVHD is the result of a dysregulation of cytokines and consists of three main steps. In the first, the irradiation and chemotherapy used to condition the patient lead to damage to host tissues and cell activation, resulting in the secretion of inflammatory cytokines, for example, tumor necrosis factor-alpha (TNF-) and interleukin (IL)-1. This results, in turn, in increased expression of adhesion molecules and MHC class II antigens, which facilitates the recognition of normal host cells by donor T cells post-transplant. In the second phase, naïve T cells may be stimulated to differentiate into type 1 (Th1) or type 2 helper (Th2) T cells. Repeated stimulation in the presence of IL-12 (but not IL-4) results predominantly in the generation of Th1 cells. These secrete IL-2 and interferon (IFN)- which, in the third phase, stimulate the production of proinflammatory cytokines by accessory cells (donor and host monocytes and macrophages). These cells may also receive secondary triggering stimuli, such as endotoxin/lipopolysaccharide released from damaged intestinal mucosa, which amplify cytokine production further, resulting in the tissue damage characteristic of acute GVHD.

In contrast, stimulation of naïve T cells in the presence of

IL-4 results in the generation of Th2 cells that secrete IL-4 and IL-10. This promotes anti-inflammatory responses, resulting ultimately in chronic GVHD. A similar dichotomy of function may also hold true for CD8+ T cells. For more comprehensive descriptions of the cytokine storm hypothesis, the reader is referred to recent reviews and Chapter 93 .[29] [30]

Clinical evidence favoring cytokine dysregulation during GVHD comes from Tanaka and colleagues, [31] who described different patterns of cytokine gene expression post-transplant. They found that IL-4, IL-10, and IL-13 gene expression was suppressed in patients with severe GVHD, whereas IL-12 gene expression was increased. They felt that this indicated that severe GVHD might occur when Th1 cells were induced by a change in the balance between Th2 cytokines and IL-12. This supports the role of IL-12 as a crucial cytokine in the etiology of GVHD. Yang and colleagues [32] have reported that a single injection of this cytokine on the day of transplant markedly inhibited acute GVHD in a minor and major MHC-mismatched transplant animal model, in which CD4+ cells mediate GVHD. In contrast, CD8+-mediated graft-versus-leukemia (GVL) responses were retained. The effects of IL-12 on both of these responses appeared to be mediated by IFN-, and increased levels of this cytokine have been reported in transplant recipients suffering from GVHD. [33] There is now increasing evidence that many other factors may be intimately involved in the generation and pathophysiology of GVHD, including nitric oxide [30] [34] and IgE.[35]

Cells other than T cells also appear to be capable of mediating or exacerbating GVHD. These include natural killer (NK) cells [36] and lymphokine-activated killer (LAK) cells.[37] NK cells have been shown to promote engraftment and post-transplant immune reconstitution in mice. [38] In some animal models, however, they have been found to prevent GVHD if administered in the early post-transplant period via a pathway involving tumor growth factor (TGF)-. Later administration and the use of IL-2, however, resulted in exacerbation of acute GVHD.[38] Differences in the activities of LAK and NK cells derived from marrow versus cord blood have been implicated as an explanation for the lower level of GVHD reported in cord blood transplantation. [39] When compared to cord blood cells, marrow cells had deficient apoptotic cytotoxic activity and a lower cell surface expression of the IL-2 receptor.

Despite the undoubted complexity underlying the pathophysiology of GVHD, it is clear that a relatively simple procedure, such as T-cell depletion of the graft, is capable of achieving effective prophylaxis. This may be bought, however, at a considerable price.

GRAFT-VERSUS-LEUKEMIA RESPONSES

A graft-versus-leukemia (GVL) effect was originally described 40 years ago in animal transplant models [40] in which it was shown that animals receiving syngeneic (identical twin) marrow primarily died from relapse of their disease, whereas those receiving histoincompatible grafts showed lower rates of relapse, but ultimately died of GVHD. The term graft-versus-leukemia was used to describe this effect 20 years later by Bortin et al. [41] Considerable effort has been expended to determine whether these effects are functionally separable, with the goal of stimulating GVL in the absence of GVHD. This has proved to be easier in animal models, where various effectors of GVL have been identified. [42] [43] These are thought to exert their effects by direct cytotoxic action toward antigens expressed specifically by leukemic cells or to minor histocompatibility antigens, expressed by both normal and leukemic host cells. Other GVL pathways may include MHC nonrestricted cytotoxicity by T-cell and nonT-cell effectors, or the release of lymphokines with direct or indirect antileukemic activity. In all cases, however, T-cell subpopulations have been implicated as the primary mediators.

The evidence for GVL in humans has come mainly from the observations that (1) the rate of leukemic relapse in patients receiving allografts is significantly lower than in recipients of syngeneic grafts; [44] (2) there is a lower incidence of relapse in recipients of allografts who develop GVHD than in those who do not; [45] and (3) there is lower incidence of relapse in recipients of allogeneic marrow who do not develop GVHD than in recipients of syngeneic grafts. [46]

The involvement of T cells as mediators of GVL in humans came initially from the observation that the incidence of relapse in patients with chronic phase chronic myelogenous leukemia (CML) was higher (50%) in recipients of T-cell-depleted grafts than in those receiving unmodified transplants (10%). [47] A retrospective analysis of data from the International Bone Marrow Transplant Registry in patients with chronic phase CML [46] also revealed that there was a significantly higher relative risk of relapse in recipients of T cell-depleted grafts who developed GVHD, than in recipients of nondepleted grafts in whom GVHD did not develop. This suggested that GVL could occur in the absence of GVHD and that this effect was dependent, directly or indirectly, on the presence of T cells within the graft. The effect is probably composed of several components. These include a direct cytotoxic activity of T cells against leukemic cells and interaction, either directly or via the release of cytokines, between T-cell populations and nonT-cell effectors, such as NK cells. Although well established initially in CML, GVHD responses have been described or evoked in a variety of diseases, including myelogenous leukemias, [45] [48] acute lymphoblastic leukemia (ALL), [49] chronic lymphocytic leukemia, [50] [51] lymphoma, [52] [53] and myeloma. [54] Passweg and colleagues reviewed International Bone Marrow Transplant Registry data on 1,132 patients with T- and B-cell lineage ALL who had received matched sibling donor transplants. [55] They were able to confirm that the development of GVHD in these patients was associated with a decreased risk of relapse that implicated a GVL response in this disease.

This immune reaction is now regarded as an important component in the development of effective therapy for a variety of leukemias and potentially also for solid tumors. [56] The exact identities and modes of action of the primary and secondary effector cells in humans remain to be determined definitively. [56] [57] Animal studies confirm that the best candidates appear to be T cells, [43] or particular T-cell subsets, [58] activated killer cells, [59] and NK cells. [60] This lack of understanding has not, however, prevented attempts or proposals to induce the effect postallogeneic transplantation to prevent or treat relapsed disease. Approaches have included tapering or sudden cessation of immunosuppression; [61] infusion of leukocytes obtained from the graft donor [62] [63] [64] (with and without use of systemic recombinant cytokines, [65] [66] or depletion of particular T-cell subsets [67]); infusion of lymphokine-activated cells and IL-2; [68] and administration of cytokines, such as IL-2, alone. [69]

There is also now a concerted effort to develop methods to generate leukemia-directed effector populations ex vivo for this type of therapy. [70] Potential effectors have included autologous T cells isolated from follicular lymphomas, [71] and CD8+ T cells primed against leukemic target cells expressing the B7 co-stimulatory molecule. [72] [73] It is possible that cell lines derived from these effectors could be used to provide a GVL effect. Irradiated MHC nonrestricted T-cell lines have shown antitumor activity when injected into tumor-bearing mice or incubated with leukemia-seeded human marrow, [74] and the use of a cytotoxic NK cell line for tumor purging of autologous grafts has been reported by Klingemann and colleagues. [75]

Any strategy for improving the outcome of allogeneic transplantation by the use of cellular manipulation, in the form of

Figure 94-1 Cellular strategies to optimize outcomes in allogeneic hematopoietic progenitor cell transplantation. Cellular conditioning: Graft recipients may be conditioned to accept grafts by the administration of enriched facilitator cell populations or to prevent graft rejection by infusion of various veto cell preparations. Seeding the marrow spaces with purified stromal cell populations in the peritransplant period may also enhance stable establishment of the hematopoietic progenitor cells. Graft manipulation: Control or prevention of GVHD can be favored by the depletion of potential effector cells (primary candidates include mature T lymphocytes, T-cell subsets, and NK populations) from the progenitor cell graft, or increasing the dose of CD34+ cells administered. Immunotherapy: Relapse of disease posttransplant (particularly in leukemias) may be abrogated or treated by infusion of tumor-directed or nonspecific alloreactive immune cells. To enhance the specificity of the intended cytotoxic response, the effector cells can be primed with tumor-associated antigen(s) ex vivo or genetically modified to provide a mechanism for deactivation if nonspecific killing is detected.

graft engineering and post-transplant immunotherapy, must therefore tread the fine line between preventing GVHD, while retaining or simulating the beneficial effects of any diseasedirected immune response (Fig. 94-1).

THE DOWNSIDE OF T-CELL DEPLETION

Balancing Graft-versus-Host Disease, Graft-versus-Leukemia, and Engraftment

The control of GVHD by pan T-cell depletion is achieved at a price. When used to prepare grafts from HLA-matched siblings, in an attempt to reduce the GVHD seen in 3050% of the recipients of these grafts (due to mismatched minor HLA and non-HLA antigens), [4] there was about a 10-fold increase in engraftment failure and a fivefold increase in leukemic relapse. [76] This was seen predominantly in patients with CML. [47] As a result, there was no overall survival advantage over using nonmanipulated grafts. This provided powerful evidence, however, that donor T cells had a role, directly or indirectly, not only in effecting GVL but also in preventing graft rejection.

Graft Failure

The risk of graft failure in recipients of matched sibling grafts increases from about 2% to >10% with T-cell depletion. [76] [77] It may be seen as failure to achieve engraftment, which is thought to be immunologically mediated. Alternatively there can be early engraftment followed by pancytopenia or late failure of a functioning graft, both of which may be effected as a result of recurrent disease. [78] Residual immunocompetent T cells in the recipient are thought to be responsible for graft rejection. [79] The phenotype of these cells appears to be dependent on the type of transplant. Matched sibling grafts are predominantly rejected by CD3+8+57+ suppressor T cells, whereas CD3+8+57 HLA-DR+ cytotoxic T cells mediate the rejection of grafts from matched unrelated donors. [80] [81] In partially matched related transplants both pathways have been seen. [82] To overcome rejection a number of strategies have been tried. These include increasing immunosuppressive therapy and changing the composition of the graft to increase the dose of T cells, $CD34^{+}$ cells, or graft facilitator cells (see later).

The variable clinical results that have been obtained by depleting different cell populations also indicate that ex vivo graft manipulation is but one component in a more comprehensive strategy that must be used to achieve the desired outcome. Other important variables include the diagnosis, the choice of conditioning and immunosuppressive therapy, and the degree and nature of HLA incompatibility.

Lymphoproliferative Disease

The risk for post-transplant lymphoproliferative disease (LPD) is increased following use of a T cell-depleted graft. [83] Although cases of T-cell LPD and late-onset lymphoma have been described, these are relatively rare when compared to the incidence of B-cell LPD. The risk of LPD is estimated at almost 12-fold higher in patients who receive T-depleted grafts than for those who receive nonmanipulated grafts. Recipients of a Treplete HLA-matched transplant have a 0.9% ± 0.2% probability of developing such a condition at 4 years, compared to a probability of 64.8% ± 17.7% in recipients of a T-depleted HLA-mismatched transplant for a primary immunodeficiency. [84] Data from the National Marrow Donor Program for matched unrelated transplants show a 2% overall incidence of LPD, which increases to 5% with T-cell depletion. [85] Interestingly, the incidence was not uniform within this group, but varied with the method used for manipulation of the graft (see later). Depletion techniques that used highly specific T cell-directed MAb resulted in an LPD incidence of 1125%, whereas methods that depleted both T and B cells, for example, lectin-based methods and CAMPATH antibodies, were associated with an incidence of <1%. [86] [87] This must be interpreted with caution, however, because

the type and intensity of post-transplant immunosuppression substantially altered the incidence.

The explanation behind this association between T-cell depletion and B-cell LPD is the depression in specific immunity to the Epstein-Barr virus (EBV) that is seen in recipients of depleted grafts. This can be detected in vitro by the use of assays for the frequency of EBV-specific cytotoxic T-lymphocyte precursors. [88] These showed depressed immunity in 21 of 26 recipients of unmodified or T-depleted grafts at 3 months; however, by 6 months normal frequencies were in the normal range in 9 of 13 recipients. This period of depressed immunity corresponded to that in which clinical LPD was observed. Recent studies have shown that it is possible to generate EBV-specific T cells ex vivo and to use these cells adoptively both for therapy of LPD and to provide immunity to the disease for as long as 18 months. [89]

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

BLOOD VERSUS MARROW AS THE GRAFT SOURCE

Attempts at engineering allogeneic grafts have predominantly focused on T-cell depletion. This presents some challenges to the cell-processing laboratory because the T-cell content of bone marrow grafts can vary widely, depending on the contamination of the harvest by peripheral blood. The switch to grafts derived from mobilized peripheral blood (peripheral blood progenitor cells, PBPCs) has not resolved this problem because this material contains approximately a 10-fold higher concentration of T cells,[90] which requires additional depletion capacity for any method that is developed for cells from both sources. Clinical data also suggest that the functional activity of T cells in blood-derived grafts is not the same as that of cells harvested with marrow. When nonmanipulated T cell-replete, HLA-identical PBPC grafts have been infused, the incidence of acute GVHD has been lower than that seen with marrow, despite the higher dose of T cells. [91] This may be at the expense of a subsequently higher incidence of chronic GVHD; the risk of developing GVHD is estimated at greater than twofold higher than that seen with marrow grafts.[92] [93]

One proposed explanation is that T cells in mobilized PBPC grafts are at a different stage of functional maturity and may, therefore, be less immunologically active in the immediate post-transplant period or may actually suppress GVHD development. Evidence for this hypothesis comes from the work of Kusnierz-Glaz and colleagues,[94] who found three different patterns of T-cell composition in normal donors mobilized with granulocyte colony-stimulating factor (G-CSF). In one group CD48+ was found in addition to the typical CD4+ and CD8+ populations. These cells were present in both the high- and low-density fractions obtained by centrifugation of the cells on discontinuous Percoll gradients. A second pattern consisted of CD48+ T cells, which collected only in the low-density fraction. In the third pattern there was no discrete population of CD48 T cells. The number of these cells in mobilized collection was about fivefold higher than that in resting blood. These double-negative cells suppressed mixed leukocyte reactions, and it was proposed that they may be used adoptively to ameliorate GVHD. [94] In a murine model system, transplantation of the low-density fraction (CD48 enriched) of G-CSF-mobilized cells resulted in the most successful reconstitution of allogeneic recipient animals. [95] These cells showed a reduced capacity to induce lethal GVHD and secreted about 10-fold more IL-4 and lower amounts of IL-2 and IFN- than unfractionated cells, suggesting that mobilization with growth factors induced a shift toward Th2 cytokine secretion in this population. The numbers of double-negative cells has, however, also been reported to increase in association with LPD, GVHD, autoimmune diseases, and liver allograft rejection, [96] suggesting that these cells may have a central role in regulation of immune responses.

If chronic GVHD continues to be a serious impediment to the use of nondepleted allogeneic PBPC grafts, it will be necessary to modify existing depletion protocols to accommodate the increased T-cell burden in these collections. Similar differences have been seen in the incidence and severity of GVHD when using cord blood in place of marrow, although the data are still somewhat confusing. The functional immaturity of cord blood T lymphocytes is usually cited as the explanation for the observations.

Hoffman: Hematology: Basic Principles and Practice, 3rd ed. , Copyright © 2000 Churchill Livingstone, Inc.

TARGET T-CELL DOSE

Kernan and colleagues have proposed that to avoid GVHD, the dose of T cells should be kept <1 × 10^5 /kg recipient weight,[97] a number that was subsequently validated in a study in which the T-cell dose in HLA-matched sibling donor marrow grafts was fixed at this value. [98] At this dose, there were no graft failures and acute GVHD was limited to grade III involvement of the skin. The T-cell concentration required to achieve sustained long-term engraftment, control of GVHD, and maintenance of the potential for GVL will depend on the disease and the degree of HLA disparity. Any recommendation for a fixed number must, therefore, be interpreted with caution, especially because the identity of the effector population(s) has yet to be determined. With this proviso, it is clear that many techniques are capable of achieving levels of depletion that have been shown to be clinically effective.

METHODS FOR T-CELL DEPLETION

Figure 94-2 shows various methods of T-cell depletion and enrichment.

Sheep Red Blood Cell Agglutination

One of the most widely used methods for pan T-cell depletion has been agglutination of mature cells using sheep red blood cells (SBA), followed by a downstream additional depletion step. This lectin binds to *N*-acetyl-glucosamine, which is apparently not present on the surface of pluripotent hematopoietic progenitor cells. [99] When a cell suspension is treated with SBA, the majority of cells will clump and can be removed by sedimentation or centrifugation on a density cushion, such as 5% bovine serum albumin.[18] In a study of 87 procedures, this was found to result in a 1.26 ± 0.34 log depletion of E rosette-forming T cells (predominantly CD4+ cells) [18] [100] and enrichment of both CD34+ progenitors and committed colony-forming cells. The T-cell content of grafts treated in this way usually provides a dose >1 × 10^5 /kg, which is associated with a 50% risk of producing grade I or higher GVHD in HLA-matched recipients. [97]

To reduce the T-cell dose below 1 × 10^5 /kg it is necessary to add an additional depletion procedure, such as E rosetting, or an antibody-mediated removal (described later). In most cases, fluid-phase SBA has been added to the cells; however, Applied Immune Sciences (now part of RPR Gencell) at one time developed a panning system in which the lectin was immobilized to a plastic surface. [18] [101]

Erythrocyte Rosetting

When human T cells are mixed with a suspension of sheep erythrocytes they form rosettes with the red blood cells (E rosetting). This effectively increases the density of the T cells and allows them to be removed by sedimentation or density-gradient centrifugation. The rosettes tend to be rather fragile, and optimum rosetting is favored by bringing the cells into direct contact by gentle centrifugation to pellet them and by overnight incubation at 4°C. More stable rosettes that form rapidly can be obtained if the sheep erythrocytes are pretreated in

Figure 94-2 Manipulation of cell populations in allogeneic stem cell transplantation. Allogeneic cell populations that are infused to provide hematologic/immunologic rescue from high-dose therapy often require ex vivo manipulation to reduce the risk of producing severe or lethal GVHD, while also retaining any antidisease activity that could be exploited to prevent or reduce the risk of relapse post-transplant. Depletion: The various depletion techniques shown are primarily used to eliminate candidate GVHD effector cell populations from the graft and rely on qualitative markers that differentiate these cells from noneffector cells. A newer approach is to identify donor cells that are capable of mounting an alloreactive response to host antigens and to deplete these functionally active cells from the allograft. Enrichment: An alternative approach is to enrich the normal progenitor/stem cell populations in the graft, thereby achieving depletion of unwanted other cell populations by default. Positive selections of this type have to date been almost exclusively based on the purification of CD34+ blood or bone marrow hematopoietic progenitor cells. Other cell populations are undoubtedly important in determining the outcome of the transplant. They may enhance engraftment (stromal cells), even across histocompatibility barriers (facilitator cells), or be used as a potent means to generate disease-targeted killer cell populations for use in immunotherapy of the disease.

2-aminoethylisothiouronium bromide, washed, and irradiated before use. [18] Once mixed with the treated erythrocytes, the graft cells can be almost immediately layered onto a density-gradient material, such as Ficoll-Hypaque, and centrifuged. The T cell-depleted fraction remains at the interface, while nonrosetted sheep cells and T cells pellet to the bottom of the tubes. In an unpublished study using this technique for up-front T depletion of HLAmismatched PBPC collections, a mean 2.16 ± 0.46 log depletion (n = 25) of CD3+ cells was achieved, as determined by flow cytometry. When rosetting was combined with SBA treatment of marrow grafts, a 2.4 ± 0.5 log depletion of clonable T cells was obtained (n = 61) with an infused T-cell dose 0.632.8 × 10^4 /kg. Recoveries of nucleated cells averaged 6.6%. It has been reported that recoveries of early progenitor cells and processing times can be improved using three cycles of depletion with neuraminidase-treated E [102] and simplified rosetting techniques.[103] When this combination of methods was used to deplete T cells from 61 HLA-matched and 26 HLA-mismatched grafts, the overall incidence of grade III GVHD in the matched recipients was 3% (n = 58) versus 16% in the mismatches (n = 25).[18] This technique is, however, liable to come under increasing regulatory scrutiny as governmental agencies move to restrict the use of animal products in human therapeutic procedures.

Counterflow Centrifugal Elutriation

Agglutination and E rosetting exploit artificially induced changes in T-cell density to effect separation. T-cell populations do, however, inherently show differences in these physical properties from other blood cell subpopulations. Under normal conditions these small differences are insufficient to allow them to be used to separate the cells by sedimentation or routine centrifugation techniques. In an elutriation centrifuge, cells are pumped into a spinning chamber and will tend to sediment under the centrifugal force, based on their size and density. [104] [105] If this force is counterbalanced by the fluid flow, the cells will line up within the chamber, such that different fractions can be sequentially collected, by changing either the centrifuge speed or the fluid flow rate. When this approach is used, a T cell-depleted fraction can be obtained for transplantation. This product predominantly contains the larger committed progenitor cells. [106] In contrast, the smaller progenitor cells tend to be concentrated in the T cell-enriched fraction, [107] from which they can be recovered by positive selection (see later), and added back to the graft. [108] Grafts prepared in this way contain similar doses of CD34+ and colony-forming progenitor cells to unfractionated harvests, and a T-cell dose of approximately 6 × 10^5 /kg.[106] Add-back improved engraftment; however, post-transplant immunosuppression was still required to reduce GVHD and morbidity. [108]

Higher levels of depletion, which may be required for HLA-mismatched grafts, can be achieved using double-cycle elutriation. [109] This results in >3 log depleted graft, to which a controlled number of T cells can be added back. When this technique was used to prepare grafts for 10 HLA-matched recipients with hematologic malignancies, and which were engineered to contain 0.50.75 × 10^5 T cells/kg, all 10 patients successfully engrafted, following conditioning with total-body irradiation (TBI) and combination chemotherapy, with pre- and post-transplant immunosuppression. Fifty percent developed grade III GVHD, and 2 of the 10 went on to develop chronic GVHD. Four died of bone marrow transplant-related complications, and 2 relapsed at 46 and 1,035 days post-transplant.

Elutriation offers a number of advantages, including the use of a closed system for cell processing, a degree of automation, and the ability to recover intact all of the various cell fractions. These can be recombined, with or without addition processing, to provide a graft of prescribed composition. The disadvantages

have been the loss of smaller HPC in the T cell-depleted fraction [107] [110] (although this has not been a universal finding [111]), and the relative complexity of the

hardware.

T Cell-Directed Cytotoxic Agents

A number of chemotherapeutic drugs have been successfully used for the therapy of a variety of T-cell malignancies, [112] [113] and may be adaptable for T-cell depletion of allogeneic grafts.

Incubation of enriched mononuclear marrow cells ex vivo with 2-deoxycoformycin (Pentostatin) for 3060 minutes at 37°C in medium containing plasma, followed by the addition of 2-deoxyadenosine, and continued incubation overnight, results in a 1.52.5 log depletion of T cells. [112] This treatment spares normal myeloid and erythroid progenitors. The nucleoside analog 9-- D-arabinosylguanine inhibits DNA synthesis in T cells. [113] Overnight incubation of lymphoblastoid cell lines, or fresh leukemia cells with 100 M of the drug, results in a 6 log depletion of T cells, without significant effects on other committed HPC. [113] A more widespread toxicity, against T cells in general, allospecific T cells, NK cells, and LAK precursors has been described following the incubation of human cells with 50250 M of the lysosomotropic drug L-leucyl-L-leucine methyl ester (LLME).[114] [115] There was, however, partial or complete inhibition of colony formation by committed myeloid, monocyte, and erythroid progenitors. In a mouse transplant model, treatment of allogeneic marrow and spleen cells protected the recipients from lethal GVHD without adversely affecting engraftment. A phase 1 clinical study involved 19 patients with high-risk disease undergoing allogeneic transplantation from an HLA-identical sibling (n = 12) or a partially HLA-matched family donor (n = 7).[116] Marrow mononuclear cells were treated ex vivo with LLME concentrations of 0.250.5 mM. Marrow NK and LAK activities were essentially eliminated at concentrations 0.375 mM LLME. CD8+ cells were also reduced, and granulocyte macrophage colony-forming unit (CFU-GM) recovery was 3% at 0.5 mM LLME. The median time to an absolute neutrophil count of 500/l was 17 days. One patient with marrow treated with 0.5 mM LLME died of secondary graft failure. Complete donor chimerism was documented in each evaluable case. Grade IIIV GVHD occurred in 4 of 18 evaluable patients.

In general, T cell-directed or specific cytotoxic agents have not been widely used, partly because of their effects on some progenitor cell populations and partly because of the difficulty in achieving controllable and reproducible levels of depletion. They have found more widespread application for purging malignant T cells from grafts that are to be used for autologous transplantation.

Antibody-based Methods for T-Cell Depletion

The aim of most graft engineering procedures is to achieve reproducibly a final product with a defined cellular composition. This goal has become much more achievable with the advent of MAb technology. The high specificity of these reagents, their ever-increasing availability, and the variety of ways in which they can be used to effect cell separation have been largely responsible for much of the development of this field. In contrast, the use of polyclonal reagents required extensive adsorption of unwanted reactivities to enhance their specificity, and these reagents had to be produced by immunization of animals with intact cells, or cell extracts, expressing the target antigen to which the antibody was required. The resulting sera or peritoneal fluids were likely to contain host viruses; the purification procedures were arduous and generally resulted in poor final yields of antibody, with tremendous variability from batch to batch. In contrast, monoclonal reagents can now be prepared under controlled manufacturing conditions from defined, well-characterized cell cultures grown in serum-free media. Purification from this material is relatively simple, and the final product shows monospecificity toward the particular antigen.

Monoclonal antibodies can be used, in combination with flow cytometric analysis, for the identification of the appropriate target cell population and to effect their elimination from the cell mixture. This can be achieved by using them, together with serum complement, to lyse the cells, or to act as a link to a solid phase onto which the target cells are immobilized. Because regulatory concerns are moving the field away from the use of serum products in therapeutic procedures, physical separation techniques have now become the predominant methods for target cell elimination. These involve the use of a solid matrix material to which is attached the capture antibody. This is incubated with the cells and can then be removed together with the attached cells. In depletion techniques the antibody on the solid phase will be directed against T cells, or other potential mediators of GVHD, and the residual cells will be used for the transplant. In positive selection, the antibody on the solid phase is targeted toward HPC (usually an anti-CD34 monoclonal reagent), and these cells are then recovered from the matrix and used for grafting.

The solid phase can take several forms, from a flat plastic sheet to a variety of particles of various sizes and types. The main advantage of using a three-dimensional solid phase is that it allows a greater amount of MAb to be presented to the cells in a much smaller physical space than can be achieved with a flat configuration. The same amount of MAb can be immobilized onto a few microliters of nanoparticles, or a few milliliters of microspheres as can be attached to many hundred square centimeters of plastic sheet. These particles can be used as the matrix for column separations or, if they possess paramagnetic properties, they can be mixed as a suspension with the antibody-treated cells and then collected within a magnetic field. The limitations on these approaches now lie mainly in the identification of the appropriate target cell population rather than in the efficiency of the separation technologies.

An alternative approach is to use the MAb in a more physiologic way. This can be achieved either by allowing it to activate serum complement, either in vitro or in vivo to produce target cell lysis, or by attaching to the antibody some toxic moiety such as a plant toxin or a radionuclide.

Antibody and Complement

The cytolytic serum complement pathway is triggered by the binding of the first component of the cascade to target cell-bound MAb. Activation of the classical complement pathway ultimately results in formation of a membrane attack complex, which is composed of terminal complement components, and is responsible for colloid osmotic lysis of the target cells.[117] Activation of the cascade is achieved by binding of the first component to a single molecule of IgM antibody or to a doublet of IgG molecules, as long as the MAb is of a complement-fixing subclass.

Technically the complement lysis procedure is relatively simple. A prerequisite is a screened source of animal complement because human serum is of limited efficacy for ex vivo lysis of human cells. Some suitable MAb, such as CAMPATH-1, do fix human complement, and can, therefore, be used for both in vitro and ex vivo depletion.[118] The most widely used source is baby rabbit serum; however, batches must be carefully screened for nonspecific toxic activity toward HPC. Usually, multiple sera are screened, and suitable lots are pooled for clinical use. Such sera are now commercially available and have undergone extensive testing for possible infectious agents and pyrogens.

The graft cell suspension is first incubated with an excess

concentration of the chosen MAb(s), usually at 4°C for 30120 minutes. In some studies, the complement has then been added directly, whereas in others, excess fluid-phase antibody is first removed by extensive washing. In either case, it is important to understand the properties of the target antigen(s), for example, are they internalized, over what period, is surface expression temperature sensitive, does their binding activate the target cell? Failure to do so can result in ineffective sensitization and poor downstream lysis. The sensitized cells are then incubated with a concentration of complement shown to be in excess in preclinical studies. Because lysis is temperature dependent, it is usual to perform this incubation either at ambient temperature or at 37°C. Higher temperatures may produce increased levels of nonspecific toxicity, although the end point of the reaction will be reached faster. Because cells are lysed during this step, intracellular products, including DNA, are released. This can result in excessive cell clumping, which can be reduced by the addition of DNAse before the addition of complement. The cells are then washed extensively with infusion grade medium to remove complement, MAb, and the enzyme before infusion or cryopreservation.

This technique, although simple, has a number of disadvantages. These include the inability to control the extent and reproducibility of lysis; the escape of cells expressing low levels of the target antigen;[119] [120] nonspecific toxicity toward HPC; the presence of anticomplementary factors[121] [122] (probably predominantly decay-accelerating factors) in marrow harvests; and sensitivity to metal chelating anticoagulants (frequently used during the collection of apheresis products). Although it has found widespread clinical application (see later) and has achieved impressive results, particularly in the preparation of mismatched grafts, there is a general move toward other methods for T-cell depletion. This has been accelerated by the decision of the Food and Drug Administration that complement preparation must meet the same test standards as those set for MAb products that are intravenously infused.[123]

Immunotoxins

The problems of specificity associated with the use of complement have led investigators to examine alternative methods to use MAb to target a toxic moiety to the cells of interest. There has been considerable interest, therefore, in using various powerful plant toxins conjugate to T cell-directed MAb. Most of the early work

focused on ricin, a toxin obtained from the castor bean.[124] The molecule is composed of an A chain, which possesses the toxic activity, and a B chain, which is important in translocation of the molecule across the cell membrane,[125] where the A chain inhibits ribosome activity, which results in shutdown of protein synthesis and cell death. Unfortunately, the B chain also binds to galactosyl residues on cells, thereby counteracting some of the specificity that is introduced by conjugating intact ricin to the MAb. This can be overcome either by blocking the receptor on the B chain, by carrying out the incubation with cells in medium containing lactose, or by using immunoconjugates prepared only with the A chain. To ensure that these A chain immunotoxins are efficiently translocated into the cytoplasm, in the absence of the B chain, it is usually necessary to add lysosomotropic amines or carboxylic ionophores to the incubation medium. [126]

In an effort to circumvent some of these problems, other toxins have been tested. Pokeweed antiviral protein is a single-chain toxin (hemitoxin) that depurinates ribosomes in a similar way to ricin; however, it has mainly been used to purge leukemic cells from autologous grafts. [124] [127] Diphtheria toxin[128] and enzymes, such as glucose oxidase and lactoperoxidase, have also been conjugated to MAb.[129] [130] The two enzyme-based immunotoxins are first added to the graft preparation where the MAb targets them to the cells of interest. Excess toxin is washed out and the substrate added to the cells. The enzymes then interact in a synergistic manner with the substrate, resulting in the generation of toxic halides and hydrogen peroxide, which kill the cells, but do not harm committed normal progenitor cells. In laboratory tests, an anti-CDw52 MAb achieved a 3 log depletion of marrow cells when used in this way, without any effect on normal marrow erythroid or myeloid precursors. [129] [130]

Immunotoxins have not yet secured a major place for engineering allogeneic HPC grafts, although they have been used clinically for T-cell depletion (see later). [126] In part, this is due to the problems of efficient delivery to the point of action within the cell cytoplasm. The use of hemitoxins or molecularly engineered toxic molecules and conjugates may help to resolve this.[131] [132] Unlike complement-mediated killing, it is also necessary to prepare a toxin conjugate with each individual MAb, instead of being able to add the toxic moiety to presensitized cells. The preparation, purification, and testing of such reagents are not trivial undertakings and, with ever-increasing regulatory scrutiny, can represent an enormous cost to any cellprocessing facility.

Panning and Column Techniques

Cytolysis of cells within the graft can result in problems of clumping because of the release of intracellular components. It also complicates analysis of the efficacy of the treatment. Cells may show only partial damage after treatment, which can be difficult to detect within conventional viability stains. On prolonged incubation or after infusion, these same cells may subsequently die, which makes it almost impossible to determine the true extent of target cell elimination ex vivo (see later). Many of these problems are resolved if cell elimination is effected using physical separation techniques. In these, the antibody is linked directly or indirectly, to a solid phase that is used to collect the target population. The bound cells can then be removed from the cell mixture by withdrawing the solid phase.

In its simplest configuration the MAb can be bound to a plastic sheet, either covalently or by passive adsorption. Nonreacted surfaces on the plastic are coated with irrelevant protein, and the cell suspension is incubated on the plastic. Nontarget cells can then be recovered by gently washing them over the surface, and in some configurations, it is also possible to detach the target cells from the surface (by physical or enzymatic means) for further study. Commercially developed systems have been clinically tested for both T cell depletion [133] and for the positive selection of HPC.[101] Panning using a CD5/CD8 device resulted in higher nucleated cell recoveries than were obtained by E rosetting but a similar frequency of clonable T cells in the product. This produced a lower overall T-cell depletion and a different distribution of T-cell subsets. [18] In a pilot study,[133] there were four graft failures in 54 evaluable patients and a 30% incidence of grade III acute GVHD.

Panning techniques require relatively large two-dimensional configurations to process the number of cells present in an average HPC graft. This makes the devices somewhat cumbersome, or multiple smaller devices have to be used simultaneously or in sequence to process the cells. This can result in prolonged processing times, with a higher degree of nonspecific cell loss. Attachment of the MAb to a particle results in a more compact configuration, while allowing the same amount of antibody to be offered to the target cell population.

Affinity chromatography has long been used for the separation of fluid-phase components from complex mixtures. For example, mouse MAb can be purified over columns of Sepharose particles to which protein A or an antimouse immunoglobulin antibody has been attached. This same approach can be used for the separation of cells. The technique has been pioneered predominantly by the CellPro Company, which has developed column-based systems for the positive selection of HPC, [134] and,

more recently, for CD2+ T cells.[135] In their stem cell enrichment device a column of avidin-coated Sepharose particles is used to collect CD34+ HPC from grafts that have been treated with an anti-CD34 IgM MAb conjugated to biotin. During passage over the column the biotinylated antibody reacts with the immobilized avidin, and the HPC are retained. Nontarget cells are washed through the column, and the CD34+ population is recovered by stirring the column matrix. The same basic approach can be adapted for other separations by changing the specificity of the MAb that is used, and investigators are currently evaluating an anti-CD2-based system for the enhanced depletion of T cells from CD34-selected allogeneic grafts. [135] A similar approach has been described using supplemental depletion with anti-CD4.[136] The CellPro separation systems are automated (but allow for some user intervention) and use a closed system for cell processing. The CD34-based system has received regulatory approval in the United States and Europe.

Traditionally, one impediment to the use of columns for cell separation has been the variable yields of target and nontarget cells. This is partly due to nonspecific trapping of cells within the matrix bed. Although this may be improved by extensive washing of the column, this may also displace the captured target cells if it is too extensive or vigorous. Improved collection capacity is achieved by increasing the volume of the matrix offered to the cells, however, this can also exacerbate nonspecific cell trapping. An alternative approach is to react the cells with MAb-coated particles in the fluid phase, and then collect the particles and attached target cells from the mixture. This is the principle behind immunomagnetic separation.

Immunomagnetic Separation

The use of MAb-coated superparamagnetic particles (i.e., particles that can be collected within a magnetic field but do not become magnetized by the field) has found widespread application in HLA typing, fractionation of subcellular components and organelles, isolation of bacteria, and for the enrichment of various cell populations. Various types of particles can be used; however, these differ widely in their properties and the method in which they are used.

At one end of the spectrum there are the large (>10 m in diameter) nickel particles under development by Coulter Cellular Therapies. [137] [138] These are coated with an antimouse immunoglobulin antibody and are being clinically evaluated for the depletion of CD8+ cells from donor leukocyte preparation used in post-transplant immunotherapy. The particles sediment rapidly under gravity, which can be used to further enhance their separability from the cell mixture. The washed, MAb-treated cell suspension is slowly rotated with washed nickel particles to which the target cells attached. The beads are allowed to sediment, which occurs rapidly, and the target cell-depleted supernatant can be aspirated, either for a second incubation with particles or to be exposed to permanent magnets to remove any residual particles. The particles show extremely low levels of nonspecific cell binding, which allows them to be used in several cycles to deplete other cell types within the mixture successively, without significant loss of nontarget populations. The reaction kinetics are also rapid, which allows even large numbers of cells to be processed in a matter of a few hours.

Investigators at the Dana Farber Cancer Center and at M.D. Anderson Cancer Institute have achieved excellent levels of depletion of the target population using several rounds of treatment with the particles on a clinically relevant scale. [138] The recovery of nontarget cells has been uniformly good, and processing has been completed within 23 hours. The utility of this method must, however, wait the formal results from the clinical trial.

The most widely used paramagnetic particles have been the 4.5-m microspheres developed originally in Norway by Ugelstad and now commercially available from Dynal. These polystyrene beads are extremely uniform in size and properties and contain magnetite dispersed throughout their volume. They can be coated with antibody, either using covalent linkage or by passive adsorption. In most clinical applications an anti-immunoglobulin antibody-coated bead is used to capture a MAb-sensitized target cell (indirect separation). This tends to optimize capture efficiency because it allows fluid-phase interaction of the MAb with the target cells at saturating concentrations. In contrast, if the MAb is directly attached to the microspheres (direct separation), there is no guarantee of an excess of MAb within the system (unless extremely large numbers of beads are added), and interaction with the target antigen occurs between two solid phases. This tends to slow the reaction kinetics and generally results in the preferential separation of cells expressing large amounts of the target antigen. In our hands, however, if the target cell is a mature T lymphocyte, antigen expression is generally uniformly high. Acceptable levels of depletion can, therefore, be achieved using either the direct technique or a semidirect technique, in which anti-Ig-coated beads are first incubated with MAb, washed, and then reacted with the cells. [139] The microspheres sediment relatively

slowly under gravity, so this contributes relatively little to the separation. For most separations, the cell suspension is incubated with an excess amount of the MAb, or MAb mixture, for 3060 minutes on ice, and then washed extensively to remove any residual fluid-phase antibody, which can block anti-immunoglobulin attached to the beads. The washed cells are then incubated under slow rotation, usually at 4°C (to reduce phagocytosis of the microspheres) for 30120 minutes to allow the target cells to attach to the beads. Effective rosetting is usually achieved by offering 550 beads per target cell, depending on the system. Rosetted cells and free beads are separated from the mixture by exposure to high-strength permanent magnets, such as neodymium-iron-boron or samarium-cobalt magnets.[140]

For clinical procedures, the separations are usually achieved first using a static collection to debulk the beads and then re-exposing the residual cells to a second magnetic field to remove any remaining beads and rosettes. A number of separation devices have been described,[141] [142] although only a positive selection device, the Isolex,[143] is commercially available. Developed by Baxter Healthcare, this system has received regulatory approval in Europe and is completing the process in the United States. The company has also produced a large-scale depletion device, the MaxSep;[144] however, this is only available for nonclinical applications or for use in company-sponsored trials.

Microsphere technology has become somewhat of a gold standard for cell separation. It is capable, with careful up-front optimization, of achieving highly efficient and reproducible selective depletions or enrichments of many cell types,[140] including normal and malignant T cells and T-cell subsets.[145] [146] [147] As with almost any biologic system, effective performance depends on both understanding the characteristics and limitations of each component and systematically evaluating and optimizing each stage of the process.[140] Recovery of the target cells (be they CD34+, HPC, or T cells) requires some care. Efficient detachment by physical means is not usually possible, although rosetted cells may proliferate if placed in culture.[140] In the case of CD34+ cells, the enzyme chymopapain has been used to clip off the region of the antigen to which the MAb is bound.[143] [148] More recently, Baxter has synthesized a peptide that competes with the MAb for the binding site on the antigen and can, therefore, be used to detach the MAb/bead complex from the HPC.[149]

Although this type of immunomagnetic separation is capable of capturing target cells that are resistant to IgG/complement-mediated cytolysis by virtue of their low target antigen density,[119] it will still tend to preferentially remove cells expressing higher densities. Perhaps surprisingly, we have also shown

that certain target cells that possess extremely high levels of a target antigen can also escape capture.[150] This is presumably due to steric hindrance effects because it can be reduced, or eliminated, if the amount of MAb in the system is reduced by coupling it to the bead surface. Another restriction on the use of the Dynal microspheres has been their relatively high cost. This can become a limiting factor for large-scale separations or where multiple rounds of treatments are required. Nevertheless, the efficiency of this approach and its long history in clinical applications still make it the leading method for immunomagnetic separation.

Nanoparticles

As the size of the matrix particle is reduced further, it is possible to increase the amount of antibody used for separation, without changing the reaction volume. This can result in faster reaction kinetics because the particles now assume some of the characteristics of a fluid, rather than a solid phase, and a reduction in steric inhibition of binding to the target cells that can occur with larger particles. This is all achieved at a cost, however, because as the size of the particles is reduced it becomes increasingly difficult to collect them efficiently using simple permanent magnets. Instead, high-gradient magnetic fields are used.[151] These are generated by placing an array of metallic wires or pins in a field generated by externally placed permanent magnets. When the nanoparticle-treated cells are passed over this array, they move away from the magnets and collect on the magnetized metal. They can then be recovered by demagnetizing the array by removing it from the magnetic field. The term nanoparticles can include matrices that behave as true colloids through to discrete particles. The majority of experience has come from the use of the dextran-based nanoparticles developed by Miltenyi,[152] although other dextran-based magnetic nanoparticles have been used; for example, biotin-coated dextran-ferritin particles were linked via fluoresceinated streptavidin to antibody-coated T cells that had incubated with biotinylated $F(ab)_2$ fragments of goat antimouse IgG.[153]

Although now available for research applications in a variety of configurations, clinical applications have focused on enrichment of CD34+ cells (see later). When using most nanoparticles for positive selection of HPC, it is not necessary to remove the particles from the surface of the enriched cells. Their presence does not appear to affect either their analysis or functional activity in vitro, and coated HPC engrafted without problems in the clinical study. This suggests that if the procedure is used for T-cell depletion, the T cells may be recovered and used for immunotherapy post-transplant. The company has developed a method to remove particles from cells;[154] however, they are extremely hard to identify, even when using electron microscopy, and so validation of removal can be very difficult.

In our hands, the nanoparticles are capable of giving uniformly efficient separations at high purities and yields. Their smaller size and faster reaction kinetics have made them suitable for use under circumstances where microspheres may give problems. For example, microbead depletion of T cells using anti-CD3 MAb can give extremely variable results, due presumably to activation of the antigen by interaction with the MAb and the beads. When nanoparticles were tested they gave very reproducible and efficient depletions, perhaps due to the faster reaction times, lack of activation of the cell, and even possible internalization of the magnetic matrix by the T cell.[155] This further illustrates the importance of dissecting and analyzing each component within a separation technology.

In an initial collaboration with Amgen, Miltenyi has produced a clinical scale magnetic separator for the enrichment of CD34+ cells.[152] The system is similar in configuration to the CellPro device. It is a computer-controlled closed system, in which the antibody and particle-treated cells are passed sequentially through two columns, the first of which is designed to remove nonspecifically adherent cells from the mixture; before selective enrichment on the second column. This second column is magnetized during the collection phase by positioning it within an externally generated magnetic field. For recovery of the selected cells, the magnets are withdrawn, the metallic matrix becomes demagnetized, and the nanoparticle-coated cells are released from the column. The device has received regulatory approval in Europe and approval in the United States is pending.

Both the Amgen/Miltenyi and the CellPro devices have been predominantly used for the enrichment of CD34+ populations as a means of depleting tumor cells from autologous grafts. More recently, investigations have begun to look at positive selection as a means for depleting T cells from allogeneic grafts.[135] [143] [156] [157] [158] Depending on the ultimate clinical application, for example, use in HLA-matched or HLA-mismatched transplantation, the 23 log depletions of T cells achievable by CD34 positive selection may not be adequate when used alone to engineer an allograft. Under these circumstances, the procedure can be supplemented or preceded by a negative selection of T cells.[135] [136] In the case of the CellPro system, the company is testing a CD2 depletion column. If, however, a similar strategy is to be used for the Miltenyi device, it will be necessary to ensure that all of the nanoparticles are removed from the CD34+ cells collected during the positive selection, to avoid these cells co-collecting with the T cells during the negative selection procedure. Alternatively, the negative selection could be performed first.

Other Positive Selection Techniques

Positive selection of HPC as a means of T-cell depletion has focused on the use of CD34 antigen to target the HPC. It is clear that this antigen is present on cells other than true pluripotent hematopoietic stem cells (although recent data suggest that a population of pluripotent stem cells may even be CD34-negative).[159] [160] As the immunophenotype of these cells becomes more clearly understood, it is apparent that the pluripotent stem cell population represents probably <1% of the CD34+ population. Production of other MAb targeted more specifically at this subpopulation could, therefore, theoretically provide an additional 2 logs of T-cell depletion, if these reagents were used in place of or to supplement anti-CD34 for positive selection. Although new antibodies have been described, they apparently do not yet identify true stem cells.[161] [162] Once these become available, the questions will be whether it will become technically too difficult to isolate and handle these very small numbers of cells efficiently and with high yields, and if they can provide stable long-term engraftment in the absence of a period of very prolonged aplasia.

Additional MAb can already be used to obtain subsets of the CD34+ population. Suitable target antigens include CD38, Thy-1 and HLA-DR.[163] Practically, as successive depletions are performed, the performance characteristics of the system become crucial. Nonspecific cell losses can become critical. Perhaps the most extensive subsetting has been performed using fluorescence-activated cell sorting (FACS) by flow cytometry. In this procedure, the target populations are identified by positive or negative binding of fluorescently tagged MAb and then identified by passage within a fluid stream through laser light beams of specific wavelengths. Cells with specific binding profiles and light scattering profiles can then be deflected from the path and collected as a highly purified population. This approach has, until recently, only become practical when used by companies with access to high-speed cell-sorting capabilities because most commercially available cytometers could not

process clinically applicable cell numbers within a reasonable time.

Much of this initial work was pioneered by SyStemix in California, [164] who used the technique to prepare highly purified HPC as a means to deplete up to 7 logs of tumor cells from autologous grafts. [165] This method could be readily adapted for processing allogeneic grafts. It remains to be determined whether it would result in the depletion of cells that may facilitate engraftment (particularly across histocompatibility barriers), or provide beneficial graft-versus-disease responses. Although turbo sorting options are becoming available for laboratory flow cytometers, the economics and time considerations associated with this technology still tend to place it in the research classification rather than the mainstream. In an effort to reduce cytometer time it is usual to do some debulking of the cells by other selection technologies before performing the sort. [164] These additional steps, in T-cell depletion applications, may be adequate alone to provide the appropriate graft composition required for transplant.

Repeated negative selection of various lineage-committed cells has also been used to achieve enrichment of progenitors. [166] In these procedures, multiple MAb recognize the committed cells and the progenitors remain by default. Although this method has been used clinically for T-cell depletion, [166] it is likely to remain a research tool because it is likely to prove too expensive to produce the multiple reagents required for clinical grade standards.

Comparative Studies

Few head-to-head studies compare methods for T-cell depletion (Table 94-1). Feugier and colleagues compared complement, CD2/CD7 immunomagnetic depletion, CD5/CD8 panning, CD34 positive selection, and centrifugal elutriation in 79 procedures. [167] Depletions of 1.33 logs were obtained with negative selection giving approximately 2 logs, whereas positive selection depleted about 3 logs. There was a consistent progenitor cell recovery of about 50% from all of the methods. Specific T-cell depletions resulted in <0.5 log loss of B cells, whereas positive selection depleted more than a log and eliminated virtually all NK cells. Frame and colleagues [168] compared the use of CAMPATH plus complement, a CD5-immunotoxin (Xomazyme-H65), immunomagnetic separation, and SBA plus and minus E rosetting. They found that, with the exception of SBA alone, all techniques gave depletions in excess of 99%. The results of any comparative study must, however, be interpreted with great caution because each method must be optimized independently and performed on a clinically appropriate scale.

CLINICAL RESULTS FROM PHENOTYPIC DEPLETIONS

The choice of antibody for specifically depleting T-cell mediators of GVHD remains unresolved, but it is clear that reagents with different specificities have produced promising clinical

TABLE 94-1 -- Characteristics of Widely Used Graft Engineering Techniques

Separation Method (Commercial Systems)[a]	Target Cells	Advantages	Disadvantages
Soybean lectin	Nonstem cells	Technically easy Clinical experience	Long procedure Yield of stem cells Regulatory issues
Cytotoxic drugs	Usually leukemic cells	Technically easy	Poor drug availability for allograft treatment Target cells not available for analysis/use
Panning (AIS/RPR Gencell)	Antibody-detemined Lectin-determined	Technically easy Target cells also recoverable Lectin/antibody combinations	Devices may be cumbersome or small and multiple Regulatory issues Device availability
Antibody + complement (C)	Antibody-determined	Technically easy Second step (C) is generic Can use antibody panels Clinical experience	Regulatory issues for C Nonspecific toxicity/lot variability Variable efficacy/antigen densitydependent Target cells not available for analysis/use
Immunotoxins	Antibody-determined	Exploits antibody specificity High potency possible Clinical experience	Immunotoxin preparation required for each antibody used Specific delivery to point of action in cells
Immunoaffinity columns (CeprateCellPro)	Antibody-determined	Exploits antibody specificity Technically easy/rapid Approved in USA and elsewhere Clinical experience	Limited application for T-cell depletion Trapping of cells in matrix May require ve/+ve sequence in some separations Most experience for +ve selection only
Immunomagnetic (IsolexBaxter/Nexell) (CliniMACSMiltenyi)	Antibody-determined	Exploits antibody specificity Positive and negative separation Low toxicity/generic 2nd step Capable of good yields and purity Clinical experience	Cost Removal of particles between +ve/ve separation Some trapping of nontarget cells Some antigen density issues, less than with C Regulaory issues/one approved device
Molecular techniques	Depends on system	May offer high specificity Many possible applications	Still in early stages of development Too sophisticated for simple manipulation

[a] Not all systems are currently available or approved by the U.S. Food and Drug Administration.

results. In some cases, the method of use will have a major impact on the efficacy, both quantitatively and qualitatively, on the outcome, as will the context in which the manipulated graft was used. The data must, therefore, be interpreted with these factors in mind.

CAMPATH Antibodies

The CAMPATH series of antibodies has been extensively used in Europe for in vitro and in vivo depletion. These reagents are predominantly IgG_{2c} or IgM monoclonals, which identify a 12-amino acid antigen with a single N-linked carbohydrate and a glycosylphosphatidyl anchor, designated CDw52. [169] [170] The antibodies bind to most B and T cells, macrophages, and monocytes.[118] The IgM reagent was used together with donor serum to treat 11 HLA-matched grafts with promising control of GVHD, but three graft failures were thought to be due to rejection. [171] Subsequently a graft failure rate of 20% was reported in studies of patients with malignant disease, who showed a 17% incidence of grade I GVHD and a 7% incidence of grade IIIIV disease. Rejection was reduced to 413% by administration of cyclosporin A (CsA), with and without total lymphoid irradiation respectively. [172] Pretransplant administration of IgG_{2b} CAMPATH combined with the use of a CAMPATH-depleted graft without additional GVHD prophylaxis was studied in HLA-matched patients. The graft failure rate was 9% with a 2% incidence of severe acute GVHD and no severe chronic disease.[118] The antibody has also been used in the absence of added complement to treat grafts ex vivo, with the aim of using in vivo activation of complement-mediated lysis. This was reported to result in a low incidence of graft failure and severe GVHD, with improvements in transplant-related deaths and leukemia-free survival.[173] [174] Use of the MAb in vivo and in vitro was reported in a study of 28 patients, where it resulted in no GVHD but a 25% incidence of graft failure, attributed partly to delayed engraftment and possible destruction of graft facilitation cells. [118]

In a review of the use of CAMPATH antibodies for in vitro and in vivo T-cell depletion in matched sibling transplants, with a 10-year follow-up, the risk of relapse in acute myelogenous leukemia (AML) and ALL plateaued at 30%.[118] In CML the risk of relapse continued for at least 5 years and plateaued at 60% at 7 years, re-emphasizing the important role of GVL in this disease. In a review of 180 non-HLA-identical transplants, from matched unrelated and related partially matched donors, the incidence of graft failure was 51% for those who did not receive the antibody in vivo and 24% for those who did. [118] LPD is always a concern in patients who receive T-depleted grafts and is reported as 10 cases in 1,529 CAMPATH-manipulated grafts; however, there was a high incidence of cytomegalovirus viremia and delayed T-cell reconstitution. [87] [175]

Anti-CD3

Anti-CD3 MAb have been used with varying success. They are particularly attractive for depletion applications due to the high expression of the antigen on T lymphocytes and the commercial availability of a clinical grade preparation of the antibody. [176] Binding of the antibody blocks the function of a 20,000-dalton

component of the antigen receptor on T cells and results in a mitogenic stimulus, which leads to release of cytokines and colony-stimulating factors. [177] [178] It has been used in vivo to treat steroid-resistant GVHD. [179] In vitro, marrows from 10 patients with hematologic malignancies were incubated with anti-CD3 prior to infusion, and all engrafted in a mean of 22 days; however, 50% developed acute GVHD. [180] A subsequent study in 17 patients who received antibody-treated HLA-matched or minor mismatched grafts as part of a protocol including methotrexate as prophylaxis produced fatal GVHD in 2 recipients (with accompanying cytomegalovirus infection) and severe GVHD in a third, to give an overall incidence of 18% (compared to an incidence of 79% in historical controls). [181] These studies anticipated that the antibody-treated cells would be lysed by the patients serum complement; however, in vitro studies suggest that this may not be the case. [182]

The antibody has also been used with xenogeneic complement to treat grafts that are to be transplanted across major histocompatibility barriers. In a study of six children with juvenile CML, all engrafted granulocytes and platelets within 21 days and developed grade II or lower GVHD. [183] Three remained alive and well at 1802,400 days post-transplant, two died from infections, and one had relapsed. A larger series of marrows has been treated by Henslee-Downey and colleagues using the OKT3 preparation MAb in combination with baby rabbit complement. [184] This resulted in a 2.49 log depletion of T cells, and an infused T-cell dose of 4.63×10^4 /kg (n = 110). The probability of engraftment was 98% with a median of 15 days to a neutrophil count of 1,000/l. The incidence of grade IIIV GVHD was 32% and of grades IIIIV disease, 16% (n = 109).

Anti-CD3 MAb has also been linked to ricin A chain to form an immunotoxin, which was used to treat HLA-identical grafts in a study of eight patients. In vitro incubation produced a 3 log depletion of T cells and no acute GVHD was seen in the recipients, although there was a 25% incidence of graft failure. [185] These antibodies have also been used with Dynal microspheres for immunomagnetic depletion and produced a 1.7 log removal of T cells, resulting in an infused cell dose of 0.49×10^6 CD3+ cells/kg. This produced engraftment in 96% of HLA-matched unrelated (n = 36) and single-antigen mismatched recipients (n = 10). There were three late graft failures, and a 37% incidence of grades IIIV GVHD, which correlated with the infused dose of CD3+ cells. [186]

We have reported that anti-CD3 MAb do not work reproducibly with Dynal microspheres and have attributed this, in part, to activation of the cells during separation, with an associated attempt to internalize the bead, resulting in breakage of the link between the T cell and the microsphere. [140] When nanoparticles are used, in contrast, very reproducible results could be obtained with anti-CD3 MAb, due probably to a combination of faster reaction kinetics, and the possibility of internalization of the particles, which would not interfere with the ability to collect the T cells in the magnetic field. [139]

Anti-CD3 has also been used in the form of a tetrameric anti-CD3/antidextran complex with immunomagnetic nanoparticles to deplete T cells from 47 grafts for patients with leukemia or myelodysplastic syndromes. [153] There was a high incidence of graft failure and disease relapse after the first 27 transplants, which was attributed to overdepletion of the T cells in the graft. The protocol was amended to add back T cells to produce an infused dose of 2×10^5 /kg and CsA prophylaxis was administered. The mean level of depletion achieved was 3.64 ± 0.67 logs. Add-back of T cells reduced the incidence of graft failure from 22% to 8%; however, the incidence of grade II and grade III GVHD increased from 43% to 85% and from 18% to 54%, respectively, resulting overall in an increase in GVHD-related deaths from 15% to 46%. There was a 41% incidence of relapse in the recipients of heavily T-depleted grafts and a 0% incidence in those on the T-cell add-back protocol. Many of these problems were attributed to the activation of clonal T cells by the anti-CD3 antibody and the possible involvement of NK cells as effectors of GVHD.

Anti-CD3 reagents have also been combined with anti-CD2 to treat matched sibling grafts in 10 patients with hematologic diseases with poor prognosis in a regimen containing post-transplant methotrexate prophylaxis. [187] The levels of T-cell depletion were relatively low (88%), but all patients engrafted and no GVHD was seen. Seven (70%) were still alive, although the follow-up time was extremely short (210 months). Vartdal and colleagues with Dynal microspheres to deplete T cells in

laboratory studies used the same antibody combination. [145] This resulted in a 23 log removal, which was confirmed and reported by Gee [146] and by Knobloch et al., [188] who described 2.76 log depletion, in contrast to 3.39 logs obtained using an SBA plus rosetting technique.

Anti-CD2

Anti-CD2 MAb have also been used alone to reduce GVHD. The CT-2 MAb was used to treat grafts for 40 leukemia patients in a randomized double-blind trial. [189] This reduced the incidence of acute GVHD from 65% to 15%; however, graft failures increased from 0% to 12.5%. The incidence of disease relapse and survival was not significantly different in the two groups. When used to treat histoincompatible (n = 15) versus histocompatible (n = 8) grafts, without post-transplant GVHD prophylaxis, engraftment was seen in 7 of the 8 histocompatible recipients, but only in 4 of the 15 incompatible recipients, 2 of whom went on to develop grades IIIV GVHD. [190]

Anti-CD5

Anti-CD5 has been widely used for depletion both alone and in combination with other MAb. The T101 antibody has been used in its intact form and as an $F(ab)_2$ fragment to prepare immunotoxins with ricin A chain. [191] The fragment was particularly effective, depleting 2 log more cells than the immunotoxin prepared with intact anti-CD5. In clinical studies it achieved 99.5% depletion of T cells and the incidence of acute GVHD was 9.1% with an 18% incidence of graft failure. Anti-CD5 immunotoxins have also been used by Antin et al. to deplete 38 HLA-matched and 17 HLA-mismatched grafts for patients with acute or chronic leukemia. [126] This resulted in >95% removal of T cells, with an infused dose of $6.2 \pm 4.9 \times 10^5$ /kg. There was engraftment of all recipients within 1233 days (median 18 days) to 500 granulocytes/l, and platelet engraftment to 50,000 at a median 31 days for the matched recipients and 29 days for the mismatches. There were late graft failures in two of the matches and one of the mismatches, and the incidence of grades IIIV GVHD was 26% and 41%, respectively. Chronic GVHD was seen in 13% and 0%, respectively, of evaluable cases. There were four cases of LPD in the matched recipients, three of whom died, and one of whom responded to donor leukocyte infusions (DLI), but died from chronic GVHD.

Filipovich and colleagues used an anti-CD5 immunotoxin to treat histocompatible grafts for 29 patients with advanced leukemia and achieved complete donor engraftment in 28. [192] An increase in the dose of the reagent from 300 to 1,000 ng reduced the incidence of acute GVHD in the recipients from 100% to 34%; however, there was no direct correlation between GVHD and the T-cell dose infused. A better correlation was, however, seen between the T cells detected in the graft following 16 days in culture with IL-2.

Anti-CD6

Anti-CD6 binds to an antigen that is not expressed on myeloid precursors, nor B and NK cells, but is found on mature T cells. The antibody was used with rabbit complement to purge 112 matched sibling grafts for transplant to patients with hematologic malignancies, who received no post-transplant GVHD prophylaxis. [193] Each graft received three rounds of ex vivo treatment. Three patients (2.7%) failed to engraft, 18% developed grades IIIV GVHD, and 7.1% developed chronic GVHD. In 50 good-risk patients, the estimated probability of 3-year disease-free survival was put at 50% with a median follow-up of 44 months. A 10-year review of the use of anti-CD6 to deplete HLA-matched grafts revealed an initial engraftment rate of 98%, a 15% incidence of acute GVHD, and a 5% incidence of chronic GVHD, with 17% transplant-related mortality. [194]

Anti-CD6 has been used in combination with Dynal magnetic beads by Egeland et al. [195] in laboratory studies, where it resulted in 23 log depletions; however, residual CD2+ and CD3+ cells were detected, as was functional response to both mitogens and IL-2. This was attributed to failure of the beads to capture cells with low surface expression of CD6.

The MAb has also been combined with anti-CD8 and complement to treat HLA-matched grafts for 31 patients. [196] There was one graft failure (3.3%) and a 24% incidence of acute GVHD, of which 87.5% was grade I disease (six patients) and the remainder (one patient) grade III disease. A later review of 37 patients revealed low-level reconstitution of CD8+ cells at 60 days post-transplant, but later recovery of the CD4+ population. [197] Results using this MAb combination were compared to those obtained using T-replete matched sibling grafts and GVHD prophylaxis with methotrexate and CsA in 46 leukemia patients. [198] Forty-five patients engrafted, with slightly faster reconstitution times in recipients of T-depleted grafts. There was a 23% incidence of grades IIIII GVHD in the recipients of depleted grafts, versus 12% in those receiving T-replete transplants, and the incidence of chronic GVHD was substantially higher (51% vs. 23%, respectively). The cumulative incidence of relapse was 39% in the T-depleted group and 54% in the remainder.

Multiple Pan T Antibodies

Various antibody panels have been formulated in an attempt to increase the efficiency of T-cell depletion. Fifty-one HLA-identical grafts were treated with combinations of antibodies to CD2, CD5, and CD7 together with complement for transplant to patients with leukemia, most of whom received conditioning with TBI and cyclophosphamide, but no post-transplant prophylaxis.[199] Graft failure was seen in 19.1% and 23% died from graft-related complications. A similar antibody panel was used in HLA-identical grafts for 62 patients with poor-prognosis hematologic malignancies, 26 of whom received post-transplant GVHD prophylaxis with either CsA or methotrexate.[200] There was a 19% incidence of graft failure, but only one case of severe acute GVHD. Unlike the previous study, this one did not find any significant correlation between the infused T-cell dose and the incidence of graft failure. Wang et al. achieved a 23 log depletion of T cells using antibodies to CD2, CD5, and CD7 independently.[147] This increased to 4 logs when the three were combined. When this panel was used to purge two autologous grafts, there was complete removal of T cells, as determined by immunocytochemistry, and there was multilineage stable engraftment in the recipients.

T-Cell Subsets

An improved understanding of the T-cell subsets involved in mediating responses to histocompatibility differences (see earlier) has prompted the use of antibodies to CD4 and CD8 for allogeneic graft manipulation. Anti-CD8 has been used with both complement and immunomagnetic beads with the aim of depleting the cells responsible for mediating GVHD and retaining those with GVL efficacy. [201] In a randomized clinical trial, HLA-matched leukemia patients received grafts that were depleted of 1.52.0 logs of CD8+ cells and post-transplant CsA. This reduced the incidence of GVHD without any increase in the relapse rate. The antibody has been used by Jansen et al.[202] with immunomagnetic beads to deplete >95% of CD8+ cells from 20 matched sibling and 9 alternative donor grafts. The patients received 1.4 ± 2.7 × 10^5 CD8+ cells/kg and were given CsA prophylaxis starting the day before the infusion. There was one failure to engraft, and the median engraftment time to 500 granulocytes/l was 17 days. There was a 20% incidence of

grade II GVHD in the matched recipients, which increased to 63% in those receiving depleted grafts from alternative donors.

In an attempt to improve engraftment rates and also to decrease relapse, Gallardo and colleagues have used a combination of immunomagnetic depletion of CD4+ cells with add-back of a fixed dose of purified CD8+ cells (0.25 × 10^6 /kg).[203] Twelve patients with CML in first chronic phase were treated, and all were at a high risk of developing acute GVHD. All received CsA and methotrexate post-transplant. There were no graft failures and the incidence of grade IIIIV GVHD was 16.6% with an actuarial 3-year survival rate of 81.8%, with no observed relapses.

An antibody to the heterodimer of the T-cell receptor (T10B9.1A31) has been widely used in kidney allograft rejection [204] and also to T-cell deplete matched sibling grafts[205] and for transplant to recipients showing varying degrees of haplodisparity. [206] [207] [208] [209] In a study of 48 patients with CML who received both T10B9.1A31-treated grafts that were matched (n = 20) or mismatched at one or more major HLA loci (n = 28) and post-transplant CsA, 94% achieved engraftment. [207] The incidence of grade IIIV GVHD was 39.6%, with 8.3% developing chronic GVHD. There was no statistically significant difference in the incidence of grade IIIV GVHD in recipients of matched or mismatched grafts, and 2-year disease-free survival rates were 49% and 51%, respectively. In a subsequent analysis, the incidence of disease relapse was lower in patients who received a treated graft from an unrelated donor as opposed to an HLA-identical sibling. This was attributed to an increased opportunity for a GVL response due to a higher level of HLA disparity. [205]

Henslee-Downey et al. have used this antibody, in combination with complement, to T deplete 98 grafts from partially mismatched related donors, achieving a median 1.85 log depletion of T cells by limiting dilution analysis, and a median infused T-cell dose of 6.77 × 10^4 /kg. Engraftment was achieved in >90% of the patients in a median of 18 days to 1,000 granulocytes/l, with a 21% incidence of grade IIIV GVHD and an 11% incidence of grades IIIIV disease. [208] [209] Interestingly, Lamb et al.[210] have reported that statistically significant improved disease-free survival was seen in patients who received T10B9.1A31-treated grafts and went on to exhibit higher numbers of circulating T cells post-transplant. This could suggest a role for this subpopulation in mediating GVL activity. Kawanishi and colleagues, however, implicated this population in promoting engraftment of T10B9-treated grafts and suggested that the + population was associated with acute GVHD. [211]

Indirect Depletion by CD34-Based Positive Selection

The demonstration that long-term stable engraftment can be achieved by the transplantation of enriched CD34+ has stimulated interest in this approach as an alternative method for T-cell depletion. A number of methods have been developed, predominantly based on capturing the target cells onto a solid phase (see earlier), such as plastic plates (AISRPR Gencell), Sepharose columns (CellPro), paramagnetic microspheres (Baxter, Nexell, Dynal), or nanoparticles (Miltenyi). De Wynter and colleagues have compared techniques on a small scale. They reported that the most effective methods were fluorescence-activated cell sorting, which may be impractical for most routine clinical applications, and immunomagnetic nanoparticles. They found that the Sepharose column technology gave excellent purities but lower overall recoveries of colony-forming progenitor cells. [212]

Clarke and colleagues reported a comparison of the CellPro column and CAMPATH-1M for T-cell depletion. They achieved a 99.8% depletion of T cells with a 55 ± 12% recovery of the CD34+ cells using the CellPro laboratory scale separator and similar results with the clinical scale device. [213] This compared to a 98.4% depletion of T cells and a 50 ± 7% recovery of CD34+ cells using CAMPATH-1M. T cells, which could subsequently be used for immunotherapy, could be recovered in the unadsorbed fraction from the CEPRATE device.

Cottler-Fox and colleagues have described the use of the CellPro device to deplete T cells from marrow grafts (n = 10) and PBPC collections (n = 11). They achieved about a 3 log depletion of T cells and a CD34+ cell purity of 53.3 ± 27.9% for PBPC products and 65.4 ± 10.9% for marrow. [214] Based on these figures, an average patient would receive 3.4 × 10^4 T cells/kg in a CD34-enriched marrow graft and 1.2 × 10^5 T cells in a PBPC product. Urbano-Ispizua reported results from a study of 20 patients whose HLA-matched PBPC grafts were T-cell depleted using the CellPro system.[215] The median doses of CD34+ and CD3+ cells infused were 2.9 (range 1.58.6) × 10^6 /kg and 0.42 (range 0.12.0) × 10^6 /kg, respectively. All patients engrafted in a median of 14 days to 500 granulocytes/l and 10 days to 10,000 platelets/l. GVHD prophylaxis consisted of CsA and methylprednisolone. No patient developed grade IIIV acute or extensive chronic GVHD. Seventy-five percent of the patients were alive and in remission at a median follow-up of 7.5 months.

CellPro is currently evaluating a double-column procedure in which CD34-based positive selection is followed by negative depletion of CD2+ cells. In a case report, Martin-Hernandez and colleagues indicate that a 4.2 log depletion of a single PBPC apheresis collection could be achieved using this approach, giving a final CD3+ cell dose of 0.11 × 10^6 /kg, and a CD34+ cell dose of 5.05 × 10^6 /kg. [216]

The Isolex immunomagnetic separator (Baxter, Nexell) was used in a study of 14 patients who underwent HLA-identical sibling-matched transplants. [217] All received TBI, thiotepa, cyclophosphamide, antithymocyte globulin, and methylprednisolone before marrow infusion. No post-transplantation immunosuppressive therapy was given except for a 5-week course of steroids. The mean purity of CD34 product was 64.9 ± 6.0%, and the patients received a mean dose of 1.24 ± 0.21 × 10^6 CD34 cells/kg. A mean of 9.4 ± 1.7 × 10^4 CD3 T cells/kg was present in the CD34-enriched product, representing a 2.7 ± 0.1 log depletion. There were no graft rejections and patients achieved a sustained absolute granulocyte count of >500 in a median of 10.5 days and a sustained platelet engraftment of >20,000 in a median of 27 days. Patients were discharged a median of 21.5 days after marrow infusion. There were no instances of grade III or IV GVHD and no unexpected adverse events during the transplant hospitalization. With a median follow-up of 12 months, the estimated 100-day survival was 86 ± 9%.

There is likely to be increasing interest in this technology with the proposal from various investigators that crossing histocompatibility barriers is facilitated by the use of higher doses of stem cells. Sierra and colleagues reported that marrow-nucleated cell doses in excess of 3.65 × 10^8 /kg were associated with faster neutrophil and platelet engraftment and a decreased incidence of acute GVHD in matched or minor mismatched, unrelated marrow transplants. [218] The mechanism by which this occurs is not completely understood. It may be due to a decreased incidence of early post-transplant infections, which are thought to amplify GVHD. It may also involve veto activity by a population of cells present within the enriched stem cells, which serves to impede immunologically mediated rejection of the graft. [219] [220] [221] Doses of CD34+ cells in excess of 6 × 10^6 /kg have been recommended. [222] [223] These are difficult to achieve in routine marrow harvests. Apheresis collections from normal donors who have achieved a good mobilization may provide the requisite cell number; however, these collections contain large numbers of T cells. The use of a CD34-enrichment procedure provides the opportunity to deplete the T cells from the PBPC, and the enriched cells can be used to supplement the HPC obtained in

the T-depleted marrow harvest. This approach has been described

by Aversa and colleagues,[223] [224] who used a combination of marrow and PBPC that were T-cell depleted by a combination of E rosetting and lectin treatment. In a preliminary study of 17 leukemia patients, they were able to increase the number of colony-forming cells in the graft by 10-fold over that in the marrow alone. The patients were conditioned with TBI, cyclophosphamide, thiotepa, and antithymocyte globulin. All but one engrafted; however, 16 (56%) died of transplant-related toxicity within 18180 days of graft infusion, and a further patient died from grade IV GVHD. [223] In the subsequent 24 patients the protocol was modified to deplete the marrow using lectin and the PBPC by a combination of E rosetting and CD34 selection. [225] This resulted in a graft containing 13.7 × 10^6 CD34+ and 3 × 10^4 CD3+ cells/kg. The conditioning regimen was modified to substitute fludarabine for cyclophosphamide to reduce toxicity. Twenty-two patients (94%) engrafted and one achieved secondary engraftment.[224] At a median of 6 months (19 month range), <5% had developed acute GVHD and there was no chronic GVHD. Eight hematologic deaths (29%) and one disease relapse occurred. Interestingly, they described the appearance and persistence of a population of CD3+/8+ cells post-transplant. These cells also expressed NK receptors for HLA-C alleles and were able to lyse fresh leukemia cells.

Grafts containing the required 6 × 10^6 CD34+ cell dose and <3 × 10^4 CD3+ cells/kg can be obtained entirely from PBPC collections using a combination approach for T-cell depletion. This involves sequential use of centrifugation over light-density Percoll, E rosetting, and CD34 enrichment on a CEPRATE SC device. In a preliminary study of 29 depletion procedures, a mean 4.5 log depletion of CD3+ cells was achieved, with approximately equal contributions coming from the rosetting and CD34 enrichment steps.

Other Cell Populations in the Graft

It is likely that stem cells grafts, however they are manipulated, contain as yet poorly characterized populations of cells with potent immunologic functions. These would include a variety of veto[221] and facilitating cells.[226] One type of veto cell has been described by Thomas and colleagues in a rhesus monkey transplant model in which allogeneic $Dr^{/dim}$ marrow cells were transplanted and used to condition the animal to receive a kidney graft from the same donor. [227] The marrow cells were shown to possess veto properties, in that they could produce clonal inactivation of allospecific T-cell precursors, with minimal effects on third-party responsiveness. The veto cells were sensitive to ultraviolet-B irradiation and displayed a CD32+8+ phenotype. The authors felt that these properties may indicate that veto activity resided in a dendritic cell population. Veto activity toward allospecific T cells has also been described for lymphokine-activated killer cells when added to mixed lymphocyte cultures.[228] This was abrogated by depletion of CD56+ cells and increased by depletion of CD3+ cells. Recent results also suggest that CD34+ cells may possess veto activity in that they induce tolerance in the recipients (see later). [229] Facilitator cells, as described by Ildstad and colleagues, [226] represent about 0.4% of nucleated marrow cells, and have a characteristic CD8+/3/Thy1+/$DR^{dim/intermediat}$ / / phenotype. In a murine transplant model 3 × 10^4 of these cells could facilitate transplant of allogeneic stem cells in an MHC-specific manner. They are now being indirectly enriched by depletion of committed lymphoid and myeloid cells and the manipulated graft used for transplant across major and minor histocompatibility barriers. To date all patients are reported to have engrafted. This approach is being extended for use in solid organ transplant,[230] in which the recipient would be preconditioned using a nonmyeloablative regimen and would receive a donor-derived facilitator-enriched graft to develop a chimeric state before receipt of the allogeneic organ.

FUNCTIONAL DEPLETIONS

The early identification of T cells as primary candidates as mediators of GVHD, combined with the empirical observations that removal of these cells from allografts did indeed result in clinical benefit, has resulted in an emphasis on the quantitative removal of these cells. To a certain extent, any antigen that was present on mature T cells was felt to be a suitable target to be used in their depletion, and, again within certain limits, this has proved to be the case. The problems of graft failure and disease relapse that have emerged as side effects of T cell depletion have, however, raised the question of whether it is more appropriate to target specific T-cell subsets. This could be achieved either by depleting T-cell subsets identified by restricted expression of an antigen(s) whose function may still not be fully understood or by targeting antigens that are more clearly identified with some T-cell function, such as the IL-2 receptor. [70]

Cavazzano-Calvo and colleagues have activated donor blood and marrow T cells by co-culture with the intended recipients cells for 2 days. [231] This results in expression of the IL-2 receptor on the alloreactive donor cells. These were then targeted using an anti-IL-2 receptor B chain MAb conjugated to ricin. This treatment abolished both primary responses in a mixed lymphocyte reaction (MLR), and also cytotoxicity toward recipient cells, but retained activity against third-party cells. Chaudhary and colleagues developed a recombinant single chain immunotoxin composed of variable regions of an anti-Tac MAb and truncated diphtheria toxin. [232] This killed cells that had been activated in an MLR with resulting expression of the p55 subunit of the IL-2 receptor. Mavroudis and colleagues used two *Pseudomonas* exotoxin-based immunotoxins with specificity toward the receptors for IL-2 and IL-4 to deplete alloreactive cells generated by co-cultivation of donor and recipient cell. This resulted in removal of >92% of reactivity against the recipients stimulator cells, with retention of >64% of reactivity toward third-party stimulators.[233] The immunotoxin had no effect on the growth of CFU-GM of normal marrow cells.

Rencher and colleagues have used fluorescence-activated cell sorting to remove donor cells that were activated by co-culture with host-derived lymphoblastoid cell lines and then stained using a panel of MAb directed against activation markers. [234] The sorted population did not contain cells responsive to HLA antigens, but retained helper and cytotoxic activity responses to foreign antigens. These techniques have mainly been used to process cells for administration as DLI post-transplant. The practicality of using this approach to process the primary graft remains to be established.

Another potential primary target is the leukocyte function antigen (LFA-1) that is expressed on cytotoxic T cells, monocytes, and NK cells. LFA-1+ cells are decreased in the peripheral circulation of animals with GVHD, suggesting that they have been recruited into the inflammatory sites. [235] When an immunotoxin was prepared using anti-LFA-1 MAb, it prevented GVHD in particular mouse donor recipient combinations. In vitro it reduced T-cell cytotoxicity by about 2 logs and also significantly impaired NK cell activity. There was, however, also a significant increase in failure to engraft, which was thought to be caused by depletion of either stem cells or graft facilitating populations. Many of these approaches are still in development or in early clinical trials; however, they provide an interesting indicator as to the future direction of the field.

EVALUATION OF ALLOGRAFTS EX VIVO

Most allograft engineering has focused on T-cell depletion and has emphasized quantitative rather than qualitative removal. The majority of allografts are infused immediately on preparation rather than after cryopreservation and storage, and the implications of infusing large numbers of T cells can be severe or

lethal. It is, therefore, important to have available methods that can rapidly enumerate the numbers of T cells within the graft. Although early methods used detection of E rosette-forming cells (see earlier), or manual immunofluorescence following staining with pan T cell-directed MAb, most laboratories currently rely on flow cytometry. This technology is widely used in routine clinical laboratories; however, some precautions must be taken when it is used for T-depleted allografts.

Flow Cytometry

Accurate enumeration of very small numbers of target cells by cytometry requires rare event analysis. In this technique, large numbers of events must be accumulated and carefully analyzed if reliable data are to be obtained. This approach has been widely adopted for counting CD34+ cells, [236] but is still neglected often when enumerating T cells in depleted grafts. The choice of antibodies for detection of the T-cell population is also critical, when an MAb-mediated depletion technology is used. The same MAb should not be used for both depletion and analysis because cells that became coated with the antibody during the depletion phase, but which were not effectively removed, will be blocked from detection. They can, however, be detected by addition of an anti-immunoglobulin antibody conjugated to a fluorochrome different from the one conjugated to the T cell-directed MAb. The most sensitive detection is achieved by using panels of noncross-blocking antiT-cell antibodies directed against a variety of epitopes. [140]

In addition, it is important to include a viability stain in the analysis panel. Although this is less crucial when T-cell depletion is achieved by physical removal of the target cells, it is extremely important when in situ elimination methods are used. Under these circumstances, the depleted allograft may contain dead or dying T cells that will be detected by flow, but which may not contribute to postinfusion events. Suitable viability stains include propidium iodide and 7-aminoactinomycin. The analysis of cell viability after ex vivo depletion is not straightforward, however, because cell death may not be expressed immediately, but develop in the hours or days after processing and infusion. It may be possible to obtain a more accurate estimate by incubating the cells for a period before analysis. This has been particularly true in the case of depletion by immunotoxins that require the cells to divide to exert their toxic effects. [126] Stimulation of the cells with IL-2 and ex vivo culture has also been used to facilitate the detection of the residual T cells by flow cytometry. In some cases, this has provided a correlation between the numbers of T cells in the cultured sample and the development of clinical GVHD in the graft recipient. [192]

The discovery of new T-cell activation markers and the availability of MAb to these antigens may provide new tools to improve correlation between laboratory assays and the likelihood of developing clinical GVHD. The OX-40 molecule (CD134) is an early T-cell activation marker that appears on CD4+ T cells. [237] In a rat transplant model increased numbers of OX-40+ cells identified an alloreactive population of T cells that was involved in acute GVHD. In early clinical studies high numbers of positive cells appeared before clinical manifestations of the disease, and their numbers fell during effective steroid therapy. It remains to be determined whether the expression of activation markers, such as OX-40, by cells in the graft (either immediately after preparation or following ex vivo incubation) will provide a more accurate method for quality control of the T-depletion procedure. Another potentially useful assay may be levels of various cytokines, soluble cytokine receptors, and inhibitors in graft cultures.

Proliferative Assays

There is often, however, tremendous disparity between residual T-cell numbers as detected by flow cytometry, measurements of cell viability, and ultimate clinical outcome. This has prompted the development of other methods to detect residual T cells. These have focused on measuring cell function in proliferative assays.

Limiting Dilution Analysis

The most widely used has been limiting dilution analysis. In this assay, dilutions of the pre- and postdepleted graft are prepared and plated in multiple replicates in microtiter wells in medium containing growth factors (often in the presence of irradiated feeder cells). [237] [238] [239] [240] Within 23 weeks T cells in the cultures will proliferate and form small colonies, each of which is derived from a single T cell. These may be detected either by direct counting under a microscope or by uptake of a radiolabeled precursor molecule, such as tritiated thymidine. [239] For a series of replicate wells plated for a single dilution of the graft, only a certain proportion of the wells will grow out T-cell colonies. This proportion can be related to the original number of T cells present in the dilution using the Poisson distribution, and from this number the frequency of T cells in the graft may be determined. Although, at first sight, this would appear to be an ideal method for scoring T cells, the readout time is 23 weeks, meaning that, unless the graft is cryopreserved for future infusion, the results are not available at the time of the transplant. Scoring is also somewhat subjective and requires extensive intra- and interlaboratory standardization if reliable results are to be achieved. As is usual for most estimates of T-cell numbers or activity, the results obtained frequently still do not provide reliable prediction of clinical events.

T-Cell Precursor Assays

Attempts have been made to improve clinical correlations by adapting these assays to detect precursor cytotoxic and helper T cells. [240] [241] [242] In this procedure, donor cells are co-cultured with irradiated patient cells in a limiting dilution design (see earlier), and the proliferating cells are subsequently tested for cytotoxicity toward various targets, including the patients normal and leukemic cells and cells from a third-party donor.

In the helper cell assay, dilutions of donor cells are co-cultured with a constant number of irradiated patient cells at a range of ratios. The cultures medium initially contains IL-2, which is subsequently washed away. Irradiated lymphoblastoid cells produced from the recipient are then added, and 24 hours later the supernatant medium is assayed for IL-2 content. These assays are technically complex and require inclusion of appropriate control combinations of cells to be able to demonstrate the specificity of the responses. An assay that quantitates both cytotoxic and helper cell precursors has been described by van der Meer and colleagues. [242] This again uses a limiting dilution design. IL-2 production by helper cells is measured by co-culturing the proliferating cells, after irradiation, with an IL-2-dependent cell line. The response of this cell line is measured by uptake of tritiated thymidine. Cytotoxic proliferating cells are harvested and their activity can also be measured by proliferative response to phytohemagglutinin-stimulated recipient cells. Keever-Taylor and colleagues reported that the cytotoxic precursor frequency assay was most sensitive to disparities at the HLA-A and HLA-B loci that was detectable by serology or isoelectric focusing. [241] The helper cell precursor frequency assay predominantly detected class I disparity, but also responded strongly to differences at the HLA-DRB1 locus. Cytotoxic cell precursor frequency and dose was found to correlate significantly with grades III and IV GVHD and with the development of chronic GVHD. Neither assay correlated with relapse, whereas both were associated with survival. When adjustments were made for other significant covariables, however, the association between cytotoxic precursors and acute GVHD was lost,

although the association with survival was retained. Helper

precursor frequency was associated with chronic GVHD. In contrast, Lachance[243] and Weston[244] and their colleagues, found a significant association between helper precursor frequency and both acute GVHD and disease relapse in matched sibling transplants. This correlation was only weakly seen by Pei and colleagues in HLA-class II disparate transplants.[245] In the van der Meer study,[242] the assays were used to study the suitability of potential donors for two donors. For the first, three donors were equivalently matched by standard HLA typing techniques; however, there were major differences by the cytotoxic and helper cell precursor assays. For the second patient there was no HLA-matched donor by conventional typing; however, two of the donors showed a similar pattern of cytotoxic precursor responsiveness, which was different to that shown by the third donor. All of the potential donors showed different helper precursor responses. These various patterns were attributed both to differences in major HLA antigens that could be detected by conventional methods, and also to undetectable differences in some major and multiple minor antigens. Some of the differences found in the predictive value of these assays undoubtedly reflect technical variables. Methods to optimize the assay by depleting various subpopulations of the responder and stimulator preparations have been reported to improve its sensitivity, [246] accuracy, and reliability.[237] [246] [247] To a certain extent, this type of assay represents a more sophisticated reincarnation of the mixed lymphocyte reaction, in which combinations of patient and donor leukocytes were co-cultured in an attempt to detect alloreactivity by proliferative response. Although this also was thought to give promising early results, it has proved to be of very limited value in predicting clinical responses and has now been dropped by some donor registries as a required test.

As our understanding of the etiology and mediators of GVHD and GVL improves, it is possible that the existing assays can be modified by the discovery of antibodies to new antigen markers or marker combinations and by development of more sophisticated and specific culture assays. These may give results that are of true predictive value and that can be obtained within the required time frame.

ENGINEERING-ENHANCED ENGRAFTMENT

Although GVHD occurs in 3050% of patients who receive HLA-matched grafts, the incidence and severity of the disease is higher in recipients of mismatched transplants.[5] [9] This has prompted the use of more radical T-cell depletion and investigation into what other manipulations could be used to promote the engraftment of extensively T-depleted grafts.

For many years it has been hypothesized that a single or very small number of pluripotent stem cells may be capable of eventually engrafting a recipient. Nonetheless, for practical purposes, there has also been considerable work to try to define the effective therapeutic dose of stem cells (usually defined in this context as CD34+ cells), that is required for rapid and stable hematopoietic engraftment. [248] This has been prompted largely by the switch to mobilized peripheral blood as the source of HPC because it is necessary to determine when an adequate graft has been collected and apheresis collections can be discontinued.

Despite numerous technical differences, it is now generally agreed that 15×10^6 blood CD34+ cells/kg provides an adequate dose, with faster engraftment occurring at the higher doses.[249] [250] Above a certain plateau, higher doses do not confer any particular advantage to the recipient, in terms of speed or stability of engraftment.[248] Recently, however, Aversa et al. have shown that higher doses of CD34+ cells (i.e., $>6 \times 10^6$) may be of value in promoting engraftment across histocompatibility barriers.[222] This is based on animal studies by Reisner et al., which suggested that at higher stem cell doses there may be some type of veto effect against graft rejection.[219] In laboratory experiments, Rachamim and colleagues have found that addition of purified CD34+ cells to primary mixed lymphocyte cultures leads to a marked reduction in both the frequency of alloreactive cytotoxic T-cell precursors and in their activity. [229] The tolerizing activity requires cell contact and is abrogated by irradiation. The CD34+ population producing these veto effects were MHC class I and II positive, but lacked costimulatory molecules of the B7 family. This suggests that the stem cell population, or more specifically, the CD34+ cells within an allograft may no longer simply be regarded as passengers. The total numbers, and perhaps their composition, may play a vital role in counteracting the side effects of radical T-cell depletion, to ensure the stable re-establishment of hematopoiesis by extensively T cell-depleted grafts.

Improved engraftment across histocompatibility barriers may also be achieved by administration of graft facilitator cells (described earlier). [226] [230] Infusion of marrow and PBPC preparations enriched for these cells by negative selection has resulted in 100% engraftment of one to three antigen-disparate grafts (Ildstad, personal communication). Kawanishi and colleagues have also implicated + T cells as promoters of engraftment in both matched related and unrelated transplants. [211] These cells were not found to be associated with any increase in the risk of acute GVHD, whereas + T cells produced the reverse finding. These approaches hold promise for the manipulation of cell subpopulations to both reduce the risk of nonengraftment in recipients of heavily T-depleted grafts and to permit the use of increasingly haplodisparate donors. In addition, stromal cells are believed to provide the necessary environment for the homing and proliferation of HPC. Infusion of purified and expanded stromal cells may, therefore, also provide a means to enhance engraftment. These ex vivo approaches can, of course, be supplemented by increasing immunosuppressive preconditioning of the intended recipient to reduce the numbers of functional recipient T lymphocytes.

ENGINEERING ANTITUMOR RESPONSES

At present, most of the clinical efforts at engineering allograft have focused on pan T-cell depletion, with occasional attempts at removing T-cell subsets, with the aim of abrogating GVHD while retaining GVL activity. Subset depletions have primarily focused on the removal of CD8+ cells and have met with some success clinically.[201] [202] [203] Although depletion of donor cells that have been activated by co-culture with cells from the recipient has produced some promising results in preclinical experiments, some technical hurdles still must be overcome before it can be used routinely in the clinical setting. These include procuring the appropriate numbers of recipient and donor cells, optimizing co-culture conditions, and developing an effective separation technology that targets activation antigens, which tend to be more labile and motile.

If long-term survival is to be achieved, however, it will be necessary to maintain or boost antimalignancy responses. Many studies are, therefore, currently focused on the generation of tumor-directed immune responses.

Immunotherapy

Donor Leukocyte Infusions

The importance of the immune response in eradicating leukemic cells has, in addition, been re-emphasized recently by the success of donor lymphocyte infusions in controlling leukemia post-transplant.[64] [250] In this approach, allograft recipients who are at high risk of relapse of disease, or who have relapsed, were given small numbers of leukocytes collected from their original graft donor. These cells were infused in an unmodified form intravenously, and subsequently were shown to produce dramatic

clinical responses, particularly in patients with CML,[64] and subsequently in those with a variety of acute leukemias.[251]

The hypothesis is that the infused cells contain leukocytes that predominantly recognize antigens expressed on the recipients leukemic cells, and that after a period during which they proliferate, they will mount an immune response to these cells. Because the donor leukocytes are infused into a recipient who has already become engrafted with donor stem cells, the environment does not appear to favor the proliferation and generation of cells with GVHD activity. Such cells can, however, be produced if large numbers of donor leukocytes are infused post-transplant, or if the infusions are not properly timed. This can result in considerable severe or fatal toxicity from GVHD.[251] [252] Recent studies suggest that it is possible to use the original mobilized PBPC as the source of donor leukocytes for post-transplant immunotherapy. This would avoid the need to subject the donor to additional apheresis collections.[253] Alternatively the infusions can be manipulated to remove particular T-cell subsets. For example, CD8+ cells,[254] alloreactive cells, or clones can be selected for clinical use based on specificities measured in vitro.[255]

Based on the hypothesis that Th1 and Th2 T cells may play functionally different roles in mediating GVHD and GVL, Halverson and colleagues have generated these cells ex vivo by incubating CD8+ cells with allogeneic marrow-derived stimulator cells (predominantly CD3+ cells) in the presence of different panels of cytokines.[256] Conditions were found under which the CD8+ population developed into allospecific type 1 or type 2 cells with the typical patterns of cytokine secretion (see earlier). These cells may prove extremely useful, both to determine their roles in mediating post-transplant immune responses and for therapeutic applications.

Suicidal Lymphocytes

It is still not clear whether it will be possible to completely separate subpopulations of cells with GVL versus GVHD activity. The use of unfractionated populations carries the great risk that severe or fatal GVHD may be triggered in certain patients. In an attempt to prevent this, suicide genes can be inserted into the cells that are infused. The patients are then monitored for the earliest signs of GVHD, at which time the gene is activated to destroy the effector cells. The most common approach has been to transduce the cells with the herpes simplex thymidine kinase gene that confers sensitivity to the antiherpes drug ganciclovir.[257] Although this represents a new type of application for gene therapy, there are a number of technical hurdles. High transfection rates are required to reduce the likelihood of infusing nonsuicidal GVHD effector cells and to provide optimal numbers of suicidal cells for therapy. Secondly, it is not clear whether clinical GVHD can be detected at a time when it can still be stopped, or if irreversible proliferation of the effector cells has occurred prior to the first obvious clinical manifestation of disease.

Initial animal studies appear promising in that GVHD was prevented by administration of ganciclovir in the immediate post-transplant period; however, the animal still maintained a pool of donor T cells that responded normally to mitogens and third-party alloantigens, but were tolerant to recipient alloantigens.[257] Human clinical trials are currently in progress to evaluate this approach. Bonini and colleagues have shown that the transduced cells can persist in vivo for 12 months and were capable of mediating antitumor activity in patients with lymphoma.[258] [259] Development of GVHD was effectively controlled by the administration of ganciclovir. As further results from these studies are published they should provide useful information on the etiology, detection, and therapy of GVHD. These observations have restimulated work on immunotherapy of cancer because the clinical responses have been particularly impressive, probably because of the low initial tumor burden at the time of infusion of the leukocytes and the previously documented role of immune responses in the control of CML. They also suggest that conditions can be achieved that favor the development of GVL over GVHD, although these may still be relative rather than absolute.

Many of the questions that have remained unanswered in the field of graft engineering may be addressed more successfully in the context of DLI-based immunotherapy. Although, the strongest evidence of efficacy has come from patients with CML, there are reports of similar responses in patients with other leukemias.[251] The time course of the response may also shed light on the pathways of GVHD and GVL, by studying the sequence of events during the latency period, and even allowing us to isolate, characterize, identify, and expand potential effector populations.

Targeted Immunotherapy

These promising results from a more generic type of immunotherapy have stimulated the development of a number of specific immunotherapy protocols. This has been spurred by new work on the methods by which T cells become activated to generate cytotoxic responses toward cells bearing particular antigens. Jiang and colleagues were able to generate 122 recipient-reactive donor T-cell clones from CML recipient/donor pairs by incubating donor T cells with CML cells from the recipient.[260] They found that 32 of 78 clones recognized leukemia and normal lymphoblastoid cells, and 19 recognized only CML. The latter preferentially showed a V5, 6/7 pattern of T-cell receptor use, whereas those that recognized normal cells predominantly used V3 and 8. In the case of GVHD, very restricted and preferential expression of certain V gene segments has been described in patients with post-transfusion GVHD, although there were tremendous differences between individuals.[261] It may eventually prove possible to exploit these differences to identify and enrich subpopulations that mediate GVL for use in post-transplant

immunotherapy.

Dendritic Cell Immunotherapy

Central to the generation of specific T-cell responses is the antigen-presenting cell (APC) (described earlier). These cells process and present antigen on their surfaces in the context of MHC molecules to T lymphocytes. This triggers a series of reactions involving the proliferation of T-cell subsets, release of cytokines, and, ultimately, the generation of T cells with specific cytotoxicity toward cells expressing that antigen. Presentation of the antigen to the T cell within the appropriate context is a vital step in this process, and the ability to culture, expand, and prime APC with antigen is central to the goal of generating T cells with specific cytotoxic activity for immunotherapeutic applications. This has become more realistic with the demonstration that dendritic cells, some of the most potent APC, can be cultured and expanded from CD34+ precursors in the bone marrow, or from the peripheral blood, and that these cells can be primed ex vivo with antigen. Infusion of antigen-primed dendritic cells directly has been reported to produce antitumor responses, when the priming antigen was tumor associated. [262] Alternatively, the primed dendritic cells may be co-cultured with T cells, which can then be infused alone or together with the dendritic cells, with the aim of generating an antitumor response.

In the case of CML, the bcr-abl-positive dendritic cells can be generated from CD34+ precursors, thereby avoiding the necessity of priming the cells with a tumor-associated antigen.[263] [264] In contrast, Nieda and colleagues used a 16mer peptide that spans the b3a2 breakpoint of bcr-abl to pulse dendritic cells. [265] These were then used to generate CD8+ autologous bcr-abl-specific

cytotoxic T cells. The T cells lysed CML cells exhibiting the b3a2 breakpoint, but not those with the b2a2 breakpoint, or normal lymphoblastoid cells from the same individual. Cytotoxicity was found to be dependent on, but not restricted by, MHC class I molecules. Molldrem and colleagues reported that T cells that showed specificity toward a peptide derived from the primary granule enzyme proteinase 3 were able to inhibit CML CFU preferentially, suggesting that these cells could be used for immunotherapy.[266] These studies support the idea that it is possible to use antigen-pulsed APC to generate tumordirected effector cells ex vivo and that these cells can be specifically targeted without the risk of provoking GVHD.

Escape from Immunotherapy

Tumor cells may escape immune destruction by lacking the target antigens or certain co-stimulatory molecules required to trigger a T-cell response. Dermime and colleagues described decreased susceptibility to T- and NK-mediated cell killing and reductions in the expression of class I and II MHC in relapsed leukemias. [267] It is now possible to introduce genetic material coding for some of these missing factors into the tumor cells. This has been described by Boyer and colleagues, who have transfected murine leukemia cells with genes for the B7 co-stimulatory molecules needed to generate leukemia-reactive T cells. [73] They were able to produce cytotoxic T-cell lines that could then be used for specific immunotherapy. Cardoso and colleagues have found that optimal priming and expansion of autologous cytotoxic T cells directed toward pre-B leukemia cells is obtained when the B7 co-stimulatory molecule is expressed directly by the tumor cell. [268] They were able to transfect the B7 gene into leukemic cells to use as the source of antigen to stimulate dendritic cells and generate specific cytotoxic CD8+ effectors. These were found to kill the leukemic targets by induction of apoptosis via the perforin-granzyme pathway. Such an approach could ultimately be transferred into human trials. The complexity of these approaches is illustrated by the recent finding that T cells that lack the CD28 molecule, which binds to B7 on APC, can still mediate GVHD in a mouse model.[269]

Future Developments in Post-transplant Immunotherapy

Other potential important effector cells that could be used to mediate an antitumor effect include allogeneic T cell [74] and NK cell lines,[75] and T cells isolated from the patients tumor (tumor-infiltrating lymphocytes), and expanded ex vivo.[71] Ultimately, we may see these approaches develop into a new type of transplantation, in which high doses of T-depleted stem cells are administered with nonmyeloablative therapy to achieve chimerism. Targeted donor leukocytes, generated ex vivo, could then be used to provide a specific immune response to the patients disease, in the absence of severe or fatal GVHD. Work is already in progress to develop these types of protocols.[270] [271]

Studies such as those described above re-emphasize that a multifactorial approach may be used to address the linked issues of preventing GVHD, facilitating engraftment, and maintaining or enhancing a graft-versus-disease effect. A variety of graft and postengraftment immunoengineering techniques have been used with varying success. In addition, the regimens used to condition the patient and to provide post-transplant immunosuppression also have a major impact on the success of allograft transplantation. This is illustrated by the success of the regimens developed and applied by Henslee-Downey and colleagues for transplantation of partially HLA-matched grafts from related donors. These protocols have used graft modification by pan T-cell depletion. This by itself may be insufficient to achieve control of GVHD in the mismatched setting; however, when combined with carefully developed conditioning and post-transplant immunosuppression regimens, impressive rates of engraftment and control of GVHD have been achieved.[208] In these studies, relapse of disease has been a major complication; however, it is still difficult to determine to what extent this is the result of immune manipulation or to the very high-risk nature of the patients entered onto these protocols. The relative contributions of in vivo and ex vivo treatment can only ultimately be resolved in carefully structured and controlled clinical trials and may differ dramatically depending on factors such as the diagnosis, stage of disease, time of treatment, prior therapy, treatment regimen, and intercurrent clinical events.

SUMMARY AND FUTURE DIRECTIONS

New biotechnologies have frequently found their first applications in the field of stem cell transplantation. The necessity of engineering both autologous and allogeneic grafts to improve outcome has provided the vehicle for some of the earliest clinical uses of MAb, immunomagnetic separation and antisense oligonucleotides.

In allogeneic transplantation it is clear that the problem of GVHD can be partially solved by ex vivo alteration of the cellular composition of the graft. This can be efficiently accomplished by a variety of different technologies; however, the identity of the target cell still remains to be unequivocally established. There have been major advances in our understanding of the etiology of GVHD, which suggest that the process is extremely complex, involving multiple cell types and humoral mediators. In parallel, however, relatively simple procedures, such as panT-cell depletion, have produced encouraging clinical results. Adding to the complexity is the close inter-relationship between GVHD, engraftment, and GVL. Achievement of the optimal balance between these has become the holy grail of allogeneic transplantation. It is still unclear whether the cellular mediators of these reactions are indeed functionally separable, and there is still conflicting experimental evidence on the identities of the effector populations. The discovery of the GVL effect has, however, reawakened the area of cancer immunotherapy, and this should, in turn, provide more information on the identity of the effector cell populations mediating graft/host interactions. The technology for separating, manipulating, activating, and expanding these various cell populations already exists and awaits an improved understanding of the appropriate cellular target populations.

A change in the nature of transplantation is already occurring. There is a gradual move away from myeloablative high-dose therapy with stem cell rescue toward using the transplanted cells to achieve other goals. Alterations of the dose of cells and enrichment of facilitating populations should improve engraftment rates of heavily T cell-depleted grafts and allow the use of donors of increasing haplodisparity, thereby extending transplantation to a larger patient population. Stem cells are now being used to induce tolerance for the transplantation of solid organs in the absence of myeloablative conditioning. They can also be used to establish a chimeric environment, into which donor lymphoid cells can be introduced to produce an antimalignancy response. Developments in gene therapy, cell culture, and molecular biology will have a tremendous impact on the direction in which we will move in the coming years. Whatever the direction, the journey promises to be an eventful and exciting one.

Chapter 95 - Gene Therapy for Hematologic Disorders

Johnson M. Liu
Christopher E. Walsh
Arthur W. Nienhuis

INTRODUCTION

Advances in recombinant DNA technology over the past several decades have offered the promise that inherited disorders may be treated by gene replacement. Acquired disorders such as AIDS and cancer may also become amenable to modulation via the introduction of selected genes that block viral replication or neoplasia. Although the concept of human gene therapy is simple, its application to clinical disorders has been slow because of the complexities inherent in achieving efficient gene transfer and appropriate gene expression. The most direct model for gene therapy is the introduction of a correctly functioning gene into the appropriate target cell of an affected individual. The newly inserted gene is transcribed and translated into a protein that alters the phenotype of the target cell. For hematologic disorders, the cells in which gene expression is required may be lymphocytes, monocytes, neutrophils, or other mature blood elements (Fig. 95-1). In the ideal case, gene transfer could be targeted to the pluripotent hematopoietic stem cell. Introduction of the genetic material into stem cells would ensure the continuous production of genetically modified blood elements over the lifetime of the patient. Theoretically, any genetic disease affecting one of the stem cell-derived lineages could be treated by gene insertion into a repopulating cell, provided that regulated, cell-specific gene expression could be maintained. A number of technical difficulties have hampered the application of gene transfer into stem cells. Other potential target cells include lymphocytes, tumor cells, muscle cells, hepatocytes, and endothelial cells. This chapter focuses on both the methods of gene delivery and target cells relevant to gene therapy of hematologic disorders, and discusses some of the unresolved issues in this rapidly changing scientific discipline.

GENE DELIVERY

Retroviruses, parvoviruses, adenoviruses, herpes viruses, and vaccinia viruses are currently being developed for gene transfer into human cells. [1] Most methods of gene delivery use viral vectors to capitalize on the inherent efficiency of viruses to transfer and express genetic material in host cells. Typically, viruses bind specific cellular receptors and enter host cells by membrane fusion or endocytosis. Viral vectors can either lead to transient or stable transfer of the foreign gene. The process of stable transfer of foreign genetic material into the host chromosome is referred to as transduction. Alternatively, a latent viral infection may occur with the viral genome maintained in an extrachromosomal state. This may lead to high-level but transient gene expression.

Viral Methods

Retroviral Vectors

Among the retroviruses being developed for gene therapy are oncoretroviruses and lentiviruses. Vectors derived from components of the murine leukemia virus (MuLV) have been used in clinical trials to date. [2] In the future, vector systems based on the lentiviruses such as human immunodeficiency virus (HIV) and its relatives may offer advantages for many gene therapy applications.

Retroviruses are single-stranded RNA viruses that bind to a specific cell surface receptor for entry into the cells. [3] Once inside the cell, the viral RNA is converted into double-stranded DNA by the enzyme reverse transcriptase before integration into the host cell genome as provirus. The recombinant retroviral vectors in current clinical use (Fig. 95-2) contain the gene of interest flanked by the MuLV long terminal repeats (LTRs); the LTRs contain the promoter, polyadenylation signals and the sequences required for viral replication and integration. [4] The utility of retroviruses as vectors for gene therapy has been greatly enhanced by the ability to engineer packaging cell lines that secrete retroviral virion particles (Fig. 95-3). These cell lines are designed to express a helper genome encoding MuLV viral proteins. A separate vector plasmid that contains the gene to be transferred (along with *cis* elements necessary for RNA encapsidation, replication, and integration) is then stably introduced into these cell lines to generate a producer packaging line. Split function packaging cell lines separate the retroviral genes onto different transcriptional units, [5] significantly reducing the risk of generating replication-competent retroviruses by homologous recombination.

The main advantages of MuLV vectors are their ability to integrate into the host cell genome and confer long-term expression of the transferred gene. The primary concern regarding the use of retroviral vectors is the generation of replication-competent retroviruses and the possible induction of a neoplasm by insertional mutagenesis following integration. [6] The major limitation of MuLV vectors is that the target cells must be actively replicating for the vector to be able to integrate into a host chromosome. [7] [8]

Receptors for retroviral vectors have been identified recently [9] and appear to be broadly expressed in human tissues. [10] Low levels of receptors on target cells such as hematopoietic stem cells, however, may impede vector entry. [11] Pseudotyped retroviral vectors such as those containing the gibbon ape leukemia virus (GALV) envelope have been developed by using packaging cell lines that express alternative envelope proteins such as the GALV envelope. [12]

In recent years, researchers have been interested in the development of vectors based on lentiviruses such as HIV. [13] Lentiviruses are much less dependent on cell division to achieve transduction since reverse transcription results in a relatively stable intermediate that is transported by virtue of signals in associated proteins through the nuclear membrane. [13] Consequently, HIV-based vectors may be suitable for gene transfer to such targets as liver, muscle, and neurons, [13] and possibly quiescent hematopoietic stem cells.

Adenovirus Vectors

These vectors are important because of their potential for in vivo gene delivery. Human adenoviruses are non-enveloped DNA viruses. Out of nearly 50 known serotypes, only types 2

Figure 95-1 Cell targets for gene transfer and corresponding therapeutic gene products or disorders amenable to gene therapy.

(Ad2) and 5 (Ad5) have been used for gene transduction strategies. [14] Adenoviruses exhibit two phases of gene expression during their lytic life cycle: early and late, separated by the onset of viral DNA replication. Their genome includes four distinct early regions (E1E4) and a major late region consisting of five components (L1L5). Recombinant replication-deficient adenoviral vectors have an extensive deletion of the E1 gene region that blocks transcriptional upregulation, viral replication, and cell death. In most recombinant adenoviral vectors, the gene to be transferred (referred to as the transgene) is located within the deleted E1 region.

The major advantages of adenoviral vectors include the ease with which they can be engineered by deletion of critical regulatory genes, their efficiency as in vivo gene transfer vehicles, their ability to transduce both dividing and nondividing cells, and the fact that they can be produced at high titers (10^{11} 10^{12} viral particles/ml). One limitation of adenoviral vectors is transient expression in the target cell resulting from the absence of chromosomal integration. In addition, inflammatory and immune reactions directed against viral proteins can limit their use. [15] Their most promising role in gene therapy of hematologic disorders appears to be in the transduction of cancer cells in vivo with tumor suppressor genes, cytokine genes, and drug sensitivity genes.

Adeno-associated Virus Vectors

Adeno-associated viruses (AAV) are single-stranded DNA parvoviruses. [2] The viral genome consists of *rep* genes encoding regulatory proteins and *cap* genes that encode the capsid proteins. The genome is flanked by inverted terminal repeats (ITR) that function as viral origins of replication and are necessary for encapsidation and integration of viral DNA into the cellular genome. In the absence of a helper virus such as adenovirus, AAV causes a latent infection characterized by the integration of viral DNA into the cellular genome. The wild-type virus has a property unique among viruses of integrating into a defined region of the human genome (chromosome 19q13).

Recombinant AAV vector production involves co-transfection of a permissive cell line (such as the 293 line) with a recombinant plasmid containing the gene to be transferred (with a promoter and polyadenylation signal) flanked by the AAV ITRs and a helper plasmid carrying the *rep* and *cap* genes but lacking the AAV ITRs (Fig. 95-4). The 293 cells are coinfected with adenovirus to generate AAV virion particles. These particles are released with cell lysis and are contaminated with helper adenovirus. Subsequent heating to destroy adenovirus is followed by purification and concentration of heat-stable recombinant AAV particles. The production of recombinant AAV vectors has

Figure 95-3 Generation of a producer cell line following transfection of a packaging cell line with a recombinant retroviral vector genome. The element refers to the encapsidation signal, which is provided by the transfected vector genome (see text for details).

Figure 95-4 Generation of rAAV by co-transfection of recombinant and helper genomes and co-infection with adenovirus.

improved with the development of packaging cell lines and the generation of virus stocks without an absolute requirement for helper adenovirus. [16]

The major advantages of AAV vectors include lack of pathogenicity in humans, a broad range of infectivity, and, as with lentiviral vectors, the capability of infecting nondividing cells such as muscle cells, liver cells, and neurons. [17] The packaging limitation of 5.2 kb precludes the use of AAV for transferring larger genes. In the instances in which it has been studied, recombinant AAV does not demonstrate the same site-specific integration as the wild-type virus. [17]

Nonviral Methods

These methods rely on receptor-mediated endocytosis or fusion of cell membranes. DNA delivered by nonviral methods is maintained in an extrachromosomal (episomal) state and not integrated into the cellular genome. [18]

Physical Methods, Cationic Liposomes, and Virosomes

Transfection (including calcium phosphate co-precipitation and electroporation), microinjection into the target cell nucleus, particle bombardment using a gene gun, [19] and direct intramuscular injection of purified DNA have all been used, but these methods are variably efficient and may result in transient expression of the transferred gene.[20]

Cationic liposomes are positively charged artificial lipid vesicles that incorporate negatively charged DNA. Under optimal conditions, it is often possible to transduce greater than 90% of cells in vitro with cationic liposomes. [21] Commercially available liposome preparations are routinely used for in vitro gene transfer. Cationic lipids have also been shown to be effective gene transfer agents in vivo. They have been used to successfully transfer 1-antitrypsin and cystic fibrosis transmembrane conductance regulator (CFTR) genes to the lungs. They have also been used to transfer the HLA B7 gene to tumor cells to boost antitumor immune responses. [22] The favorable features of this system include the absence of viral sequences, no cDNA size constraints in vector construction, and the ease of preparation.

Virosomes are liposomes that contain viral proteins, such as hemagglutinin, intercalated in the lipid bilayer that facilitate fusion of the liposomal bilayer with the membrane of the target cell.[23] The efficiency of gene transfer can be further enhanced by encapsulating DNA with nuclear proteins within liposomes. [24] These proteins can enhance DNA delivery to the nucleus as a result of nuclear-targeting signals.

Receptor-Mediated Gene Delivery

Receptor-mediated gene transfer involves creation of a protein ligand-polylysine-DNA complex that binds specifically to a ligand receptor. Studies with ligand-DNA complexes using transferrin and erythropoietin as ligands have demonstrated effective

in vitro gene delivery to various cell types, including hematopoietic cells. [25] Most methods of DNA delivery involve entry into the cells by endocytosis, and most of the DNA that enters the endosome is destroyed before it reaches the nucleus. In order to improve transduction efficiencies, it might be important to enhance the release of intact DNA from the endosome. In this modification, ligand-polylysine-DNA complex is coupled with inactivated adenovirus particles. The adenovirus particles disrupt lysosomes in the target cells, reducing DNA degradation and releasing DNA into the cytoplasm. In vitro studies using transferrin and folate as ligands have claimed increases in the efficiency of gene delivery by 100- to 1000-fold. [26] However, adenoviral complexes have not been shown to be effective in vivo.

TARGET CELLS FOR GENE TRANSFER

Lymphocytes

Diseases in which genetically modified lymphocytes have been used include cancers (melanoma and Epstein-Barr virus-induced lymphoproliferative disease), inherited immunodeficiency diseases (adenosine deaminase deficiency), and infectious disorders (acquired immunodeficiency syndrome or AIDS). Lymphocytes may be good targets for gene transfer because they are easily isolated from peripheral blood and they can be induced to proliferate in tissue culture, thus facilitating transduction by retroviral vectors.[27] However, unlike pluripotent hematopoietic stem cells, lymphocytes are terminally differentiated and may persist for months but eventually will be cleared from the circulation. Some of the clinical uses of lymphocytes in gene therapy are summarized in the following sections.

Inherited Immunodeficiency Disorders

Adenosine deaminase deficiency (ADA), a rare inherited disorder caused by profound deficiency of the enzyme adenosine deaminase, was the first disease to be treated by gene replacement therapy. The first clinical protocol for ADA deficiency used peripheral blood T lymphocytes as the target cells. The cells were expanded ex vivo by exposure to interleukin-2 and anti-T-cell receptor antibodies, repeatedly infected with recombinant retroviral vector supernatant to achieve a transduction efficiency of 510%, and reinfused into the patients. T-cell number and function and serum ADA levels rose in two patients treated in this manner. [28] [29]

Neoplastic Disorders

Tumor infiltrating lymphocytes (TIL) are T lymphocytes that tend to localize in tumor masses. A gene marking trial using the neomycin resistance gene was designed to analyze trafficking, homing, and survival of TILs. [30] In this trial, TILs were obtained from biopsies of melanoma tissues, expanded in vitro in the presence of IL-2, and then returned to the patients by intravenous injection. Polymerase chain reaction (PCR) analysis demonstrated the presence of gene-marked TILs in the circulation for three months and in tumor biopsy specimens for two months. The study also demonstrated the safety of the retroviral gene marking procedure. TILs are also being used to deliver cytokine genes into the tumor bed. In a clinical protocol designed for advanced melanoma patients, TILs were transduced by a retroviral vector containing the gene for human tumor necrosis factor (TNF).[31] It is hoped that these cells will migrate to sites of tumor and achieve a high local concentration of TNF, inducing cytotoxicity without causing serious systemic toxicity.

Gene marking has been used to evaluate the efficacy of in vitro expanded, donor cytotoxic T-lymphocytes (CTLs) for the prophylaxis and treatment of Epstein-Barr virus (EBV) induced lymphoproliferative disease following allogeneic transplantation from a matched unrelated donor. Persistence of infused CTLs for several months, amplification of CTLs in the context of recrudescence of EBV infection, and infiltration of marked CTLs into EBV-induced tumors have been documented. [32] [33] Based on these important results, development of CTL infusion therapy for other forms of cancer has become an important goal.

In another application of gene transfer to lymphocytes, a herpes simplex virus thymidine kinase (HSV-TK) gene was introduced into donor lymphocytes collected for recipients of allogeneic stem cell transplantation (SCT).[34] In patients with recurrent chronic myelogenous leukemia, acute leukemia, lymphoma, and multiple myeloma following SCT, donor lymphocyte infusions have been shown to be effective in inducing remissions (as a result of graft-versus-leukemia or GVL) but can also induce severe and potentially lethal graft-versus-host disease (GVHD). Italian investigators showed that the HSV-TK-transduced lymphocytes had antitumor activity in five patients. In three patients who developed GVHD as a result of the donor lymphocyte infusions, administration of ganciclovir effectively controlled the GVHD by eliminating the transduced donor lymphocytes.[34]

AIDS

Current strategies of gene therapy against AIDS can be classified into: (1) elimination of human immunodeficiency virus (HIV)-infected cells; [35] (2) inhibition of HIV replication in infected cells;[36] [37] [38] and (3) protection of susceptible cells from HIV infection. [39] One ingenious approach involves the expression of an intracellular antibody to the HIV reverse transcriptase. Resulting inhibition of the enzyme made cells resistant to HIV infection, presumably by blocking this early stage of HIV viral replication.[40]

Hematopoietic Progenitor and Stem Cells

In principle, hematopoietic stem cells represent an ideal target for gene therapy because they can be harvested from bone marrow, peripheral blood, or umbilical cord blood and can be cultured and transduced ex vivo. Their properties of self-renewal and repopulation of progeny blood cells should result in the continuous maintenance of the transgene in blood cells of the patient. There are several biologic obstacles that limit gene transfer into hematopoietic stem cells. [41] First, no in vitro assay to identify and quantitate true stem cells exists. Second, the pluripotent cells appear to be predominantly in G_0 phase of the cell cycle, making these cells resistant to proviral integration and transduction with retroviral vectors in current clinical use. Third, the receptors for a number of vectors, including retroviruses and adeno-associated viruses, are expressed at low levels in primitive hematopoietic cells. Fourth, since chromosomal integration is necessary for delivery of the transgene to progeny cells, non-DNA integrating delivery systems will result in only transient expression.

The clinical trials of gene transfer to hematopoietic stem cells can be classified as indicated in the following sections.

Gene Marking Studies

Gene marking studies, appended to autologous stem cell transplantation protocols, have been conducted in order to determine, in cases of disease relapse, whether the source of relapse is residual endogenous disease or tumor contamination of the donor inoculum. In a study of patients with acute myeloid leukemia undergoing autologous transplantation, gene-marked tumor cells were found to contribute to relapse, thus arguing for

ex vivo purging in order to eliminate contaminating tumor cells in the autologous graft. [42]

Inherited Disorders

One of the major objectives of gene therapy is the replacement of defective or missing genes in congenital diseases affecting the hematopoietic system (Fig. 95-1). A

number of single gene disorders such as the hemoglobinopathies,[43] chronic granulomatous disease,[44] and Gaucher disease[45] are potential candidates for hematopoietic stem cell gene therapy. We will focus here on two congenital disorders involving defects in the lymphohematopoietic organ, ADA, and Fanconi anemia (FA). The hematologic deficiencies in both of these disorders can be successfully treated by stem cell transplantation, implying that normal stem cells can reconstitute hematopoiesis.

For ADA, a number of patients have been treated with autologous gene-modified progenitor cells of either bone marrow or cord blood origin. These cells were transduced ex vivo with retroviral vectors carrying the ADA cDNA. In an Italian trial, two patients were treated with repeated infusions of ADA-transduced bone marrow cells and peripheral blood lymphocytes (transduced by two different vectors).[46] There was no reported toxicity, and a small number of ADA-positive cells were detected in the peripheral lymphocyte and granulocyte population that expressed the marrow-derived ADA as opposed to the lymphocyte-derived ADA. Presumably, these results indicate that transduction of more primitive lymphohematopoietic stem cells can provide long-term reconstitution with ADA-corrected cells. In a second trial, umbilical cord blood hematopoietic progenitor and stem cells were transduced with an ADA retroviral vector and returned to three ADA-deficient infants.[47] In this study, ADA-positive T cells were found in the peripheral blood at least 2 years after gene transfer.

Another disorder that may be amenable to progenitor/stem cell transduction is FA. Fanconi anemia is a rare, genetically heterogeneous

HEMATOPOIETIC STEM CELL GENE TRANSFER: PROGRESS AND PROBLEMS

The first decade of serious effort to develop gene therapy applications in which hematopoietic stem cells were targeted focused on the use of vectors developed from murine leukemia virus (MuLV). These viruses were studied intensely because of their oncogenic potential in animal models. Knowledge of the MuLV genome permitted the development of packaging cell lines that express the viral genes. From these cells, producer clones could be developed for vectors carrying marker or therapeutic genes that remained free of potentially dangerous replication-competent retroviruses.[1] [2] In the mid-1980s, the discovery that retroviral vectors could integrate genes into murine repopulating stem cells triggered an intense effort to achieve human stem cell targeted gene transfer. Work in larger animals demonstrated a much lower efficiency of gene transfer into stem cells than can now be routinely achieved in the murine models and a similar low efficiency has been observed in early clinical trials.[45] Lymphocytes from peripheral blood emerged as an alternative target because these cells can be induced to proliferate in culture, rendering them susceptible to transduction by MuLV vectors.[29] Interesting clinical results have been obtained in patients with immunodeficiency but stem cells remain a preferred target because of the potential persistence of the therapeutic effect and the broad spectrum of diseases that could be effectively treated if efficient gene transfer into stem cells were achieved.

During the past 57 years, attention has turned from a predominant focus on MuLV vectors for stem cell targeted gene therapy to a much more diversified effort to understand the barriers to stem cell transduction and to develop strategies and alternative vectors to overcome these barriers. By purification and study of primitive hematopoietic cell populations that are more than 1,000-fold enriched in stem cells, we have come to know that the receptor for the amphotropic MuLV vectors used in human clinical trials is expressed at very low levels in such cells,[51] that their metabolically inactive cytoplasm does not support reverse transcription of the vector genome[52] and that the nuclear membrane of these quiescent cells prevents access of the viral genome to human DNA,[53] effectively preventing viral integration. These properties are more than sufficient to explain the low levels of gene transfer observed in human clinical trials to date.

Lentiviral viruses such as human immunodeficiency virus (HIV) have the capacity to transduce nondividing cells.[13] A stable reverse transcription intermediate is formed that, by virtue of signals in its protein components, can traverse the nuclear membrane without cell division. Adeno-associated viruses can also transduce nondividing cells but primary hematopoietic cells have proved refractory to this vector system. Lentiviral vectors encoding marker or therapeutic genes have been developed, and these can be packaged into pseudotyped particles having the internal proteins of HIV and the external co-protein of vesicular stomatitis virus (VSV-G).[13] The VSV-G protein facilitates cellular entry via a ubiquitously expressed membrane phospholipid. Cellular activation is still likely to be required for successful transduction of stem cells but recent data suggest that such activation may be achieved with complex cytokine mixtures that include high concentrations of stem cell factor (kit-ligand and Flk-3 ligand).[54] Harvest of stem cells after cytokine administration has also been shown to increase gene transfer efficiency even with MuLV vectors.[55] Unification of these promising leads into an integrated experimental protocol has yet to be accomplished but may well result in stem cell transduction efficiencies of up to 10%. Recent results in murine models have unequivocally established that inclusion of a gene for a drug resistance marker in the vector genome allows stable amplification of the genetically modified hematopoietic population from 10% to more than 60%.[56] All of these advances encourage optimism that therapeutically useful gene transfer into stem cells will be achieved in the next few years.

The next decade is likely to bring many applications of gene therapy. Immunodeficiency disorders in which there are powerful selective advantages for gene-corrected cells[57] are likely to be among the first diseases treated effectively by stem cell targeted gene transfer. Effective gene therapy for hemoglobin disorders is likely to require more time because high-level, regulated gene expression must be achieved in a significant proportion of bone marrow erythroblasts. Both lentiviral and AAV vectors have the capacity to transduce fully differentiated, quiescent cells in vivo including muscle and liver cells. Accordingly, the hemophilias have emerged as target diseases for gene therapy in the relatively near future.

disorder characterized by bone marrow failure, physical anomalies, and a predisposition to malignancy. At the cellular level, the phenotypic defect is marked by hypersensitivity to DNA-damaging agents. We demonstrated phenotypic correction of hematopoietic progenitor cells derived from FA patients using retroviral and adeno-associated virus vectors.[48] [49] A clinical trial using the retroviral vector is currently being conducted.[50] As in ADA, there may be a selective advantage for gene-corrected cells, since transduction of the mutant hematopoietic cells markedly improves viability in culture.

Induction of Chemoprotection

Bone marrow suppression is one of the most common toxicities of chemotherapy regimens. One approach to increasing the dose of chemotherapy administered is introduction of drug-resistance genes such as the multidrug resistance (MDR) gene into bone marrow stem and progenitor cells. The protein product of this gene, called P-glycoprotein, extrudes various chemotherapy drugs, rendering the progenitors chemoresistant. Mice with MDR-gene modified marrow cells have been shown to tolerate much higher doses of chemotherapy.[58] Clinical trials using this approach are currently in progress. Two other promising new strategies for chemoprotection involve using variants of the dihydrofolate reductase (DHFR) gene to confer resistance to antifolates[56] and using the methylguanine methyltransferase (MGMT) gene to confer protection against nitrosourea drugs such as BCNU and CCNU.[59]

Tumor Cells

In addition to the induction of chemoresistance in hematopoietic cells, gene therapy directed at cancer cells has been the focus of intensive efforts and can be divided into three major strategies: (1) immunomodulation using cytokine genes; (2) induction of chemosensitivity by suicide genes; (3) modification of oncogenes and tumor suppressor genes.

Immunomodulation

These trials are based on observations in animal models that have shown that local expression of cytokine genes in tumors leads to immune-mediated tumor regression. A number of clinical trials based on this strategy have been initiated.[60] In the first approach, tumors from patients are resected and transfected ex vivo with vectors containing different cytokine genes such as interleukin-2 or interleukin-12, TNF, or granulocyte-macrophage colony stimulating factor. Subsequently, the genetically modified cells are irradiated and returned to the patient as a form of autologous tumor vaccine. In the second approach, a single standardized transduced cell line or mixture of transduced cell lines is used as an allogeneic vaccine. In this circumstance, the vaccine cells must share antigens with the patients tumor (as has been shown for melanoma) and probably must also match at least one HLA class I allele with the patient.

Induction of Chemosensitivity

Induction of chemosensitivity involves introduction of suicide genes directly into tumors. These genes include the HSV-TK gene that confers sensitivity to

ganciclovir[61] and *E. coli* cytosine deaminase conferring sensitivity to 5-fluorocytosine. There are several ongoing clinical trials using this approach in brain tumors and intraperitoneal ovarian cancers. The brain tumor protocol involved stereotactic injection of retroviral vector producer cells containing murine HSV-TK gene into intracranial tumors. Only the transduced tumor cells should be able to convert ganciclovir to its toxic form, thereby causing cell death. Preliminary results from this trial indicated responses in only very small tumors in which a high density of vector-producing cells had been placed. [62]

Modification of Oncogenes and Tumor Suppressor Genes

In vitro interference with oncogenes in some tumor cell lines may reduce malignant potential. For example, in a lung cancer model with *k-ras* oncogene overexpression, antisense gene expression made cells less tumorigenic. [63] Conversely, in tumors with a mutated p53 gene, transfer and expression of wild-type p53 gene may result in the elimination of the malignant clone. [64] A novel variation on this idea was the development of adenovirus mutants that may replicate selectively in p53-deficient human tumor cells.[65] As alluded to earlier, adenoviruses can be genetically engineered lacking the *E1B* gene. This gene encodes for a 55-kD protein that inactivates p53. Initial studies have suggested that the *E1B*-deficient adenovirus mutants were able to selectively lyse p53-deficient human tumor cells but not cells with functional p53.

Vascular Endothelial Cells

There has been great interest in transducing vascular endothelial cells in vivo in order to develop therapeutic strategies for vascular disorders. [66] [67] [68] [69] [70] At this time, the best vector for vascular cells, based on in vitro and animal studies, may be recombinant adenovirus. However, the major limitation to adenoviral vector use remains transient expression. Several growth factor and cytokine genes including platelet-derived growth factor-, fibroblast growth factor-1, and transforming growth factor-1 have been expressed in porcine arteries in vivo. These studies help in defining the role of these growth factors in vascular injury, repair, and vasculitis.

Many proteins are associated with the cell membrane via a glycosyl phosphatidylinositol (GPI) linkage. Recently, GPI-linked proteins such as CD59 were shown to undergo transfer from erythrocytes to endothelial cells following transplantation of the erythroid cells. [71] These findings raise the possibility of specific protein delivery to the endothelium.

Solid Organs

This approach is aimed at delivering gene products to the circulation by transferring genes to keratinocytes, fibroblasts, myocytes, or hepatocytes. Muscle tissue has recently become an attractive target for constitutive expression of secretable proteins such as hematopoietic growth factors and clotting factors. While several non-viral (naked DNA) and viral (retrovirus and adenovirus) vectors have been tested using intramuscular injection, gene transfer is limited to a small percentage of cells near the injection site. Each of these gene transfer methods has some drawback: plasmid DNA remains episomal and is expressed transiently, [72] whereas MuLV-based retroviral vectors inefficiently transduce nondividing muscle cells. [73] Adenovirus that infects muscle is rapidly eliminated by the host immune response. [74] HIV-based vectors are capable of infecting nondividing tissue such as muscle, but safety issues concerning contaminating wild-type HIV have not yet been fully resolved.[75]

Stable transduction of muscle tissue with an AAV vector has been reported and carried out beyond one year. [76] A recombinant AAV vector carrying the *lacZ* marker gene and delivered by local injection transfected a greater number of muscle fibers when compared with an adenovirus vector. The number of positively staining cells did not change from 4 days to 19 months, suggesting that the majority of transduction events went on to form stable integrants or episomes. In contrast to adenovirus-mediated gene transfer, no cell-mediated immune reaction against either the virus or the gene marker was detected. Neutralizing

antibody against AAV capsid proteins did not prevent readministration of vector. [77]

Hormones, growth factors, and clotting factors are products that potentially could be delivered by muscle cells transduced with AAV vectors. Injection of an AAV vector carrying a human erythropoietin gene into murine muscle tissue increased mouse hematocrits in a dose-dependent fashion. [78] The absolute increase in red cell mass correlated with human erythropoietin levels in mouse sera. Similar experiments have explored the use of AAV for leptin treatment of obese mice [79] and proinsulin production in diabetic animals.

AAV-mediated gene transfer of the hemophilia clotting factor IX is highly promising. Portal vein infusion of an AAV vector carrying the human factor IX gene (rAAV/hF.IX) into mice resulted in transduction of hepatocytes and achieved plasma levels of human factor IX which were 20% of normal. [80] The levels of human factor IX were persistent, without any morphologic or biochemical signs of liver toxicity. Intramuscular injection of rAAV/hF.IX into mice produced a similar therapeutic effect, with plasma factor IX levels at 6% of normal.[81] Intramuscular injection of rAAV/hF.IX into hemophilia B dogs increased clotting activity in a dose-dependent manner prior to anti-human F.IX inhibitor antibody development. [82] Immunohistochemical analysis of injected muscle confirmed persistent human factor IX expression. Limited areas of focal lymphocytic infiltration and myofiber pathology correlated with staining for the helper adenovirus but not AAV itself. Based on these results, new methods for the removal of adenovirus, concentration, and scale-up of AAV vectors will be needed before clinical trials can begin.

SUMMARY

In many respects, gene therapy has been a logical extension of the application of molecular biology to medicine. The first genetic disease elucidated at the molecular level was sickle cell anemia, and our understanding of inherited and acquired blood disorders continues to become more sophisticated. While gene therapy of the hemoglobinopathies has been more difficult to achieve than anticipated, it seems likely that at least certain genetic hematologic disorders, such as adenosine deaminase deficiency, will soon become amenable to effective gene replacement therapy. To some extent, scientific progress in this field will depend upon a better understanding of human hematopoiesis as well as the development of simple and reliable vectors for gene transfer. Whether or not complex disorders such as neoplasia can be effectively treated by gene transfer is unclear at the present time, but it seems reasonable to expect that novel and important research will continue to result from the interface between this applied science and hematology.
